Springer

Springer Handbook
of Lasers and Optics

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical sciences and engineering. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of physical and technical information.

The volumes are designed to be useful as readable desk reference books to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook
of Lasers and Optics

Frank Träger (Ed.)

With CD-ROM, 978 Figures and 136 Tables

Springer

Foreword

After working for more than four decades in the field of laser science, I am delighted that Springer-Verlag has devoted one of the first volumes of the new Springer Handbook series to lasers and optics. The exhilarating pace of technological advances in our field is still accelerating, and lasers and optical techniques are becoming ever more indispensible as enabling tools in almost any field of science or technology. Since no single physicist, engineer, or graduate student can be an expert in all the important subfields of optical science, a concise, balanced, and timely compilation of basic principles, key applications, and recent advances, written by leading experts, will make a most valuable desk reference. The chosen readable style and attractive, well-illustrated layout is even inviting to casual studying and browsing. I know that I will keep my Springer Handbook of Lasers and Optics close at hand, despite the infinite amount of information (and misinformation) that is readily accessible via the Internet.

Prof. Theodor W. Hänsch
Nobel Laureate in Physics 2005
Department of Physics
Ludwig–Maximilians–
Universität (LMU)
Munich, Germany

Munich, February 2007   Theodor W. Hänsch

Preface

It is often said that the 21st century is the century of the photon. In fact, optical methods, materials, and components have reached an advanced state of sophistication hitherto unknown. Optical techniques, particularly those based on lasers, not only find applications in the classical fields of physics and engineering but have expanded into many other disciplines such as medicine, the life sciences, chemistry and environmental research, to mention only a few examples. Nevertheless, progress in optics, photonic materials and coherent light sources continues at a rapid pace: new laser materials are being developed; novel concepts such as optics far beyond the diffraction limit, or nanooptics, are being explored; and coherent light sources generate wavelengths in ranges not previously accessible.

In view of the pronounced interdisciplinary nature of optics, the *Springer Handbook of Lasers and Optics* is designed as a readable desk reference book to provide fast, up-to-date, comprehensive, and authoritative coverage of the field. The handbook chapters are grouped into four parts covering basic principles and materials; fabrication and properties of optical components; coherent and incoherent light sources; and, finally, selected applications and special fields such as terahertz photonics, X-ray optics and holography.

I hope that all readers will find this Springer Handbook useful and will enjoy using it.

Part B Fabrication and Properties of Optical Components

List of Abbreviations

A

AEL	accessible emission limit
AFM	atomic force microscope
ANL	Argonne National Laboratory
AOM	acoustooptic modulator
AOPDF	acoustooptic programmable dispersive filter
APCVD	atmospheric pressure chemical vapor deposition
AR	antireflection
ARS	angle-resolved scattering
ASE	amplified spontaneous emission
AWG	arrayed waveguide

B

BBO	β-Barium-Borate
BH	buried heterostructure
BLIP	background-limited infrared photodetector
BZ	Brillouin zone

C

C–D	Cole–Davidson fractional exponent β
CALIPSO	Cloud-aerosol lidar and infrared pathfinder satellite observations
CARS	coherent anti-Stokes Raman scattering
CAT	coplanar air transmission
CCD	charge-coupled device
CCIS	charge-coupled image sensor
CCRF	capacitively coupled RF
CGH	computer generated hologram
CIPM	Comité International des Poids et Mesures
CMOS	complementary metal–oxide–semiconductor detector
COC	cyclic olefin copolymer
COP	cyclic olefin polymer
CPA	chirped-pulse amplification
CRDS	cavity-ring-down spectroscopy
CRI	color rendering index
CTIS	charge transfer image sensor
CVD	chemical vapor deposition
CW	continuous wave

D

DARPA	United States Defense Advanced Research Projects Agency
DBF	distributed feedback
DBR	distributed Bragg reflector
DCF	dispersion-compensating fiber
DEPFET	depleted field effect transistor structure
DESY	Deutsches Elektronen-Synchrotron
DEZn	diethylzinc
DFB	distributed feedback
DFG	difference-frequency generation
DFWM	degenerate four-wave mixing
DGD	differential group delay
DIAL	differential absorption LIDAR
DLA	direct laser acceleration
DOE	diffractive optical element
DOM	dissolved organic matter
DOS	density of states
DRO	doubly resonant OPO configurations
DRS	double Rayleigh scattering
DWDM	dense wavelength division multiplexed

E

ECDL	extended-cavity diode laser
EDFA	erbium-doped fiber amplifier
EEDF	electron energy distribution function
EFDA	Er-doped fiber amplifiers
EFS	equi-frequency surface
EL	electroluminescence
ELA	excimer laser annealing
EM	electromagnetic
EMC	electromagnetic compatibility
EMT	effective-medium theory
EO	electrooptic
EOM	electrooptic modulator
erf	error function
ESA	excited-state absorption
ESRF	European Synchrotron Radiation Facility
EUV	extreme ultraviolet
EWOD	electrowetting on dielectrics
ErIG	erbium iron garnet

F

FBG	fiber Bragg grating
FDPM	frequency-domain phase measurement
FDTD	finite-difference time domain
FEL	free-electron laser
FET	field effect transistor
FIFO	first-in first-out
FLASH	free-electron-laser Hamburg
FOM	figure of merit
FOV	field of view

FP	Fabry–Pérot
FR	Faraday rotator
FROG	frequency-resolved optical gating
FTS	Fourier-transform spectroscopy
FWHM	full width at half-maximum
FWM	four-wave mixing
FZP	Fresnel zone plate
FoM	figure of merit

G

GAC	grating assisted coupler
GASMAS	gas in scattering media absorption spectroscopy
GC	gain-coupled
GCF	geometrical configuration factor
GDD	group delay dispersion
GLAS	geoscience laser altimeter system
GLS	sulfide glasses GaLaS
GRIN	gradient index
GSA	ground-state absorption
GTI	Gires–Tournois interferometer
GVD	group velocity dispersion

H

HDPE	high-density polyethylene
HDSS	holographic data storage system
HHG	high-order-harmonic generation
HMO	heavy metal oxide
HOMO	highest occupied molecular orbital
HR	highly reflecting
HVPE	hydride-vapor-phase epitaxy

I

IAD	ion-assisted deposition
IBAD	ion-beam-assisted deposition
IBS	ion-beam sputtering
ICLAS	International Coordination Group for Laser Atmospheric Studies
ICP	inductively coupled plasma
IL	interference lithography
ILRC	International Laser Radar Conferences
IR	infrared
ITO	indium–tin oxide

K

KB	Kirkpatrick–Baez

L

lcp	left-circularly polarized light
LC–SLM	liquid-crystal spatial light modulator

LCVD	laser(-induced) chemical vapor deposition
LCoS	liquid crystal on silicon
LD	laser diode
LEAF	large effective area
LH	left-handed
LIBS	laser-induced breakdown spectroscopy
LIDAR	light detecting and ranging
LIDT	laser-induced damage threshold
LIF	laser-induced fluorescence
LMJ	laser megajoule
LOQC	linear optics quantum computing
LPCVD	low-pressure CVD
LPE	liquid-phase epitaxy
LSHB	longitudinal spatial hole burning
LSO	laser safety officer
LT	low-temperature
LT-GaAs	low-temperature GaAs
LTG-GaAs	low-temperature-grown GaAs
LUMO	lowest unoccupied molecular orbital
LWFA	laser wakefield acceleration

M

MCP	microchannel plate
MCVD	modified chemical vapor deposition
MFD	multilayer fluorescent disk
MI	modulation instability
MIS	metal–insulator–semiconductor
MMA	methyl methacrylate
MOCVD	metalorganic chemical vapour epitaxy
MOPA	master-oscillator power-amplifier
MOS	metal–oxide–semiconductor
MOT	magnetooptical trap
MPC	metallic photonic crystal
MPE	maximum permissible exposure
MPMMA	modified poly(methyl methacrylate)
MQW	multiquantum well
MSR	magnetic super-resolution
MTF	modulation transfer function

N

NA	numerical aperture
NCPM	noncritical phase matching
NEP	noise equivalent power
NFL	nanofocusing lenses
NGL	next-generation lithography
NIF	National Ignition Facility
NIM	nearly index-matched
NLSE	nonlinear Schrödinger equation
NLSG	nonlinear signal generator
NLTL	nonlinear transmission line
NOHD	nominal ocular hazard distance
NRI	nonresonant intrinsic
NSIC	National Storage Industry Consortium

O

OCT	optical coherence tomography
OFA	optical fibre amplifier
OFHC	oxygen-free high conductivity
OFI	optical-field ionization
OLED	organic light-emitting device
OP	oriented-patterned
OPA	optical parametric amplifier
OPCPA	optical parametric chirped pulse amplification
OPD	optical path difference
OPG	optical parametric generation
OPL	optical path length
OPO	optical parametric oscillator
OPS	optically pumped semiconductor laser
ORMOSIL	organically modified silicates
OSNR	optical signal-to-noise ratio
OTF	optical transfer function
OVD	outside vapor deposition

P

PA	photon avalanche
PB	photonic band
PBG	photonic band gap
PBS	photonic band structure
PBS	polarizing beam splitter
PC	photonic crystal
PCB	printed circuit board
PCF	photonic-crystal fibers
PD	photodetector
PDH	Pound-Drever-Hall technique
PDLC	polymer-dispersed liquid crystal
PDMS	polydimethylsiloxane
PECVD	plasma-enhanced chemical vapor deposition
PEDT/PSS	polyethylenedioxythiophene/ polystyrylsulfonat
PESRO	pump-enhanced SRO
PG	polarization gate
PIC	particle-in-cell
PICVD	plasma impulse CVD
PL	photoluminescence
PLD	pulsed-laser deposition
PMD	polarization mode dispersion
PMMA	polymethylmethacrylate
PMT	photomultiplier tube
POLLIWOG	polarization-labeled interference versus wavelength for only a glint
PPE	personal protective equipment
PPKTP	periodically poled potassium titanyl phosphate
PPLN	periodically poled lithium niobate
PPV	poly-para-phenylenevinylene
PQ	phenanthraquinone

PS	polystyrene
PSA	projected solid angle
PSF	point spread function
PTV	peak-to-valley
PVD	physical vapor deposition
PWM	pulse width modulator
PZT	piezoelectric transducer

Q

QC	quasicrystals
QCL	quantum cascade laser
QD	quantum dot
QDIP	quantum-dot infrared photodetector
QND	quantum nondemolition
QPM	quasi-phase matching
QW	quantum well
QWIP	quantum well infrared photodetector
QWOT	quarter-wave optical thickness
QWP	quarter-wave plate

R

RAM	residual amplitude modulation
rcp	right-circularly polarized light
RCWA	rigorous coupled wave analysis
RDE	rotating disc electrode
RDS	relative dispersion slope
RE	rare-earth
RESOLFT	reversible saturable optical fluorescence transition
RF	radio frequency
RFA	Raman fiber amplifier
RGB	red, green and blue
RIE	reactive-ion etching
RIKE	Raman-induced Kerr effect
RLVIP	reactive low-voltage ion plating
RMS	root-mean-square
RPE	retinal pigment epithelium
R/W	rewritable

S

SAR	synthetic-aperture radar

1. The Properties of Light

The mystery of light has formed the core of creation stories in every culture, and attracted the earnest attentions of philosophers since at least the fifth century BCE. Their questions have ranged from how and what we see, to the interaction of light with material bodies, and finally to the nature of light itself. This chapter begins with a brief intellectual history of light from ancient Greece to the end of the 19th century. After introducing the physical parameterization of light in terms of standard units, three concepts of light are introduced: light as a wave, light as a quantum particle, and light as a quantum field. After highlighting the distinctive characteristics of light beams from various sources – thermal radiation, luminescence from atoms and molecules, and synchrotron light sources – the distinctive physical characteristics of light beams are examined in some detail. The chapter concludes with a survey of the statistical and quantum-mechanical properties of light beams. In the appropriate limits, this treatment not only recovers the classical description of light waves and the semiclassical view of light as a stream of quanta, but also forms a consistent description of quantum phenomena – such as interference phenomena generated by single photons – that have no classical analogs.

1.1 Introduction and Historical Sketch

1.1.1 From the Greeks and Romans to Johannes Kepler

The history of optics from the fifth century BCE until the early 17th century CE can be read as a single, prolonged attempt to elucidate, first qualitatively and then quantitatively, the nature of light as it is revealed through the phenomena of propagation, reflection and refraction.

The earliest known theories about the nature of light originated with Empedocles of Agrigentum (fifth century BCE) and his contemporary, Leucippus. To the latter is attributed the notion that external objects are enveloped by eidola, "a kind of shadow or some material simulacrum which envelopes the bodies, quivers on the surface and can detach itself from them" in order to convey to the soul "the shape, the colors and all the other qualities of the bodies from which they emanate" [1.1]. A century later, Plato and his academy characterized light as a variant of elemental fire and theorized that seeing results from a conjunction of a ray emitted by the object seen and a "visual ray," emitted by the seeing eye [1.2]. This picture was contentious from the start: Plato's pupil Aristotle fumed that "to say, as the Ancients did, that colors are emissions and that this is how we see, is absurd" [1.1]. Nevertheless, the emission theory was debated well into the 16th century.

Another of Plato's pupils, the mathematician Euclid, wrote treatises on optics and catoptrics that were still being translated seven centuries later. Euclid's work is distinguished from that of his predecessors by conclusions deduced from postulates; in the *Optics*, he adduces a model of ray optics that can be translated into recognizable principles of geometrical optics including the law of reflection from a plane surface; the concept of a near point for the eye; and the focusing of light by concave surfaces [1.3]. The Roman philosopher Lucretius (early first century BCE) gave to the world in his *De Rerum Natura* the most detailed ancient understanding of not only the geometry of light propagation, but also the effects of intensity on the observer.

Two other ancient texts – by Hero (first century CE) and Ptolemy (second century CE), both of Alexandria – are important historically. Hero postulated the law of reflection in a form strikingly similar to that which emerged much later as Fermat's principle of least time. Heros's countryman Ptolemy produced a text on optics distinguished by its use of axiomatics coupled to experimental studies of reflection from curved surfaces and an attempt at developing a law of refraction. The data on refraction are remarkably accurate, [1.4] and his attempt to provide a mathematical model, though unsuccessful, nevertheless stamps the work as modern.

Building on the philosophical foundation laid by Aristotle, medieval opticians focused primarily on the phenomenon of refraction and made important predictions about the nature of light [1.1]. The ninth-century Baghdad philosopher Abu Hsuf Yaqub Ibn Is-haz (Alkindi) improved on the concept of the visual ray by requiring that it should have a physiological effect on the eye. In *De Aspectibus*, he mounted the first serious attack, supported by observations, on the theory of light as a stream of simulacra. Abu Ali al-Hasan ibn al-Haitham – known widely by his Latin name, Alhazen – published *The Book of Optics* (*De aspectibus*, or *On Vision*) in the 11th century CE. This text was translated into Latin and used until the early 17th century. His diagrams of the human visual apparatus correct some, though not all, the errors made by Galen, who worked only from dissections of animals. Because Alhazen understood how the eye lens refracted incoming rays of light, he was able to show that every point on the surface of an object in the visual field of the eye maps onto a point on the optic nerve to make a faithful, small-scale image of the object.

By the beginning of the 12th century, western European scholars had in their possession both the works of the Greeks and those of the Muslim scholars. These centuries see a working out of the contradictions inherent in these competing views by late-medieval thinkers in England, France and Italy, [1.5] including Robert Grosseteste and Roger Bacon who were unwilling to accept the dogmatism of the Scholastics. In particular, they saw the phenomenology of the rainbow as a key to the understanding of refraction and reflection. The origin of the rainbow was correctly explained for the first time by Theodoric of Freiburg in the 15th century.

1.1.2 From Descartes to Newton

By the time of Johannes Kepler's death in the mid-17th century, the concept of light as a geometrical ray emanating from an object and collected by the eye was firmly established, and the emphasis shifted to theoretical questions about the mechanisms of refraction and reflection that could only be answered by understanding the properties of light. Moreover, there was increasing emphasis from the mid-17th century onward on carefully controlled experimentation, not simply ob-

servation. Harmonized with mathematical models, this experimental philosophy proved to be the way to establish scientific knowledge of light on the strongest foundation [1.6].

René Descartes and the Cartesian thinkers who followed his lead, built a science of light and optics as part of a more general mathematical theory of physics, with his *Dioptrics* and the *Discourses* [1.7]. The Cartesian theory is distinguished by the concept of light as a vibration in a diaphanous medium that transmits the undulations from object to eye, a tendency to motion in particles of the embedding medium. Robert Hooke, Thomas Hobbes and Christiaan Huygens were likewise committed to vibrational theories of light. The first experimental evidence of what would eventually be convincing evidence for the wave theory of light came in 1658 with the publication of Grimaldi's first memoir on diffraction.

Pierre Fermat (1601–1665) solved one of the problems that the *Dioptrics* had treated badly, and did so in a way that was characteristic of what Newton would later call "mathematical philosophy." Fermat's simple idea was based on the rectilinear propagation of light, and the postulate that light travels less rapidly in a dense, material medium than in air. From this, he hypothesized that a light ray always follows that path that allows it to travel a given trajectory in the shortest time. It is possible to derive Snell's law of refraction from this principle of least time [1.8].

Fermat based his theory on the assumption that the speed of light was finite, and that it was slower in material bodies than in air or vacuum – clearly contradicting Descartes, who believed the speed of light to be infinite. The Cartesian postulate was disproved when Cassini (in 1675) and Ole Römer (a year later), measured the time it took light to pass across the earth's orbit based on observation of the transit time of Jupiter: about 11 minutes. The surveyors – Cassini in Paris and Jean Richer in Guyana – were measuring the Earth's orbit. Christiaan Huygens, court astronomer to Louis XIV, proposed a figure of 12, 000 earth diameters for the orbital diameter, and thereby arrived in his *Treatise on Light* at an estimate of 2.3×10^8 m/s, within 20% of the currently accepted value and very close to the value calculated by Newton [1.9]. Grimaldi (1658) had discovered the phenomenon of diffraction, the explanation of which led in time to the ascendance of the wave theory. Progress in the science of light during this period was also aided immensely by the development of the differential and integral calculus and by the invention of high-quality clear glass for lenses, prisms and optical instruments such as telescopes, microscopes and eventually spectrometers [1.10].

1.1.3 Newton and Huygens

The early part of the 18th century saw the rise of the two competing theories about the nature of light that were to dominate the next century and a half. These are embodied in the lives and work of the two principals: Isaac Newton (1642–1728) and Christiaan Huygens (1629–1695).

The dispersion of light in a prism was known well before the young Isaac Newton "procured . . . a prism with which to try the celebrated phenomenon of colors." Newton's *experimentum crucis* was designed to show that white light could be decomposed into constituent colors that were dispersed according to a corpuscular model [1.11]. However, Newton's *Opticks*, when published in 1710, was a curious admixture of *projectile* or *corpuscular* ideas and crude wave theories. Newton believed in the ether as a required medium to support the projectiles, and expected that the ether would undulate as light corpuscles passed through it. However, he was convinced on the basis of the corpuscular model that light traveled faster in material media, an assumption that would not be conclusively disproved until Foucault's experiments in 1850.

Challenges to Newton's corpuscular theory came from kinematical theories that viewed light as one or another kind of vibrational motion: a vibratory motion supported by an ether (Hooke, 1665); or a propagating pulse-like disturbance in the ether (Huygens, 1690) [1.12]. Leonhard Euler explained refraction at an interface based on the vibrational theory, arguing that dispersion resulted from a variation of vibrational motion with color [1.13]. In Germany at least, Euler was seen as the originator of a wave model that could replace Newton's corpuscular theory. In France, Huygens developed a geometrical construction of secondary wavelets to trace the propagation of a wave in time, laying a conceptual foundation for early 19th-century experiments in interference and diffraction that ultimately undermined the corpuscular hypothesis.

1.1.4 The 19th Century: The Triumph of the Wave Picture

By the last quarter of the 18th century, it was clear that Newton's corpuscular theory could not match the experimentally measured velocity of light in materials; moreover, experiments by Malus and Arago had shown

that light has a new property, which came to be called polarization, that does not fit within the corpuscular picture at all. The earliest systematic studies of polarization phenomena associated with the propagation of light waves are due to Étienne Malus in 1808, in response to a prize competition offered by the Paris Academy for a mathematical description of the phenomenon of double refraction in Iceland spar (calcite). Malus's discoveries led to the recognition that light is a transverse electromagnetic wave, in which the electric and magnetic fields are perpendicular to each other and to the direction of propagation. Malus, using his ingenious refractometer, demonstrated in 1807 that the phenomenon of double refraction could be explained mathematically by Huygens' construction. Fresnel, a dozen years later, was to win the prize competition for his theory of diffraction, even anticipating the objection of Poisson that light diffracted around a tiny opaque object would produce a bright spot in the middle of the geometrical shadow – to be known afterwards as *Poisson's spot* [1.4]. Moreover, increasingly powerful mathematical descriptions [1.14] were applied to the phenomena of interference and diffraction studied experimentally by Thomas Young, the London polymath, and Fresnel. It was at last becoming clear that light constituted a qualitatively new kind of wave in which the vibrations were transverse to the direction of propagation of the light [1.15]. Indeed, the transverse character of the vibrations was first suggested by Young in a letter to Arago in 1812, thus hinting that Young was already reinterpreting his interference experiments in a way that differed sharply from previous thinking based on analogies with acoustic waves [1.16].

At virtually the same time, Biot and Savart, Ampère and Faraday were generating the experimental underpinnings for the eventual unification of optics and electromagnetism. Galvani's experiments on the stimulus of what was then called *animal electricity* had shifted attention from electrostatics, the major preoccupation of the eighteenth century, to time-dependent phenomena associated with electricity. However, it was Alessandro Volta who successfully showed that this phenomenon was not due to some *vital* magnetic force, but that it was no different from ordinary magnetism. While electrophysiology continued to be of major interest to biologists and students of medicine, it was thereafter studied by physicists primarily in relation to other electromagnetic phenomena. Oersted, by showing the deflection of a compass placed next to a current-carrying wire, demonstrated the interconnection of electrical and magnetic phenomena. And Faraday, in 1845, showed that the polarization of light could be rotated by applying a strong magnetic field to a medium through which the light was propagating.

Thus the stage was set for the grand synthesis of classical electromagnetic theory. The first step was the publication of James Clerk Maxwell's theory of electromagnetism in 1869. Maxwell's theoretical prediction of electromagnetic radiation was verified experimentally by Heinrich Hertz in 1888 with the discovery of *Hertzian waves* in what now would be called the radiofrequency range of the spectrum. The classical theory of the electron developed by H. A. Lorentz would be the next step in the creation of a 19th-century *theory of everything*. The only clouds on the horizon were the unsolved problems of black-body radiation and the photoelectric effect, problems whose solutions would lead to the development of quantum physics and the evolution of a new view of light based on its dual character as wave and particle, and later of its accommodation into a fully quantum-mechanical field theory.

1.2 Parameterization of Light

The properties of light are parameterized in similar ways in both the classical (wave) and semiclassical (photon) pictures of light. The fundamental physical properties of an electromagnetic wave are its wavelength λ, frequency ν and polarization state; alternatively, the first two of these properties may be stated in the form of a *wave number* $k = 2\pi\lambda$ and *angular frequency* $\omega = 2\pi\nu$. The photon model associates with individual light quanta a particle-like *photon energy* $E_{\mathrm{photon}} = \hbar\omega$ and momentum $p_{\mathrm{photon}} = \hbar k$, where $h = 2\pi\hbar$ is Planck's constant. Photons are also associated with a helicity (photon spin) of ± 1 that can be related to wave polarization.

The properties of light have been defined by international commissions in four kinds of units now in general use, depending on what properties are to be emphasized: radiometric units, based on the physical units, such as energy, and power, are used to describe the properties of electromagnetic waves or photons; photometric units, which refer to the properties of light as discerned by the human eye; photon units analogous to radiometric units that are normalized to photon energy; and spectral units that parameterize light in terms of its properties at specific frequencies or wavelength.

1.2.1 Spectral Regions and Their Classification

The electromagnetic spectrum extends over an enormous range of frequencies and wavelengths, from low-frequency radio wavelength vibrations to extremely high-energy, short-wavelength nuclear gamma radiation. Figure 1.1 shows a typical classification scheme, relating wavelengths, frequencies, wave numbers and photon energies to the common designations of spectral regions of interest in optics, extending from the vacuum ultraviolet through the far-infrared. Some of the units employed match the Système International (SI) convention, others are habitually used in specialized science or technology communities.

1.2.2 Radiometric Units

Radiometric units measure the properties of light in terms of physical units of energy and power, without reference to wavelength, and are therefore the most fundamental of the parameters used to describe light [1.19, 20]. The fundamental radiometric units are: radiance, a vector L whose magnitude is the power passing through a surface of unit area into a unit solid angle about the normal to the surface; irradiance, again a vector E, defined as the total power per unit spectral interval passing through a surface of unit area. As shown in Fig. 1.2, the magnitude of the radiance and irradiance depends on the shape of the surface over which one integrates, that is, over the projected area $A_\perp$ as well as the solid angle $d\Omega$ into which light is emitted and the perpendicular area of the detector. The definition of spectral interval is not uniform; depending on the resolution or the parameterization desired, it might be given in Å, nm, cm^{-1} (not the same as 1/cm), or Hz, as here. To convert any radiometric unit X to the corresponding spectral radiometric unit X_ν, recall that $X = X_\nu \, d\nu$ for values of the frequency lying between ν and $\nu + d\nu$.

1.2.3 Photometric Units

Photometry refers to the measurement of light as it is perceived by the human eye; thus these units pertain principally to light with wavelengths of 380–760 nm. In astronomy, photometry also refers to the measurement of apparent magnitudes of celestial objects. Since these quantities depend on the spectral amplitude of light, it is not possible to convert photometric values directly into energy values. The photometric units use the same terminology and symbols as the radiometric units, but with a subscript V for *visual*.

The four fundamental photometric quantities, listed in Table 1.2, are: *luminous intensity*, the amount of light emitted by a source; *luminous flux*, the quantity of light transmitted in a given direction; *illuminance*, the measure of light falling on a surface; and *luminance*, which measures the brightness of a surface

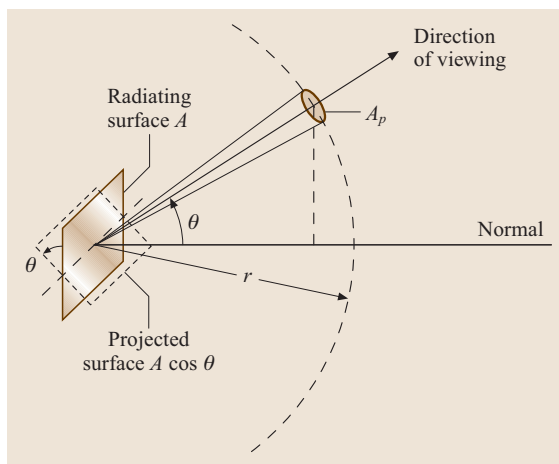
Fig. 1.1 Chart showing the wavelengths, frequencies, wave numbers and photon energies of electromagnetic radiation of interest in optics. (After [1.17])


Fig. 1.2 Geometry used to define radiometric units of radiance and irradiance in terms of emitting area, detecting area and solid angle of emission. The projected surface area in a given angular direction Θ is $A_\perp = A \cos \Theta$, while the solid angle in radiometric units is determined by the projected detector area A_p perpendicular to the viewing direction, $d\Omega = A_p/r^2$. (After [1.18])

Table 1.1 Radiometric units

	Symbol	SI unit	Definition
Radiant energy	Q_e	J = W s	–
Radiant energy density	w_e	J/m^{-3}	$w_e = \langle dQ_e/dV \rangle$
Radiant flux (power)	Φ_e	W	$\Phi_e = \langle dQ_e/dt \rangle$
Radiant exitance	M_e	W m^{-2}	$M_e = \langle d\Phi_e/dA \rangle$
Irradiance	E_e	W m^{-2}	$E_e = \langle dQ_e/dt \rangle$
Radiant intensity	I_e	W sr^{-1}	$I_e = \langle d\Phi_e/d\Omega \rangle$
Radiance	L_e	W m^{-2} sr^{-1}	$L_e = I_e/\Delta A \equiv \langle d^2\Phi_e/d\Omega \cdot dA \rangle$

Table 1.2 Photometric units

	Symbol	SI unit	Photometric unit	Definition
Luminous energy	Q_V	J=W s	lm s (talbot)	—
Luminous energy density	W_V	J / m^3	lm s/m^3	$w_V = \overline{dQ_V/dV}$
Luminous intensity	I_V	W sr^{-1}	lm sr^{-1} = candela (cd)	$I_V = \overline{d\Phi_V/d\Omega}$
Luminous power	Φ_V	W	lm (lumen)	$\Phi_V = \overline{dQ_V/dt}$
Luminous exitance	M_V	W m^{-2}	lm m^{-2}	$M_V = d\Phi_V/dA$
Illuminance	E_V	Wsr^{-1}	lux (lx) = lm m^{-2}	$E_V = d\Phi_V/dA$
Luminance (Apostilb)	L_V	W m^{-2} sr^{-1}	asb = $1/\pi$ cd/m^2	$L_V = \overline{d^2\Phi_V/dA \cdot d\Omega}$

considered as a light source. The standard source, or international standard candle, is defined as the intensity of a black-body radiator with an area of $1/60\,\text{cm}^2$

Fig. 1.3 The standard CIE luminous efficacy curve for the human eye, used as the basis for converting between photometric and radiometric units

heated to the melting point of platinum. Two auxiliary quantities, *luminous energy* and *luminous energy density*, correspond to the analogous radiometric units. The photometric units carry a subscript V for *visual*, to distinguish them from their radiometric counterparts; the overbar in the table below signifies an averaged quantity.

The Commission Internationale de l'Eclairage (CIE) has developed a standard luminous efficacy curve for the human eye, with respect to which the photometric units are referred (Fig. 1.3). The lumen is defined such that the peak of the photopic (light-adapted) vision spectrum of an average eye has a luminous efficacy of 683 lm/W.

1.2.4 Photon and Spectral Units

In the photon picture, there is a different set of descriptive quantities normalized to photon energy or photon number, as shown in Table 1.3. The overbarred quantities denote an average over photon wavelengths as well as over area and solid angle.

In some cases – for example, when discussing the spectral brightness of laser or synchrotron sources – it is useful to distinguish physical quantities by their frequency ν. For example, in most cases involving spectroscopy or materials processing with lasers, the

Table 1.3 Photon units

	Symbol	SI unit	Definition
Photon number	$\bar{n}$	Number	$\bar{n} = Q_v/\hbar\bar{\omega}$
Photon density	w_n	Number m^{-3}	$w_n = \overline{d\bar{n}/dV}$
Photon flux (power)	Φ_n	Number s^{-1}	$\Phi_n = \overline{d\bar{n}/dt}$
Photon irradiance	E_n	Number s^{-1} m^{-2}	$E_n = \overline{d\Phi_n/dA}$
Photon intensity	I_n	Number s^{-1} sr^{-1}	$I_n = \overline{d\Phi_n/d\Omega}$
Photon radiance	L_n	Number s^{-1} m^{-2} sr^{-1}	$L_n = \overline{d^2\Phi_n/dA \cdot d\Omega}$

Table 1.4 Spectral radiometric units

	Symbol	SI unit	Definition
Spectral radiant energy	Q_ν	J Hz^{-1} = W s Hz^{-1}	–
Spectral radiant energy density	w_ν	J Hz^{-1} m^{-3}	$w_\nu = \overline{dQ_\nu/dV}$
Spectral radiant flux (power)	Φ_ν	W Hz^{-1}	$\Phi_\nu = \overline{dQ_\nu/dt}$
Spectral radiant exitance	M_ν	W m^{-2} Hz^{-1}	$M_\nu = \overline{d\Phi_\nu\,dA}$
Spectral irradiance	E_ν	W m^{-2} Hz^{-1}	$E_\nu = \overline{dQ_\nu/dt}$
Spectral radiant intensity	I_ν	W sr^{-1} Hz^{-1}	$I_\nu = \overline{d\Phi_\nu/d\Omega}$
Spectral radiance	L_ν	W m^{-2} sr^{-1} Hz^{-1}	$L_\nu = \overline{d^2\Phi_\nu/d\Omega \cdot dA}$

quantity of interest is not simply the intensity or radiance, but the intensity or radiance available within a certain spectral bandwidth that defines the effective region of laser-materials interaction, in other words, the *spectral brilliance*. In Table 1.4, the overbarred quantities indicate averages over time, space or solid angle, but *not* over frequency. To convert any radiometric unit X to the corresponding spectral radiometric unit X_ν, recall that $X = X_\nu\,d\nu$ for values of the frequency lying between ν and $\nu + d\nu$.

1.3 Physical Models of Light

By the end of the 19th century, it was generally accepted that the battle between the corpuscular (or emission) and wave theories of light had been resolved in favor of the latter. However, experimental developments – and the inability of classical electrodynamics and statistical mechanics to account for either the photoelectric effect or the shape of the black-body spectrum – drove Planck, Einstein and de Broglie to develop a semiclassical theory of the light quantum (eventually christened the "photon" by *G. N. Lewis* [1.21]). The picture of light as a quantum field emerged in the second half of the 20th century as it became experimentally possible to investigate phenomena associated both with small numbers of photons, statistically distinct ensembles of photons, and correlations between photons emitted in atomic cascades. We now consider the basic concepts underlying the classical, semiclassical and quantum models of light.

1.3.1 The Electromagnetic Wave Picture

Maxwell's classical theory of electromagnetism [1.22] is based on: Gauss's law, a mathematical relationship governing the spatial properties of vector fields with or without sources; Faraday's law of magnetic induction; and Ampère's law linking currents with spatial variations in magnetic field. Maxwell's recognition of the displacement current – the induced current due to time-varying electromagnetic fields – made it possible finally to establish the static and dynamical relationships between the electric field E (the force per unit charge) and magnetic induction B (the force per unit current). Together with the constitutive relations for the electric displacement and the magnetic field, Maxwell's four equations, given below in differential and integral form, govern all classical

electromagnetic phenomena including electromagnetic waves.

$$\nabla \cdot \boldsymbol{D} \equiv \nabla \cdot (\varepsilon_0 \boldsymbol{E} + 4\pi\varepsilon_0 \boldsymbol{P}) = \rho \,,$$

$$\int\limits_{\text{volume}} \nabla \cdot \boldsymbol{D}\, \mathrm{d}V = \frac{Q}{\varepsilon_0} \,,$$

$$\nabla \cdot \boldsymbol{B} = 0 \,,$$

$$\int\limits_{\text{volume}} \nabla \cdot \boldsymbol{B}\, \mathrm{d}V = 0 \,,$$

$$\nabla \times \boldsymbol{E} = -\frac{\partial \boldsymbol{B}}{\partial t} \,,$$

$$\oint\limits_{\text{open surface}} (\nabla \times \boldsymbol{E}) \cdot \mathrm{d}\boldsymbol{S} = -\frac{\partial}{\partial t} \oint\limits_{\text{loop}} \boldsymbol{B} \cdot \mathrm{d}\boldsymbol{s} \,,$$

$$\nabla \times \boldsymbol{H} = \left(\boldsymbol{J} + \frac{\partial \boldsymbol{D}}{\partial t} \right) \,,$$

$$\oint\limits_{\text{surface}} (\nabla \times \boldsymbol{H}) \cdot \mathrm{d}\boldsymbol{S} = \oint\limits_{\text{loop}} \left(\boldsymbol{J} + \frac{\partial \boldsymbol{D}}{\partial t} \right) \cdot \mathrm{d}\boldsymbol{s} \qquad (1.1)$$

where ρ is the charge density and Q the enclosed charge. The constitutive relations electric displacement vector $\boldsymbol{D}$ and for magnetic field $\boldsymbol{H}$ are

$$D_\alpha = \varepsilon_0 E_\alpha + \left(P_\alpha - \sum_\beta \frac{\partial}{\partial x_\beta} Q_{\alpha\beta}^{(2)} + \dots \right) \,,$$

$$H_\alpha = \frac{1}{\mu_0} B_\alpha - (M_\alpha + \dots) \,, \qquad (1.2)$$

where the terms in parentheses represent the contributions of dielectric and magnetic materials to the electric field (e.g., linear polarization P_α, quadrupole contributions $Q_{\alpha\beta}^{(2)}$, and so on) and the magnetic induction (e.g., the bulk magnetization M_α). The dielectric function and the magnetic susceptibilities are properties of materials, and vanish in vacuum. Further information on the constitutive relations, including their relativistic forms, may be found in textbooks [1.23, 24]

The second term in Ampère's law – the last of the four Maxwell equations – was deduced by James Clerk Maxwell from the asymmetry between the electric and magnetic fields that would exist if this *displacement current* were omitted. The last two of these equations can be combined using the vector identity $\nabla \times (\nabla \times \boldsymbol{V}) = \nabla(\nabla \cdot \boldsymbol{V}) - \nabla^2 \boldsymbol{V}$ to yield a wave equation that describes the propagation of transverse electromagnetic waves in a medium with a dielectric function $\varepsilon = n^2$ and

magnetic susceptibility μ_0

$$\nabla^2 \boldsymbol{E} - \frac{n^2}{c^2} \frac{\partial^2 \boldsymbol{E}}{\partial t^2} = 0 \,,$$

$$\nabla^2 \boldsymbol{B} - \frac{n^2}{c^2} \frac{\partial^2 \boldsymbol{B}}{\partial t^2} = 0 \,,$$

$$c^2 = (\varepsilon_0 \mu_0)^{-1} \,. \qquad (1.3)$$

The solutions to this equation include near-field or *static-field* terms that decrease as $1/r^3$, an intermediate-range oscillatory field that exists in the so-called *induction zone*, and the propagating-wave terms whose amplitude decreases as $1/r$.

A time-dependent scalar field satisfying the wave equation in a source-free region may be decomposed into Fourier components at angular frequencies ω_i, $i = 0, 1, 2, 3, \dots$ that satisfy a Helmholtz wave equation, as follows:

$$E_\alpha (\boldsymbol{r}, t) = \int\limits_{-\infty}^{\infty} E_\alpha (\boldsymbol{r}, \omega_i)\, \mathrm{e}^{-\mathrm{i}\omega_i t}\, \mathrm{d}\omega_i \,,$$

$$\Rightarrow \left(\nabla^2 + k_i^2 \right) E_\alpha (\boldsymbol{r}, \omega_i) = 0 \,,$$

$$k_i^2 = \frac{\omega_i^2}{c^2} \,. \qquad (1.4)$$

The Maxwell equations are generally presented in terms of the *force fields* $\boldsymbol{E}$ and $\boldsymbol{B}$. However, it is often more convenient to represent electromagnetic waves in terms of vector and scalar potentials; this is particularly true for making the transition between the classical and quantum field pictures. Given the two homogeneous Maxwell equations, we can define a vector potential that is related to the electric field, the electric potential and the magnetic induction. Furthermore, because the magnetic induction remains unchanged by the addition of the gradient of a scalar function, we have an additional degree of freedom, the choice of gauge, which, in this case, is conveniently chosen to be the so-called *Lorentz gauge*:

$$\boldsymbol{B} = \nabla \times \boldsymbol{A} \,,$$

$$\boldsymbol{E} + \frac{\partial \boldsymbol{A}}{\partial t} = -\nabla \Phi \,,$$

$$\nabla \cdot \boldsymbol{A} + \frac{1}{c^2} \frac{\partial \Phi}{\partial t} = 0 \,. \qquad (1.5)$$

With this choice of gauge, the inhomogeneous Maxwell equations can be decoupled to form a pair of inhomogeneous wave equations in the potentials, in which the sources of the wave fields are the charge and current

densities [1.24]:

$$\nabla^2 \Phi - \frac{1}{c^2} \frac{\partial^2 \Phi}{\partial t^2} = -\frac{\rho}{\varepsilon_0}$$

$$\nabla^2 \boldsymbol{A} - \frac{1}{c^2} \frac{\partial^2 \boldsymbol{A}}{\partial t^2} = -\mu_0 \boldsymbol{J} \,. \tag{1.6}$$

The other common gauge is the Coulomb or transverse gauge, which is so named because the source term is only the transverse component of the current density $\boldsymbol{J}$. The radiation fields are determined by the vector potential alone; the Coulomb potential contributes only to the near field. However, although it will not be discussed further here, the optical near field has assumed significant importance as a probe of nanoscale phenomena now that there are optical techniques for sampling it and coupling it to far-field radiation that can be transported and observed [1.25, 26].

The ratio of electric to magnetic field amplitudes derivable from the Maxwell equations for a plane wave is $|E(\boldsymbol{r}, t)| = c|B(\boldsymbol{r}, t)|$; in fact, it turns out that this is a general property of electromagnetic waves. This means that for almost all practical purposes in describing the properties of electromagnetic waves, it is safe to focus on the electric field alone.

For most purposes, three traveling-wave solutions of the scalar wave equation are sufficient to encompass the most common phenomena of wave optics: the spherical wave typical of light emanating from a point source; the plane wave that is the asymptotic form of the wavefront of a spherical wave at large distances from the source; and the Gaussian beam that describes light emitted by a laser source that is constrained in two spatial dimensions by the laser resonator.

Spherical Wave
The scalar solution for electromagnetic radiation emitted from a point source, in spherical coordinates, takes the form of a spherical wave

$$E(\boldsymbol{r}, \omega) = \sum_{l,m} \left[A_{lm}^{(1)} h_l^{(1)}(kr) + A_{lm}^{(2)} h_l^{(2)}(kr) \right]$$
$$\times Y_{lm}(\vartheta, \varphi) \, e^{i\omega t} \,, \tag{1.7}$$

where $h_l^{(i)}(kr)$, $i = 1, 2$ are the Hankel functions of the first and second kind, $Y_{lm}(\vartheta, \varphi)$ are the spherical harmonics, and the coefficients $A_{lm}^{(i)}$, $i = 1, 2$ are determined by the boundary conditions. Since the electric field in general is a vector, the general solution is significantly more complex but systematic presentations may be readily found elsewhere [1.24].

Plane Wave
The simplest possible solution to Maxwell's equations is the *plane wave*, in which the phase fronts are infinite planar surfaces perpendicular to the direction of propagation. In Cartesian coordinates, assuming that the wave propagates in the z-direction, the plane wave for the Fourier component with frequency ω is described by the equation

$$\boldsymbol{E}(\boldsymbol{r}, t) = \boldsymbol{E}_0(x, y) \exp[i(k_z z - \omega t)] \,. \tag{1.8}$$

The plane wave is a convenient approximation to a small segment of an electromagnetic wave far from a point source where the spherical wavefronts have a very large radius of curvature.

Gaussian Beam
The beam of light emitted by a laser has properties that are determined by the geometry of the optical resonator for the laser, and for a cylindrically symmetric beam propagating in the z-direction is described by a function of the form [1.23]:

$$E(r) = E_0(r, z) \exp\left(-\frac{r^2}{w^2(z)} \right) \,,$$

$$w^2(z) = w_0^2 \left[1 + \left(\frac{\lambda z}{\pi w_0^2} \right)^2 \right] \,,$$

$$E_0(r, z) = \frac{1}{w(z)} \left[\frac{\sqrt{2} r}{w(z)} \right]^m L_l^m \left(\frac{2r^2}{w^2(z)} \right)$$
$$\times e^{im\varphi} \exp\left[i\left(\Phi(z) + \frac{kr^2}{2R(z)} \right) \right] \,, \tag{1.9}$$

$$\Phi(z) = -(2l + m + 1) \tan^{-1} \left(\frac{z - z_0}{z_R} \right) \,,$$

$$R(z) = z \left(1 + \frac{z_R^2}{z^2} \right) \,,$$

$$z_R = \frac{\pi w_0^2}{\lambda} \,. \tag{1.10}$$

Here the functions $L_l^m(r, z)$ are the generalized Laguerre polynomials, a complete orthogonal set of functions. The indices $\{l, m\}$ represent different spatial modes of the Gaussian beam; for most laser experiments, one tries very hard to have a beam in the *fundamental Gaussian mode*, in which $\{l = 0, m = 0\}$. The quantity w_0 is frequently called the *beam waist*, and represents the minimum focal spot size that will be reached at some point along the propagation axis. The intensity falls off

exponentially from the central maximum, and the rate at which that happens is governed by the beam waist at the given z coordinate. At that point, the wavefront is planar and perpendicular to the axis of propagation. The behavior of a Gaussian beam is often specified by the *Rayleigh range* z_R (or the *confocal beam parameter* $b = 2z_R$) and the *divergence angle* Θ, shown schematically in Fig. 1.4; these are given respectively by

$$b = \frac{2\pi w_0^2}{\lambda} \,,$$
$$\Theta = \frac{2\lambda}{\pi w_0} \tag{1.11}$$

Wave Packets

Although all of these solutions to the Maxwell equations are monochromatic waves, in fact light beams often are mixtures of waves of differing frequencies. This comes about because of the spread in wavelengths of white-light sources, the natural line width of even spectrally pure atomic sources, the broadening mechanisms (e.g., Doppler broadening) typical of many atomic or molecular light sources, and because of mode hopping from one frequency to another in laser sources. Mathematically, of course, this fact causes no difficulties because of the superposition principle for harmonic functions. The term *wave packet* refers to such a superposition of waves of many different modes. This should not be confused with the so-called wave-packet model of the photon found in many elementary texts; this model, usually presented as a way of thinking about wave–particle duality, presents a number of philosophical and pedagogical problems [1.27].

For coherent sources, there is an additional constraint on pulse duration and bandwidth, rather like the indeterminacy principle in quantum mechanics and

sometimes derived from it. This constraint says that, for a source with duration $\Delta\tau$, the spectral bandwidth satisfies the condition $\Delta\tau \cdot \Delta\nu \geq 1$, where ν is the frequency. Hence, light that comes from continuous-wave coherent sources can have extremely narrow bandwidths (i.e., high spectral purity). The best achieved so far is a bandwidth of order 1 kHz. On the other hand, the shortest laser pulses made to date, with durations of 4 fs, have spectral bandwidths of 200 nm or more.

1.3.2 The Semiclassical Picture: Light Quanta

The theory of light quanta developed by Planck and Einstein explained the salient characteristics of black-body radiation spectra in a semiclassical picture that quantized the allowable frequencies of radiation, but otherwise treated electromagnetic radiation in terms of classical fields [1.28]. This picture was incorporated into the quantum theory developed by Schrödinger, Heisenberg and especially Dirac; importantly, it avoided the troublesome mathematical divergences that occurred in a quantum-mechanical treatment of electromagnetic radiation. It eventually turned out, as noted by Heitler in a classic text, that these difficulties were primarily of a formal mathematical character [1.29] that was resolved in the modern version of quantum electrodynamics by Dyson, Feynman, Schwinger and Tomonaga [1.30]

The spectrum of radiation from a body at thermal equilibrium at a temperature T, when modeled on the basis of classical theory, produced a catastrophic divergence of the predicted radiated intensity at ultraviolet wavelengths. Planck solved this problem by treating the radiation field as a collection of simple harmonic oscillators in the cavity (Hohlraumstrahlung), and then taking a new approach to calculating the density of modes based on Boltzmann statistics [1.31]. Since the radiation field must satisfy Maxwell's wave equation, the three components of the electric field must satisfy the equations

$$E_x(\boldsymbol{r}, t) = E_x(t) \cos(k_x x) \sin(k_y y) \sin(k_z z) \,,$$
$$\quad k_x = \pi \nu_x L \,, \quad \nu_x = 0, 1, 2, 3, \ldots$$
$$E_y(\boldsymbol{r}, t) = E_x(t) \sin(k_x x) \cos(k_y y) \sin(k_z z) \,,$$
$$\quad k_y = \pi \nu_y L \,, \quad \nu_y = 0, 1, 2, 3, \ldots$$
$$E_z(\boldsymbol{r}, t) = E_x(t) \sin(k_x x) \sin(k_y y) \cos(k_z z) \,,$$
$$\quad k_z = \pi \nu_z L \,, \quad \nu_z = 0, 1, 2, 3, \ldots . \tag{1.12}$$

Any possible radiation field must be expressible as a sum of these cavity modes; the *spatial quantization* here is

Fig. 1.4 Schematic of the spatial profile of a Gaussian beam near a beam waist, showing the Rayleigh range or confocal beam parameter and the divergence angle Θ. The envelope of the beam represents the point at which the field has decreased to $1/e$ of its maximum value on the beam axis

the consequence of the boundary conditions at the cavity walls applied to the Maxwell equations. The density of modes is readily calculated to be

$$\rho_k \, dk = \frac{k^2 \, dk}{\pi^2}$$

$$\Rightarrow \rho_\omega \, d\omega = \frac{\omega^2 \, d\omega}{\pi^2 c^3} \ . \tag{1.13}$$

For a system of harmonic oscillators in thermal equilibrium, the probability that an oscillator is excited into the nth mode is given by the Boltzmann probability

$$\begin{aligned} P_n &= \frac{\exp(-E_n/k_B T)}{\sum\limits_m \exp(-E_m/k_B T)} \\ &= \frac{\exp[-(n+1/2)\hbar\omega/k_B T]}{\sum\limits_{m=0}^{m} \exp[-(m+1/2)\hbar\omega/k_B T]} \\ &= \frac{\exp(-n\hbar\omega/k_B T)}{\sum\limits_{m=0}^{m} \exp(-m\hbar\omega/k_B T)} \ , \end{aligned} \tag{1.14}$$

where $\hbar$ is Planck's constant. From this, with the substitution $U \equiv \exp(-\hbar\omega/k_B T)$ the average occupation number of a cavity radiation mode for one polarization direction is calculated to be

$$\begin{aligned} \langle n \rangle &= \sum_m m P_m = (1-U) \sum_m m U^m \\ &= (1-U) \, U \frac{\partial}{\partial U} \sum_m U^m \\ &= \frac{1}{\exp(\hbar\omega/k_B T)} \ . \end{aligned} \tag{1.15}$$

This distribution function correctly reproduced the extant spectral measurements on black-body radiators, as well as the empirically derived Wien displacement law, which gave the shift in the measured maximum intensity as a function of wavelength.

The energy density per unit angular frequency in a Hohlraum or cavity radiator is directly proportional to the irradiance (or intensity) of the radiation, and is found by multiplying the density of radiation modes (1.13) by the energy per quantum times the average occupation number:

$$\begin{aligned} U(\omega) \, d\omega &= \hbar\omega \rho_\omega \langle n \rangle \, d\omega \\ &= \frac{\hbar\omega^3}{\pi^2 c^3} \frac{1}{\exp(\hbar\omega/k_B T) - 1} \, d\omega \ . \end{aligned} \tag{1.16}$$

1.3.3 Light as a Quantum Field

Neither Planck's explanation of black-body radiation nor Einstein's theory of the photoelectric effect required one to think of light as a quantum object. In their semiclassical approach, light was treated as a classical electromagnetic wave and only the interaction with matter (e.g., in absorption or emission) was described in terms of quanta. However, working from experimental data of *Kocher* and *Commins*, [1.32], *Clauser* showed that polarization correlations of photons emitted in cascaded atomic transitions could not be accounted for by a semiclassical theory [1.33]. This turned out to be only one instance of what now is understood to be generally true: higher-order photon correlations, single-photon experiments, photon entanglement and photon squeezing cannot be properly described without a fully quantum-mechanical theory of the radiation field.

Such a theory requires, first of all, a prescription for converting the field variables E and B of classical radiation theory into a quantum mechanical operators [1.34]. This is accomplished by introducing the vector potential A in the Coulomb gauge, satisfying the conditions

$$\begin{aligned} B &= \nabla \times A \ , \\ E &= -\nabla \phi \ , \\ \nabla \cdot A &= 0 \ . \end{aligned} \tag{1.17}$$

In free space, the vector potential satisfies the same wave equation that is satisfied by the electric and magnetic fields. For traveling waves subject to periodic boundary conditions, the vector potential can be expanded in a Fourier series. The vector potentials associated with the kth frequency mode of the radiation field can be expressed in terms of generalized position and momentum variables, Q_k and P_k, associated with the kth oscillatory mode, as follows

$$\begin{aligned} A_k &= \frac{1}{4\pi\varepsilon_0 \omega_k^2} \frac{1}{V} (\omega_k Q_k + i P_k) \, \varepsilon_k \\ A_k^* &= \frac{1}{4\pi\varepsilon_0 \omega_k^2} \frac{1}{V} (\omega_k Q_k - i P_k) \, \varepsilon_k \quad \Rightarrow \\ \bar{E}_k &= \frac{1}{2} \int\limits_{\text{cavity}} \left(\varepsilon_0 \overline{E_k^2} + \mu_0^{-1} \overline{B_k^2} \right) dV \\ &= \frac{1}{2} \left(P_k^2 + \omega_k^2 Q_k^2 \right) \ , \end{aligned} \tag{1.18}$$

where the overbar indicates spatial and temporal averages. Thus the quantum-mechanical description of light associates with each mode of the radiation field an oscillator with a frequency ω_k, and likewise associates

the quantum canonical coordinates with the electric and magnetic fields.

The quantized radiation field is obtained by converting the dynamical variables $\{Q_k, P_k\}$ into corresponding operators $\{\hat{q}_k, \hat{p}_k\}$, and inserting these operators into the appropriate Hamiltonian for the field. The Hamiltonian operator for a harmonic oscillator of mass $m = 1$ (in some natural units) is $\hat{H} = (\hat{p}^2 + \omega^2\hat{q}^2)$; the operators obey the commutation relation $[\hat{q}, \hat{p}] = \mathrm{i}\hbar$.

It turns out to be useful to work not with these artificial coordinates and momenta, but with the so-called creation and annihilation operators for the oscillators, which are defined, together with their commutator, as follows:

$$\hat{a} = \left(\frac{1}{2\omega\hbar}\right)^{1/2} (\omega\hat{q} + \mathrm{i}\hat{p}) \;,$$

$$\hat{a}^\dagger = \left(\frac{1}{2\omega\hbar}\right)^{1/2} (\omega\hat{q} - \mathrm{i}\hat{p}) \;,$$

$$\left[\hat{a}, \hat{a}^\dagger\right] = 1 \;. \tag{1.19}$$

With these definitions, the harmonic-oscillator Hamiltonian for the radiation field turns out to be

$$\begin{aligned}
\hat{H} &= \frac{1}{2}\left(\hat{p}^2 + \omega^2\hat{q}^2\right) \\
&= \frac{1}{2}\left[\mathrm{i}^2\left(\frac{\hbar\omega}{2}\right)\left(\hat{a} - \hat{a}^\dagger\right)^2 \right. \\
&\quad \left. + \omega^2\left(\frac{\hbar}{2\omega}\right)\left(\hat{a} - \hat{a}^\dagger\right)^2\right] \\
&= \hbar\omega\left(\hat{a}^\dagger\hat{a} + 1/2\right) \;. \tag{1.20}
\end{aligned}$$

A particularly important combination of these operators is the *number operator* given by $\hat{n} = \hat{a}^\dagger\hat{a}$. Rewriting the Hamiltonian and the corresponding eigenvalue equation for the radiation field in terms of the annihilation and creation operators, we have

$$\begin{aligned}
\hat{H} &= \hbar\omega\left(\hat{a}^\dagger\hat{a} + \frac{1}{2}\right) \\
&\equiv \hbar\omega\left(\hat{n} + \frac{1}{2}\right) \Rightarrow
\end{aligned}$$

$$\hat{H}\left|n\right\rangle = E_n\left|n\right\rangle = \hbar\omega\left(n + \frac{1}{2}\right)\left|n\right\rangle \;. \tag{1.21}$$

As expected, the vacuum – the state with no quanta ($n = 0$) – still has an associated zero-point energy. The field operators corresponding to the number states are found by substituting the annihilation and creation operators into the expressions for the vector potentials and the electromagnetic fields; the operator for the electric field, for example, is found to be [1.34]

$$\begin{aligned}
\hat{E}_k = \mathrm{i}&\left(\frac{\hbar\omega_k}{2\varepsilon_0 V}\right)^{1/2} \\
&\times \hat{\varepsilon}_k\big[\hat{a}_k \exp\left(-\mathrm{i}\omega_k t + \mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}\right) \\
&\quad - \hat{a}^\dagger \exp\left(\mathrm{i}\omega_k t - \mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}\right)\big] \;, \tag{1.22}
\end{aligned}$$

where $\hat{\varepsilon}_k$ is a unit polarization vector corresponding to the wave-vector mode $\boldsymbol{k}$ and the distance vector $\boldsymbol{r}$ has its usual meaning. This provides the required correspondence between the classical electromagnetic vector fields and the field operators needed for quantum field theory.

In this quantum-mechanical model, the photon is not treated as a classical particle with definite energy, momentum and helicity, but as a quantum excitation associated with the normal modes of the electromagnetic field, specified by a wavevector $\boldsymbol{k}$ and the polarization $\boldsymbol{\varepsilon}$. Localization of the photon – in essence, defining a wave packet comprising photons – is achieved by introducing a linear superposition of one-photon Fock states $|1, \boldsymbol{k}, \boldsymbol{\varepsilon}\rangle$ (states with a well-defined number of photons), rather like any other quantum-mechanical superposition of states

$$\begin{aligned}
|\psi\rangle = C\sum_{\boldsymbol{k}} \exp&\left[-\left(\boldsymbol{k} - \boldsymbol{k}_0\right)^2/2\sigma^2\right] \\
&\times \exp\left[-\mathrm{i}\boldsymbol{k}\cdot r_0\right]|1, \boldsymbol{k}, \boldsymbol{\varepsilon}\rangle \;, \tag{1.23}
\end{aligned}$$

where C is a normalization constant. This wave function may be regarded as the quantum-mechanical analog of the classical wave packet described earlier.

1.4 Thermal and Nonthermal Light Sources

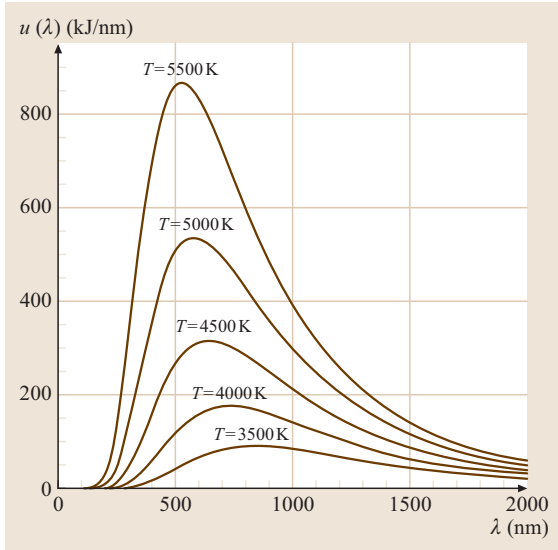
The early papers on light quanta by Planck and Einstein implicitly assumed that it was possible to treat light as a classical electromagnetic wave, while treating matter quantum mechanically. This approach was successful in providing a theoretical understanding of many important phenomena, including the spectrum of black-body radiation, spontaneous emission, stimulated absorption and stimulated emission, resonance fluorescence, the photo-


Fig. 1.5 Calculated spectrum of black-body radiators at several different temperatures based on (1.16)

electric effect, the Lamb shift and vacuum polarization. In this context, it is useful to note the different characteristics of light from thermal, nonthermal (or luminescent) and particle-beam sources.

Both thermal and nonthermal light originate from atomic or molecular transitions from higher- to lower-energy states, conventionally labeled as a transition from state 2 to state 1. In the semiclassical picture, these transitions are the outcome of a quantum process that may either be spontaneous or stimulated; the transition rates are described by the Einstein A and B coefficients:

$$A_{2\to 1} = \frac{1}{\tau} \, ,$$
$$B_{2\to 1} = \frac{\pi^2 c^3}{\hbar\omega^3} A_{2\to 1} = \frac{\pi^2 c^3}{\hbar\omega^3\tau} \, , \tag{1.24}$$

where τ is the mean lifetime of a given species. Because of the quantum-mechanical indeterminacy in the mean lifetime at which an atom or molecule will decay, there is a corresponding uncertainty in the distribution of frequencies that is described by the Lorentzian line-shape function of (1.45)

$$|E(\omega)|^2 = \frac{E_0^2}{(\omega-\omega_0)^2 + \gamma^2} \, , \ \gamma \equiv 1/\tau \, . \tag{1.25}$$

The Lorentzian line shape is also predicted for a driven classical harmonic oscillator with natural frequency ω_0. However, in this case the lifetime is not determined by

the properties of individual atoms, as it would be in quantum theory; instead, it is given by a classical radiative lifetime function defined by

$$\tau = \left(6\pi\varepsilon_0 m_e c^2\right)/e^2\omega^2 \, , \tag{1.26}$$

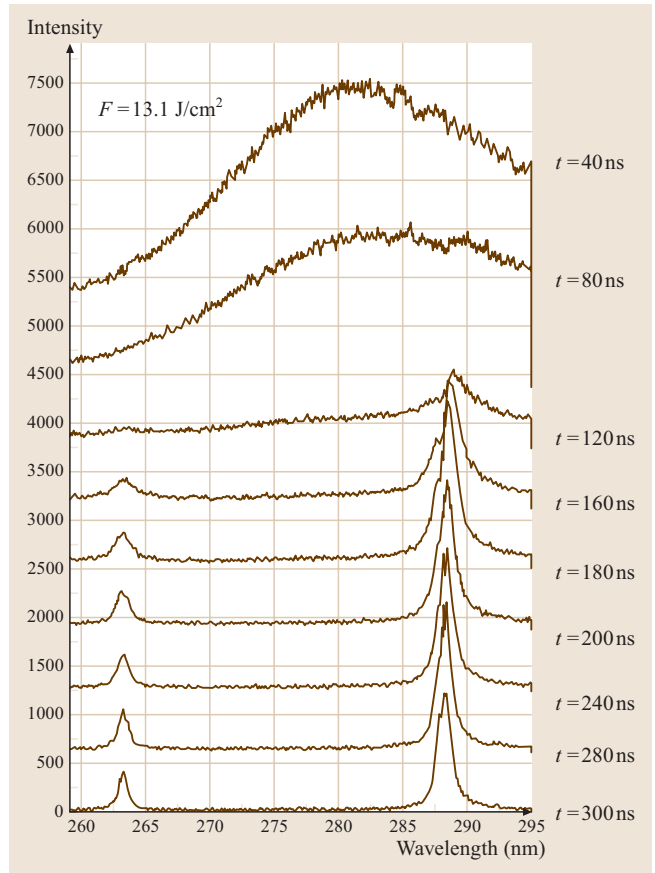
where m_e is the mass of the electron. This classical lifetime turns out to be of the order of nanoseconds, typical for the lifetimes of many atomic transitions in the visible as calculated from quantum theory and measured using modern spectroscopic techniques.


Fig. 1.6 Time-lapse spectra of a laser-produced plasma generated by Nd : YAG laser irradiation of silicon at a fluence of 13.1 J/cm². At early times, one observes only the black-body radiation of the large volume of material ablated from the surface; note that the peak of the black-body radiation curve shifts to the red with time, indicating a decrease in temperature. At later times, the spectra exhibit the luminescence lines from atomic transitions in silicon superimposed on a gradually disappearing black-body background. (After [1.35])

1.4.1 Thermal Light

Thermal or chaotic light sources are represented by the idealized black-body radiator, a large ensemble of emitters in thermal equilibrium with each other and with their

Fig. 1.7a,b Spectral distribution of light from various synchrotron light sources identified in the caption. **(a)** Measured photon flux from the synchrotron light sources. **(b)** Measured spectral brilliance of several synchrotron sources. (After [1.36])

surroundings. The intensity spectrum of a black body calculated from (1.16) is shown in Fig. 1.5 for several different temperature. The Planck distribution formula in (1.16) yields two important empirical relations between the spectral and thermodynamic properties of black-body radiation laws. The peak wavelength of black-body spectra is described by Wien's displacement law, which shows a shift in the wavelength λ_{max} at which the distribution function is a maximum proportional to the inverse temperature

$$\lambda_{max} = \frac{2.8978 \times 10^{-6}}{T} \, , \tag{1.27}$$

where T is the absolute temperature in Kelvin. This law can be derived by substituting in (1.16) and finding its extreme value in the usual way.

The areal power density radiated through a small aperture in an enclosure containing radiation in thermodynamic equilibrium at a temperature T is given by the Stefan-Boltzmann law. This law was discovered empirically by Josef Stefan in 1879, and postulated on the basis of thermodynamics by Ludwig Boltzmann in 1884. This law states that the radiated power per unit area is

$$\frac{P(T)}{A} \equiv E(T) = \sigma T^4 \, ,$$

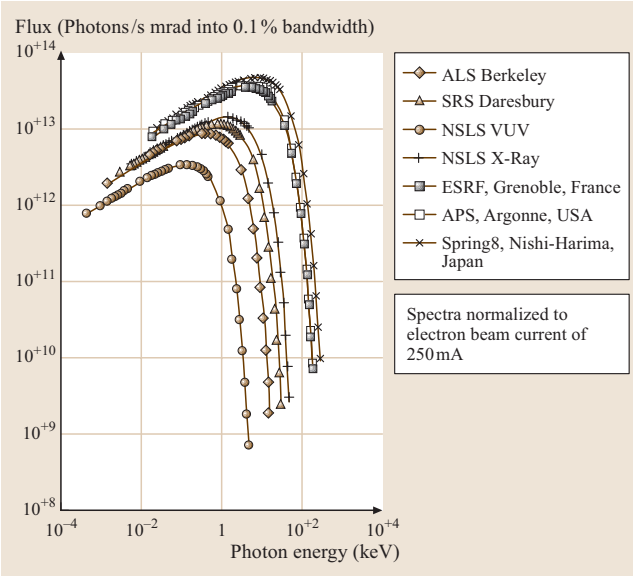
$$\sigma = \frac{\pi^2}{60} \frac{k_B^4}{h^3 c^2} = 5.67 \times 10^{-8} \, \text{W/(m}^2\text{K}^4) \, . \tag{1.28}$$

This relationship requires that one integrate the radiated power for an ensemble of atoms over all wavelengths, again beginning with the Planck distribution. This integral can be carried out with the aid of (1.25) by a change of variables $x = \hbar\omega/k_B T$ to yield the required result:

$$E(T) = \frac{c}{4} \int_0^\infty \frac{\hbar\omega^3}{\pi^2 c^3} \frac{d\omega}{\exp(\hbar\omega/k_B T) - 1}$$

$$= \frac{\hbar}{4\pi^2 c^2} \left(\frac{k_B T}{\hbar}\right)^4 \int_0^\infty \frac{x^4 \, dx}{e^x - 1} \propto T^4 \, . \tag{1.29}$$

1.4.2 Luminescence Light

Electromagnetic radiation emitted by excited atoms and molecules not in thermal equilibrium with their surroundings typically exhibits much narrower spectra than black-body radiation, and is called luminescence. The excitation could come from any number of energy sources: energetic electrons (cathodoluminescence), light (photoluminescence), applied electric


fields (electroluminescence), sound waves (sonoluminescence), or chemical reactions (chemiluminescence). Light produced in this way exhibits a spectrum that is indicative both of its natural frequency and line width, and also characteristic of its environment. For example, impurity atoms in a solid, or excited atoms in a gas-discharge tube at moderate pressure, will exhibit line widths that convolute the natural (Lorentzian) line width with the Gaussian profile due to homogeneous or inhomogeneous broadening by the local electronic environment to produce the Voigt profile of (1.52).

It is also possible for light sources to produce thermal and nonthermal light simultaneously from coupled equilibrium and nonequilibrium processes. Light produced by high-intensity laser irradiation of materials, for example, often has this characteristic. Figure 1.6 shows the spectrum of light emitted by a laser-produced plasma that at later times shows narrow luminescence lines riding on a broader, gradually decreasing blackbody background. In this case, the luminescence has the characteristics of radiation from individual atoms (with a line shape that convolutes the natural line width, Doppler and pressure broadening) and black-body radiation (due to hot ablated material in local thermodynamic equilibrium).

1.4.3 Light from Synchrotron Radiation

In recent years, accelerator-driven light sources have assumed an important place in both science and technology. Sources such as synchrotron storage rings [1.36, 37] and free-electron lasers [1.38, 39] generate light by bending relativistic electron beams either with dipole magnets or in insertion devices called undulators or wigglers. From such sources, extremely broad spectra can be generated that range from X-rays to the infrared region of the spectrum, with spectral brightnesses far exceeding those of any thermal source. The temporal and spatial characteristics of such radiation are not related to atomic or molecular properties, but instead to the particular characteristics of the associated electron accelerators or bending magnets. Bending magnets produce relatively narrow-band but incoherent radiation, and wavelength selectivity is achieved by the use of monochromators. Undulators and wigglers produce coherent beams of extremely high spectral brightness. In free-electron lasers, a quasi-monochromatic spectrum is produced by placing the wiggler inside an optical resonator.

The spectral profile of light from synchrotron sources follows a universal curve derived from the classical theory of radiation by electrons moving on the arc of a circle. This distribution is quite unlike that of black-body radiation. This is illustrated in Fig. 1.7a, where the measured photon flux from a number of synchrotron sources is compared for constant electron current. The spectral brilliance of some of the same sources is shown in Fig. 1.7b, illustrating the point that this quantity can be highly variable even for sources that have similar photon flux. Besides its broad spectral distribution, synchrotron light produced by wigglers and undulators (*insertion devices*) can have a high degree of spectral coherence.

1.5 Physical Properties of Light

This section outlines the measurable physical properties of light associated with both the wave and photon pictures. These include intensity or irradiance, velocity of propagation, polarization, energy, power and momentum transport. These properties underlie the radiometric, photometric and spectral characterizations of light presented in Sect. 1.2.

1.5.1 Intensity

Almost all measurements of the effects of light interacting with matter depend either on energy incident per unit volume, energy incident per unit area (fluence), power per unit area (intensity or irradiance), or a combination of these quantities. The time-averaged intensity or irradiance of an harmonic electromagnetic wave described by an electric field vector $\boldsymbol{E}(\boldsymbol{r}, t) \equiv \boldsymbol{E}_0(\boldsymbol{r}) \mathrm{e}^{\pm i\omega t}$ is

$$
\begin{aligned}
I(\boldsymbol{r}) &= \frac{1}{T} c\varepsilon_0 \int_0^T |E(\boldsymbol{r}, t)|^2 \, \mathrm{d}t \\
&= c\varepsilon_0 \left\langle |E(\boldsymbol{r}, t)|^2 \right\rangle = \frac{c\varepsilon_0}{2} |E_0(\boldsymbol{r})|^2 \ .
\end{aligned} \tag{1.30}
$$

In the photon picture, the analog of the intensity is the areal number density of photons per unit time, or photon flux; it is related to the energy density by $I(\omega) = cU(\omega)/4$, thus

$$
\begin{aligned}
I(\omega) &= \frac{cU(\omega)}{4} \\
&= \frac{\hbar\omega^3}{4\pi^2 c^2} \frac{1}{\exp(\hbar\omega/k_B T) - 1} \ .
\end{aligned} \tag{1.31}
$$

The fluence is the integral of the intensity over a suitable time interval; in the case of laser beams, this interval is often simply the duration of the laser pulse.

1.5.2 Velocity of Propagation

Two different concepts of velocity are associated with the idea of electromagnetic radiation. Phase velocity refers to the propagation of points with the same phase on a wavefront, while group velocity generally refers to the propagation velocity of energy or information in a wave packet. The phase velocity for a wave of frequency ν and vacuum wavelength λ in a medium with an index of refraction n is

$$v_p = \frac{c}{n} = \frac{\lambda}{n}\nu = \frac{\omega}{kn} \Rightarrow \omega = v_p kn \ . \tag{1.32}$$

While this velocity represents the movement of the phase fronts, it is not the speed at which energy or information propagates; that requires some interaction with the oscillations that make up the wave. The group velocity v_g is conventionally defined in terms of these quantities and the index of refraction of the medium in which the wave propagates as

$$\begin{aligned}\frac{d\omega}{dk} &= \frac{c}{n}\left(1 - \frac{k}{n}\frac{dn}{dk}\right) \\ &= v_p\left(1 - \frac{k}{n}\frac{dn}{dk}\right) \ . \end{aligned} \tag{1.33}$$

Evidently in a medium with constant index of refraction, the phase velocity and group velocities are equal, while in a medium which exhibits normal dispersion ($dn/dk > 0$) the group velocity is at most equal to the phase velocity. However, in the case of anomalous dispersion ($dn/dk < 0$), the group velocity may actually exceed the speed of light in vacuum c; in such cases, it is always possible to demonstrate that the group velocity is not the speed at which information or energy propagates. This is the case, for example, in hollow waveguides with a cut-off frequency ω_0, in which the dispersion is $k = \sqrt{\omega^2 - \omega_0^2}/c$, and also on the blue side, of many atomic resonances.

1.5.3 Polarization

The polarization of a light wave is widely used as a marker and diagnostic in various spectroscopic techniques, [1.40] especially in laser spectroscopy, [1.41] and is conventionally described by three formalisms: the Mueller calculus, the Jones calculus, and the Poincaré sphere.

The Mueller calculus is based on a scheme first given by G. G. Stokes for measuring the polarization observables of a light beam; it uses four-component vectors to describe the measured intensities (all real numbers), and 4×4 matrices to describe the interaction of the light with various polarizing elements or materials. The Jones calculus is somewhat simpler computationally because it uses only two-component vectors and 2×2 matrices to calculate the polarization in a light beam; however, the parameters in the Jones vectors are complex. The Stokes vectors do not, however, constitute the basis of a linear vector space, while the Jones vectors do. The Poincaré sphere method is based, not on a numerical parameterization of polarized light, but on a mathematical way of relating different polarization forms to points on a sphere; transformations from one polarization form to another are embodied by rotations of the sphere. It is a useful qualitative construct, particularly in making experimental judgments where phase retardation effects rather than changes of intensity are involved. Various states of polarization are illustrated schematically in Fig. 1.8. The matrices that represent the operation of material polarizers such as wave-plates and phase retarders on Jones or Mueller vectors can be found in most optics textbooks.

The Jones Calculus

Consider a light wave propagating in the z-direction, so that the electric field has components only in the x–y-plane. In the previous notation, the electric field is then

$$\begin{aligned}\boldsymbol{E} &= E_{0x} \exp\left[i\left(kz - \omega t + \phi_x\right)\right]\hat{\boldsymbol{x}} \\ &+ E_{0y} \exp\left[i\left(kz - \omega t + \phi_y\right)\right]\hat{\boldsymbol{y}} \ . \end{aligned} \tag{1.34}$$

$E_x \neq E_y$ $E_x = E_y$ $E_x \neq E_y$

$\phi_x = \phi_y$ $\phi_x = \phi_y + \pi/2$ $\phi_x > \phi_y$
Fig. 1.8 Schematic representation of linear, right-hand circular and elliptical states of polarization. The propagation direction is taken to be the z-axis of a Cartesian coordinate system. The various polarization states are characterized by differing relative values of electric-field amplitudes E_x and E_y and of the phase shifts Φ_x and Φ_y

Factoring out the time and z dependence, and writing the x- and y-components of the electric field as a column vector, we have

$$\boldsymbol{E} = \exp\left[\mathrm{i}\,(kz - \omega t)\right] \begin{bmatrix} E_{0x}\,\mathrm{e}^{\mathrm{i}\phi_x} \\ E_{0y}\,\mathrm{e}^{\mathrm{i}\phi_y} \end{bmatrix}$$

$$\equiv \exp\left[\mathrm{i}\,(kz - \omega t)\right] \boldsymbol{J} \;. \tag{1.35}$$

The column vector, omitting the z and t dependence is called the *full Jones vector $\boldsymbol{J}$* (or in some circles, the *Maxwell column*) of the light wave. The use of the same symbol as the electric current density rarely causes problems in optics, where electrical currents are usually negligible.

Because the Jones vectors are the bases of a vector space, it is easy to calculate the action of a polarizing device on light having a given polarization state by simple matrix multiplication. For example, consider linearly polarized light with the polarization making equal $45°$ angles with the x- and y-axes of a quarter-wave plate (QWP). The action of the QWP, which introduces a quarter-wave phase delay between x- and y-components of the electric field, is represented by the matrix $(M)_{\mathrm{QWP}}$. As shown below, the outgoing light beam is right-circularly polarized.

$$\boldsymbol{E}_{\mathrm{out}} = (M)_{\mathrm{QWP}}\,(\boldsymbol{J})_{\mathrm{in}}$$

$$= \exp\left[\mathrm{i}\,(kz - \omega t)\right] \begin{pmatrix} 1 & 0 \\ 0 & \mathrm{i} \end{pmatrix} \begin{pmatrix} E_{0x} \\ E_{0y} \end{pmatrix}$$

$$\equiv \exp\left[\mathrm{i}\,(kz - \omega t)\right] \begin{pmatrix} E_{0x} \\ \mathrm{e}^{\mathrm{i}\pi/2}E_{0y} \end{pmatrix} \tag{1.36}$$

Mueller Matrices

The Mueller calculus for describing the polarization of a light beam is based on a measurement scheme for polarization developed by *Stokes* [1.42] The column-vector representation of the Stokes parameterization is

$$\boldsymbol{S} = \begin{pmatrix} I \\ Q \\ U \\ V \end{pmatrix} = \begin{pmatrix} I \\ I_{0°} - I_{90°} \\ I_{+45°} - I_{-45°} \\ I_{\mathrm{rcp}} - I_{\mathrm{lcp}} \end{pmatrix}$$

$$= \begin{pmatrix} E_{0x}^2 + E_{0y}^2 \\ E_{0x}^2 - E_{0y}^2 \\ 2E_{0x}E_{0y}\cos\Delta \\ 2E_{0x}E_{0y}\sin\Delta \end{pmatrix}\;. \tag{1.37}$$

The Stokes parameter I is the total intensity; the quantity I_ϕ is the intensity measured at the angle ϕ; the phase dif-

ferential Δ satisfies $-\pi \leq \Delta = \phi_y - \phi_x \leq \pi$; and rcp/lcp refers to right-/left-circularly polarized light. The derivation of the relationships in the second column vector above is complicated, but may be found in a variety of sources [1.40]. An important advantage of the Mueller calculus is the fact that this formalism is able to describe unpolarized or partially polarized light, by taking time averages in time over the Stokes parameters [1.43]. For unpolarized light, only I is nonvanishing, and for partially polarized light, the remaining Stokes parameters must satisfy $0 < (Q^2 + U^2 + V^2) < I$. On the other hand, for a completely polarized beam, $(Q^2 + U^2 + V^2) = I$, so that the points (Q, U, V) lying on a unit sphere represent well-defined polarization states.

The Poincaré Sphere

In general, the polarization of a light wave is described by an ellipse, which can be characterized by the angle α describing the inclination of the ellipse with respect to a polar axis and by its ellipticity ε. These quantities can be related to the Stokes parameters by

$$S_1 \equiv Q/I = \cos(2\varepsilon)\cos(2\alpha)\;,$$
$$S_2 \equiv U/I = \cos(2\varepsilon)\sin(2\alpha)\;,$$
$$S_3 \equiv V/I = \sin(2\varepsilon)\;. \tag{1.38}$$

With these definitions, any desired polarization state can be represented as a point or collection of points on a sphere, as shown in Fig. 1.9 [1.44]. States of constant ellipticity are represented by the locus of points

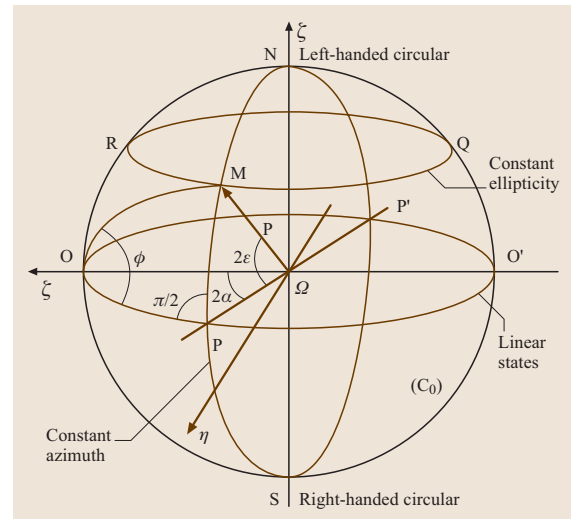


Fig. 1.9 Schematic representation of polarization states on the surface of the Poincaré sphere

on circles parallel to the equatorial plane; the equatorial plane itself is the locus of points representing linear polarization. States of circularly polarized light are represented by the poles. Unpolarized light is represented by the points constituting the surface of the sphere, while partially polarized light would be represented by a subset of points on the surface clustered around a particular point representing the highest degree of polarization.

Photon Spin and Polarization

In classical electromagnetic theory, the polarization of a light wave is determined by the transverse character of vibrations in the electromagnetic field. In the quantum theory of the photon, it becomes necessary to endow the photon with a property of angular momentum just as one does for the electron, but it is also necessary that this concept should be consistent with the wave description of polarization. The photon is a boson and has unit spin; since the photon is massless, it does not have orbital angular momentum, but only its intrinsic spin $s = 1$. A spin-1 particle can have possible spin projections $+1$, 0 and -1 with respect to some given axis; however, since light waves are transverse, the 0-component is ruled out.

From quantum electrodynamics, it is known that photons with helicities of ± 1 are related to left- and right-handed circular polarization states. The basis helicity states of the photon can be represented as column vectors assuming that the quantization axis is the direction of propagation:

$$|s = 1\rangle \equiv |+\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, |s = -1\rangle \equiv |-\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix}.$$
$$(1.39)$$

Taking the quantization axis to be the z-axis, as well as the direction of light-wave propagation, we construct linearly polarized light in the x- and y-directions from these basis states as follows:

$$|e_x\rangle = \frac{1}{\sqrt{2}} (|+\rangle + |-\rangle) ,$$
$$|e_y\rangle = \frac{1}{\sqrt{2}} (|+\rangle - |-\rangle) .$$
$$(1.40)$$

Once this correspondence is established, the overall polarization of an ensemble of photons, as in a light beam, can be treated in the same way that other ensembles of quantum particles are treated in the density-matrix formalism [1.45]. Suppose we have a beam of photons that is a mixture of two beams, prepared independently in polarization states characterized by the state vectors and e_a, and e_b with intensities I_a and I_b, respectively. If we use the vectors of (1.39) as the basis states, then the state vectors characterizing the polarization are, respectively,

$$|e_a\rangle = c_+^{(a)} |+\rangle + c_-^{(a)} |-\rangle ,$$
$$|e_b\rangle = c_+^{(b)} |+\rangle + c_-^{(b)} |-\rangle .$$
$$(1.41)$$

This seemingly quite abstract expression corresponds directly to the Stokes parameters defined for a classical light beam, using the standard projection-operator formalism of quantum mechanics. The normalized density matrix for this system of two beams in two possible states is

$$\rho = I_a |e_a\rangle \langle e_a| + I_b |e_b\rangle \langle e_b|$$
$$= \begin{pmatrix} \langle +1|+1\rangle & \langle +1|-1\rangle \\ \langle -1|+1\rangle & \langle -1|-1\rangle \end{pmatrix}$$
$$\equiv \begin{pmatrix} \rho_{+1,+1} & \rho_{+1,-1} \\ \rho_{-1,+1} & \rho_{-1,-1} \end{pmatrix} .$$
$$(1.42)$$

Now consider, for example, the Stokes parameter V, which is defined to be the difference of the right- and left-circular polarized intensities $I_{rcp} - I_{lcp}$. From the definition of the photon helicity, it is clear that V and the density matrix elements are related by $IV = -(\rho_{1,-1} + \rho_{-1,1})$. Following the same approach for the other Stokes parameters, it is found that

$$\rho = \frac{I}{2} \begin{pmatrix} 1+U & -V+iQ \\ -V-iQ & 1-U \end{pmatrix} ,$$
$$(1.43)$$

thus clearly exhibiting the link between the classical and quantum descriptions of the polarization of the light wave and/or photons. Not surprisingly, it is the Stokes parameters – the classical observables – that also turn up in the quantum-mechanical treatment.

1.5.4 Energy and Power Transport

In general, the energy density in a region of free space occupied by electric and magnetic fields E and B is given by

$$u = \frac{1}{2} \left(\frac{B^2}{\mu_0} + \varepsilon_0 E^2 \right)$$
$$= \frac{\varepsilon_0}{2} \left(\frac{B^2}{\varepsilon_0 \mu_0} + E^2 \right)$$
$$= \frac{\varepsilon_0}{2} \left(c^2 B^2 + E^2 \right) .$$
$$(1.44)$$

In material media, this energy density would be modified by replacing the vacuum values of the dielectric permittivity and magnetic permeability by their values in the

material, namely, ε and μ. If we now consider a plane electromagnetic wave traveling in the z-direction for the sake of definiteness, the electric and magnetic fields are given respectively by

$$E_y = E_{0y} \cos(kz - \omega t + \phi) ,$$
$$B_x = -B_{0x} \cos(kz - \omega t + \phi) . \tag{1.45}$$

The time-dependent volumetric energy density associated with this wave is therefore given by

$$u = \frac{\varepsilon_0}{2} \left(c^2 B_{0x}^2 + E_{0y}^2 \right) \cos^2(kz - \omega t + \phi) . \tag{1.46}$$

This equation exhibits explicitly the wave-like transport of energy associated with the existence of the electromagnetic wave.

The total energy and power associated with the radiation field can be calculated by introducing the hypothesis that the energy in the field is related to the classical average field energy by

$$\langle U \rangle_{\text{field}} = \frac{1}{2} \int\limits_{\text{cavity}} \varepsilon_0 |E_\omega(r, t)|^2 \, dV$$
$$= (n + 1/2) \hbar\omega . \tag{1.47}$$

1.5.5 Momentum Transport: The Poynting Theorem and Light Pressure

The momentum and radiation pressure exerted by a light beam can be developed from the definition of energy contained in the beam. The total energy U delivered by a light beam in a time Δt is related to the change in radiative momentum transferred and the radiation pressure p_{rad} by:

$$U = uAc\Delta t$$
$$\Rightarrow \Delta p_{\text{rad}} = \frac{U}{c} = uA\Delta t$$
$$\Rightarrow F_{\text{rad}} = \frac{\Delta p_{\text{rad}}}{\Delta t} = uA$$
$$\Rightarrow P_{\text{rad}} = \frac{F_{\text{rad}}}{A} = u . \tag{1.48}$$

The flow of energy and momentum carried by electromagnetic waves is described by Poynting's theorem for a vector $S = E \times B / \mu_0$ with units of energy/(time $\times$ area). With this definition, the energy density of the electromagnetic field U and the momentum density $g = \varepsilon_0 E \times B$ satisfy

$$\frac{\partial U}{\partial t} = -\nabla \cdot S$$
$$\frac{\partial g}{\partial t} = -\rho E - \overleftrightarrow{\mathbf{T}}^{(\text{M})} \cdot \hat{n} \tag{1.49}$$

where ρE is the Lorentz force per unit volume, $\overleftrightarrow{T}^{(\text{M})}$ is the Maxwell stress tensor and the unit vector $\hat{n}$ is directed along the *outward* normal to the surface bounding the relevant volume. In vacuum, the energy and momentum densities are equal apart from a factor $1/c$; in material media the situation is much more complicated [1.23].

Planck's quantum hypothesis asserts that the energy of a light quantum is related to the angular frequency of an electromagnetic wave ω by $E = \hbar\omega$, where $\hbar \equiv h/2\pi$, with h being Planck's constant 6.67×10^{-34} J s. Similarly, the momentum of a light quantum can be expressed as $p = h/\lambda = \hbar k$. A similar relationship for the momentum of a material particle, of course, was famously postulated by de Broglie and has been verified in experiments with electrons and other quantum particles.

1.5.6 Spectral Line Shape

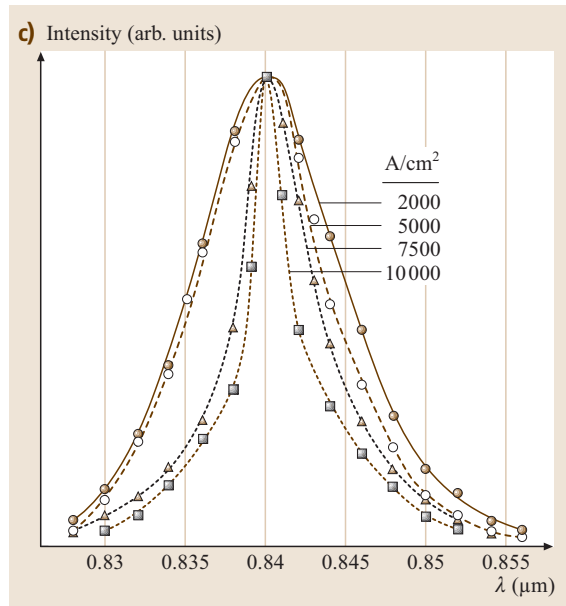
One of the most important physical characteristics of a stream of light is its spectral line shape, which gives the probability density of intensity or irradiance as a function of wavelength or frequency. The line shape is also a unique signature of the source from which the light emanates.

The line shape of a thermal or chaotic source is that of the black-body spectrum described by the Planck irradiance function, (1.16). The position of the peak in that spectrum is characteristic of the temperature, while its overall form is governed by the Bose–Einstein distribution, the second factor in (1.16). The shape of this function is illustrated in Fig. 1.7a for several temperatures. The shifting position of the peak wavelength at each temperature follows Wien's displacement law (Sect. 1.4.1).

Light from electronic transitions between energy levels E_2 and E_1 in an ensemble of non-interacting atoms (as, for example, in a dilute gas) has a resonance or Lorentzian line shape having the normalized form

$$L(\omega; \omega_0, \gamma) = \frac{\gamma}{\pi \left[(\omega - \omega_0)^2 + \gamma^2 \right]} , \tag{1.50}$$

where F_0 is an appropriately normalized field amplitude, ω is the angular frequency of the light, $\omega_0 = (E_2 - E_1)/\hbar$ is the frequency at the centroid of the line, and γ is called the natural line width. The natural line width γ is related to the intrinsic lifetime of the atom τ_0 by $\gamma = 1/2\tau_0$.

Should those same atoms be in an environment in which the spectrum of light from the atoms is broadened because of, say, collisions or the Doppler effect, the line shape typically has a Gaussian intensity distribution. Its


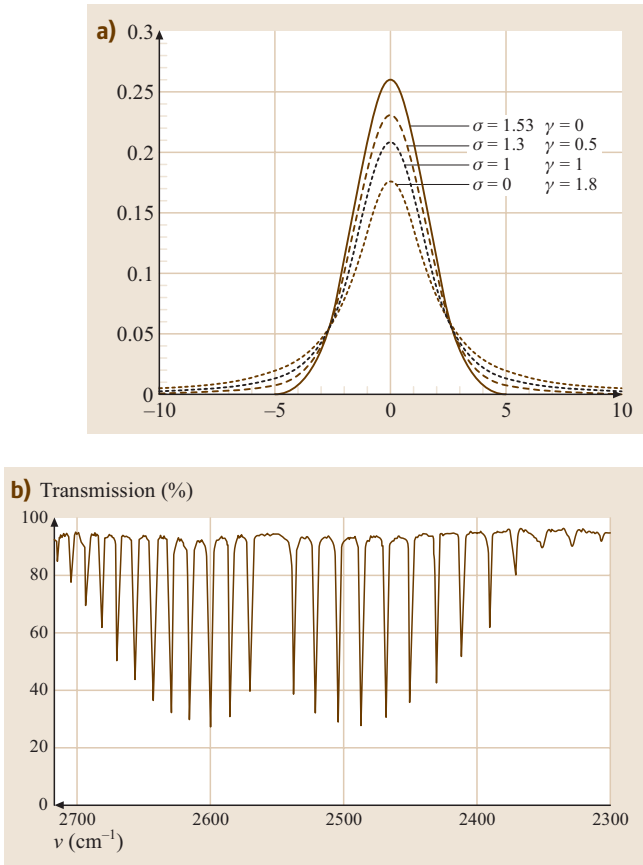


Fig. 1.10a–c Spectral characteristics of light from various sources. (**a**) Comparison of spectral line shapes from isolated atoms or molecules (Lorentzian), collisionally broadened sources (Gaussian) and from sources exhibiting both characteristics (Voigt profile). (**b**) Vibrational-rotational spectrum of HBr molecules, illustrating the band-like structure of radiation from even quite simple molecules. (After [1.46]). (**c**) Spectrum of light from a GaAs semiconductor laser as a function of driving current, showing the narrowing of the spectrum as the lasing threshold is exceeded. (After [1.47])

normalized form is

$$G(\omega; \omega_0, \sigma) = \frac{1}{\sigma\sqrt{\pi}} \exp\left(-\frac{(\omega - \omega_0)^2}{2\sigma^2}\right), \quad (1.51)$$

where the angular frequencies have the same meaning as before and σ is the variance of the line-shape. For Doppler broadening of an atom with mass m_0 at a temperature T, the variance is $\sigma = \omega_0\sqrt{k_B T/m_0 c^2}$, where k_B is Boltzmann's constant. When the atomic emitters all experience the same broadening mechanism, the line shape is said to be homogeneously broadened; when the broadening mechanism differs within the ensemble, such as when the emitting atoms occupy different kinds of lattice sites in a solid, the emission line is said to be inhomogeneously broadened.

In most realistic situations, of course, the broadening of atomic or molecular lines arises from a combination of Lorentzian and Gaussian mechanisms. In this case, the line shape assumes the so-called Voigt profile, which is the convolution of the Gaussian and Lorentzian

functions:

$$V(\omega, \omega_0; \sigma, \gamma)$$
$$= \int_{-\infty}^{\infty} G(\omega', \omega_0; \sigma) L(\omega', \omega_0; \gamma)\, d\omega'$$
$$= \frac{1}{\sigma\sqrt{2\pi}} \operatorname{Re}\left[\operatorname{erf}\left(\frac{\omega - \omega_0 + i\gamma}{\sigma\sqrt{2}}\right)\right], \quad (1.52)$$

where erf is the complex error function. The contrasting line shapes are illustrated in Fig. 1.10a; notice the greater amplitude of the Gaussian function far from the line center frequency ω_0.

Light emission from molecules may arise from electronic, vibrational and/or rotational transitions, and this produces complex spectra in which the individual spectral lines are similar to those of atoms, but which appear in groups or bands of lines with rather regular spacings.

An example is shown in Fig. 1.10b for the diatomic molecule HBr. The spacing of the lines is determined by the selection rules for transitions between rotational or vibrational energy levels. In this example, the spacing is approximately given by

$$
\Delta E\,(v,\,J) =
\begin{cases}
\hbar\omega_v - 2BJ\,, \\
J = 1, 2, 3, \ldots (P\ \text{branch}) \\
\\
\hbar\omega_v + 2B(J+1)\,, \\
J = 0, 1, 2, \ldots (R\ \text{branch})
\end{cases}
,
\tag{1.53}
$$

where B is the rotational constant of the molecule, J is the rotational quantum number, and ω_v is the angular frequency of the vibrational transition. In practice, molecular spectra are complicated by anharmonicities, changes in rotational constants induced by stretching and so on; these issues are treated in a multitude of specialized monographs [1.48].

Coherent light from laser sources exhibits another characteristic line-shape phenomenon, the narrowing of the emission line as laser action begins. This line narrowing, illustrated in Fig. 1.10c, is due to the higher emission probability – and hence preferential amplification – of wavelengths near the line center. However, depending on the mechanism of line broadening, the narrowing effect may actually be reversed as amplification enters the saturation regime.

1.5.7 Optical Coherence

The coherence phenomena associated with fundamental properties of light can be divided into spatial and temporal coherence [1.49]. The former refers to the effects on electromagnetic radiation emitted by sources of finite size, the latter to radiation emitted by sources with finite bandwidth.

A beam of light is said to be spatially coherent when the phase difference between points on the wavefront remains constant in time, even if the phase fluctuates randomly at any given point. Thus an extended source comprising an ensemble of randomly fluctuating point sources can produce spatially coherent light if the interference fringes from nearby point sources accidentally overlap. For example, starlight of wavelength λ is coherent over a spot of diameter d_{coh} given by

$$
d_{\text{coh}} = 0.16\frac{\lambda R}{\rho} = 0.16\frac{\lambda}{\vartheta}\,,
\tag{1.54}
$$

where the stellar diameter is ρ, the distance to the point of observation is R, and ϑ is the angle that the star subtends at the point of observation. The coherence area associated with this diameter is $A_{\text{coh}} = \pi(d_{\text{coh}}/2)^2$.

A light beam in which phase differences between points on the wavefront remain constant in time is said to be temporally coherent. Given the Fourier-transform relationship between time and frequency, this also implies that a temporally coherent beam has a high degree of spectral purity. If a light source emits a beam with frequencies ranging from ν to $\nu + \delta\nu$, hence with a spectral bandwidth of $\delta\nu$, the extreme frequencies in the beam will lose temporal synchronization in a comparatively short time, called the coherence time, given by

$$
\tau_{\text{coh}} = \frac{1}{2\pi\delta\nu}\,.
\tag{1.55}
$$

The coherence length associated with this coherence time is simply $l_{\text{coh}} = c\tau_{\text{coh}}$. The coherence volume for a source with given coherence properties is then $V_{\text{coh}} = A_{\text{coh}}l_{\text{coh}}$.

The physical process giving rise to light emission largely determines the coherence of a source. In a thermal source, such as a gas-discharge lamp or an incandescent bulb, light is produced by microscopic or even atomic sources emitting spontaneously, hence at random times relative to one another. Wave packets from different emission events are essentially uncorrelated, and the degree of temporal and spatial coherence is low, though not zero [1.50]. In a laser source, on the other hand, the light is produced by stimulated emission and the degree of coherence is high; however, since temporally and spatially independent transverse and longitudinal modes can coexist simultaneously, only single-mode lasers can achieve the highest degree of temporal coherence.

The coherence of a light source can be quantitatively characterized by interferometry [1.51]. For example, in a two-slit interference experiment (*Young's experiment*), slits separated by a distance d and illuminated by monochromatic light of wavelength λ will produce intensity maxima and minima on a screen at a distance L, separated by a distance $\Delta y = \lambda L/d$. The contrast between maxima and minima can be characterized by the fringe visibility defined in terms of the measured intensities:

$$
V = \frac{I_{\text{max}} - I_{\text{min}}}{I_{\text{max}} + I_{\text{min}}}\,.
\tag{1.56}
$$

An important development in the last half century has been the recognition that coherence and polarization

are inextricably intertwined [1.52]. This convergence has made it possible to develop deep and detailed connections between the classical and quantum theories of light. It has also resulted in the discovery that single-point descriptions of polarization – such as those provided by the Jones or Mueller calculus – are inadequate to explain experimental observations of changes in polarization that occur during propagation, even in empty space [1.53, 54]. These discoveries have led to the development of a generalized coherence matrix in a vector electromagnetic theory that correctly describes these interrelated coherence and polariza-tion phenomena. The form of this hermitian coherence matrix is similar to the matrices found in the Jones calculus:

$$J = \begin{bmatrix} \langle E_x(\mathbf{r}, t) E_x^*(\mathbf{r}, t) \rangle & \langle E_x(\mathbf{r}, t) E_y^*(\mathbf{r}, t) \rangle \\ \langle E_x^*(\mathbf{r}, t) E(\mathbf{r}, t) \rangle & \langle E_y(\mathbf{r}, t) E_y^*(\mathbf{r}, t) \rangle \end{bmatrix},$$

$$\mathrm{tr}(J) = \bar{I}. \tag{1.57}$$

However, in this case, the elements of the coherence matrix are not simply complex scalars, as in the Jones matrices, but components of the generalized coherence tensors.

1.6 Statistical Properties of Light

The foregoing discussions are based on models either involving light rays or single photons with well-defined properties of wavelength and frequency, polarization, momentum and energy. However, all real light sources fluctuate in frequency and polarization, and a full treatment of the properties of light requires an accounting for this statistical character through probability density functions, correlation functions and such standard statistical measures as the variance.

The next paragraphs present a statistical characterization of thermal (sometimes called chaotic) or black-body sources, coherent sources (such as lasers) and nonclassical light sources. More detailed treatments are available in many recent textbooks and review articles.

1.6.1 Probability Density as a Function of Intensity

Consider a beam of unpolarized light from a thermal source, in a coordinate system defined such that the beam propagates in the z-direction. Such a beam comprises an equal mixture of x- and y-polarized components, with random amplitude and phase, each of which can be shown to obey a Rayleigh probability distribution given by [1.55].

$$p(I_x) = \frac{2}{\bar{I}} \exp\left(-2\frac{I_x}{\bar{I}}\right),$$

$$p(I_y) = \frac{2}{\bar{I}} \exp\left(-2\frac{I_y}{\bar{I}}\right), \tag{1.58}$$

where the average intensity $\bar{I}$ is related to the standard deviation σ_I by $\sigma_I = \bar{I}/\sqrt{2}$. The joint density function of the two independent random variables I_x and I_y is found from a standard theorem of probability theory to be equal to

$$p(I) = \frac{2}{\bar{I}} \int_0^I \exp\left(-2\frac{\xi}{\bar{I}}\right) \exp\left(-2\frac{I-\xi}{\bar{I}}\right) \mathrm{d}\xi$$

$$= \left(\frac{2}{\bar{I}}\right)^2 I \exp\left(-2\frac{I}{\bar{I}}\right). \tag{1.59}$$

A plot of this function is shown in Fig. 1.11; the physical interpretation of this is that the probability has a maximum value of 0.5, while the integral under the curves, as with all probability functions has the value 1. Applying the same general analysis, the probability distribution for light with varying degrees of polarization P from a thermal source is given by:

$$p_I(I) = \frac{1}{P\bar{I}} \left[\exp-\left(\frac{2I}{(1+P)\bar{I}}\right) - \exp\left(\frac{2I}{(1-P)\bar{I}}\right) \right]. \tag{1.60}$$

It is instructive to compare this distribution function to that of light from a laser source. The laser is proverbially a source of *highly organized* light, but its statistical character changes dramatically depending on whether the laser is operated below, near or well above the threshold for laser oscillation [1.56]. For a laser in the steady state, Mandel and Wolf show that the probability density $p(I)$ as a function of intensity can be written as [1.57]

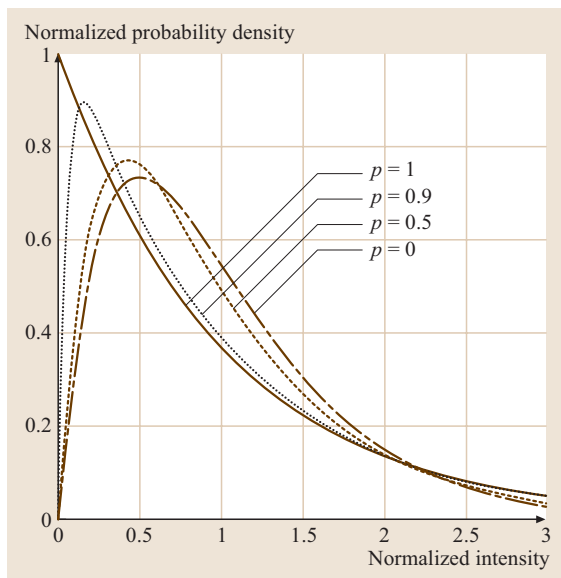
$$p(I) = C \exp\left[-\frac{1}{4}(I-a)^2\right], \tag{1.61}$$


Fig. 1.11 Probability density $p(I)$ for light with varying degrees of polarization from a thermal or chaotic source, calculated from (1.58) and (1.59)

Fig. 1.12 Probability densities $p(I)$ for a laser as a function of various pump parameters, as described above

where a is a pump parameter and C is a normalization constant. Below threshold, $a < 0$ and the thermal or chaotic output of the laser follows Bose–Einstein statistics; the probability density falls off exponentially. At threshold, $a = 0$ and the probability density has the form of a half-Gaussian cut off at $I = 0$. Above threshold, $a > 0$, and the probability density more nearly resembles the Gaussian distribution characteristic of coherent oscillators; far above threshold it is the closest we can make to a completely coherent source. The probability densities for these several cases are illustrated in Fig. 1.12.

1.6.2 Statistical Correlation Functions

A particularly useful set of statistical measures are the correlation functions between either classical field variables or quantum field operators. The first-order classical and quantum-mechanical correlation functions are identical in form, and are given by

$$g^{(1)} (\boldsymbol{r}_1 t_1, \boldsymbol{r}_2 t_2) \equiv \frac{\langle E^* (\boldsymbol{r}_1 t_1) \, E (\boldsymbol{r}_2 t_2) \rangle}{\left[\langle |E (\boldsymbol{r}_1 t_1)|^2 \, |E (\boldsymbol{r}_2 t_2)|^2 \rangle \right]^{1/2}} \,,$$
(1.62)

where $\{\boldsymbol{r}_1 t_1, \boldsymbol{r}_2 t_2\}$ are the space–time variables that define the two electromagnetic fields. The quantum-mechanical expression is constructed analogously, with

the field operators defined in (1.62) replacing the classical field variables. The significance of the function $g^{(1)}(\boldsymbol{r}_1 t_1, \boldsymbol{r}_2 t_2)$ is that it falls in the interval between 0 and 1, with 1 representing coherent light, 0 incoherent or chaotic light, and intermediate values representing varying degrees of partially coherent light. The results that follow from the first-order coherence properties of light, such as the results of Young's experiment, are identical regardless of whether one chooses the classical or quantum-mechanical description. This follows from the fact that $0 \leq |g^{(1)}| \leq 1$. Experimentally this is tantamount to saying that the same kinds of interference phenomena are observed classically as well as quantum mechanically.

On the other hand, the second-order coherence function leads to quite different and unanticipated differences between the quantum and classical cases. The second-order coherence for quantum fields is defined by analogy with the classical quantities, and is

$$g^{(2)} (\boldsymbol{r}_1 t_1, \boldsymbol{r}_2 t_2; \boldsymbol{r}_2 t_2, \boldsymbol{r}_1 t_1)$$
$$\equiv \frac{\langle E^- (\boldsymbol{r}_1 t_1) \, E^- (\boldsymbol{r}_2 t_2) \, E^+ (\boldsymbol{r}_2 t_2) \, E^+ (\boldsymbol{r}_1 t_1) \rangle}{\left[\langle E^- (\boldsymbol{r}_1 t_1) \, E^+ (\boldsymbol{r}_2 t_2) \rangle \langle E^- (\boldsymbol{r}_2 t_2) \, E^+ (\boldsymbol{r}_1 t_1) \rangle \right]} \,.$$
(1.63)

The classical version of this equation is generated by replacing operators with the corresponding classical fields, whereupon one finds that the

classical second-order correlation function satisfies $1 \leq g^{(2)}(0) \leq \infty$, $g^{(2)}(\tau) \leq g^{(2)}(0)$. To see what this implies, consider a simple model for a thermal source such as an atomic discharge lamp, with Doppler-broadened lines and a Gaussian line shape. Its second-order correlation function turns out to be

$$g^{(2)}(\tau) = 1 + \exp\left[-(\tau/\tau_{\mathrm{coll}})^2\right] , \quad (1.64)$$

where τ_{coll} is the mean time between collisions. For perfectly coherent light, it is also easy to show that (1.54) implies $g^{(2)}(\tau) = 1$ for all values of τ. Figure 1.13 illustrates the differences between the two correlation functions; an experimental verification of this comparison for a discharge lamp and a laser was first published in 1966 [1.58].

In addition to these rather straightforward examples, however, there is also a range of values for which $0 \leq g^{(2)}(0) < 1$, $g^{(2)}(0) < g^{(2)}(\tau)$ that corresponds to quantum-mechanical second-order coherence phenomena that have no equivalent in the classical realm, most commonly for photon streams with small, well-defined photon number [1.59].

1.6.3 Number Distribution Functions of Light Sources

Another way of classifying the statistical properties of light beams is by comparing the number distribution functions of photons impinging on a detector, and comparing the variance in those distributions for different light sources.

The statistical distribution of photon numbers arriving at a detector depends on the source of the light. We can generally distinguish thermal light, in which the process producing the photons is random, and coherent light, when it is not. A coherent light field can be viewed as one which is the closest thing to a *perfectly classical* state attainable in the quantum realm; such states are readily achieved in lasers, as seen in the previous section [1.60]. If the arrival and detection of photons in a stream are independent events, the probability distribution $p(n)$ for n photons is given by the Poissonian distribution, with mean $\bar{n}$ and standard deviation σ_n^2 is given by

$$p(n) = \frac{\bar{n}^n \, \mathrm{e}^{-\bar{n}}}{n!}, \sigma_n^2 = \bar{n} . \quad (1.65)$$

In other words, for a Poisson distribution, the mean photon number equals the variance.

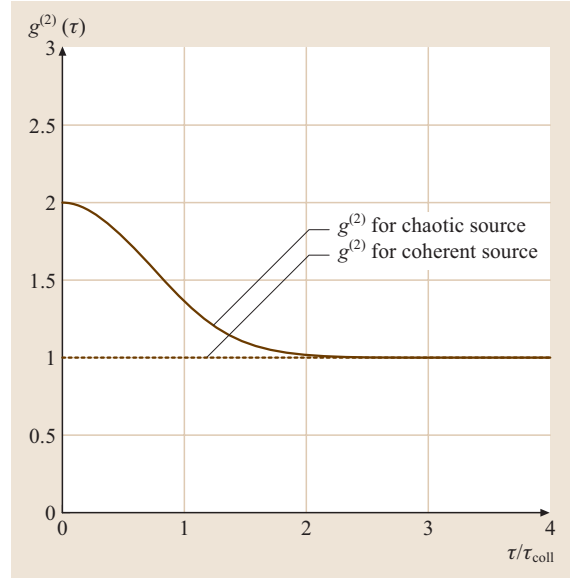
Chaotic light, on the other hand, has a distribution function that can be described as *super-Poissonian*,


Fig. 1.13 Second-order correlation functions $g^{(2)}(\tau/\tau_{\mathrm{coll}})$ for perfectly coherent light and chaotic light from a Doppler-broadened atomic discharge lamp

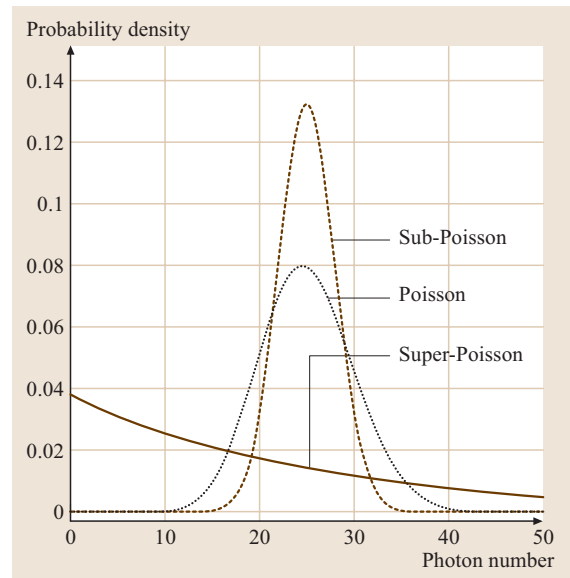
which is derivable from the Bose–Einstein or Planck distribution of photons in thermal equilibrium with their surroundings. That distribution function is readily shown


Fig. 1.14 Probability density as a function of mean photon number $\bar{n}$ for Poissonian (coherent), sub-Poissonian (nonclassical) and super-Poissonian (chaotic) light sources

to be [1.17]

$$p(n) = \frac{1}{\bar{n}+1} \left(\frac{\bar{n}}{\bar{n}+1} \right)^n \propto \left(e^{-\hbar\omega/k_B T} \right)^n ,$$

$$\bar{n} = \frac{1}{e^{\hbar\omega/k_B T} - 1} . \tag{1.66}$$

The variance for the Bose–Einstein distribution is $\sigma_n^2 = \bar{n} + \bar{n}^2$, which is always greater than it is for a Poissonian distribution. Interestingly, another characteristic of this thermal light is that the signal-to-noise ratio is always less than 1, so that thermal light cannot be used to transmit digital information. The difference between the two cases is illustrated in Fig. 1.14.

In the case of nonclassical light, on the other hand, there are states in which $\sigma_n^2 < \bar{n}$ as shown in Figure 1.14; squeezed states of light (discussed in more detail below) are an example.

A single-parameter way of characterizing the statistical characteristics of the various light sources is the Mandel Q-parameter, defined by

$$Q \equiv \frac{\left\langle (\hat{n})^2 \right\rangle - \langle \hat{n} \rangle}{\langle \hat{n} \rangle} = \frac{\left\langle (\hat{n})^2 \right\rangle}{\langle \hat{n} \rangle} - 1 . \tag{1.67}$$

Evidently, the case of chaotic or thermal light corresponds to $Q > 0$, coherent light to $Q = 0$, and sub-Poissonian light when $0 > Q > -1$. Nonclassical light can be created in a number of different ways; some examples are fluorescence emitted by a single ion in an electromagnetic trap, [1.61] fluorescence from trapped atoms [1.62] and semiconductor quantum dots, [1.63, 64] and essentially arbitrary photon streams generated through cavity quantum electrodynamics [1.65–67].

1.7 Characteristics and Applications of Nonclassical Light

Although the application of classical light – whether viewed in the electromagnetic wave or photon (semi-classical) models – are now ubiquitous, and the stuff of undergraduate textbooks, the study of nonclassical light, in the quantum-field model, is still an intensely active field of research. In this section, we describe in greater detail some of the characteristics of nonclassical light and consider one of its many interesting applications.

1.7.1 Bunched Light

A particularly interesting statistical property of light is the arrival-time distribution of photons coming from the various sources described previously [1.68, 69]. It was experimentally observed a long time ago that light coming from thermal sources tends to be *bunched*, that is, the probability of a second hit on a detector immediately after one photon is detected is enhanced over the chances of a random detection event [1.70]. In contrast, the arrival-time distribution of photons from a coherent source is random, in keeping with the Poissonian nature of the emission process from a laser. Finally, however, there are light sources that generate arrival-time distributions exhibiting *anti-bunching*, with photons being detected at regular intervals. This anti-bunching phenomenon was first detected in fluorescence from sodium atoms [1.71], and has since been observed in quantum dots [1.72], atom [1.62] and ion traps, and even in atom lasers [1.73]. The transition between bunching and anti-

bunching behavior has also been observed [1.74, 75]. However, there is apparently no connection between sub-Poissonian statistics and anti-bunching, [1.76] so that the underlying physics of the two statistical properties may well likewise be different.

1.7.2 Squeezed Light

In a classical wave, the phase and amplitude are independent variables. In quantum mechanics, however, these quantities are coupled through the uncertainty principle applied to the operators that define the quantum fields. Squeezed states are states of minimum uncertainty in which one or the other variable – number density or phase – is reduced below the Poissonian level [1.77–79] The origin of these states can be understood quantitatively by rewriting (1.22) as follows:

$$\hat{E}_k = i \left(\frac{\hbar\omega_k}{2\varepsilon_0 V} \right)^{1/2}$$
$$\times \hat{\varepsilon}_k \left[\hat{q}_k \cos(\mathbf{k} \cdot \mathbf{r} - \omega_k t) - \hat{p}_k \sin(\mathbf{k} \cdot \mathbf{r} - \omega_k t) \right] , \tag{1.68}$$

where the operators or canonical variables $\{\hat{q}_k, \hat{p}_k\}$ are the quadrature amplitudes into which the electromagnetic field operator can be decomposed. These operators satisfy the standard indeterminacy relationship for the canonical variables in quantum mechanics. It follows, therefore, that while the product of their fluctuations
Fig. 1.15a–c Relationships between the various quadrature states for light that is **(a)** quadrature squeezed in the vacuum state; **(b)** number-squeezed; and **(c)** phase-squeezed

must satisfy $\langle(\Delta \hat{q}_k)^2\rangle\langle(\Delta \hat{p}_k)^2\rangle \geq 1$, it is possible to generate coherent light in which the fluctuations in one variable are decreased at the expense of the other.

It is conventional to redefine the complex electric field operator in (1.60) to make so-called dimensionless field quadratures X_1 and X_2, as follows:

$$\hat{X}_1(t) \equiv \left(\frac{\varepsilon_0 V}{4\hbar\omega}\right)^{1/2} \hat{E}_{k0} \sin(\omega t)$$

$$= \left(\frac{\hbar}{2\omega}\right)^{1/2} \hat{q}_k(t) \ ,$$

$$\hat{X}_2(t) \equiv \left(\frac{\varepsilon_0 V}{4\hbar\omega}\right)^{1/2} \hat{E}_{k0} \cos(\omega t)$$

$$= \left(\frac{\hbar}{2\omega}\right)^{1/2} \hat{p}_k(t) \ . \qquad (1.69)$$

In this formalism, it is evident that the field quadratures obey the same indeterminacy relations as the quantum harmonic oscillator. Both the vacuum state and coherent states have minimum uncertainties, and moreover, the

Fig. 1.16 Schematic of an experiment demonstrating photon entanglement by correlations at a distance ([1.80]). The details of the experiment are described in the text

uncertainties in the two field quadratures can in principle be equal

$$\Delta X_1 = \Delta X_2 = \frac{1}{2} \ . \qquad (1.70)$$

However, the indeterminacy relation requires only that the product of the uncertainties be a minimum. Hence, it is possible to imagine and to construct minimum-uncertainty states in which the uncertainty in one field quadrature is reduced at the cost of increasing the uncertainty in the other quadrature [1.81]. Coherent light with such properties is said to be quadrature squeezed; the properties of such states are explored in detail in [1.57].

Another kind of coherent light is formed from the so-called number states of the electromagnetic field. These states, first used to describe optical correlations by *Glauber* [1.82–84] and *Sudarshan* [1.85], can in fact exhibit the properties of light that is number- or amplitude-squeezed. Additionally, of course, it is possible to squeeze the conjugate phase variable of the number states. Figure 1.15 illustrates the different relationships of the quadratures in the various kinds of squeezed light.

1.7.3 Entangled Light

In 1935, Einstein, Podolsky and Rosen (EPR) published their observation that for *entangled states* (Schrödinger's terminology [1.86]), quantum mechanics predicted that measurements on objects far apart could show a correlation. How then, argued Einstein, was it possible for quantum mechanics to be a complete, causal description of reality if the local results of a measurement could be influenced by quantum correlations at a large distance? Three decades later, J. S. Bell transformed this philosophical question into an experimentally testable issue by demonstrating that the quantum-mechanical predictions for a pair of interacting spin-1/2 particles were not consistent with the predictions of EPR for a system based on the idea of strict local causality [1.87, 88]

In the event, it turned out to be easier to test these predictions using spin-1 photons instead of spin-1/2 particles, following procedures suggested by *Clauser* and *Shimony* [1.89]. Experiments by *Aspect* [1.90] and later by *Zeilinger* et al. [1.80] showed conclusively that photons emitted from a single source violated Bell's inequality, and were thus entangled by correlations at a distance of precisely the kind that EPR argued were impossible.
The schematic of the experiment is shown in Fig. 1.16. Two photons are emitted from a common source, and pass through polarization-measuring devices that measure the photons emitted with orientations a and b perpendicular to the z-axis. At each terminus of the experiment, a computer monitors the orientation of the polarization as measured and the precise timing signal provided by an atomic clock. In the Zeilinger experiments, the polarization measurements are separated by 400 m, a distance that precludes semiclassical correlations by virtue of the use of ultrashort light pulses and random switching of the preferred orientation of the polarization analyzers.

The results appear to clearly demonstrate that quantum correlations at large distance are one of the novel realities of quantum physics. They also have applications in quantum cryptography [1.91, 92] and quantum teleportation [1.93, 94].

1.8 Summary

The properties of light at this point in the history of optical science are as varied as the multiple ways in which light can now be generated and detected. The kinds of sources that can generate light range from classical thermal (chaotic) sources and coherent sources such as lasers, wigglers and undulators – and most recently to nonclassical sources generated by exquisite control of light-emission processes at the single-quantum level. While the statistical properties of light governed by first-order correlations are virtually indistinguishable for both classical and quantum light sources, the second-order correlations reveal distinctive differences, particularly in the statistical properties of the light generated by these different sources. The wide-ranging impact of these studies, underlined by the recent award of a Nobel prize for the theory of quantum coherence, suggests not only that the field has reached the stature of a major part of physics, but that it has grown measurably in importance and is likely to continue to do so in the future.

From a review written for the World Year of Physics in 2005 [1.95], one finds that two of the three celebrated papers in Einstein's *annus mirabilis* had deep intellec-

tual connections with questions about the properties of light. The paper on special relativity was derived from a profoundly insightful critique of the classical theory of electromagnetic radiation [1.96]. In the second paper, Einstein literally solidified the concept of the light quantum (later christened the photon), which Planck had regarded as a mere heuristic, a mathematical device for saving appearances [1.97]. Einstein did so by showing from the Planck distribution that the entropy of cavity radiation has the same volumetric dependence as the entropy of an ideal gas – and therefore, he inferred, it was appropriate to treat light quanta as particles. But Einstein was also profoundly critical of the quantum physics of his time, even though, or perhaps because, his own interpretation of quantum phenomena – as in the EPR paradox – turned out not to be commensurate with experimental reality [1.98]. Nevertheless, and notwithstanding his objections, perhaps Einstein would also find it amusing that contemporary studies of both classical and quantum optics continue to generate informed criticism and new, exciting interpretations of the quantum physics whose foundations he helped to lay.

2. Geometrical Optics

This chapter shall discuss the basics and the applications of geometrical optical methods in modern optics. Geometrical optics has a long tradition and some ideas are many centuries old. Nevertheless, the invention of modern personal computers which can perform several million floating-point operations in a second also revolutionized the methods of geometrical optics and so several analytical methods lost importance whereas numerical methods such as ray tracing became very important. Therefore, the emphasis in this chapter is also on modern numerical methods such as ray tracing and some other systematic methods such as the paraxial matrix theory.

We will start with a section showing the transition from wave optics to geometrical optics and the resulting limitations of the validity of geometrical optics. Then, the paraxial matrix theory will be used to introduce the traditional parameters such as the focal length and the principal points of an imaging optical system. Also, an extension of the paraxial matrix theory to optical systems with non-centered elements will be briefly discussed. After a section about stops and pupils the next section will treat ray tracing and several extensions to analyze imaging and non-imaging optical systems. A section about aberrations of optical systems will give a more vivid insight into this matter than a systematic treatment. At the end a section about the most important optical instruments generally described with geometrical optics will be given. These are the achromatic lens, the camera, the human eye, the telescope, and the microscope.

For more information about the basics of geometrical optics we refer to text books such as [2.1–8].

2.1 The Basics and Limitations of Geometrical Optics

2.1.1 The Eikonal Equation

Geometrical optics is normally defined to be the limiting case of wave optics for very small wavelengths $\lambda \to 0$. In fact it is well-known that electromagnetic waves with a large wavelength λ such as radio waves cannot generally be treated with geometrical optical methods. X-rays and gamma radiation on the other hand propagate nearly like rays. They can generally be described quite well with geometrical optical methods provided the size of the optical elements (especially stops) is at least several hundred wavelengths. The accuracy of a geometrical optical calculation increases if the size of the optical element increases compared to the wavelength of the light used.

The basic equations of geometrical optics [2.1, 7] are derived directly from the Maxwell equations. The restriction here is that only linear and isotropic materials are considered. Additionally, the electric charge density ρ is assumed to be zero.

In this case the four Maxwell equations are (see Sects. 1.3, 3.1.1):

$$\nabla \times \boldsymbol{E}(\boldsymbol{r}, t) = -\frac{\partial \boldsymbol{B}(\boldsymbol{r}, t)}{\partial t} , \tag{2.1}$$

$$\nabla \times \boldsymbol{H}(\boldsymbol{r}, t) = \frac{\partial \boldsymbol{D}(\boldsymbol{r}, t)}{\partial t} + \boldsymbol{j}(\boldsymbol{r}, t) , \tag{2.2}$$

$$\nabla \cdot \boldsymbol{B}(\boldsymbol{r}, t) = 0 , \tag{2.3}$$

$$\nabla \cdot \boldsymbol{D}(\boldsymbol{r}, t) = 0 , \tag{2.4}$$

where the following quantities of the electromagnetic field are involved: electric vector $\boldsymbol{E}$, magnetic vector $\boldsymbol{H}$, electric displacement $\boldsymbol{D}$, magnetic induction $\boldsymbol{B}$ and electric current density $\boldsymbol{j}$. The arguments illustrate that all quantities are in the general case functions of the spatial coordinates x, y, z with position vector $\boldsymbol{r} = (x, y, z)$ and of the time t. The so called nabla operator

$$\nabla = \begin{pmatrix} \frac{\partial}{\partial x} \\ \frac{\partial}{\partial y} \\ \frac{\partial}{\partial z} \end{pmatrix} \tag{2.5}$$

is used and the symbol "×" indicates the vector product of two vectors whereas "·" indicates the scalar product of two vectors.

The material equations in the case of linear and isotropic materials link the electromagnetic quantities with each other:

$$\boldsymbol{D}(\boldsymbol{r}, t) = \epsilon(\boldsymbol{r})\epsilon_0 \boldsymbol{E}(\boldsymbol{r}, t) , \tag{2.6}$$

$$\boldsymbol{B}(\boldsymbol{r}, t) = \mu(\boldsymbol{r})\mu_0 \boldsymbol{H}(\boldsymbol{r}, t) , \tag{2.7}$$

$$\boldsymbol{j}(\boldsymbol{r}, t) = \sigma(\boldsymbol{r})\boldsymbol{E}(\boldsymbol{r}, t) . \tag{2.8}$$

The function ϵ is the dielectric function, μ is the magnetic permeability and σ is the specific conductivity. The constants ϵ_0 and μ_0 are the dielectric constant of vacuum and the magnetic permeability of vacuum, respectively. A quite general approach for stationary monochromatic waves is used to describe the electric and the magnetic field

$$\boldsymbol{E}(\boldsymbol{r}, t) = \boldsymbol{e}(\boldsymbol{r})\mathrm{e}^{\mathrm{i}k_0 L(\boldsymbol{r})}\mathrm{e}^{-\mathrm{i}\omega t} , \tag{2.9}$$

$$\boldsymbol{H}(\boldsymbol{r}, t) = \boldsymbol{h}(\boldsymbol{r})\mathrm{e}^{\mathrm{i}k_0 L(\boldsymbol{r})}\mathrm{e}^{-\mathrm{i}\omega t} . \tag{2.10}$$

The real function L is the optical path length and the vectors $\boldsymbol{e}$ and $\boldsymbol{h}$ are in the general case complex-valued to be able to represent all polarization states. The surfaces with constant optical path length L are the wave fronts, and the term $\Phi(\boldsymbol{r}) = k_0 L(\boldsymbol{r})$ is the phase of the wave; $\boldsymbol{e}$ and $\boldsymbol{h}$ are slowly varying functions of the position $\boldsymbol{r}$ whereas the term $\exp(\mathrm{i}k_0 L)$ varies rapidly because the constant k_0 is defined as $k_0 = 2\pi/\lambda$ with the vacuum wavelength λ. The angular frequency ω of the wave is linked to λ by $\omega = 2\pi c/\lambda = ck_0$, where c is the speed of light in vacuum.

By applying these equations to the Maxwell equations the so called time-independent Maxwell equations result:

$$\nabla \times \left[\boldsymbol{e}(\boldsymbol{r})\mathrm{e}^{\mathrm{i}k_0 L(\boldsymbol{r})} \right] = \mathrm{i}\omega\mu(\boldsymbol{r})\mu_0 \boldsymbol{h}(\boldsymbol{r}) \\ \cdot \mathrm{e}^{\mathrm{i}k_0 L(\boldsymbol{r})} , \tag{2.11}$$

$$\nabla \times \left[\boldsymbol{h}(\boldsymbol{r})\mathrm{e}^{\mathrm{i}k_0 L(\boldsymbol{r})} \right] = [-\mathrm{i}\omega\epsilon(\boldsymbol{r})\epsilon_0 + \sigma(\boldsymbol{r})] \\ \cdot \boldsymbol{e}(\boldsymbol{r})\mathrm{e}^{\mathrm{i}k_0 L(\boldsymbol{r})} , \tag{2.12}$$

$$\nabla \cdot \left[\mu(\boldsymbol{r}) \mu_0 \boldsymbol{h}(\boldsymbol{r}) \mathrm{e}^{ik_0 L(\boldsymbol{r})} \right] = 0 , \qquad (2.13)$$

$$\nabla \cdot \left[\epsilon(\boldsymbol{r}) \epsilon_0 \boldsymbol{e}(\boldsymbol{r}) \mathrm{e}^{ik_0 L(\boldsymbol{r})} \right] = 0 . \qquad (2.14)$$

Equation (2.13) is not independent of (2.11) because it is well known that the quantity $\nabla \cdot (\nabla \times \boldsymbol{f})$ of an arbitrary vector function $\boldsymbol{f}$ is always zero [2.9]. Therefore, if (2.11) is fulfilled, (2.13) will also be fulfilled. In the case of nonconducting materials, i. e. $\sigma = 0$, the same is valid for the relation between (2.12) and (2.14). In the more general case $\sigma \neq 0$, (2.12) and (2.14) require that

$$\nabla \cdot \left[\sigma(\boldsymbol{r}) \boldsymbol{e}(\boldsymbol{r}) \mathrm{e}^{ik_0 L(\boldsymbol{r})} \right] = 0 . \qquad (2.15)$$

Using the rules of the nabla calculus the left-hand sides of (2.11) and (2.12) can be transformed to

$$\nabla \times \left[\boldsymbol{e}(\boldsymbol{r}) \mathrm{e}^{ik_0 L(\boldsymbol{r})} \right]$$
$$= \nabla \left(\mathrm{e}^{ik_0 L(\boldsymbol{r})} \right) \times \boldsymbol{e}(\boldsymbol{r}) + \mathrm{e}^{ik_0 L(\boldsymbol{r})} \nabla \times \boldsymbol{e}(\boldsymbol{r})$$
$$= [ik_0 \nabla L(\boldsymbol{r}) \times \boldsymbol{e}(\boldsymbol{r}) + \nabla \times \boldsymbol{e}(\boldsymbol{r})] \, \mathrm{e}^{ik_0 L(\boldsymbol{r})} , \qquad (2.16)$$

$$\nabla \times \left[\boldsymbol{h}(\boldsymbol{r}) \mathrm{e}^{ik_0 L(\boldsymbol{r})} \right]$$
$$= [ik_0 \nabla L(\boldsymbol{r}) \times \boldsymbol{h}(\boldsymbol{r}) + \nabla \times \boldsymbol{h}(\boldsymbol{r})] \, \mathrm{e}^{ik_0 L(\boldsymbol{r})} . \qquad (2.17)$$

So, (2.11) and (2.12) give:

$$\nabla L(\boldsymbol{r}) \times \boldsymbol{e}(\boldsymbol{r}) - c\mu(\boldsymbol{r}) \mu_0 \boldsymbol{h}(\boldsymbol{r})$$
$$= \frac{i}{k_0} \nabla \times \boldsymbol{e}(\boldsymbol{r}) , \qquad (2.18)$$

$$\nabla L(\boldsymbol{r}) \times \boldsymbol{h}(\boldsymbol{r}) + c\epsilon(\boldsymbol{r}) \epsilon_0 \boldsymbol{e}(\boldsymbol{r})$$
$$= \frac{i}{k_0} [\nabla \times \boldsymbol{h}(\boldsymbol{r}) - \sigma(\boldsymbol{r}) \boldsymbol{e}(\boldsymbol{r})] . \qquad (2.19)$$

For the limiting case $\lambda \to 0$, i. e. $k_0 \to \infty$, the right sides of both equations become zero

$$\nabla L(\boldsymbol{r}) \times \boldsymbol{e}(\boldsymbol{r}) - c\mu(\boldsymbol{r}) \mu_0 \boldsymbol{h}(\boldsymbol{r}) = 0 , \qquad (2.20)$$

$$\nabla L(\boldsymbol{r}) \times \boldsymbol{h}(\boldsymbol{r}) + c\epsilon(\boldsymbol{r}) \epsilon_0 \boldsymbol{e}(\boldsymbol{r}) = 0 . \qquad (2.21)$$

Now, (2.20) is inserted into (2.21) and the calculus for a double vector product is applied

$$\frac{1}{c\mu(\boldsymbol{r}) \mu_0} \nabla L(\boldsymbol{r}) \times [\nabla L(\boldsymbol{r}) \times \boldsymbol{e}(\boldsymbol{r})] + c\epsilon(\boldsymbol{r}) \epsilon_0 \boldsymbol{e}(\boldsymbol{r}) = 0$$
$$\Rightarrow \quad [\nabla L(\boldsymbol{r}) \cdot \boldsymbol{e}(\boldsymbol{r})] \nabla L(\boldsymbol{r})$$
$$- [\nabla L(\boldsymbol{r})]^2 \boldsymbol{e}(\boldsymbol{r}) + n^2(\boldsymbol{r}) \boldsymbol{e}(\boldsymbol{r}) = 0 . \qquad (2.22)$$

Here, $\mu_0 \epsilon_0 = 1/c^2$ and $\mu\epsilon = n^2$ are used, where n is the refractive index of the material.

Equation (2.21) shows that the scalar product $\nabla L \cdot \boldsymbol{e}$ is zero and the final result is the well-known eikonal equation

$$[\nabla L(\boldsymbol{r})]^2 = n^2(\boldsymbol{r}) . \qquad (2.23)$$
Fig. 2.1 Optical ray: the trajectory which is perpendicular to the surfaces of equal optical path length L

This is the basic equation of geometrical optics which provides e.g. the basis for the concept of optical rays. A ray is defined as that trajectory which is always perpendicular to the wave fronts, which are the surfaces of equal optical path length L (Fig. 2.1). Therefore, a ray points in the direction of ∇L. Equation (2.23) has the name eikonal equation because the optical path length L is for historical reasons sometimes called the eikonal [2.1].

2.1.2 The Orthogonality Condition of Geometrical Optics

Equations (2.20) and (2.21) can be solved for $\boldsymbol{e}$ and $\boldsymbol{h}$:

$$\boldsymbol{h}(\boldsymbol{r}) = \frac{1}{c\mu(\boldsymbol{r}) \mu_0} \nabla L(\boldsymbol{r}) \times \boldsymbol{e}(\boldsymbol{r}) , \qquad (2.24)$$

$$\boldsymbol{e}(\boldsymbol{r}) = -\frac{1}{c\epsilon(\boldsymbol{r}) \epsilon_0} \nabla L(\boldsymbol{r}) \times \boldsymbol{h}(\boldsymbol{r}) . \qquad (2.25)$$

This shows on the one hand that $\boldsymbol{h}$ is perpendicular to $\boldsymbol{e}$ as well as ∇L and on the other hand that $\boldsymbol{e}$ is perpendicular to $\boldsymbol{h}$ as well as ∇L. Therefore, in the limiting case $\lambda \to 0$ ∇L, $\boldsymbol{e}$ and $\boldsymbol{h}$ have to form an orthogonal triad of vectors. This confirms the well-known fact that electromagnetic waves are transversal waves.

At the end of the last section a light ray has been defined as being parallel to ∇L and in Sect. 2.4 the important method of ray tracing will be explained. An extended method of ray tracing is polarization ray tracing where the polarization state of a ray which locally represents a wave is transported along with each ray [2.10, 11]. Using the results of this section it is clear that the vector $\boldsymbol{e}$, which indicates the polarization (and amplitude) of the ray, has to be perpendicular to the ray direction ∇L.

2.1.3 The Ray Equation

A surface with constant values L is a surface of equal optical path length. Now, a ray is defined as that trajectory starting from a certain point in space which is

perpendicular to the surfaces of equal optical path length. Therefore, ∇L points in the direction of the ray. We use the arc length s along the curve that is defined by the ray (Fig. 2.2). Then, if r describes now the position vector of a point on the ray, dr/ds is a unit vector which is tangential to the ray curve and the eikonal equation (2.23) delivers:

$$\nabla L = n\frac{dr}{ds} \tag{2.26}$$

Here and in the following L and n are not explicitly indicated as functions of the position to tighten the notation. From (2.26) a differential equation for the ray can be derived by again using (2.23) and the definition of $d\nabla L/ds$ as being the directional derivative of ∇L along dr/ds:

$$\frac{d}{ds}\left(n\frac{dr}{ds}\right) = \frac{d}{ds}\nabla L = \frac{dr}{ds}\cdot\nabla(\nabla L)$$
$$= \frac{1}{n}\nabla L\cdot\nabla(\nabla L) = \frac{1}{2n}\nabla(\nabla L)^2$$
$$= \frac{1}{2n}\nabla n^2 = \nabla n\ ,$$

$$\Rightarrow\quad \frac{d}{ds}\left(n\frac{dr}{ds}\right) = \nabla n\ . \tag{2.27}$$

This is the differential equation for a ray in a general inhomogeneous isotropic and linear substance. Such materials where the refractive index is a function of the position are often called graded index (GRIN) materials. In this case the solution of the differential equation may be a quite complex curve.

However, the most important case is that n is independent of the position, i.e. the ray propagates in
Fig. 2.2 A curved light ray in a general (inhomogeneous) material. $r(s)$ is the position vector of a point on the ray, where s is the arc length along the curve and O is the origin of the coordinate system. Then, the vector dr/ds is a unit vector tangential to the ray

a homogeneous material. Then, a simple differential equation for the ray is obtained:

$$\frac{d^2r}{ds^2} = 0\ . \tag{2.28}$$

The solution of this equation is a straight line. So, the ray equation in homogeneous materials is

$$r = sa + p \tag{2.29}$$

with constant vectors a and p. This means that light rays propagate rectilinearly in a homogeneous and isotropic material if the eikonal equation is valid. Moreover, a has to be a unit vector, i.e. $|a| = 1$, because s is the geometrical path length along the ray. So, for the distance between two points P_1 and P_2 with position vectors r_1 and r_2 we have ($s_2 > s_1$):

$$|r_2 - r_1| = (s_2 - s_1)\,|a| = s_2 - s_1 \Rightarrow |a| = 1\ .$$

The limitations of the validity of the eikonal equation will be investigated in the next section.

2.1.4 Limitations of the Eikonal Equation

Besides using directly the Maxwell equations the eikonal equation can also be derived from the wave equation and, in the case of a monochromatic wave, from the Helmholtz equation. This will be done in the following for a homogeneous, isotropic and linear dielectric material, i.e. where n is constant and $\sigma = 0$. Moreover, it is assumed that the scalar case is valid, i.e. that polarization effects can be neglected and only one component $u(r)$ of the electric or magnetic vector has to be considered. In this limiting case it is easier to start directly with the scalar Helmholtz equation (Sect. 3.1.5) than to start as in Sect. 2.1.1 with the Maxwell equations and then to make the transition to the scalar case.

The scalar Helmholtz equation is:

$$\left[\nabla\cdot\nabla + (nk_0)^2\right]u(r) = 0\ . \tag{2.30}$$

Analogously to (2.9) or (2.10) the following approach for u is used

$$u(r) = A(r)e^{ik_0 L(r)}\ , \tag{2.31}$$

where the amplitude A and the optical path length L are both real functions of the position and A varies only slowly with the position.

Then, by omitting the arguments of the functions we can write

$$\nabla u = \nabla \left(A\, e^{ik_0 L} \right) = e^{ik_0 L} \nabla A + ik_0 A\, e^{ik_0 L} \nabla L$$

$$= \left(\frac{\nabla A}{A} + ik_0 \nabla L \right) u \,,$$

$$\Delta u = \nabla \cdot \left[\left(\frac{\nabla A}{A} + ik_0 \nabla L \right) u \right]$$

$$= \left(\frac{\nabla A}{A} + ik_0 \nabla L \right)^2 u$$

$$+ \left(\frac{\Delta A}{A} - \frac{(\nabla A)^2}{A^2} + ik_0 \Delta L \right) u$$

$$= \left[\frac{\Delta A}{A} - k_0^2 (\nabla L)^2 \right.$$

$$\left. + 2ik_0 \frac{\nabla A \cdot \nabla L}{A} + ik_0 \Delta L \right] u \,.$$

Here, $\Delta := \nabla \cdot \nabla$ is the Laplace operator or Laplacian. So, by inserting the expression for Δu into the Helmholtz equation and dividing it by u the result is

$$\frac{\Delta A}{A} - k_0^2 (\nabla L)^2 + n^2 k_0^2 + 2ik_0 \frac{\nabla A \cdot \nabla L}{A}$$

$$+ ik_0 \Delta L = 0 \,. \tag{2.32}$$

Since A, L, k_0 and n are all real quantities the real and the imaginary part of (2.32) can be simply separated and both have to be zero.

To obtain the eikonal equation only the real part is considered:

$$\frac{\Delta A}{A} - k_0^2 (\nabla L)^2 + n^2 k_0^2 = 0 \,,$$

$$\Rightarrow \quad (\nabla L)^2 = n^2 + \underbrace{\frac{1}{k_0^2} \frac{\Delta A}{A}}_{=: \gamma} \,. \tag{2.33}$$

In the limiting case $\lambda \to 0 \Rightarrow k_0 \to \infty$ the term γ can be neglected and again the eikonal equation (2.23) is obtained

$$(\nabla L)^2 = n^2 \,.$$

But (2.33) shows that the eikonal equation can also be fulfilled for a finite value of λ with good approximation as long as the term γ is much smaller than 1, because the order of magnitude of n^2 is typically between 1 (vacuum) and 12 (silicon for infrared light). Therefore, the condition is:

$$\gamma \ll 1 \Rightarrow \frac{\lambda^2}{4\pi^2} \frac{\Delta A}{A} \ll 1 \,. \tag{2.34}$$

This is fulfilled with good approximation if A is a slowly varying function of the position, i.e. if the relative curvature of A over the distance of a wavelength is very small. If the term γ is not very small the right-hand side of (2.33) depends on the position (because A depends generally on $\mathbf{r}$) even though n is constant. Formally this is equivalent to an eikonal equation with position-dependent refractive index n so that light rays would formally be bent in regions of a rapidly changing amplitude, as e.g. in the focus. Therefore, the results of ray-tracing calculations (Sect. 2.4), which assume rectilinear rays in a homogeneous material, are not correct in the neighborhood of the focus where the amplitude changes rapidly. If aberrations are present the variation of the amplitude in the focal region will be less severe and the accuracy of geometrical optical calculations improves with increasing aberrations. In practice, a rule of thumb is that the focal region of an aberrated wave calculated with ray tracing approximates the actual focus very well if the result of the ray-tracing calculation gives a focus that has several times the size of the corresponding diffraction limited focus (Airy disc), which can easily be estimated (Sect. 3.4, PSF (point spread function)).

There are also scalar waves which fulfill exactly the eikonal equation so that the term γ is exactly zero. One example is a plane wave with $u(\mathbf{r}) = u_0 \exp(ink_0 \mathbf{a} \cdot \mathbf{r})$. $\mathbf{a}$ is a constant unit vector in the direction of propagation and u_0 is also a constant. So, we have

$$A = u_0 \Rightarrow \Delta A = 0 \Rightarrow \gamma = 0 \,,$$

$$L = n\mathbf{a} \cdot \mathbf{r} \Rightarrow \nabla L = n\mathbf{a} \Rightarrow (\nabla L)^2 = n^2 \,.$$

Of course, a plane wave is also a solution of the Maxwell equations.

A second example is a spherical wave, which is a solution of the scalar Helmholtz equation but not of the Maxwell equations themselves because the orthogonality conditions (2.24) and (2.25) cannot be fulfilled for a spherical wave in the whole of space. Nevertheless, a spherical wave $u(r) = u_0 \exp(ink_0 r)/r$ with $r = |\mathbf{r}|$ is a very important approximation in many cases and a dipole radiation behaves in the far field in a plane perpendicular to the dipole axis like a spherical wave. For the spherical wave we obtain:

$$A = \frac{u_0}{r} \Rightarrow \Delta A = u_0 \nabla \cdot \left(-\frac{\mathbf{r}}{r^3} \right)$$

$$= -\frac{3u_0}{r^3} + \frac{3u_0 \mathbf{r} \cdot \mathbf{r}}{r^5} = 0 \Rightarrow \gamma = 0 \,,$$

$$L = nr \Rightarrow \nabla L = n\frac{\mathbf{r}}{r} \Rightarrow (\nabla L)^2 = n^2 \,.$$

Here, the coordinate system has been chosen in such a way that the center of curvature of the spherical wave

is at the origin. Of course, it is quite straightforward to formulate the spherical wave with an arbitrary center of curvature r_0 by replacing r with $|r - r_0|$.

So, plane waves and spherical waves, which are very important in geometrical optics, fulfill both the eikonal equation (2.23) not only in the limiting case $\lambda \to 0$ but also for finite wavelengths λ.

2.1.5 Energy Conservation in Geometrical Optics

The imaginary part of (2.32) gives information about the intensity of the amount of transported light:

$$\Delta L + 2\nabla L \cdot \frac{\nabla A}{A} = 0 . \tag{2.35}$$

Since the intensity I of a light wave is proportional to the square of the amplitude A^2 the following equality holds:

$$\frac{\nabla I}{I} = \frac{\nabla (A^2)}{A^2} = \frac{2A\nabla A}{A^2} = 2\frac{\nabla A}{A} .$$

Therefore, (2.35) delivers

$$I\Delta L + \nabla L \cdot \nabla I = 0$$

or

$$\nabla \cdot (I\nabla L) = 0 . \tag{2.36}$$

Now, the integral theorem of Gauss can be applied

$$\int_V \nabla \cdot (I\nabla L)\, \mathrm{d}V = \oint_S I\nabla L \cdot \mathrm{d}S = 0 , \tag{2.37}$$

where the left integral symbolizes a volume integral over a volume V and the right integral a surface integral over the closed surface S which confines the volume V.

A light tube (Fig. 2.3) is a tube-like entity (simple forms are e.g. a cylinder or a cone) where light rays form

the mantle surface. Therefore, on the mantle surface the vectors ∇L (ray direction) and $\mathrm{d}S$ (surface normal) are perpendicular to each other and therefore $\nabla L \cdot \mathrm{d}S = 0$. At the two face surfaces of the light tube (refractive index n) with surface vectors $\mathrm{d}S_1$ and $\mathrm{d}S_2$, which are assumed to have an infinitesimally small size, the electromagnetic power flux P_1 and P_2 are given by

$$P_j = \frac{I_j}{n}|\nabla L_j \cdot \mathrm{d}S_j| ; \quad j \in \{1, 2\} .$$

Using (2.37) the result is

$$\oint_S I\nabla L \cdot \mathrm{d}S = 0 = I_1\nabla L_1 \cdot \mathrm{d}S_1 + I_2\nabla L_2 \cdot \mathrm{d}S_2 . \tag{2.38}$$

Hereby, the surface normals $\mathrm{d}S_1$ or $\mathrm{d}S_2$ always point out of the closed surface S and therefore $\nabla L_1 \cdot \mathrm{d}S_1$ and $\nabla L_2 \cdot \mathrm{d}S_2$ have opposite algebraic signs. In total, the power flux $P_1 = -I_1\nabla L_1 \cdot \mathrm{d}S_1/n$ which enters the light tube at the left is equal to the power flux $P_2 = I_2\nabla L_2 \cdot \mathrm{d}S_2/n$ which leaves the light tube at the right: $P_1 = P_2$. This means that the energy is conserved and we can formulate the following lemma: In the scope of geometrical optics the electromagnetic power (energy) is transported along the light rays and the total light power is conserved in a light tube if no light is absorbed.

2.1.6 Law of Refraction

Let us consider the interface between two materials with refractive index n_1 on one side and n_2 on the other. This interface is assumed to be replaced by a very thin layer in which the refractive index varies quite rapidly but continuously from n_1 to n_2. An infinitesimally small rectangular closed loop C is then constructed at the interface in such a way that two of the edges of the loop are parallel to the interface and the other two edges are parallel to the surface normal N ($|N| = 1$) of the interface

Fig. 2.3 Scheme of a light tube which is bounded by a bundle of rays
Fig. 2.4 The parameters used in deriving Snell's law

where N points from material 2 to material 1 (Fig. 2.4). Since the direction vectors a of the light rays can be expressed as the gradient of a scalar function (2.26) the following identity is valid:

$$\nabla \times \left(n \frac{\mathrm{d}r}{\mathrm{d}s} \right) = \nabla \times \nabla L = 0 . \tag{2.39}$$

The ray direction vector is written in the following as $a = \mathrm{d}r / \mathrm{d}s$.

Using the integral theorem of Stokes equation (2.39) delivers

$$\int_S \nabla \times (na) \cdot \mathrm{d}S = \oint_C na \cdot \mathrm{d}r = 0 ,$$

where the left integral is a surface integral over the infinitesimally small rectangular surface S which is bounded by the closed loop C. The right integral is a line integral over the closed loop C.

If now the length of the side lines of the loop C parallel to N tends to zero the line integral is

$$0 = lt \cdot (n_2 a_2 - n_1 a_1) \tag{2.40}$$

with l being the length of a side line of the loop parallel to the interface and t being a unit vector parallel to the interface. Another unit vector b is defined as being perpendicular to both N and t and therefore also perpendicular to the surface S. This means that N, t and b form an orthogonal triad of unit vectors with $t = b \times N$ and therefore it holds that

$$(b \times N) \cdot (n_2 a_2 - n_1 a_1) = 0 ,$$
$$\Rightarrow \quad [N \times (n_2 a_2 - n_1 a_1)] \cdot b = 0 .$$

But the rectangular integration area can be rotated about N serving as axis. Therefore, the direction of b can be chosen arbitrarily as long as it is perpendicular to N. By fulfilling the upper equation for an arbitrary vector b we obtain the following equation, which is the vectorial formulation of the law of refraction,

$$N \times (n_2 a_2 - n_1 a_1) = 0 . \tag{2.41}$$

This means that $n_2 a_2 - n_1 a_1$ is parallel to N (or $n_2 a_2 - n_1 a_1 = 0$ what is only possible for the trivial

case $n_1 = n_2$) and therefore all three vectors a_1, a_2 and N have to lie in the same plane. This means particularly that the refracted ray with direction vector a_2 lies in the plane of incidence formed by N and a_1.

By defining the acute angles θ_j between the rays a_j ($j \in \{1, 2\}$) and the surface normal N (Fig. 2.4) the modulus of (2.41) results in:

$$n_1 \sin \theta_1 = n_2 \sin \theta_2 . \tag{2.42}$$

This is the well-known Snell's law.

If n_2 is bigger than n_1 there is always a solution θ_2 for a given angle θ_1. But, if n_2 is smaller than n_1 there is the so-called critical angle of total internal reflection $\theta_{1,\text{critical}}$ for which the refracted ray grazes parallel to the interface, i. e. $\theta_2 = \pi/2$:

$$n_1 \sin \theta_{1,\text{critical}} = n_2 \sin \theta_2 = n_2$$
$$\Rightarrow \theta_{1,\text{critical}} = \arcsin \frac{n_2}{n_1} . \tag{2.43}$$

For angles $\theta_1 > \theta_{1,\text{critical}}$ there exists no refracted ray because the sine function $\sin \theta_2$ cannot be larger than 1. Then, all light is reflected at the interface and only a reflected ray exists.

2.1.7 Law of Reflection

If a plane wave enters the interface between two materials there is, as well as a refracted wave, a reflected wave and in the case of total internal reflection there is only a reflected wave. A ray represents locally a plane wave and the law of reflection is formally obtained from (2.41) by setting $n_2 = n_1$. Of course, the algebraic signs of the scalar products $N \cdot a_1$ and $N \cdot a_2$ have to be different in order to obtain a reflected ray whereas they have to be identical to obtain a refracted ray. This will be discussed later in Sect. 2.4 by finding explicit solutions of (2.41).

After having now discussed the basics of geometrical optics the next section will treat the paraxial ray tracing through an optical system by using a matrix theory [2.12–15].

2.2 Paraxial Geometrical Optics

2.2.1 Paraxial Rays in Homogeneous Materials

Some Basic Definitions

In a homogeneous material the refractive index n is constant and therefore, according to the ray equation (2.29),

a ray propagates rectilinear. This means that a ray is definitely described by the position vector p of one point on the ray and the ray direction vector a. So, six scalar parameters (each vector with three components) are necessary. In principle one component of a is redundant (apart from the algebraic sign of this com-

ponent) because $\boldsymbol{a}$ is a unit vector $(a_x^2 + a_y^2 + a_z^2 = 1)$. Another component can be saved if a reference plane is defined, e.g. the x–y plane at $z = 0$. Then, the x- and y-components of the point of intersection of the ray with this plane are sufficient. However, in the case of non-paraxial ray tracing (Sect. 2.4) all components of the two vectors $\boldsymbol{p}$ and $\boldsymbol{a}$ are stored and used since not all rays start in the same plane and the algebraic sign of each component of $\boldsymbol{a}$ is needed. Moreover, it is often more efficient to store a redundant parameter instead of calculating it from other parameters.

Most convenient optical systems consist of a sequence of rotationally symmetric centered refractive and reflective components. The rotation axis is called the optical axis of the system. For a simple lens with two spherical surfaces the optical axis is defined by the two centers of curvature C_1 and C_2 of the spherical surfaces (Fig. 2.5). Using (2.41) it has been shown that a refracted ray (and also a reflected ray) remains in the plane of incidence. Therefore, it is useful to define the meridional plane, which is a plane containing an object point P and the optical axis (Fig. 2.6). All rays which come from the object point P and lie in the meridional plane are called meridional rays. A plane perpendicular to the meridional plane which contains a special reference ray, mostly the chief ray (Sect. 2.3), is called the sagittal plane and rays lying in it are called sagittal rays. In this section only meridional rays are discussed and moreover only so-called paraxial rays are considered. Paraxial rays are rays which fulfill the following conditions:
- The distance x of the ray from the optical axis is small compared to the focal length of each optical element of the system.
- The angle φ between the optical axis and the ray is small, i. e. $\varphi \ll 1$. The same has to be valid for other angles, e.g. for the refraction angles at a lens.

For the angles this means that the following approximations have to be valid:

$$\sin \varphi \approx \tan \varphi \approx \varphi, \quad \cos \varphi \approx 1 .$$

The most important optical systems consist of optical elements (refractive, reflective or diffractive elements) which are embedded into piecewise homogeneous materials. Therefore, ray tracing (in the paraxial as well as non-paraxial case) through an optical system consists of the alternating sequence of propagation in a homogeneous material and refraction (or reflection or diffraction) at an element.

Optical Imaging

At this point some words on the term optical imaging have to be said. An object point which is either illuminated by external light or self-illuminating emits a ray fan, i. e. in geometrical optics an object point is the source of a ray fan. On the other side an image point is the drain of a ray fan and in the ideal case all rays of the fan should intersect each other in the image point (Fig. 2.7a). Therefore, the image point can be defined in the ideal case by the point of intersection of only two rays. However, this is only useful in the case of paraxial ray tracing where all aberrations of the optical system are neglected. If the aberrations of an optical system also have to be taken into account, non-paraxial ray tracing (Sect. 2.4), also simply called ray tracing, has to be used. Then, there are several definitions of an image point because there is in general no longer a single point of intersection of all rays of the ray fan coming from the object point (Fig. 2.7b). The lateral deviation of the actual point of intersection of a ray with the image plane from the ideal image point is called ray aberration.

A more advanced definition of optical imaging has of course to take into account interference effects between the different rays coming from the object point since the image point is a multiple-beam interference phenomenon. A typical example where the simple ray-based model fails would be an ideal spherical wave where a half-wave plate is introduced in half of the aperture (Fig. 2.7c). Then, the ray directions are unchanged and an ideal point of intersection of all rays exists, i. e. there are no ray aberrations. But, the image point would be

Fig. 2.8 Scheme showing the parameters of paraxial ray tracing for the transfer between two parallel planes with distance d

A Note on the Validity of the Paraxial Approximation

The approximation of $\sin \varphi$ by φ means that the next term of the Taylor series $-\varphi^3/6$ and all higher order terms are neglected. In the case of $\tan \varphi$ the next term of the Taylor series which is neglected is $+\varphi^3/3$. So, the equivalence of $\sin \varphi$ and $\tan \varphi$ is only valid if the difference of both third-order terms $\varphi^3/2$ is so small that it can be neglected. This is the case if the alternation of the optical path length from the object point to the image point by neglecting this term is smaller than the Rayleigh criterion of $\lambda/4$, where λ is again the wavelength. In the case of two rays with an optical path difference of $\lambda/4$ the phase difference is $\Delta\Phi = \pi/2$, i.e. the rays are in phase quadrature and the intensities have to be added because the interference term $\cos(\Delta\Phi)$ is then zero. If the optical path difference is $\lambda/2$ the phase difference is $\Delta\Phi = \pi$ and the amplitudes of both rays cancel each other (if the amplitudes have equal modulus). Then, the image point is strongly aberrated. So, the validity of the Rayleigh criterion is useful to define the limitations of the paraxial approximation.

In practice, the paraxial theory is quite important because it allows the definition of such important parameters as the focus, the focal length or the principal points of a lens or optical system. An optical designer [2.16–19] will always first design an optical system by using the paraxial matrix theory (or another paraxial method) so that the paraxial parameters are right. Afterwards he will try to optimize the non-paraxial parameters using ray tracing in order to correct aberrations of the system.

Definition of a Paraxial Ray

In the paraxial theory only rays in the meridional plane, which is here defined as the x–z-plane, are regarded. Then, the y-component of the ray direction

massively disturbed because there is destructive interference in the center of the image point due to the different optical path lengths of the rays. Therefore, a more advanced ray-based model additionally calculates the optical path length along each ray. The deviation in the optical path length of a ray from the ideal optical path length is called wave aberration.

However, in this section we will treat the very simple model of paraxial ray tracing, which takes into account neither ray aberrations nor wave aberrations. Aberrations will be taken into account in Sect. 2.4 when we consider non-paraxial ray tracing.

vector $\boldsymbol{a}$ and the y-component of the starting point $\boldsymbol{p}$ of the ray are both zero: $a_y = 0$ and $p_y = 0$. We define for the x-component of the ray direction vector $a_x = \sin\varphi \approx \tan\varphi \approx \varphi$. The z-component of the ray direction vector in the paraxial approximation is then $a_z = \cos\varphi \approx 1$. Therefore, a meridional paraxial ray at a certain z-position z can be described by the angle φ with the optical axis and the ray height x, which is indeed the x-component p_x of the starting point $\boldsymbol{p}$ of the ray. The z-component p_z of a ray is noted in the paraxial matrix theory externally because in many cases several rays starting at the same z-position $z = p_z$ but having different values x and φ are considered.

So, in total a paraxial ray is described by x and φ. Since matrix methods play an important role in optics [2.12, 13] these two parameters are noted as the components of a vector

$$\begin{pmatrix} x \\ \varphi \end{pmatrix}$$

so that the optical operations which we will discuss now can be represented as 2×2 matrices.

Transfer Equation

The paraxial ray tracing between two planes with a separation d and which are perpendicular to the optical axis is one of the basic operations. Here, only the lines of intersection of these two planes with the meridional plane are regarded (Fig. 2.8), even though later we will use the term planes slightly incorrectly. The ray parameters in the first plane shall be x and φ and those in the second plane x' and φ'. Then, the transfer from the first plane to the second plane with distance d is done by (Fig. 2.8):

$$\begin{pmatrix} x' \\ \varphi' \end{pmatrix} = \begin{pmatrix} x + \varphi d \\ \varphi \end{pmatrix} . \tag{2.44}$$

This means that ray directions are not changed during the propagation of paraxial rays in a homogeneous material. Equation (2.44) can also be written by using a two times
Fig. 2.9 Paraxial refraction at a (locally) plane surface

two matrix [2.12–15]:

$$\begin{pmatrix} x' \\ \varphi' \end{pmatrix} = \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ \varphi \end{pmatrix} = M_{\mathrm{T}} \begin{pmatrix} x \\ \varphi \end{pmatrix} . \tag{2.45}$$

The matrix M_{T} is called the paraxial transfer matrix in a homogeneous material.

2.2.2 Refraction in the Paraxial Case

Paraxial Law of Refraction

The law of refraction connects the angle i between the incident ray and the surface normal with the angle i' between the refracted ray and the surface normal (Fig. 2.9). The law of refraction (2.42) in the paraxial formulation is

$$ni = n'i' \tag{2.46}$$

where n and n' are the refractive indices of the two homogeneous materials in front of the surface and behind the surface, respectively.

Refraction at a Plane Surface

A paraxial ray with parameters x and φ hits a plane surface which is perpendicular to the optical axis (Fig. 2.9). The refractive index is n in front of the surface and n' behind the surface. Then, the ray height x remains unchanged and only the ray parameter φ changes according to the paraxial law of refraction (2.46):

$$\begin{pmatrix} x' \\ \varphi' \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & \frac{n}{n'} \end{pmatrix} \begin{pmatrix} x \\ \varphi \end{pmatrix} = M_{\mathrm{R}} \begin{pmatrix} x \\ \varphi \end{pmatrix} \tag{2.47}$$

The matrix M_{R} is the paraxial matrix for refraction at a plane surface.

Refraction at a Plane Parallel Plate

The plane parallel plate is the simplest case for a sequence of several surfaces and can be used to demonstrate the principle of tracing paraxial rays through an optical system by using the paraxial matrix theory. It is well known that the order of two matrices A and B is very important if two matrices have to be multiplied, i.e.

$$AB \neq BA .$$

Therefore, the matrix for the first operation has to be positioned immediately to the left of the vector (x, φ) of the paraxial ray that has to be traced through the system. The matrix of the next operation then has to be multiplied from the left side and so on for all other matrices. Using the notations of Fig. 2.10 the parameters

of the paraxial ray on the right side of a plane parallel plate with thickness d and refractive index n_P are:

$$\begin{pmatrix} x' \\ \varphi' \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & \frac{n_P}{n'} \end{pmatrix} \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & \frac{n}{n_P} \end{pmatrix} \begin{pmatrix} x \\ \varphi \end{pmatrix}$$

$$= \begin{pmatrix} 1 & d \\ 0 & \frac{n_P}{n'} \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & \frac{n}{n_P} \end{pmatrix} \begin{pmatrix} x \\ \varphi \end{pmatrix}$$

$$= \begin{pmatrix} 1 & d\frac{n}{n_P} \\ 0 & \frac{n}{n'} \end{pmatrix} \begin{pmatrix} x \\ \varphi \end{pmatrix} .$$

Here, n is the refractive index left of the plane parallel plate and n' is the refractive index right to the plane parallel plate.

In total the parameters x' and φ' of a paraxial ray immediately behind the plane parallel plate are obtained from the parameters x and φ of the incident ray immediately in front of the plane parallel plate by multiplying them by the matrix M_P of a plane parallel plate

$$\begin{pmatrix} x' \\ \varphi' \end{pmatrix} = \begin{pmatrix} 1 & d\frac{n}{n_P} \\ 0 & \frac{n}{n'} \end{pmatrix} \begin{pmatrix} x \\ \varphi \end{pmatrix} = M_P \begin{pmatrix} x \\ \varphi \end{pmatrix} . \tag{2.48}$$

The most important practical case is a plane parallel plate in air ($n = n' = 1$). Then it holds that

$$\begin{pmatrix} x' \\ \varphi' \end{pmatrix} = \begin{pmatrix} 1 & \frac{d}{n_P} \\ 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ \varphi \end{pmatrix} . \tag{2.49}$$

This means that the matrix of a plane parallel plate is identical to the transfer matrix in a homogeneous material on substitution of the transfer distance d in the
Fig. 2.10 Application of the paraxial matrix theory at a plane-parallel plate. The order of the multiplication of the matrices has to be reverse since the first matrix has to be directly left of the paraxial ray vector and the second matrix left of the first matrix, and so on
Fig. 2.11 Sign conventions in the paraxial matrix theory

homogeneous material by the term d/n_P. A lateral ray shift $\Delta x = x_{\text{without plate}} - x_{\text{with plate}}$ results at a plane parallel plate with thickness d compared to the propagation in air by a distance d

$$\Delta x = x + \varphi d - \left(x + \varphi \frac{d}{n_P} \right) = \varphi d \frac{n_P - 1}{n_P} .$$

For normal glass with $n_P \approx 1.5$ the lateral ray shift is $\Delta x = \varphi d/3$. This effect is used in optical systems to introduce a lateral shift where the size of the shift increases with the ray angle φ. So, in practice the plane parallel plate is tilted by an angle φ with respect to the optical axis of the system to introduce such a lateral shift. However, a plane parallel plate can also introduce aberrations if the incident wave is not a plane wave. Therefore, the introduction of a lateral shift by using a plane parallel plate has to be used with care.

Some Notes on Sign Conventions
Up to now no sign conventions have been made for the paraxial matrix theory. This will be included now and is illustrated graphically in Fig. 2.11.

- Ray angles φ are positive if the acute angle between the optical axis and the ray is mathematically positive.
- Refraction angles are all treated as positive angles.
- All angles are acute angles.
- Light rays always travel from left to right for positive propagation distances d. A negative propagation distance d means that the light is traveling from right to left and is only used for virtual rays.
- Ray heights x are upwards positive.
- Radii of curvature R are positive if the center of curvature is right of the vertex of the surface.

Refraction at a Spherical Surface
A spherical surface with radius of curvature R and refractive indices n in front of and n' behind the surface is hit by a paraxial ray with parameters x and φ. In the paraxial approximation the ray height x at the point of
Fig. 2.12 Parameters for refraction at a spherical surface

intersection of the ray with the spherical surface is the same as in the vertex plane since the radius of curvature R is assumed to be large compared to x. According to Fig. 2.12 and the paraxial law of refraction (2.46) the following relations are valid:

$$\varphi' + \alpha = i' \, ,$$

$$\varphi + \alpha = i \quad \Rightarrow \quad \varphi' = i' - \alpha = \frac{n}{n'}(\varphi + \alpha) - \alpha \, ,$$

$$n'i' = ni \, .$$

Additionally, the angle α between the optical axis and the line connecting the center of curvature of the spherical surface and the point of intersection of the ray with

Fig. 2.13 Cardinal points of an optical system: F and F' are the foci in the object space and the image space, respectively. N and N' are the nodal points in the object and image space and U and U' are the unit or principal points in the object and image space

the spherical surface is, in the paraxial approximation, defined as

$$\sin \alpha = \frac{x}{R} \quad \Rightarrow \quad \alpha = \frac{x}{R} \, .$$

Together, these results allow one to express the ray angle φ' of the refracted paraxial ray as a function of the parameters of the incident ray and the spherical surface

$$\varphi' = \frac{n}{n'}\varphi - \frac{n' - n}{n'}\frac{x}{R} \, . \tag{2.50}$$

The ray height x itself remains constant in the case of refraction. Therefore, the matrix M_S for refraction at a spherical surface is defined as

$$\begin{pmatrix} x' \\ \varphi' \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ -\frac{n'-n}{n'R} & \frac{n}{n'} \end{pmatrix} \begin{pmatrix} x \\ \varphi \end{pmatrix} = M_S \begin{pmatrix} x \\ \varphi \end{pmatrix} \, . \tag{2.51}$$

The validity of the sign conventions can be shown by regarding some concrete cases:

- For $\varphi = 0$, $n' > n > 1$ and $R > 0$ (convex surface) a positive ray height x of the incident ray results in a negative ray angle φ' of the refracted ray. This means that the convex spherical surface with lower refractive index on the left side has a positive refractive power and focuses a plane wave.
- For $\varphi = 0$, $n' > n > 1$ and $R < 0$ (concave surface) the angle φ' of the refracted ray is positive if the ray height x of the incident ray is also positive. This means that two rays would only intersect virtually in front of the lens. Therefore, a concave spherical surface with a lower refractive index on the left-hand side has a negative focal power.

2.2.3 The Cardinal Points of an Optical System

An optical imaging system has several cardinal points [2.1, 3], and by knowing these values the paraxial properties of the optical system are determined definitely. The cardinal points are the principal points, the nodal points and the focal points and they are all situated on the optical axis. In order to define them some additional definitions have to be made.

The cardinal points will be calculated in this section for a general optical system using the paraxial matrix theory [2.6]. At the end of this section the cardinal points of the simplest optical system, a refracting spherical surface, will be calculated explicitly to demonstrate the method.

Assume a general optical imaging system such as that symbolized in Fig. 2.13. An object point P_O with
a lateral distance x_O from the optical axis, which is called the object height, is imaged by the optical system to an image point P_I with lateral distance x_I, called the image height. The refractive indices are n in the object space and n' in the image space.

The lateral magnification β of an imaging system is defined as the ratio of the image height x_I to the object height x_O:

$$\beta := \frac{x_I}{x_O}. \qquad (2.52)$$

According to our sign convention the lateral magnification in Fig. 2.13 is negative since x_O is positive and x_I negative.

The Principal Points

The principal plane $\mathcal{U}$ or unit plane in the object space is the plane perpendicular to the optical axis that has the property that an object point in this principal plane is imaged to a point in the principal plane $\mathcal{U}'$ of the image space with a lateral magnification $\beta = +1$. The points of intersection of the principal planes in the object and image space with the optical axis are called the principal or unit points U and U', respectively. So, U' is the image of U.

An important practical property of the principal planes following from this definition is that a ray which intersects the principal plane $\mathcal{U}$ in the object space at a height x is transferred to the principal plane $\mathcal{U}'$ of the image space at the same height (Fig. 2.13). This property is e.g. used to construct the path of a paraxial ray graphically.

The Nodal Points

The second cardinal points of an optical system are the nodal points N (in the object space) and N' (in the image space). A ray in the object space which intersects the optical axis in the nodal point N at an angle φ intersects the optical axis in the image space in the nodal point N' at the same angle $\varphi' = \varphi$. Therefore, the angular magnification γ defined as

$$\gamma := \frac{\varphi'}{\varphi} \qquad (2.53)$$

is $\gamma = 1$ for rays going through the nodal points. Additionally, since this has to be valid for arbitrary angles φ, the nodal point N' is the image of the nodal point N.

The Focal Points

The focal points F (in the object space) and F' (in the image space), also called principal foci or foci for short,

have the following properties. A ray starting from the focus F in the object space is transformed into a ray parallel to the optical axis in the image space. Vice versa, a ray which is parallel to the optical axis in the object space intersects the focus F' in the image space. The planes perpendicular to the optical axis which intersect the optical axis in the focal points are called the focal planes. The distance between the principal point U and the focus F is called the focal length f in the object space and the distance between the principal point U' and the focal point F' is called the focal length f' in the image space. In geometrical optics the sign convention for the focal length is usually that it is positive if the focus is right of the principal point. In Fig. 2.13 this means e.g. that the focal length f in the object space is negative whereas the focal length f' in the image space is positive.

A more general property of the focal planes is that rays starting from a point with object height x_O in the focal plane of the object space form in the image space a bundle of parallel rays making an angle $\varphi' = -x_O/f'$ with the optical axis. The relation for φ' can be easily understood by the fact that a ray starting from the object point parallel to the optical axis is transferred at the principal planes from $\mathcal{U}$ to $\mathcal{U}'$ with the same height x_O and then passes, after a distance f', the focal point F' in the image space. The negative sign has to be taken due to the sign convention.

Calculation of the Cardinal Points of a General Optical System

Assume that we have a general optical system that is formed by an arbitrary combination of refracting spherical and plane surfaces which are all situated on a common optical axis (Fig. 2.14). Then, the system can be described by a 2×2 matrix M which is the product of a sequence of matrices M_T, M_R and M_S (or further matrices for other optical elements). The matrix

$$M = \begin{pmatrix} A & B \\ C & D \end{pmatrix} = M_{S,m} \cdot M_{T,m-1} \cdot M_{S,m-1} \cdot \ldots$$

$$\cdot M_{T,2} \cdot M_{S,2} \cdot M_{T,1} \cdot M_{S,1} \qquad (2.54)$$

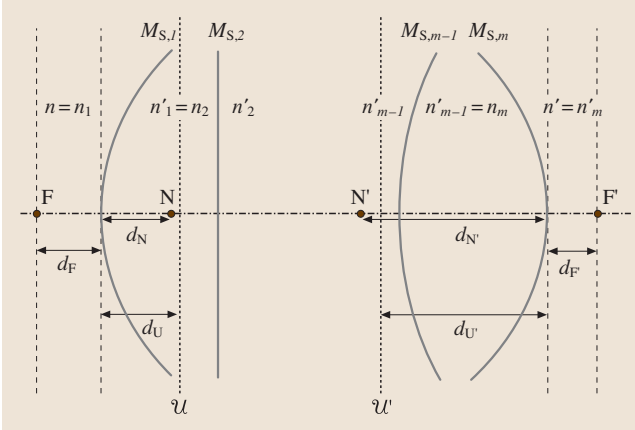
describes the propagation of a ray from a plane immediately in front of the vertex of the first surface (surface 1) to a plane immediately behind the vertex of the last surface (surface m). Here, only matrices M_S of refractive spherical surfaces are taken because a plane surface with matrix M_R can be represented as a spherical surface with radius of curvature $R = \infty$. Additionally, behind each surface (apart from the last surface) the transfer to the


Fig. 2.14 Distances between the cardinal points in the object space and the vertex of the first surface (quantities without apostrophe) and the vertex of the last surface and the cardinal points in the image space (quantities marked by an apostrophe) of a general optical system consisting of refractive surfaces. d_U and $d'_{U'}$ are negative in the scheme, d_F and $d'_{F'}$ are positive and d_N and $d'_{N'}$ are again negative. n and n' are the refractive indices in front of and behind the whole system, whereas n_i and n'_i are the refractive indices in front of and behind the single refracting surface number i

next surface is described by using a matrix $M_{T,i}$. In the special case of a thin lens (which does not exist in reality but which is an important idealization in geometrical optics) the propagation distance can just be set to zero so that the transfer matrix is identical to the unit matrix.

The restriction to spherical surfaces is not stringent because in paraxial optics an aspheric surface is identical to a spherical surface if the radius of curvature of the aspheric surface at the vertex is identical to the radius of curvature of the spherical surface. From a mathematical point of view the determination of the radius of curvature in the paraxial regime just means that in both cases the parabolic terms are taken. Moreover, also cylindrical surfaces can be calculated with this method if the radius of curvature in the selected x–z-plane is taken. For a plane which contains the cylinder axis the cylindrical surface behaves like a plane surface whereas the cylindrical surface behaves like a spherical surface if the cylinder axis is perpendicular to the considered x–z-plane.

A ray starts in front of the optical system in a material with refractive index $n := n_1$ and ends behind the system in a material with refractive index $n' := n'_m$ (Fig. 2.14). n_i and n'_i with $i \in \{1, 2, \dots, m\}$ are the refractive indices in front of and behind each refracting surface, which is described by the matrix $M_{S,i}$. Of course, there is the

relation

$$n_i = n'_{i-1} \quad \text{for} \quad i \in \{2, 3, \dots, m\} \,. \tag{2.55}$$

Now, a matrix M' is calculated which describes the propagation of a ray from a plane $\mathcal{P}$ through the optical system to a plane $\mathcal{P}'$. The plane $\mathcal{P}$ is a distance d from the vertex of the first surface of the optical system, whereas the vertex of the last surface is a distance d' from the plane $\mathcal{P}'$. Using the paraxial sign conventions d is positive if $\mathcal{P}$ is in front of (i. e. left of) the first surface. Similar d' is positive if $\mathcal{P}'$ is behind (i. e. right of) the last surface. It is very important to remember that d is measured from the plane $\mathcal{P}$ to the vertex of the first surface whereas d' is measured from the vertex of the last surface to the plane $\mathcal{P}'$. For these quantities the usual sign conventions are valid, i. e. they are positive if the propagation is from left to right and negative if the propagation is in the opposite direction.

By using equation (2.45) the matrix M' is:

$$
\begin{aligned}
M' &= \begin{pmatrix} A' & B' \\ C' & D' \end{pmatrix} = M_{T'} M M_T \\
&= \begin{pmatrix} 1 & d' \\ 0 & 1 \end{pmatrix} \begin{pmatrix} A & B \\ C & D \end{pmatrix} \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} \\
&= \begin{pmatrix} A + Cd' & Ad + B + Cdd' + Dd' \\ C & Cd + D \end{pmatrix} .
\end{aligned} \tag{2.56}
$$

Principal Points. To calculate the principal planes $\mathcal{U}$ and $\mathcal{U}'$ of the system the definition is used. If $\mathcal{P}$ is identical to the principal plane $\mathcal{U}$ and $\mathcal{P}'$ is identical to $\mathcal{U}'$ an object point in $\mathcal{P}$ has to be imaged to $\mathcal{P}'$ with lateral magnification $\beta = +1$. Imaging means that all rays with arbitrary ray angles φ starting from the object point with height x have the same height x' in $\mathcal{P}'$, independent of φ. Since the relation

$$\begin{pmatrix} x' \\ \varphi' \end{pmatrix} = \begin{pmatrix} A' & B' \\ C' & D' \end{pmatrix} \begin{pmatrix} x \\ \varphi \end{pmatrix} = \begin{pmatrix} A'x + B'\varphi \\ C'x + D'\varphi \end{pmatrix} \tag{2.57}$$

holds, this means that the matrix element B' has to be zero in order to have imaging between the planes $\mathcal{P}$ and $\mathcal{P}'$. Therefore, we have as a first condition

$$B' = Ad + B + Cdd' + Dd' = 0 \,. \tag{2.58}$$

The second condition $\beta = 1$ means, by using $B' = 0$,

$$x' = A'x + B'\varphi = (A + Cd')\,x = x \,,$$

$$\Rightarrow A + Cd' = 1 \Rightarrow d'_{U'} = \frac{1 - A}{C} \,. \tag{2.59}$$

Here, we use the name $d'_{U'} := d'$ (Fig. 2.14) to indicate that it is the distance from the vertex of the last surface of the optical system to the principal point U'. From the first condition we then obtain the distance $d_U := d$ between the principal point U and the vertex of the first surface

$$B' = Ad + B + (1-A)d + D\frac{1-A}{C} = 0 ,$$

$$\Rightarrow d_U = \frac{D}{C}(A-1) - B . \qquad (2.60)$$

It has to be mentioned that, in the case of optical imaging, the coefficient A' of the matrix M' has a concrete meaning. It is:

$$x' = A'x \Rightarrow \beta = \frac{x'}{x} = A' \qquad (2.61)$$

Therefore, the coefficient A' is identical to the lateral magnification β defined by (2.52).

Nodal Points. If $\mathcal{P}$ contains the nodal point N and $\mathcal{P}'$ contains the nodal point N' the conditions for the ray parameters are $x = x' = 0$ and $\varphi' = \varphi$. Using (2.57) this gives:

$$0 = x' = A'x + B'\varphi = B'\varphi$$
$$\Rightarrow B' = Ad + B + Cdd' + Dd' = 0 ,$$
$$\varphi' = C'x + D'\varphi = D'\varphi = \varphi$$
$$\Rightarrow D' = Cd + D = 1 . \qquad (2.62)$$

Then, the distances $d_N := d$ between the nodal point N and the vertex of the first surface of the optical system on the one hand and $d'_{N'} := d'$ between the vertex of the last surface of the optical system and the nodal point N' on the other hand are:

$$d_N = \frac{1-D}{C} , \qquad (2.63)$$

$$d'_{N'} = \frac{A}{C}(D-1) - B . \qquad (2.64)$$

Focal Points and Focal Lengths. For the calculation of the focus F in the object space it is assumed that F is in the plane $\mathcal{P}$. Then, all rays starting from the height $x = 0$ have to be in the image space rays parallel to the optical axis, i.e. $\varphi' = 0$. Since this has to be valid in all planes in the image space the distance d' in (2.56) is set to zero. So, the condition for the distance $d_F := d$ between the focus F and the vertex of the first surface of the optical system is

$$\varphi' = C'x + D'\varphi = D'\varphi = 0$$
$$\Rightarrow D' = Cd + D = 0 \Rightarrow d_F = -\frac{D}{C} . \qquad (2.65)$$

The focal length f is defined as the distance between the principal point U and the focus F, where the sign convention in geometrical optics is that f is positive if F is right of U. Therefore, by using the sign conventions for d_U and d_F it is:

$$f = d_U - d_F = \frac{D}{C}(A-1) - B + \frac{D}{C} = \frac{AD}{C} - B .$$
$$= \frac{AD - BC}{C} \qquad (2.66)$$

The focus F' in the image space can be calculated analogously. There, rays parallel to the optical axis (i.e. $\varphi = 0$) in front of the optical system in an arbitrary plane $\mathcal{P}$, e.g. at $d = 0$, have to focus in the image space in the focus F' at $x' = 0$. If F' is in the plane $\mathcal{P}'$, the distance $d'_{F'} := d'$ between the vertex of the last surface of the optical system and the focus F' is, by using (2.57),

$$x' = A'x + B'\varphi = A'x = 0$$
$$\Rightarrow A' = A + Cd' = 0 \Rightarrow d'_{F'} = -\frac{A}{C} . \qquad (2.67)$$

Analogously, the focal length f', which is positive if F' is to the right of U', can be calculated by

$$f' = d'_{F'} - d'_{U'} = -\frac{A}{C} - \frac{1-A}{C} = -\frac{1}{C} \Rightarrow C = -\frac{1}{f'} . \qquad (2.68)$$

Now, the concrete meaning of the matrix coefficient C as the negative reciprocal value of the focal length f' in the image space becomes clear.

By summarizing (2.59), (2.60), (2.63–2.65) and (2.67) the distances d_U, d_N and d_F between the cardinal points in the object space and the vertex of the first surface of the optical system as well as the distances $d'_{U'}$, $d'_{N'}$ and $d'_{F'}$ between the vertex of the last surface of the optical system and the cardinal points in the image space are:

$$d_U = \frac{D}{C}(A-1) - B ,$$
$$d_N = \frac{1-D}{C} ,$$
$$d_F = -\frac{D}{C} ,$$
$$d'_{U'} = \frac{1-A}{C} ,$$
$$d'_{N'} = \frac{A}{C}(D-1) - B ,$$
$$d'_{F'} = -\frac{A}{C} . \qquad (2.69)$$

Also, the focal lengths can now be expressed as functions of the coefficients A, B, C and D of the matrix M by summarizing (2.66) and (2.68):

$$f = \frac{AD - BC}{C} = \frac{\det(M)}{C}$$

$$f' = -\frac{1}{C} \qquad (2.70)$$

Relation Between the Focal Lengths in the Object and Image Spaces

There is a very interesting relation between the focal length f in the object space and the focal length f' in the image space. To derive it the ratio f'/f is calculated by using (2.66) and (2.68):

$$\frac{f'}{f} = \frac{-1/C}{(AD - BC)/C} = -\frac{1}{AD - BC} = -\frac{1}{\det(M)} \qquad (2.71)$$

Here, the determinant $\det(M)$ of the matrix M, defined by (2.54), has been used.

According to the calculus of linear algebra the determinant of the product of several matrices is equal to the product of the determinants of these matrices. Therefore, it holds that

$$\det(M) = \det(M_{S,m}) \cdot \det(M_{T,m-1})$$
$$\cdot \det(M_{S,m-1}) \cdot \ldots \cdot \det(M_{T,1})$$
$$\cdot \det(M_{S,1}) \,. \qquad (2.72)$$

So, we have first to calculate the determinants of the two elementary matrices of (2.45) and (2.51):

$$M_{T,i} = \begin{pmatrix} 1 & d_i \\ 0 & 1 \end{pmatrix} \Rightarrow \det(M_{T,i}) = 1 \,, \qquad (2.73)$$

$$M_{S,i} = \begin{pmatrix} 1 & 0 \\ -\frac{n'_i - n_i}{n'_i R_i} & \frac{n_i}{n'_i} \end{pmatrix} \Rightarrow \det(M_{S,i}) = \frac{n_i}{n'_i} \,. \qquad (2.74)$$

Again, n_i and n'_i are the refractive indices in front of and behind the respective surface; d_i is the distance between surface i and $i + 1$ ($i \in \{1, 2, \ldots, m-1\}$); and R_i is the radius of curvature of surface i.

Now, we define again the refractive index in front of the first surface as $n := n_1$ and the refractive index behind the last surface of the optical system as $n' := n'_m$. Since the determinants of the transfer matrices $M_{T,i}$ are

one the determinant of M is:

$$\det(M) = \prod_{i=1}^{m} \det(M_{S,m+1-i}) = \prod_{i=1}^{m} \frac{n_{m+1-i}}{n'_{m+1-i}}$$
$$= \frac{n_m}{n'_m} \cdot \frac{n_{m-1}}{n'_{m-1}} \cdot \ldots \cdot \frac{n_2}{n'_2} \cdot \frac{n_1}{n'_1}$$
$$= \frac{n'_{m-1}}{n'} \cdot \frac{n'_{m-2}}{n'_{m-1}} \cdot \ldots \cdot \frac{n'_1}{n'_2} \cdot \frac{n}{n'_1} = \frac{n}{n'} \,. \qquad (2.75)$$

Here, relation (2.55) for the refractive indices of neighboring surfaces has been used.

Therefore, the ratio of the focal length f' and f is, according to (2.71),

$$\frac{f'}{f} = -\frac{1}{\det(M)} = -\frac{n'}{n} \quad \text{or} \quad \frac{f'}{n'} = -\frac{f}{n} \,. \qquad (2.76)$$

The Cardinal Points of an Optical System with Identical Surrounding Refractive Indices

An interesting special case is when the refractive indices n in front of the first surface of the optical system and n' behind the last surface of the optical system are identical: $n = n'$. Then the determinant of the matrix M is, according to equation (2.75), $\det(M) = 1$. Therefore, the focal lengths in the object and image spaces have, due to (2.76), equal absolute value but different signs (due to the sign conventions of geometrical optics):

$$f' = -f \,. \qquad (2.77)$$

A second quite interesting property of an optical system with identical refractive indices in front of the first surface and behind the last surface is that the principal points and the nodal points coincide. This can easily be derived from (2.59), (2.60), (2.63) and (2.64) by using $\det(M) = AD - BC = 1$:

$$d_U = \frac{D}{C}(A - 1) - B = \frac{AD - D - BC}{C}$$
$$= \frac{1 - D}{C} = d_N \qquad (2.78)$$

and

$$d'_{N'} = \frac{A}{C}(D - 1) - B = \frac{AD - A - BC}{C}$$
$$= \frac{1 - A}{C} = d'_{U'} \,. \qquad (2.79)$$

The Cardinal Points of a Spherical Refracting Surface

The simplest optical imaging system is a single spherical refracting surface. As an application of (2.69) and (2.70)

the cardinal points of a spherical refracting surface shall be determined.

In this special case the matrix M is, according to (2.51),

$$M = \begin{pmatrix} A & B \\ C & D \end{pmatrix} := M_S = \begin{pmatrix} 1 & 0 \\ -\frac{n'-n}{n'R} & \frac{n}{n'} \end{pmatrix}. \qquad (2.80)$$

Then, according to (2.69), the result is:

$$d_U = \frac{D}{C}(A-1) - B = 0,$$

$$d_N = \frac{1-D}{C} = -R,$$

$$d_F = -\frac{D}{C} = \frac{nR}{n'-n},$$

$$d'_{U'} = \frac{1-A}{C} = 0,$$

$$d'_{N'} = \frac{A}{C}(D-1) - B = R,$$

$$d'_{F'} = -\frac{A}{C} = \frac{n'R}{n'-n}. \qquad (2.81)$$

This means (Fig. 2.15):

1. Both principal points coincide with the vertex of the spherical surface ($d_U = d'_{U'} = 0$).
2. Both nodal points coincide with the center of curvature of the spherical surface ($-d_N = d'_{N'} = R$). To understand this, the sign conventions have to be noticed: d_N is positive if the vertex of the surface is right to the nodal point N, but $d'_{N'}$ is positive if the vertex of the surface is left to the nodal point N'.
3. For a convex surface ($R > 0$) and $n' > n$ the surface has a positive optical power and the focus F is in front of the surface and F' behind the surface. For a concave surface ($R < 0$) but still $n' > n$ the surface has a negative optical power and the foci change their
Fig. 2.15 Cardinal points and parameters of a spherical refracting surface. (The position of F and F' is drawn for the example $n = 1$ and $n' = 1.8$)

positions, i. e. F is right of the vertex of the surface and F' is left of it.

Similar the focal lengths are calculated using (2.70):

$$f = \frac{AD - BC}{C} = \frac{\det(M)}{C} = -\frac{nR}{n'-n}$$

$$f' = -\frac{1}{C} = \frac{n'R}{n'-n}. \qquad (2.82)$$

Since the principal points coincide with the vertex of the surface, the focal length f is of course identical to $-d_F$ and the focal length f' is $f' = d'_{F'}$. The general equation (2.76) $f'/n' = -f/n$ is of course also valid.

2.2.4 The Imaging Equations of Geometrical Optics

The Lens Equation

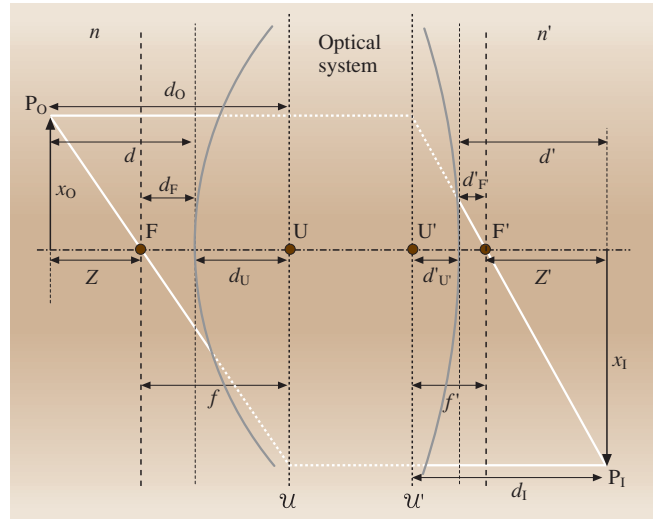
On page 46 it has already been shown what imaging means. A point P_O lying in the plane $\mathcal{P}$ a distance d in front of the vertex of the first surface of an optical system with matrix M (2.54) is imaged onto a point P_I in a plane $\mathcal{P}'$ a distance d' from the vertex of the last surface of the system. This is only the case if the matrix


Fig. 2.16 Parameters for explaining the imaging of an object point P_O to an image point P_I by a general optical system. The optical system is characterized by the vertices of the first and last surface and its cardinal points (without nodal points). The sign conventions mentioned in the text mean for the classical geometrical optical parameters: $x_O > 0$, $x_I < 0$, $d_O < 0$, $d_I > 0$, $Z < 0$, $Z' > 0$, $f < 0$, $f' > 0$. But for the other parameters, which are only used in the paraxial matrix theory, we have: $d > 0$, $d' > 0$, $d_F > 0$, $d'_{F'} > 0$, $d_U < 0$, $d'_{U'} < 0$

element B' of the matrix M' (2.56), which describes the complete ray propagation from $\mathcal{P}$ to $\mathcal{P}'$, is zero:

$$B' = Ad + B + Cdd' + Dd' = 0 . \tag{2.83}$$

Then, all rays starting from the object point P_O intersect in the image point P_I. The distance from the object point to the principal plane $\mathcal{U}$ in the object space will be named d_O and the distance from the principal plane $\mathcal{U}'$ in the image space to the image point P_I will be d_I (Fig. 2.16). According to the sign conventions of geometrical optics d_O is positive if the object point is right of $\mathcal{U}$ (i.e. d_O is negative in Fig. 2.16) and d_I is positive if the image point is also right of $\mathcal{U}'$ (i.e. d_I is positive in Fig. 2.16).

Then, the relations between d, d_O and d_U (the distance between $\mathcal{U}$ and the vertex of the first surface) on the one hand and d', d_I and $d'_{U'}$ (the distance between the vertex of the last surface and $\mathcal{U}'$) on the other hand are:

$$d_O = d_U - d , \tag{2.84}$$

$$d_I = d' - d'_{U'} . \tag{2.85}$$

Here, the different sign conventions for d_O (d_I) and d_U ($d'_{U'}$) and d (d') are taken into account. By substituting (2.84) and (2.85) into (2.83) the following equation is obtained:

$$A (d_U - d_O) + B + C (d_U - d_O) (d_I + d'_{U'})$$
$$+ D (d_I + d'_{U'}) = 0 . \tag{2.86}$$

By using (2.59) and (2.60) to express d_U and $d'_{U'}$ as functions of the matrix elements A, B, C, D of M and some calculations the result is:

$$A \left[\frac{D}{C}(A-1) - B - d_O \right] + B$$
$$+ \left\{ C \left[\frac{D}{C}(A-1) - B - d_O \right] + D \right\}$$
$$\times \left(d_I + \frac{1-A}{C} \right)$$
$$= \frac{AD}{C}(A-1) - AB - Ad_O + B$$
$$+ (AD - BC - Cd_O) \left(d_I + \frac{1-A}{C} \right)$$
$$= -Ad_O + B + ADd_I - BCd_I - Cd_Od_I$$
$$- B - (1-A)d_O$$
$$= (AD - BC) d_I - Cd_Od_I - d_O$$
$$= \det(M)d_I - Cd_Od_I - d_O = 0 . \tag{2.87}$$

The determinant of M is, according to (2.75), $\det(M) = n/n'$, where n is the refractive index in the object space and n' is the refractive index in the image space. Additionally, according to (2.68) it is $C = -1/f'$, where f' is the focal length in the image space. So, the final result is:

$$d_O - \frac{n}{n'}d_I = \frac{d_Od_I}{f'} \quad \text{or} \quad \frac{d_O}{n} - \frac{d_I}{n'} = \frac{d_Od_I}{nf'} . \tag{2.88}$$

An equivalent formulation of this equation is the well-known imaging equation of geometrical optics, which is often called the lens equation although it is valid for quite complex optical imaging systems:

$$\frac{n'}{d_I} - \frac{n}{d_O} = \frac{n'}{f'} = -\frac{n}{f} . \tag{2.89}$$

At the right side of equation (2.89), (2.76) has been used.

If the refractive indices n and n' are identical the equation is

$$\frac{1}{d_I} - \frac{1}{d_O} = \frac{1}{f'} . \tag{2.90}$$

As defined above, the object distance d_O and the image distance d_I are measured in the lens equation relative to the principal planes.

Newton Equation

Another formulation of the imaging equation is the Newton equation where the object distance and the image distance are measured relative to the focal points. Therefore, we define the distance between the focal point F in the object space and the object point P_O as Z. Analogous, Z' is the distance from the focal point F' in the image space to the image point P_I. Both quantities are again positive if the object/image point is right of the focus F/F'. In Fig. 2.16 Z is negative and Z' positive. From this figure, using the sign conventions and (2.84) and (2.85), it is clear that the following relations are valid:

$$Z = d_F - d = d_F + d_O - d_U$$
$$\Rightarrow d_O = Z + d_U - d_F = Z + f , \tag{2.91}$$

$$Z' = d' - d'_{F'} = d_I + d'_{U'} - d'_{F'}$$
$$\Rightarrow d_I = Z' - d'_{U'} + d'_{F'} = Z' + f' , \tag{2.92}$$

where (2.66) and (2.68) have been used.

Substituting these equations into the lens equation (2.88) and using (2.76) gives

$$\frac{Z+f}{n} - \frac{Z'+f'}{n'} = \frac{(Z+f)(Z'+f')}{nf'} \Rightarrow$$

$$\frac{Z}{n} + \frac{f}{n} - \frac{Z'}{n'} - \frac{f'}{n'} = \frac{ZZ'}{nf'} + \frac{Z}{n} + \frac{Z'f}{nf'} + \frac{f}{n} \Rightarrow$$

$$-\frac{f'}{n'} = \frac{ZZ'}{nf'}$$

and finally

$$ZZ' = ff' . \tag{2.93}$$

This is the well-known Newton equation for the imaging of an object point into an image point. The advantage of the Newton equation is its quite simple and symmetric form, which does not explicitly depend on n and n'. Of course, the dependence on the refractive indices in the object and image spaces is hidden in the ratio of f and f'.

Relation Between Lateral and Longitudinal Magnification

The Newton equation can also be easily explained by looking at Fig. 2.17. Due to the similar triangles the following relations are valid in the object space and the image space where the signs have to be noticed:

$$\frac{x_O}{-Z} = \frac{x_I}{f} \Rightarrow \beta = \frac{x_I}{x_O} = -\frac{f}{Z}$$

$$\frac{-x_I}{Z'} = \frac{x_O}{f'} \Rightarrow \beta = \frac{x_I}{x_O} = -\frac{Z'}{f'} \Rightarrow ZZ' = ff' . \tag{2.94}$$

Here, the lateral magnification β defined by (2.52) has been used.

The longitudinal magnification is defined as dZ'/dZ, i.e. the ratio of the axial (longitudinal) shift of the image plane to an axial shift of the object plane. According to the Newton equation (2.93) and the relation (2.76) between f and f' it holds that

$$Z' = \frac{ff'}{Z} \Rightarrow \frac{dZ'}{dZ} = -\frac{ff'}{Z^2} = \frac{n'}{n}\left(\frac{f}{Z}\right)^2 = \frac{n'}{n}\beta^2 . \tag{2.95}$$

This means that the longitudinal magnification is proportional to the square of the lateral magnification.
Fig. 2.17 Graphical explanation of the Newton equation. The distances drawn have the following signs due to our sign conventions: $d_O < 0$, $d_I > 0$, $Z < 0$, $Z' > 0$, $f < 0$, $f' > 0$, $x_O > 0$, $x_I < 0$

2.2.5 The Thin Lens

A quite important element in the paraxial theory is a so-called thin lens [2.2–4, 20]. This means that the transfer from the first to the second surface is neglected (the thickness d_1 of the lens is assumed to be zero) and a paraxial ray that intersects the first surface at a ray height of x also has, immediately behind the second surface, the same ray height x':

$$x' = x .$$

The refractive indices are $n = n_1$ in front of the first surface, $n_L := n'_1 = n_2$ between the two surfaces and $n' = n'_2$ behind the second surface. The radii of curvature of the spherical surfaces are R_1 for the first surface and R_2 for the second surface (see Fig. 2.18). The thin lens, as defined here, does of course not exist in reality but
Fig. 2.18 Parameters of a thin lens

it is a good approximation for lenses which are thin compared to their focal length.

The matrix M_{L0} of a thin lens is obtained from (2.54) using $m = 2$ and $d_1 = 0$ ($\Rightarrow M_{T,1}$ is the unit matrix) by multiplying the two matrices $M_{S,1}$ and $M_{S,2}$ for refraction at the two spherical surfaces in the correct order

$$M_{L0} = M_{S,2} M_{S,1} = \begin{pmatrix} 1 & 0 \\ -\frac{n'-n_L}{n'R_2} & \frac{n_L}{n'} \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\frac{n_L-n}{n_L R_1} & \frac{n}{n_L} \end{pmatrix}$$

$$= \begin{pmatrix} 1 & 0 \\ -\frac{n'-n_L}{n'R_2} - \frac{n_L-n}{n'R_1} & \frac{n}{n'} \end{pmatrix}. \tag{2.96}$$

In the following the important case when the external materials of the lens are identical, i.e. $n' = n$, is considered. Then, the matrix is

$$M_{L0} = \begin{pmatrix} 1 & 0 \\ -\frac{n-n_L}{nR_2} - \frac{n_L-n}{nR_1} & 1 \end{pmatrix}$$

$$= \begin{pmatrix} 1 & 0 \\ -\frac{n_L-n}{n}\left(\frac{1}{R_1} - \frac{1}{R_2}\right) & 1 \end{pmatrix}$$

$$\Rightarrow M_{L0} = \begin{pmatrix} 1 & 0 \\ -\frac{1}{f'} & 1 \end{pmatrix} \tag{2.97}$$

with

$$\frac{1}{f'} = \frac{n_L - n}{n}\left(\frac{1}{R_1} - \frac{1}{R_2}\right). \tag{2.98}$$

Here, the focal length f' of a thin lens in the image space has been defined according to (2.70) and the focal length f in the object space is of course $f = -f'$. By using (2.69) ($d_U = d'_{U'} = 0$) it can be seen that the principal points U and U' of the thin lens coincide with the vertices of the two surfaces, which themselves coincide. Of course, the nodal points also coincide with the vertices because the nodal points coincide with the principal points due to $n = n'$.

In total the ray parameters x', φ' immediately behind the thin lens are connected to the ray parameters x, φ in front of the lens by

$$x' = x, \tag{2.99}$$

$$\varphi' = \varphi - \frac{x}{f'}. \tag{2.100}$$

For a lens with a positive focal power the focal length f' is also positive and the rays intersect behind the lens in a real focus. For a lens with a negative focal power
Fig. 2.19 Different types of lenses

Biconvex   Convex-concave   Biconcave
Plane-convex   Plane-concave

the focal length f' is negative and this means that rays that were originally parallel to the optical axis would intersect in a so-called virtual focus in front of the lens. Of course, a virtual focus has its name because there is in reality no focus at this position in front of the lens but the rays behind the lens seem to come from this virtual focus.

There are several different types of lenses depending on their radii of curvature (see Fig. 2.19):

- biconvex: $R_1 > 0$ and $R_2 < 0$,
- plane–convex: $R_1 > 0$ and $R_2 = \infty$ (or $R_1 = \infty$, $R_2 < 0$)
- convex–concave (meniscus lens): $R_1 > 0$ and $R_2 > 0$ (or both negative)
- plane–concave: $R_1 < 0$ and $R_2 = \infty$ (or $R_1 = \infty$, $R_2 > 0$)
- biconcave: $R_1 < 0$ and $R_2 > 0$.

These lenses have different focal powers. For the case $n_L > n$ (e.g. for a lens made of glass which is used in air) biconvex and plane–convex lenses have generally positive focal lengths, i.e. they are positive lenses. On the other side, biconcave and plane–concave lenses have negative focal lengths, i.e. they are negative lenses. Meniscus lenses can be either positive (if the convex surface has the smaller radius of curvature) or negative (if the convex surface has the larger radius of curvature). Pay attention to the fact that in the case $n_L < n$ (which can be realized e.g. by a hollow lens made of thin plastic which is filled with air and used in water) the properties of the different types of lenses are reversed. In this case a biconvex lens has e.g. a negative focal length.

2.2.6 The Thick Lens

In the case of a thick lens the ray transfer through the thickness $d := d_1$ between the two spherical surfaces is taken into account (see Fig. 2.20). Of course, the radii of curvature of the two spherical surfaces are still assumed to be so large that the point of intersection of a paraxial ray with the surface is in the same plane as the vertex of

Fig. 2.20 Parameters of a thick lens

Fig. 2.21 The principal planes of a thick lens. Notice that d_U and $d'_{U'}$ are both negative in the figure due to our sign convention

the surface. The matrix M_{Ld} of a thick lens is the product of three single matrices: matrix $M_{S,1}$ for refraction at the first spherical surface with radius of curvature R_1, matrix $M_{T,1}$ for the transfer between the two surfaces by the distance d and matrix $M_{S,2}$ for the refraction at the second spherical surface with the radius of curvature R_2. The refractive indices in front of, in, and behind the lens are $n = n_1, n_L := n'_1 = n_2$ and $n' = n'_2$, respectively. Then the matrix M_{Ld} of a thick lens is:

$$M_{Ld}$$
$$= \begin{pmatrix} 1 & 0 \\ -\frac{n'-n_L}{n'R_2} & \frac{n_L}{n'} \end{pmatrix} \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\frac{n_L-n}{n_L R_1} & \frac{n}{n_L} \end{pmatrix}$$
$$= \begin{pmatrix} 1 & 0 \\ -\frac{n'-n_L}{n'R_2} & \frac{n_L}{n'} \end{pmatrix} \begin{pmatrix} 1 - \frac{n_L-n}{n_L R_1}d & \frac{n}{n_L}d \\ -\frac{n_L-n}{n_L R_1} & \frac{n}{n_L} \end{pmatrix}$$
$$= \begin{pmatrix} 1 - \frac{n_L-n}{n_L R_1}d & \frac{n}{n_L}d \\ -\frac{n_L-n}{n'R_1} - \frac{n'-n_L}{n'R_2} + \frac{(n'-n_L)(n_L-n)}{n_L n'R_1 R_2}d & \frac{n}{n'} - \frac{n(n'-n_L)}{n_L n'R_2}d \end{pmatrix}$$
$$(2.101)$$

In the most important case of identical external materials $n' = n$, (2.101) reduces to

$$M_{Ld}$$
$$= \left(\begin{array}{c} 1 - \frac{n_L-n}{n_L R_1}d \\ \underbrace{-\frac{n_L-n}{n}\left[\left(\frac{1}{R_1} - \frac{1}{R_2}\right) + \frac{n_L-n}{n_L}\frac{d}{R_1 R_2}\right]}_{=-1/f'} \cdots \right.$$
$$\left. \begin{array}{c} \frac{n}{n_L}d \\ \cdots \\ 1 + \frac{n_L-n}{n_L R_2}d \end{array} \right)$$
$$(2.102)$$

The matrix element C in the first column of the second row is, according to (2.70), defined as $-1/f'$, where f'

is the focal length of the thick lens in the image space

$$f' = \frac{n n_L R_1 R_2}{(n_L - n)[n_L(R_2 - R_1) + (n_L - n)d]} . \quad (2.103)$$

Because $n = n'$, the focal length f in the object space is $f = -f'$ and the nodal points and the principal points coincide. So, it is now necessary to calculate the positions of the principal points U and U' (Fig. 2.21). By using (2.69) one obtains

$$d_U = \frac{D}{C}(A-1) - B = \frac{AD - D - BC}{C} = \frac{1-D}{C}$$
$$= \frac{-\frac{n_L-n}{n_L R_2}d}{-\frac{n_L-n}{n}\left(\frac{1}{R_1} - \frac{1}{R_2} + \frac{n_L-n}{n_L}\frac{d}{R_1 R_2}\right)}$$
$$= \frac{ndR_1}{n_L(R_2 - R_1) + (n_L - n)d} ,$$
$$d'_{U'} = \frac{1-A}{C} = \frac{\frac{n_L-n}{n_L R_1}d}{-\frac{n_L-n}{n}\left(\frac{1}{R_1} - \frac{1}{R_2} + \frac{n_L-n}{n_L}\frac{d}{R_1 R_2}\right)}$$
$$= -\frac{ndR_2}{n_L(R_2 - R_1) + (n_L - n)d} . \quad (2.104)$$

The distance $d_{UU'}$ between the two principal planes, which is positive if $\mathcal{U}'$ is right of $\mathcal{U}$, is:

$$d_{UU'} = d + d_U + d'_{U'}$$
$$= d\left(1 - \frac{n(R_2 - R_1)}{n_L(R_2 - R_1) + (n_L - n)d}\right) \quad (2.105)$$

A Thick Lens in Air
Since the special case of a thick lens in air ($n = 1$) is the most important in practice, (2.102) for $1/f'$, (2.104) for d_U and $d'_{U'}$ and (2.105) for $d_{UU'}$ shall be repeated for

Part A | 2.2

this case:

$$\frac{1}{f'} = (n_L - 1)\left[\left(\frac{1}{R_1} - \frac{1}{R_2}\right) + \frac{n_L - 1}{n_L}\frac{d}{R_1 R_2}\right],$$
(2.106)

$$d_U = \frac{dR_1}{n_L(R_2 - R_1) + (n_L - 1)d},$$
(2.107)

$$d'_{U'} = -\frac{dR_2}{n_L(R_2 - R_1) + (n_L - 1)d},$$
(2.108)

$$d_{UU'} = d\left(1 - \frac{R_2 - R_1}{n_L(R_2 - R_1) + (n_L - 1)d}\right).$$
(2.109)

In the following, three important cases of thick lenses in air will be described to illustrate the optical parameters of lenses.

Special Cases of Thick Lenses in Air

Ball Lens. For a ball lens with radius of curvature $R > 0$ and refractive index n_L the lens parameters are (Fig. 2.22)

$$R_1 = R, \quad R_2 = -R, \quad d = 2R.$$

This means, according to (2.106–2.109), for the parameters in air

$$\frac{1}{f'} = \frac{2(n_L - 1)}{Rn_L} \Rightarrow f' = \frac{n_L R}{2(n_L - 1)},$$

$$d_U = -R,$$

$$d'_{U'} = -R,$$

$$d_{UU'} = 0.$$
(2.110)

This means that the principal points coincide and are at the center of curvature of the ball lens. For the special case $n_L = 2$ the focal length would be equal to the radius of curvature $f' = R$ so that the focus in the image space would be on the backside of the sphere. For $n_L < 2$ (e.g. nearly all glasses) the focus is outside of the sphere, whereas for $n_L > 2$ (e.g. a silicon ball lens illuminated with infrared light) the focus would be inside the sphere.
Fig. 2.22 Parameters of a ball lens
Fig. 2.23 The meniscus of Hoegh

The Meniscus Lens of Hoegh. For the meniscus lens of Hoegh (Fig. 2.23) with refractive index n_L and thickness d the two radii of curvature are identical, i. e. $R_1 = R_2 = R$. Then, (2.106–2.109) deliver:

$$\frac{1}{f'} = \frac{(n_L - 1)^2 d}{n_L R^2},$$

$$d_U = \frac{R}{n_L - 1},$$

$$d'_{U'} = -\frac{R}{n_L - 1},$$

$$d_{UU'} = d.$$
(2.111)

A thin meniscus with identical radii of curvature would have no optical effect. Contrary to this the thick meniscus of Hoegh has a positive optical power. At least one of the principal points is always outside of the lens and their separation is identical to the thickness of the lens (Fig. 2.23).

Plane–Convex or Plane–Concave Lenses. We assume now that the first surface of the thick lens with refractive index n_L and thickness d is curved (either convex, i. e.
Fig. 2.24 Principal planes of a plane–convex or plane–concave lens

$R_1 > 0$, or concave) and the second is plane ($R_2 = \infty$). Equations (2.106–2.109) are in this case (Fig. 2.24):

$$\frac{1}{f'} = \frac{n_L - 1}{R_1} ,$$

$$d_U = 0 ,$$

$$d'_{U'} = -\frac{d}{n_L} ,$$

$$d_{UU'} = d\left(1 - \frac{1}{n_L}\right) = \frac{(n_L - 1)d}{n_L} . \qquad (2.112)$$

This means that the first principal point coincides with the vertex of the curved surface. Moreover, the focal length of a lens with one plane surface is calculated like the focal length of a thin lens. This is not astonishing since the plane–convex/plane–concave lens can be interpreted as a combination of a thin lens with focal length f' and a plane parallel plate with thickness d and refractive index n_L. This can easily be shown by calculating the matrix $M = M_P M_{L0}$ and comparing it with M_{Ld} of (2.102) for $R_2 = \infty$.

2.2.7 Reflecting Optical Surfaces

Up to now only refracting surfaces have been treated, which form lenses and complete objectives. But there are of course also reflecting surfaces which are e.g. very important in astronomical telescopes [2.21] or which will be very important in the near future for optical lithography systems [2.22] in the extreme ultraviolet (EUV) at a wavelength of 13 nm. However, a reflecting surface can easily be included in a paraxial design by calculating its paraxial 2×2 matrix and including it instead of the surface of a refracting surface in (2.54). We will see that the determinant of the matrix of a reflecting surface is one so that our general discussions

concerning the relation between the focal lengths f and f' are valid.

A Plane Reflecting Surface

The reflection at a plane surface, which is perpendicular to the optical axis, is shown in Fig. 2.25. The law of reflection means that the angle i' of the reflected ray with the surface normal is identical to the angle i of the incident ray, i.e. $i = i'$. In the paraxial theory it is common practice not to take the reflected ray since then the light would travel from right to left. Instead, the unfolded ray path is taken, which is obtained by mirroring the reflected ray at the reflecting surface. By doing this the dashed ray in Fig. 2.25 is obtained and there is no change of the paraxial ray parameters x and φ. So, the paraxial ray matrix M_{RP} of a reflecting plane surface is just the unit matrix:

$$M_{RP} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} . \qquad (2.113)$$

Its determinant is of course one.

A Spherical Reflecting Surface

The reflection at a spherical surface is treated analogously to the case of a plane surface and is shown for a convex mirror in Fig. 2.26. The ray that is reflected at the spherical surface is mirrored at a plane which goes through the vertex of the surface and is perpendicular to the optical axis. So, the dashed ray in Fig. 2.26 results. All angles in Fig. 2.26 are positive so that the following

Fig. 2.25 Reflection at a plane surface
Fig. 2.26 Reflection at a spherical surface

relations are valid:

$$i = \varphi + \alpha$$
$$\left.\begin{array}{l} i = \varphi + \alpha \\ \alpha + i' = \varphi' \\ i = i' \\ \alpha = x/R \end{array}\right\} \Rightarrow \varphi' = \varphi + 2\alpha = \varphi + 2\frac{x}{R} \,.$$

(2.114)

Since the ray height x remains constant during reflection the paraxial ray matrix M_{RS} is

$$M_{RS} = \begin{pmatrix} 1 & 0 \\ \frac{2}{R} & 1 \end{pmatrix} \,.$$

(2.115)

Again the determinant is one.

The matrix (2.115) is also valid for a concave mirror. There, the radius of curvature R is negative so that the angle φ' is smaller than the angle φ for a positive ray height x. This is just the effect of a concave mirror with a positive optical power.

As an exercise the cardinal points of a spherical mirror shall be calculated by using (2.69) and (2.70):

$$d_U = \frac{D}{C}(A - 1) - B = 0 \,,$$

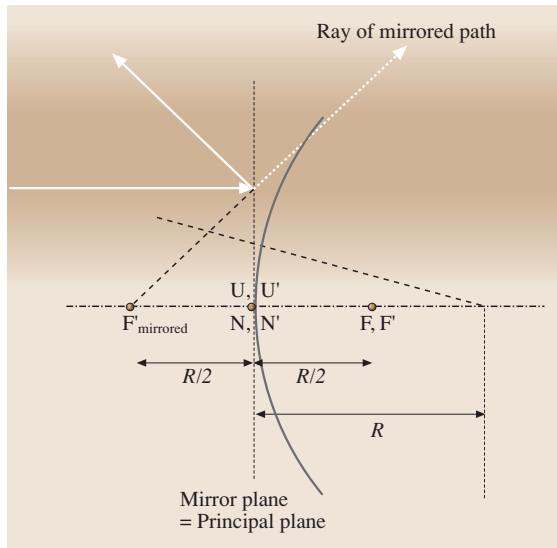
$$d_N = \frac{1 - D}{C} = 0 \,,$$


Fig. 2.27 Cardinal points of a convex mirror. A ray coming from the left parallel to the optical axis has to go into the image space (virtually) through the focus $F'_{mirrored}$. $F'_{mirrored}$ is the focus of the unfolded ray path, which is mirrored at the vertex plane. The real reflected ray would virtually go through the focus F' which then coincides with F

$$d_F = -\frac{D}{C} = -\frac{R}{2} \,,$$

$$d'_{U'} = \frac{1 - A}{C} = 0 \,,$$

$$d'_{N'} = \frac{A}{C}(D - 1) - B = 0 \,,$$

$$d'_{F'} = -\frac{A}{C} = -\frac{R}{2} \,,$$

$$f = \frac{AD - BC}{C} = \frac{\det(M)}{C} = \frac{R}{2} \,,$$

$$f' = -\frac{1}{C} = -\frac{R}{2} \,.$$

(2.116)

So, the principal points U, U' and the nodal points N, N' all coincide with the vertex of the spherical mirror (Fig. 2.27). The focus F in the object space is at half the distance between the center of curvature of the spherical surface and the vertex. On the other side, the focus F' in the image space would coincide with F for the real reflected ray. But since the unfolded ray path with the mirrored ray is taken the focus $F'_{mirrored}$ is also mirrored at the principal plane through the vertex that is perpendicular to the optical axis. The focal length is of course half the radius of curvature and a convex mirror has a negative optical power whereas a concave mirror has a positive optical power.

If an optical system containing refractive and reflective surfaces has to be analyzed so that the same lens is e.g. passed twice or more it is necessary, on the way back, to change the order of surfaces and refractive indices and also the signs of the radii of curvature.

2.2.8 Extension of the Paraxial Matrix Theory to 3×3 Matrices

The paraxial 2×2 matrix theory can only be used as long as all elements are centered around the optical axis and symmetric with respect to the optical axis. A tilted refractive plane surface or a diffraction grating, which both introduce a global tilt of all rays, can e.g. not be included in the 2×2 matrix theory. But there is an extension of this method by using 3×3 matrices [2.15]. This will be described in the following.

Paraxial Ray Tracing at a Diffraction Grating

A ray representing a plane wave with wavelength λ which hits a diffraction grating with a period Λ is diffracted according to the well-known grating equation [2.1] (Fig. 2.28):

$$\sin \varphi' = \sin \varphi + m \frac{\lambda}{\Lambda} \,.$$

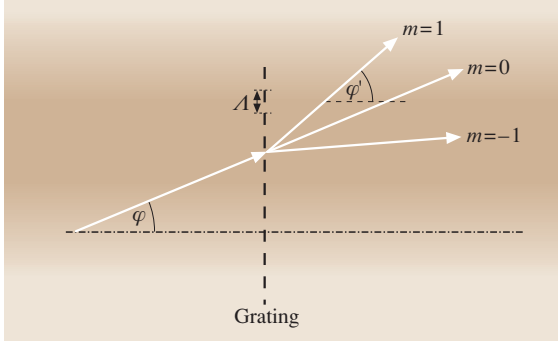
(2.117)


Fig. 2.28 The diffraction at a grating symbolized here as an amplitude grating with period Λ. Three different diffraction orders m are shown

Here, the integer m is the diffraction order of the grating and, depending on the type of the grating, there may be only one efficient order (e.g. for blazed gratings or volume holograms) or many orders with non-vanishing efficiency (e.g. for binary phase elements or amplitude gratings) [2.23–25]. In the case of many diffraction orders each order has to be calculated separately. The angles φ and φ' are the angles of the incident and diffracted ray, respectively.

In the paraxial approximation the sine of the angles is replaced by the angle itself so that the grating equation is

$$\varphi' = \varphi + m \frac{\lambda}{\Lambda} . \tag{2.118}$$

Together with the equation for the ray height x ($x' = x$), which does not change in the case of diffraction at a grating, there are two equations relating the ray parameters before and after diffraction at the grating. However, it is no longer possible to write these two equations in a pure 2×2 matrix notation since it would be

$$\begin{pmatrix} x' \\ \varphi' \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ \varphi \end{pmatrix} + \begin{pmatrix} 0 \\ m\lambda/\Lambda \end{pmatrix} . \tag{2.119}$$

So, a constant additive vector at the end would be necessary and the calculation of one 2×2 matrix for a complete optical system containing one or more diffraction gratings and several other optical elements would be impossible. However, there is a possibility to change this by using 3×3 matrices instead of 2×2 matrices and a paraxial ray vector with three components instead of two, where the third component is always 1. The 3×3 matrices and the paraxial ray vectors are of the

form

$$M_{3\times3} = \begin{pmatrix} A & B & \Delta x \\ C & D & \Delta\varphi \\ 0 & 0 & 1 \end{pmatrix} \Rightarrow \begin{pmatrix} x' \\ \varphi' \\ 1 \end{pmatrix} = M_{3\times3} \begin{pmatrix} x \\ \varphi \\ 1 \end{pmatrix}$$

$$= \begin{pmatrix} M \begin{pmatrix} x \\ \varphi \end{pmatrix} + \begin{pmatrix} \Delta x \\ \Delta\varphi \end{pmatrix} \\ 1 \end{pmatrix} , \tag{2.120}$$

where M is the normal paraxial 2×2 matrix with coefficients A, B, C and D. The coefficients Δx and $\Delta\varphi$ are constant values which symbolize a lateral shift or a tilt which is exerted on the incident paraxial ray by the element. To obtain the 3×3 matrix appendant to a pure paraxial 2×2 matrix the coefficients Δx and $\Delta\varphi$ just have to be set to zero.

The solution of our original example to define the paraxial 3×3 matrix $M_{G,3\times3}$ of a (non-tilted) diffraction grating is now quite easy:

$$M_{G,3\times3} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & m\frac{\lambda}{\Lambda} \\ 0 & 0 & 1 \end{pmatrix} . \tag{2.121}$$

Tilted Refractive Plane Surface

A refractive plane surface shall have a normal vector that is tilted by a small angle α with respect to the optical axis. The surface with refractive indices n in front of and n' behind the surface is hit by a paraxial ray with ray parameters x and φ (Fig. 2.29). Since, the tilt angle α has to be small and the ray heights x also, the variation of the z-coordinates at the points of intersection of the tilted surface and rays with different heights x can be
Fig. 2.29 The refraction at a tilted plane surface with tilt angle α

neglected:

$$\Delta z = x \tan \alpha \approx x\alpha \approx 0 , \tag{2.122}$$

i.e. it is of second order and only first-order terms are taken into account in the paraxial approximation.

Additionally, the ray height x remains constant for refraction. The ray angles, tilt angles and refraction angles depend on each other through the following equations:

$$\left.\begin{array}{c} \varphi' = i' + \alpha \\ \varphi = i + \alpha \\ ni = n'i' \end{array}\right\} \Rightarrow \varphi' = \frac{n}{n'}i + \alpha = \frac{n}{n'}(\varphi - \alpha) + \alpha$$

$$= \frac{n}{n'}\varphi + \frac{n'-n}{n'}\alpha . \tag{2.123}$$

So, the 3×3 matrix $M_{\mathrm{R},\alpha,3\times3}$ for refraction at a tilted plane surface is

$$M_{\mathrm{R},\alpha,3\times3} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{n}{n'} & \frac{n'-n}{n'}\alpha \\ 0 & 0 & 1 \end{pmatrix} . \tag{2.124}$$

As an application and to see how the matrix of a complete system is determined the matrix of a thin prism will be calculated in the next paragraph.

Thin Prism

A thin prism consists of two tilted refractive surfaces and we assume that the prism is made of a material with refractive index n' and the refractive index outside of the prism is n at both sides. Since the prism is assumed to be thin the propagation between the two refractive surfaces is neglected and the total matrix $M_{\mathrm{Prism},3\times3}$ of the prism is obtained by just multiplying the 3×3 matrices of the
Fig. 2.30 The refraction at a thin prism with prism angle γ. The incident ray is deflected by an angle δ

single surfaces. The tilt angles of the two surfaces are α_1 and α_2 so that we have

$$M_{\mathrm{Prism},3\times3} = M_{\mathrm{R},\alpha_2,3\times3} M_{\mathrm{R},\alpha_1,3\times3}$$

$$= \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{n'}{n} & \frac{n-n'}{n}\alpha_2 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{n}{n'} & \frac{n'-n}{n'}\alpha_1 \\ 0 & 0 & 1 \end{pmatrix}$$

$$= \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & \frac{n'-n}{n}(\alpha_1 - \alpha_2) \\ 0 & 0 & 1 \end{pmatrix} . \tag{2.125}$$

By defining the prism angle $\gamma := \alpha_1 - \alpha_2$ the total deflection angle δ of a thin prism with prism angle γ is $\delta = (n' - n)\gamma/n$. For the most important case of a thin prism in air ($n = 1$) it is $\delta = (n' - 1)\gamma$.

The Transformation Matrices

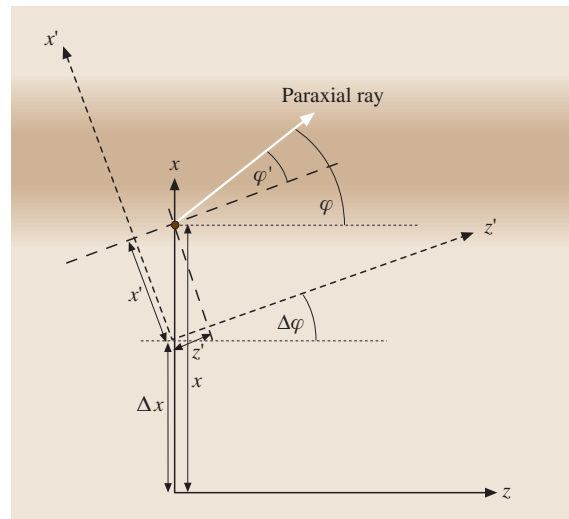
The matrix of a tilted plane surface or other tilted and also laterally shifted surfaces can be calculated quite formally by introducing the paraxial transformation matrix between two coordinate systems. The first coordinate system with axes x and z will be named the global coordinate system. The second coordinate system with axes x' and z' is called the local coordinate system because, in this coordinate system, the surface will have a simple


Fig. 2.31 Transformation between two relatively tilted and shifted coordinate systems. The local x'–z'-coordinate system is laterally shifted with respect to the global x–z-coordinate system by a distance Δx and tilted by an angle $\Delta\varphi$

form, i. e. it is non-tilted and non-shifted in this local co-ordinate system. The local coordinate system is obtained from the global one by shifting a copy laterally in the x-direction by the small distance Δx and rotating it by an angle $\Delta \varphi$ (Fig. 2.31). So, a paraxial ray with ray parameters (x, φ) in the global coordinate system has ray parameters (x', φ') in the local coordinate system and the following relations are valid

$$x' = (x - \Delta x) \cos(\Delta \varphi) \approx x - \Delta x \,, \qquad (2.126)$$
$$z' = (x - \Delta x) \sin(\Delta \varphi) \approx (x - \Delta x) \Delta \varphi \approx 0 \,, \qquad (2.127)$$
$$\varphi' = \varphi - \Delta \varphi \,. \qquad (2.128)$$

Here, the paraxial approximations are used and since Δx, $\Delta \varphi$, x and φ are all paraxial (i. e. small) quantities, only terms of first order are taken into account whereas terms of second order such as $(x - \Delta x)\Delta \varphi$ are set to zero. So, the z'-coordinate remains zero if the ray has a global coordinate $z = 0$, what is always the case by choosing the global coordinate system accordingly.

Therefore, the matrix $M_{G \to L, 3\times 3}$ for the transformation of a paraxial ray from the global coordinate system to a local coordinate system is

$$M_{G \to L, 3\times 3} = \begin{pmatrix} 1 & 0 & -\Delta x \\ 0 & 1 & -\Delta \varphi \\ 0 & 0 & 1 \end{pmatrix} \,. \qquad (2.129)$$

Vice versa, the matrix $M_{L \to G, 3\times 3}$ for the transformation of a paraxial ray from the local coordinate system to the global coordinate system is the inverse matrix to $M_{G \to L, 3\times 3}$:

$$M_{L \to G, 3\times 3} = M_{G \to L, 3\times 3}^{-1} = \begin{pmatrix} 1 & 0 & \Delta x \\ 0 & 1 & \Delta \varphi \\ 0 & 0 & 1 \end{pmatrix} \,. \qquad (2.130)$$

It is also important to notice that in the paraxial approximation with small shifts Δx and small angles $\Delta \varphi$ the order of shifting and tilting is arbitrary whereas this is not the case for finite quantities. Mathematically, this can be proved by calculating that the two matrices for a pure shift (i. e. $\Delta \varphi = 0$) and for a pure tilt (i. e. $\Delta x = 0$) permute:

$$\begin{pmatrix} 1 & 0 & \Delta x \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & \Delta \varphi \\ 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 & \Delta x \\ 0 & 1 & \Delta \varphi \\ 0 & 0 & 1 \end{pmatrix}$$
$$= \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & \Delta \varphi \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & \Delta x \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \,. \qquad (2.131)$$

This means, that in the paraxial approximation it is identical if the coordinate system is first tilted and afterwards shifted or if it is first shifted and then tilted. So, we can use one matrix for the whole transformation without taking care of the order of the single transformations.

As an application of the transformation matrices the 3×3 matrix for refraction at a tilted and laterally shifted spherical surface with a radius of curvature R shall be calculated. The refractive indices are again n in front of the surface and n' behind it. The vertex of the spherical surface is laterally shifted by a distance Δx with respect to the optical axis (global coordinate system) and the surface is rotated around an axis perpendicular to the meridional plane by an angle $\Delta \varphi$. The local coordinate system is of course that system in which the surface is neither tilted nor rotated. Then, a ray in the local coordinate system can be calculated by multiplying the incident ray (in the global coordinate system) by the transformation matrix $M_{G \to L, 3\times 3}$. In the local coordinate system, the ray is multiplied by the matrix of a normal non-tilted and non-shifted spherical surface $M_{S, 3\times 3}$. Afterwards, the ray in the local coordinate system is transformed back into the global system by multiplying it with $M_{L \to G, 3\times 3}$. So, the matrix $M_{S, \Delta x, \Delta \varphi, 3\times 3}$ for refraction at a tilted and shifted spherical surface in the global coordinate system is just the product of the three matrices:

$$M_{S, \Delta x, \Delta \varphi, 3\times 3} = M_{L \to G, 3\times 3} M_{S, 3\times 3} M_{G \to L, 3\times 3}$$
$$= \begin{pmatrix} 1 & 0 & \Delta x \\ 0 & 1 & \Delta \varphi \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ -\frac{n'-n}{n'R} & \frac{n}{n'} & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & -\Delta x \\ 0 & 1 & -\Delta \varphi \\ 0 & 0 & 1 \end{pmatrix}$$
$$= \begin{pmatrix} 1 & 0 & \Delta x \\ 0 & 1 & \Delta \varphi \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & -\Delta x \\ -\frac{n'-n}{n'R} & \frac{n}{n'} & \frac{n'-n}{n'R}\Delta x - \frac{n}{n'}\Delta \varphi \\ 0 & 0 & 1 \end{pmatrix}$$
$$= \begin{pmatrix} 1 & 0 & 0 \\ -\frac{n'-n}{n'R} & \frac{n}{n'} & \frac{n'-n}{n'R}\Delta x + \frac{n'-n}{n'}\Delta \varphi \\ 0 & 0 & 1 \end{pmatrix} \,. \qquad (2.132)$$

The result shows that the ray height x remains, as expected, unchanged by refraction at the surface ($x' = x$) and that there is for the ray angle φ', besides the usual term of a spherical surface, an additional term which does not depend on the angle of incidence but on the shift Δx and the tilt $\Delta \varphi$. It can also be seen that this additional term is zero if the condition $\Delta x/R = -\Delta \varphi$ is fulfilled. This is the well-known fact that a lateral shift of a spherical surface can be compensated by tilting it.

A special case is $R \to \infty$ so that the spherical surface becomes a plane surface. In this case the matrix of (2.132) becomes

$$M_{S,\Delta x,\Delta \varphi,3\times 3} \overset{R\to\infty}{\Longrightarrow} \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{n}{n'} & \frac{n'-n}{n'}\Delta\varphi \\ 0 & 0 & 1 \end{pmatrix} = M_{R,\Delta\varphi,3\times 3} \,.$$

(2.133)

This is of course the same result for the matrix $M_{R,\alpha,3\times 3}$ for refraction at a tilted plane surface with $\Delta\varphi = \alpha$ as that obtained in (2.124), which we derived directly from Fig. 2.29.

2.3 Stops and Pupils

In the preceding section about paraxial optics only rays and object points in the neighborhood of the optical axis were considered. So, in the paraxial calculations stops have no influence. But this changes dramatically for the case of non-paraxial optics. There, stops are quite important optical elements which determine the light-gathering power of an optical system, its resolution, the amount of aberrations, its field and so on. In the following only some elementary definitions about stops and pupils can be given. For more information we refer to the literature [2.1, 3, 8, 20]. There are two especially important stops, the aperture stop and the field stop.

2.3.1 The Aperture Stop

Assume first of all a light-emitting object point which radiates in all directions. Then, the aperture stop is that physical stop which limits the cross-section of the image-forming pencil of rays. To determine the aperture stop the size and position of the images of all stops (e.g. lens apertures or real stops) in the system by that part of the system which precedes the respective stop have to be calculated. To do this the paraxial matrix theory of the last section can, for example, be used. If the distance of the image of stop i from the object point is l_i and the diameter of the stop image is d_i, then the aperture angle φ_i which can pass that stop is

$$\tan \varphi_i = \frac{d_i}{2l_i} \,.$$

(2.134)

The aperture stop is now that stop number i that provides the minimum value φ_O of φ_i. The image of the aperture stop made by that part of the optical system which precedes the aperture stop is called the entrance pupil and the image of the aperture stop made by that part of the optical system which follows the aperture stop is called the exit pupil. The full aperture angle $2\varphi_O$ is called the

angular aperture on the object side and the corresponding quantity $2\varphi_I$ on the image side is called the angular aperture on the image side. φ_I can be determined by calculating the diameter d_I of the exit pupil and the distance l_I between the exit pupil and the image point and using again an equation like (2.134), replacing d_i with d_I and l_i with l_I.

If the aperture stop is in front of the optical system the aperture stop and the entrance pupil will be identical. On the contrary, if the aperture stop is behind the whole optical system the aperture stop and the exit pupil are identical. In the general case, where the aperture stop is somewhere in the optical system the entrance pupil and the exit pupil can also be somewhere and they can be real or virtual images of the aperture stop. If an optical system consists of only one (thin) single lens the aperture stop, entrance pupil and exit pupil are of course all identical to the aperture of the lens itself. Another interesting case is e.g. an optical system where the aperture stop is in the back focal plane of the preceding part of the optical system. Then the entrance pupil is at infinity and the system is called telecentric on the object side. In this case all chief rays on the object side (see later in this section) are parallel to the optical axis. Similarly, if the aperture stop is in the front focal plane of the part of the optical system which follows the aperture stop the exit pupil will be at infinity and the system is called telecentric on the image side. Optical systems which are telecentric on both sides are quite important in optical metrology because in this case object points in different object planes have the same lateral magnification because the chief rays in the object and image spaces are both parallel to the optical axis. Therefore, the measured size of the object will be correct in a given image plane even though the object may be out of the object plane that is imaged sharply.

A quite important quantity to characterize an optical system is the numerical aperture NA. The numerical

aperture NA_O on the object side is defined as

$$NA_O = n_O \sin \varphi_O \qquad (2.135)$$

and the numerical aperture NA_I on the image side is

$$NA_I = n_I \sin \varphi_I , \qquad (2.136)$$

where n_O and n_I are the refractive indices in the object and image space, respectively. It is an elementary property of optical imaging systems that NA_O and NA_I are connected by the lateral magnification β (2.52) of the optical system if the sine condition is fulfilled

$$NA_I = \frac{NA_O}{\beta} . \qquad (2.137)$$

In fact, by replacing β by the ratio x_I/x_O of the image size and the object size this equation can be written as

$$x_I n_I \sin \varphi_I = x_O n_O \sin \varphi_O \qquad (2.138)$$

which is the usual formulation of the sine condition [2.1]. For the paraxial case this invariant reduces to the Smith–Helmholtz invariant:

$$x_I n_I \varphi_I = x_O n_O \varphi_O \qquad (2.139)$$

The numerical aperture determines how much light the optical system can gather from the object. It also determines (in the case of no aberrations) the resolution of the system due to diffraction. We will see in Sect. 2.5.3 that many aberrations depend on the numerical aperture. The position of the aperture stop in an optical system also influences the aberrations [2.26].

Another quite important definition of geometrical optics is the so-called chief ray or principal ray. This is that ray coming from the object point (which can of course be off-axis) which passes through the center of the aperture stop. Since the entrance pupil and the exit pupil are both images of the aperture stop the chief ray also passes through the centers of the entrance pupil and exit pupil. If there are strong aberrations in the system this may not be exactly the case for object points which are strongly off-axis.

2.3.2 The Field Stop

The second quite important stop is the field stop, which limits the diameter of the object field which can be imaged by an optical system. To find the field stop we calculate again the images of all stops by that part of the optical system which precedes the respective stop. Let us assume that the image of stop number i has again a diameter d_i and that the distance between the image of the stop and the entrance pupil of the system is L_i. The field stop is then that stop which has the smallest value ϕ_O of all values ϕ_i with

$$\tan \phi_i = \frac{d_i}{2L_i} \qquad (2.140)$$

The value $2\phi_O$ is called the field angle. The image of the field stop by that part of the optical system which precedes the field stop is called the entrance window and the image by that part of the optical system which follows the field stop is called the exit window.

If the line connecting an (off-axis) object point and the center of the entrance pupil is blocked by the entrance window the chief ray cannot pass the field stop and so this object point cannot be imaged in most cases. However, there are cases where other rays coming from the object point can pass anyway and then there is no sharp border of the object field but the outer parts of the object field are imaged with lower intensity. This effect is called vignetting.

2.4 Ray Tracing

It has been shown in Sect. 2.1.3 that light can be described by rays as long as the approximation of geometrical optics is valid. The propagation of such rays through an optical system is a very important tool to develop optical systems and to calculate their expected quality. The propagation of light rays through an optical system is called ray tracing [2.27, 28] and it is the basic tool of optical design, i.e. the design and optimization of optical systems concerning their imaging quality or other properties (e.g. tolerance of a system against misalignments or fabrication errors of components). In this section the principle of ray tracing and some applications will be described. There is of course no room to discuss the basics of optical design itself. For this we refer to the literature [2.16–19].

2.4.1 Principle

According to (2.29) a light ray propagates rectilinearly in a homogeneous and isotropic material. At an interface to another material the ray is partially refracted and partially reflected depending on the properties of the in-
Fig. 2.32 Propagation of some light rays in a typical microscopic objective ($NA = 0.4$, magnification 20×, focal length $f' = 11.5$ mm) calculated with our internal software RAYTRACE. In this case the microscopic objective is used in the reverse order, i. e. to focus light

terface. If a material is inhomogeneous (e.g. in GRIN lenses or in air films with different temperatures) the light ray is curved during the propagation and the path of the ray has to be calculated by solving (2.27), in most cases numerically [2.29, 30]. However, in this section it is assumed that the optical system consists of different homogeneous materials which are separated by refracting or reflecting interfaces.

Ray tracing means that the path of a bundle of rays, which are e.g. emitted by an object point or form a plane wave (i. e. object point with infinite distance), is determined in an optical system (see Fig. 2.32 for tracing rays through an microscopic objective). In the approximation of geometrical optics the calculation is exact and no other approximations, such as e.g. paraxial approximations, are made. Since ray tracing can be easily automated with the help of computers it is nowadays the most important tool for designing lenses, telescopes and complete optical systems [2.16–19]. For complex optical systems it is even today with the help of modern computers not possible to replace ray tracing by pure wave-optical methods. Moreover, for most macroscopic optical systems, ray tracing in combination with wave-optical evaluation methods like the calculation of the point spread function [2.18], assuming that only the exit pupil of the system introduces diffraction, is a sufficiently accurate method to analyze imaging systems. Another quite modern application of ray tracing

is the analysis of illumination systems with incoherent light. This will be discussed in Sect. 2.4.8 about non-sequential ray tracing.

A precondition for ray tracing is that the optical system is known very well. It is not sufficient to know some paraxial parameters but it is necessary to know the following data of the surfaces as well as the materials:

- Type of the surface, e.g. plane, spherical, parabolic, cylindrical, toric or other aspheric surface.
- Characteristic data of the surface itself, e.g. the radius of curvature in the case of a spherical surface or the aspheric coefficients in the case of an aspheric surface.
- Shape and size of the boundary of the surface, e.g. circular with a certain radius, rectangular with two side lengths or annular with an interior and an outer radius.
- Position and orientation of the surface in all three directions of space.
- Refractive indices of all materials and their dependence on wavelength.

The tracing of a given ray through an optical system has the following structure:

1. Determine the point of intersection of the ray with the following optical surface. If there is no point of intersection or if the hit surface is absorbing mark the ray as invalid and finish the tracing of this ray. Depending on the type of ray tracing it may also be necessary in this case to leave the ray unchanged and to go to step 4. If there is a point of intersection go to step 2.
2. Calculate the surface normal in the point of intersection.
3. Apply the law of refraction or reflection (or another law e.g. in the case of diffractive optical elements [2.31, 32]). Then, the new direction of the deflected ray is known and the point of intersection with the surface is the new starting point of the ray.
4. If there is another surface in the optical system go back to step 1 or, if not, then finish the tracing of this ray.

In the case of step 1 the following surface can either be the physically next surface of the optical system which will really be hit by the ray (i. e. non-sequential ray tracing) or just the next surface in the computer list of surfaces where the order of the surfaces has been determined by the user (i. e. sequential ray tracing).

In the next sections the mathematical realization of the different steps of ray tracing will be described.

2.4.2 Mathematical Description of a Ray

A light ray (in a homogeneous material) can be described mathematically as a straight line with a starting point p and a direction vector a parallel to the ray (see Fig. 2.33). Here, a is a unit vector, i. e. $|a| = 1$. According to (2.29) an arbitrary point on the ray with position vector r is described by

$$r = p + sa \ . \tag{2.141}$$

The scalar parameter s is the arc length of the ray, i. e. in this case of rectilinear rays it is just the distance between r and p. The virtual part of the ray is described by $s < 0$ whereas that part where there is really light has $s \geq 0$. In practice, there is also a maximum value s_{max} if the ray hits a surface where it is deflected.

2.4.3 Determination of the Point of Intersection with a Surface

The determination of the point of intersection of a light ray described by (2.141) with a surface requires of course a mathematical description of a surface. It is well known from mathematics that a surface can be described in an implicit form with a function F fulfilling

$$F(r) = 0 \ . \tag{2.142}$$

Concrete examples will be given later. By combining (2.141) and (2.142) the determination of the point of intersection is mathematically equivalent to the determination of the roots of a function G with the variable s

$$G(s_0) := F(p + s_0 a) = 0 \ . \tag{2.143}$$

After having determined the value s_0 at the root of G the position vector r_0 of the point of intersection itself is obtained by applying s_0 to (2.141).

In many cases there can be several roots of G and it is also necessary to check whether the point of intersection is in the valid part of the surface, which is in practice limited by a boundary. Then, that root with the smallest positive value of s_0 lying in the valid part of the surface has to be taken. These queries can be quite complex in a computer program.

For general aspheric surfaces the solution of (2.143) will only be possible numerically, but for some simple cases the analytic solutions will be given in the following.

Plane Surface

A plane surface can be described by the position vector C of a point on the surface (typically this point is in the center of the plane surface) and by the surface normal n_z (see Fig. 2.34). Then, each point r of the surface fulfills

$$F(r) = (r - C) \cdot n_z = 0 \ . \tag{2.144}$$

The solution of (2.143) in this case is

$$(p - C) \cdot n_z + s_0 a \cdot n_z = 0$$
$$\Rightarrow \quad s_0 = \frac{(C - p) \cdot n_z}{a \cdot n_z} \ . \tag{2.145}$$

In the case $a \cdot n_z = 0$ there is no definite point of intersection with the surface.

Of course, (2.144) describes an unlimited surface whereas the surfaces of an optical system are limited. Therefore, it has to be checked whether the point of intersection is in the valid area of the surface.

For a circular surface with radius R and center C this means e.g. that the point of intersection r_0 has to fulfill the condition $|r_0 - C| \leq R$.

For a rectangular surface a second vector n_x (with $n_x \cdot n_z = 0$ and $|n_x| = 1$) along one of the sides (the vector n_y along the second side is then just

**Fig. 2.33** Mathematical representation of a light ray as a straight line. O symbolizes the origin of the coordinate system

Fig. 2.34 Mathematical description of a plane surface

$\boldsymbol{n}_y := \boldsymbol{n}_z \times \boldsymbol{n}_x$) and the side lengths l_x and l_y of the rectangle have to be defined, additionally. Then, it has to be checked whether the conditions $|(\boldsymbol{r}_0 - \boldsymbol{C}) \cdot \boldsymbol{n}_x| \leq l_x/2$ and $\left|(\boldsymbol{r}_0 - \boldsymbol{C}) \cdot \boldsymbol{n}_y\right| \leq l_y/2$ are fulfilled.

Spherical Surface

A sphere whose center of curvature has position vector $\boldsymbol{C}$ and whose radius is R is described by

$$F(\boldsymbol{r}) = |\boldsymbol{r} - \boldsymbol{C}|^2 - R^2 = 0 . \tag{2.146}$$

Therefore, (2.143) results in a quadratic equation for s_0:

$$s_0^2 + 2s_0 (\boldsymbol{p} - \boldsymbol{C}) \cdot \boldsymbol{a} + |\boldsymbol{p} - \boldsymbol{C}|^2 - R^2 = 0 .$$

The two solutions are

$$s_0^{1,2} = (\boldsymbol{C} - \boldsymbol{p}) \cdot \boldsymbol{a}$$
$$\pm \sqrt{[(\boldsymbol{C} - \boldsymbol{p}) \cdot \boldsymbol{a}]^2 - |\boldsymbol{C} - \boldsymbol{p}|^2 + R^2} , \tag{2.147}$$

where the superscript 1, 2 is an index marking the two solutions. Depending on the argument of the square root there exist no (if the argument is negative), one (if the argument is zero) or two (if the argument is positive) solutions.

After having determined the points of intersection with the full sphere it has to be checked whether the points of intersection are in the valid part of the spherical surface. To do this an additional vector $\boldsymbol{n}_z$ ($|\boldsymbol{n}_z| = 1$) along the local optical axis and the lateral diameter D of the surface have to be defined (Fig. 2.35). The radius of curvature R is positive if the vector $\boldsymbol{n}_z$ points from the vertex to the center of curvature. In Fig. 2.35 R is, for example, positive. By using some trigonometric relations
Fig. 2.35 Mathematical representation of a spherical surface (*solid line*) which is part of a full sphere (*dashed plus solid line*). O symbolizes the origin of the coordinate system

it is easy to see that the condition

$$\frac{(\boldsymbol{C} - \boldsymbol{r}_0) \cdot \boldsymbol{n}_z}{R} \geq \sqrt{1 - \frac{D^2}{4R^2}}$$

has to be fulfilled by the point of intersection $\boldsymbol{r}_0$ if it lies on the valid spherical surface.

General Surface $z = f(x,y)$

There are many important surfaces in optics, e.g. aspheric surfaces, which are described by a function f and the equation $z = f(x, y)$. The implicit formulation with the function F is then

$$F(\boldsymbol{r}) = z - f(x, y) = 0 , \tag{2.148}$$

with $\boldsymbol{r} = (x, y, z)$.

For a general function f the points of intersection of such a surface with a ray cannot be calculated analytically. But there are numerical methods such as Newton's method combined with bracketing [2.33] to determine the roots of (2.143) where F of (2.148) is used.

An important case is e.g. the description of rotationally symmetric aspheric surfaces with their axis of rotation along z by using the function [2.18]:

$$z = f(x, y) = f(h) = \frac{ch^2}{1 + \sqrt{1 - (K+1)c^2 h^2}}$$
$$+ \sum_{i=1}^{i_{\max}} a_i h^i \tag{2.149}$$

with $h = \sqrt{x^2 + y^2}$; $c = 1/R$ is the curvature of the conical part of the surface with the conic constant K ($K < -1$ for a hyperboloid, $K = -1$ for a paraboloid and $K > -1$ for ellipsoids, with the special case $K = 0$ for a sphere). a_i are aspheric coefficients describing a polynomial of h. In most cases, only coefficients with even integers $i \geq 4$ are used and $i_{\max}$ is in most cases less than or equal to ten. But in modern aspheric surfaces there may also be odd terms of i and $i_{\max} > 10$.

Coordinate Transformation

In many cases there is a quite simple description of a surface in a local coordinate system [e.g. the description of a rotationally symmetric aspheric surface by using (2.149)] and it would not be useful to find the implicit function F in the global coordinate system if the surface is e.g. tilted. In these cases it is more useful to transform the ray parameters $\boldsymbol{p}$ and $\boldsymbol{a}$ from the global coordinate system to the local system. Then, finding the point of intersection with the surface and the refraction or reflection (or "diffraction" if the element is a diffractive
Fig. 2.36 Parameters for transforming a vector $\boldsymbol{p}$ defined in a global coordinate system to a vector $\boldsymbol{p}'$ defined in a local coordinate system. O symbolizes the origin of the global coordinate system

optical element) are done in the local coordinate system. Afterwards, the new ray is transformed back into the global coordinate system.

Assume that the origin of the local coordinate system has the position vector $\boldsymbol{C}$ in the global coordinate system and the three unit vectors along the coordinate axes of the local system are $\boldsymbol{n}_x$, $\boldsymbol{n}_y$ and $\boldsymbol{n}_z$ in the global system (Fig. 2.36). To transform between the position vector $\boldsymbol{p} = (p_x, p_y, p_z)$ in the global system and $\boldsymbol{p}' = (p'_x, p'_y, p'_z)$ in the local system one has the equations:

$$\boldsymbol{p} = \boldsymbol{C} + p'_x \boldsymbol{n}_x + p'_y \boldsymbol{n}_y + p'_z \boldsymbol{n}_z \tag{2.150}$$

and

$$\begin{aligned}
p'_x &= (\boldsymbol{p} - \boldsymbol{C}) \cdot \boldsymbol{n}_x , \\
p'_y &= (\boldsymbol{p} - \boldsymbol{C}) \cdot \boldsymbol{n}_y , \\
p'_z &= (\boldsymbol{p} - \boldsymbol{C}) \cdot \boldsymbol{n}_z .
\end{aligned} \tag{2.151}$$

For the ray direction vector with coordinates $\boldsymbol{a}' = (a'_x, a'_y, a'_z)$ in the local system and $\boldsymbol{a} = (a_x, a_y, a_z)$ in the global system the analogous equations are valid (but with $\boldsymbol{C} = 0$ because direction vectors are measured from the origin of the respective coordinate system and can be shifted arbitrarily):

$$\boldsymbol{a} = a'_x \boldsymbol{n}_x + a'_y \boldsymbol{n}_y + a'_z \boldsymbol{n}_z \tag{2.152}$$

and

$$\begin{aligned}
a'_x &= \boldsymbol{a} \cdot \boldsymbol{n}_x , \\
a'_y &= \boldsymbol{a} \cdot \boldsymbol{n}_y , \\
a'_z &= \boldsymbol{a} \cdot \boldsymbol{n}_z .
\end{aligned} \tag{2.153}$$

Of course it would also be possible to write the coordinate transformation using 3×3 matrices with the vectors $\boldsymbol{n}_x$, $\boldsymbol{n}_y$ and $\boldsymbol{n}_z$ as column or row vectors, but we prefer the vector notation here.

2.4.4 Calculation of the Optical Path Length

The optical path length L along a ray at the point of intersection with the next surface is calculated by adding to the original optical path length L_0 at the starting point $\boldsymbol{p}$ of the ray the distance s_0 between the starting point of the ray and the point of intersection with the next surface multiplied by the refractive index n of the material in which the ray propagates. Therefore, the optical path length is

$$L = L_0 + ns_0 . \tag{2.154}$$

If the optical path length on another point $\boldsymbol{r} = \boldsymbol{p} + s\boldsymbol{a}$ on the ray has to be calculated this is done by just replacing s_0 in equation (2.154) by s.

2.4.5 Determination of the Surface Normal

If the function F of the implicit representation of the surface is known the surface normal $\boldsymbol{N}$ at the point of intersection is defined as the normalized gradient of F at the point of intersection $\boldsymbol{r}_0$

$$\boldsymbol{N} = \frac{\nabla F}{|\nabla F|} . \tag{2.155}$$

Some examples of surface normals are given in the following.

Plane Surface
According to (2.144), one has

$$F(\boldsymbol{r}) = (\boldsymbol{r} - \boldsymbol{C}) \cdot \boldsymbol{n}_z = 0 \Rightarrow \boldsymbol{N} = \boldsymbol{n}_z . \tag{2.156}$$

Spherical Surface
A spherical surface is described by (2.146):

$$F(\boldsymbol{r}) = |\boldsymbol{r} - \boldsymbol{C}|^2 - R^2 = 0 ,$$
$$\Rightarrow \boldsymbol{N} = \frac{\boldsymbol{r}_0 - \boldsymbol{C}}{|\boldsymbol{r}_0 - \boldsymbol{C}|} . \tag{2.157}$$

General Surface $z = f(x, y)$

$$F(\boldsymbol{r}) = z - f(x, y) = 0 ,$$
$$\Rightarrow \boldsymbol{N} = \frac{(-f_x, -f_y, 1)}{\sqrt{1 + f_x^2 + f_y^2}} , \tag{2.158}$$

where $f_x := \partial f / \partial x$ and $f_y := \partial f / \partial y$ are the partial derivatives of f at the point of intersection r_0 with the surface.

2.4.6 Law of Refraction

For ray tracing a vectorial formulation of the law of refraction is necessary. In (2.41) an implicit formulation of the law of refraction (and also of the law of reflection) was given

$$N \times (n_2 a_2 - n_1 a_1) = 0 \,,$$

where n_1 and n_2 are the refractive indices of the two materials and a_1 and a_2 are the unit direction vectors of the incident and refracted ray, respectively (Fig. 2.37). N is the local surface normal at the point of intersection of the incident ray with the surface.

A solution of this equation can be found by the following steps:

$$\left(a_2 - \frac{n_1}{n_2} a_1\right) \times N = 0 \,.$$

This means that the term in round brackets has to be parallel to N or itself zero. The later case is only possible for $n_1 = n_2$ so that, for $n_1 \neq n_2$, we have

$$a_2 = \frac{n_1}{n_2} a_1 + \gamma N$$

with a real value γ. Taking the square of both sides yields (as a_1, a_2 and N are all unit vectors, i. e. $|a_1| = |a_2| = |N| = 1$)

$$1 = \left(\frac{n_1}{n_2}\right)^2 + \gamma^2 + 2\gamma \frac{n_1}{n_2} a_1 \cdot N$$

and therefore

$$\gamma_{1,2} = -\frac{n_1}{n_2} a_1 \cdot N \pm \sqrt{1 - \left(\frac{n_1}{n_2}\right)^2 \left[1 - (a_1 \cdot N)^2\right]} \,.$$

In total the result is:

$$a_2 = \frac{n_1}{n_2} a_1 - \frac{n_1}{n_2} (a_1 \cdot N) N$$
$$\pm \sqrt{1 - \left(\frac{n_1}{n_2}\right)^2 \left[1 - (a_1 \cdot N)^2\right]} N \,. \qquad (2.159)$$

The vector term in front of the square root is parallel to the surface (the scalar product with N is zero). This means that the sign in front of the square root decides whether the component of a_2 along N is parallel or antiparallel to N. Since the ray is refracted the sign of the component of a_1 along N has to be equal to the sign of the component of a_2 along N:

$$\text{sign}(a_1 \cdot N) = \text{sign}(a_2 \cdot N) \,, \qquad (2.160)$$

where the sign function is $+1$ for a positive argument and -1 for a negative argument.

Therefore, (2.159) can be written independently of the relative direction of N with respect to a_1 as

$$a_2 = \frac{n_1}{n_2} a_1 - \frac{n_1}{n_2} (a_1 \cdot N) N + \text{sign}(a_1 \cdot N)$$
$$\times \sqrt{1 - \left(\frac{n_1}{n_2}\right)^2 \left[1 - (a_1 \cdot N)^2\right]} N \qquad (2.161)$$

So, this equation allows the calculation of the direction vector a_2 of the refracted ray if the incident ray (direction vector a_1), the local surface normal N and the two refractive indices n_1 and n_2 are known.

2.4.7 Law of Reflection

The law of reflection is also formally described by (2.41) and therefore also by (2.159). But, in the case of reflection, first of all the refractive indices are identical for the incident and the reflected ray, i. e. $n_1 = n_2$, and sec-

Fig. 2.37 Parameters for refraction of a ray at a surface
Fig. 2.38 Parameters for the reflection of a ray at a surface

ond the component of a_2 along N has the opposite sign to the component of a_1 along N (Fig. 2.38). This means that the other sign in front of the square root has to be taken and (2.159) results in

$$a_2 = a_1 - (a_1 \cdot N) N - \text{sign} (a_1 \cdot N)$$
$$\times \sqrt{(a_1 \cdot N)^2} N = a_1 - 2 (a_1 \cdot N) N . \quad (2.162)$$

It is easy to prove that this equation correctly describes the reflection of a ray at a surface because all three vectors lie in a common plane (linearly dependent vectors) and the angle of incidence is equal to the angle of the reflected ray. The later can be seen by calculating the modulus of the cross product of (2.162) with N. Third, a_2 really describes a reflected ray since twice the component of a_1 along N is subtracted from a_1 to obtain a_2.

Besides refraction and reflection there is also a third quite important law for deflecting a ray at a surface, the vectorial local grating equation, which is used for ray tracing on holographic and more general diffractive optical elements. But for this equation and its solution we refer to the literature [2.31, 32, 34, 35].

2.4.8 Non-Sequential Ray Tracing and Other Types of Ray Tracing

The normal mode in most ray-tracing computer programs is so-called sequential ray tracing, i. e. the user defines the order in which the different surfaces of the optical system are passed by a ray. But this method is e.g. not useful for the analysis of illumination systems where the path of a ray and the order of surfaces can be different for each ray. The stability analysis of laser resonators [2.14, 15] is also quite exhausting with the sequential mode because the user knows the order of the surfaces but not how many times they will be hit by a ray. Of course, a stable resonator will be crossed by a light ray with an infinite number of cycles. But for unstable resonators there is a finite number of cycles before the ray leaves the resonator.

Therefore, non-sequential ray tracing is used in these cases. In this, the computer automatically calculates the next surface that is physically hit by each ray. This is done, for example, by calculating the points of intersection of the ray with all surfaces and taking the surface with the smallest positive distance s_0. If there is no point of intersection with $s_0 > 0$ the ray does not hit any surface of the system. Of course, non-sequential ray tracing is quite expensive in terms of computing time and therefore is normally only used if really necessary.

Another speciality of non-sequential ray tracing is that a ray can be split at a surface into a refracted and a reflected ray (and in the case of diffractive optical elements also into more than two rays representing the different diffraction orders). Each ray is then recursively traced through the optical system.

Some interesting modern optical systems such as Shack–Hartmann wavefront sensors [2.36] or beam homogenizers [2.37] use microlens arrays in combination with macroscopic optics. These array systems can also be analyzed with sequential or non-sequential ray tracing to obtain a first insight [2.38, 39]. Of course, one has to be careful in these cases because diffraction and interference effects (for coherent or partially coherent illumination) cannot be neglected in several cases [2.40].

Sophisticated modern computer programs for sequential or non-sequential ray tracing implement in addition polarization ray tracing [2.10, 11]. In this, the local polarization state of each ray is taken into account and, for example, the split of the local power transported by each ray to the refracted and reflected ray for refraction/reflection at a surface is calculated according to the Fresnel equations [2.1].

A third type of ray tracing is so-called differential ray tracing or generalized ray tracing [2.28, 35, 41]. In this case, each ray is assumed to represent a local wave front with two principal curvatures and two principal directions. These parameters are then traced in addition to the normal ray parameters for each ray during propagation through the optical system. This allows, for example, the calculation of the local astigmatism of the wave front belonging to the ray by just tracing one ray. It also allows the calculation of the change of local intensity of the wave during the propagation.

2.5 Aberrations

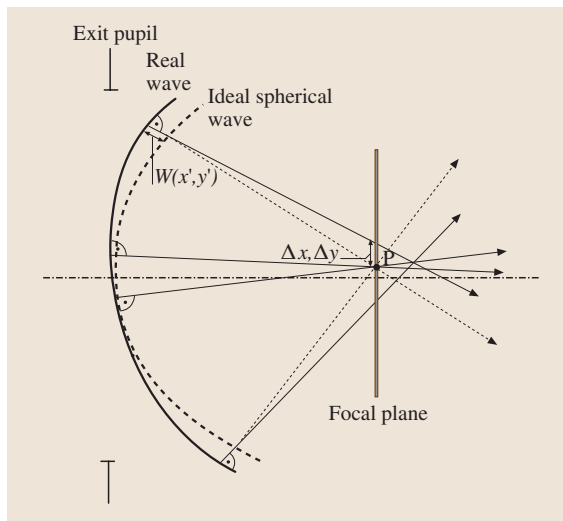
Whereas in the paraxial case the imaging quality of an optical system is ideal there are in practice aberrations of an optical system which deteriorate its imaging quality [2.1, 6, 8, 26, 42]. To explain the nature of aberrations, see Fig. 2.39. At the exit pupil of an optical system there is a real wave front (solid line), i. e. the surface of equal optical path length, which intersects the exit pupil on the optical axis and which has its paraxial focus at the


Fig. 2.39 Explanation of the wave aberrations W and the ray aberrations Δx, Δy. The solid curve is the real wave front and the dashed curve the ideal spherical wave front. The *solid rays* are rays starting from the real wave front whereas the *dashed rays* are rays starting from the ideal spherical wave front. P is the (paraxial) focus of the wave front

Fig. 2.40 Wave aberrations for the on-axis point of the microscopic objective of Fig. 2.32 (NA = 0.4, magnification 20×, focal length $f' = 11.5$ mm). The reference sphere is around the best focus of the wave aberrations. The focused spot is diffraction-limited since the peak-to-valley value is just 0.1 wavelengths (for a wavelength of 587.6 nm)

point P, which lies in the focal plane of the system. However, there are deviations between an ideal spherical wave front (dashed line) with its center of curvature at P and the real wave front in the non-paraxial region. So, a ray starting at the point (x', y') of the exit pupil has an optical path length difference between the real wave front and the ideal spherical wave front, which is called the wave aberration $W(x', y')$. Additionally, a ray with aberrations does not intersect the focal plane at the focus P but at a point with lateral displacements Δx and Δy in the x- and y-directions. These lateral deviations from the paraxial focus P are called the ray aberrations. Of course, the wave aberrations and ray aberrations are not independent of each other [2.43] and with good approximation the ray aberrations are proportional to the partial derivatives of the wave aberrations with respect to x' and y'.

2.5.1 Calculation of the Wave Aberrations

The wave aberrations can be calculated by ray tracing. To do this a sphere which intersects the exit pupil on the optical axis and which has the (paraxial) focus P as its center of curvature is defined. Then, the optical path lengths $L(x', y')$ of the points of intersection of this

reference sphere with rays starting at the exit pupil at the points (x', y') are calculated by using (2.147) and (2.154). The optical path length $L(0, 0)$ of the chief ray is subtracted from the optical path length values of all other rays, resulting in the wave aberrations $W(x', y')$:

$$W(x', y') = L(x', y') - L(0, 0) . \qquad (2.163)$$

So, the wave aberrations are known for a grid of rays, i. e. the points (x', y') in the exit pupil.

In some cases it is useful not to take the paraxial focus for P but the so-called best focus. This is the point where either the wave aberrations or the ray aberrations have their smallest mean value (Fig. 2.40). So, in fact there are two different definitions of the best focus. If there is, for example, field curvature the best focus will not be in the focal plane but on a sphere which intersects the optical axis in the focal plane.

2.5.2 Ray Aberrations and the Spot Diagram

Ray aberrations can also be calculated by ray tracing. These aberrations are just the lateral deviations Δx and Δy between the focus P itself (which can be the paraxial focus or the best focus) and the points of intersection of the rays with a plane through the focus P. The surface normal of this plane is assumed to be $\boldsymbol{n}_z$ (in most cases $\boldsymbol{n}_z$ will be parallel to the optical axis) and the focus P has the position vector $\boldsymbol{P}$. Additionally, the two unit vectors $\boldsymbol{n}_x$ and $\boldsymbol{n}_y$ lying in this plane and defining the local x- and y-axis are known ($\boldsymbol{n}_x, \boldsymbol{n}_y$ and $\boldsymbol{n}_z$ form an orthogonal triad

**Fig. 2.41** Spot diagram for the on-axis point of the microscopic objective of Fig. 2.32 with $NA = 0.4$, magnification 20×, focal length $f' = 11.5$ mm. Since the numerical aperture of the lens used to focus the light is $NA = 0.4$ on the image side and the wavelength is $\lambda = 587.6$ nm the diffraction-limited Airy disc would have a diameter of $1.22\lambda/NA = 1.8\,\mu$m, i.e. larger than the ray aberrations. So, as in Fig. 2.40, it can also be seen from the ray aberrations that the on-axis spot of this lens is diffraction-limited

of unit vectors). Then, a ray number i with starting point $\boldsymbol{p}_i$ and direction vector $\boldsymbol{a}_i$ has its point of intersection $\boldsymbol{r}_i$ with the plane according to (2.141) and (2.145) at

$$\boldsymbol{r}_i = \boldsymbol{p}_i + \frac{(\boldsymbol{P} - \boldsymbol{p}_i) \cdot \boldsymbol{n}_z}{\boldsymbol{a}_i \cdot \boldsymbol{n}_z} \boldsymbol{a}_i \ . \tag{2.164}$$

The ray aberrations are then defined as:

$$\Delta x = (\boldsymbol{r}_i - \boldsymbol{P}) \cdot \boldsymbol{n}_x \ , \tag{2.165}$$
$$\Delta y = (\boldsymbol{r}_i - \boldsymbol{P}) \cdot \boldsymbol{n}_y \ . \tag{2.166}$$

A quite demonstrative representation of the ray aberrations is a spot diagram. There, the points of intersection of the rays with a plane are graphically displayed by just drawing them as points (Fig. 2.41). This means that the spot diagram is a graphical representation of the ray aberrations ($\Delta x, \Delta y$). Sometimes it is useful to determine the spot diagram not only in a plane through the focus but also in other planes to track the focusing of the rays.

2.5.3 The Seidel Terms and the Zernike Polynomials

In classical aberration theory [2.1, 3] the primary aberration terms of Seidel (fourth-order wave aberration terms or third-order ray aberration terms) play an important role. The different terms are: spherical aberration, coma, astigmatism, curvature of field and distortion. Whereas the first three terms are point aberrations, i.e. aberrations that generate a blurred image point, the last two terms just cause a shift of the image point relative to the ideal paraxial image point but the image point itself would be sharp. There is not time in this chapter to go into details and to give a mathematical derivation so that only some facts will be stated for the different aberration terms. The distance of the object point from the optical axis will be called the object height r_O in the following whereas the distance of a ray from the optical axis in the exit pupil will be called r_A (from aperture height). For lenses with a small numerical aperture the maximum value r_A is proportional to the numerical aperture NA of the image forming pencil of rays. Therefore, in the following the numerical aperture NA and the object height r_O will be used to describe the functionality of the different Seidel terms.

Spherical Aberration

Spherical aberration is the only classical aberration that also occurs for object points on the optical axis of a rotationally symmetric optical system, i.e. for $r_O = 0$. Spherical aberration of a normal single lens causes rays with a large height r_A in the exit pupil of the lens to be refracted more strongly, so that they intersect the optical axis in front of the paraxial focus. In general optical systems the off-axis rays can also intersect the optical axis behind the paraxial focus. A typical property of spherical aberration is that it increases with the fourth power of the numerical aperture NA of the ray pencil forming the image point:

$$\text{spherical aberration} \propto (NA)^4 \tag{2.167}$$

As already mentioned above the spherical aberration is independent of the object height r_O.

Coma

Coma is an aberration which occurs only for off-axis points (of a rotationally symmetric optical system), i.e. $r_O \neq 0$. The name coma is caused by the deformation of the image point, which looks like the coma of a comet. The coma depends on the third power of the numerical

aperture and linearly on the image height

$$\text{coma} \propto r_O(\text{NA})^3 \ . \tag{2.168}$$

This is the reason why coma especially occurs for large numerical apertures whereas astigmatism dominates for small numerical apertures and large object heights (see the next paragraph).

Coma can, for example, be generated in the microscopic objective of Fig. 2.32 by a lateral shift of the first lens. A shift of 0.1 mm results in the aberrations shown in Fig. 2.42, which are dominated by coma although the spherical aberration of the original lens is still present.

Astigmatism

Astigmatism means that rays of the meridional plane and of the sagittal plane focus in different planes perpendicular to the optical axis. So, the geometrical shape of the image point is in general an ellipse. In two special planes, called the meridional and sagittal focal planes, the ellipses degenerate into two focal lines. The focal lines are perpendicular to each other. Between the meridional and the sagittal focal plane there is another plane where the shape of the image point is a circle, but of course this circle is extended whereas an ideal image point in geometrical optics would be a mathematical point. The astigmatism of an optical system is proportional to the square of the numerical aperture and the square of the object height:

$$\text{astigmatism} \propto r_O^2(\text{NA})^2 \ . \tag{2.169}$$
Fig. 2.42 Wave aberrations for the on-axis object point of the misadjusted microscopic objective of Fig. 2.32 (NA = 0.4, magnification 20×, focal length $f' = 11.5$ mm) by shifting the first lens laterally by 0.1 mm. The image point which is then no more on-axis shows mainly coma but of course mixed with the spherical aberration of Fig. 2.40
Fig. 2.43 Wave aberrations for an off-axis object point of the microscopic objective of Fig. 2.32 (NA = 0.4, magnification 20×, focal length $f' = 11.5$ mm). The image point shows in this case mainly astigmatism but of course mixed with the spherical aberration of Fig. 2.40. There is nearly no coma because the well-adjusted microscopic objective fulfills the sine condition

As mentioned above, this functionality is the reason that astigmatism also occurs for quite narrow pencils of rays. If there are cylindrical or toric surfaces in an optical system, astigmatism also occurs on the optical axis, whereas in the usual case of rotationally symmetric optical systems astigmatism occurs only for off-axis points.

If we again take the microscopic objective of Fig. 2.32 but now with an off-axis object point (object height 15 mm, resulting image height 0.74 mm because of curvature of the field) the resulting aberrations are mainly astigmatism, showing the typical saddle shape. Of course, the spherical aberration which is present on-axis remains, so that in fact the resulting aberrations represented in Fig. 2.43 are a mixture of astigmatism with a peak-to-valley value of about one wavelength and spherical aberration of 0.1 wavelength. Nearly no coma appears for off-axis points because a microscopic objective fulfills the sine condition (2.138), which guarantees that object points in the neighborhood of the optical axis are imaged without coma.

Curvature of Field

As mentioned above the curvature of field is not a point aberration but a field aberration, i.e. the image point can be sharp but the position of the image point is shifted relative to the ideal paraxial value. In the case of the curvature of the field the image points are situated on a spherical surface and, in connection with astigmatism, there are even two different spheres
Fig. 2.44 Curvature of field: ray-tracing picture of the image points of different field points of the microscopic objective of Fig. 2.32 (NA = 0.4, magnification 20×, focal length $f' = 11.5$ mm) which is used in the reverse order, i.e. to build an image with reduced size. It can be seen that the image points are situated on a curve (*dotted curve*) which is in fact part of a sphere. Note that the scaling is quite different for the x- and z-axes to see the effect of the curvature of the field

for rays in the meridional plane and in the sagittal plane.

Figure 2.44 shows the curvature of the field in the image plane of the microscopic objective of Fig. 2.32. For the off-axis points the best focus of the image points is behind the focal plane (light is coming, as usual, from the left). Of course, the off-axis points also show astigmatism so that the image points are blurred.

Distortion

The last Seidel term is distortion, which is also a field aberration and not a point aberration. Distortion means that the lateral magnification for imaging is not a constant for all off-axis points but depends to some extent on the object height r_O. The result is that each straight line in the object plane that does not pass through the optical axis is curved in the image plane. A regular grid like that in Fig. 2.45b is either pincushion-distorted (Fig. 2.45a) or barrel-distorted (Fig. 2.45c).

The Zernike Polynomials

A quite important method to calculate the different terms of the wave aberrations of an optical system
Fig. 2.45a–c Effect of distortion. The regular grid of (**b**) in the object plane is either distorted in the image plane to a pincushion shape (**a**) or a barrel shape (**c**). In (**a**) the lateral magnification increases with increasing object height whereas it decreases in (**c**)

is to fit the so-called Zernike polynomials [2.1, 44, 45] to it. The wave aberration data for this procedure can either be theoretically determined, e.g. by ray tracing, or experimentally determined, e.g. by interferometry.

The condition for using Zernike polynomials is that the aperture of the optical system is circular because the Zernike polynomials are only orthogonal on the unit circle. There, they build a complete set of orthogonal polynomials and some of the terms correspond to the classical Seidel terms for the point aberrations, i.e. spherical aberration, coma and astigmatism. Besides this there are other terms such as trefoil or tetrafoil that result, for example, if the optical elements are stressed by fixing them at three or four points. It has to be emphasized that there are no terms corresponding to the Seidel terms of curvature of field and distortion since the Zernike polynomials can only represent point aberrations and not field aberrations.

2.5.4 Chromatic Aberrations

Up to now it was implicitly assumed that only light of one wavelength is considered and the presented aberrations were all monochromatic aberrations. Besides this, there are so-called chromatic aberrations, which are a result of the dispersion of a material, i.e. the dependence of the refractive index of a material on the wavelength (or, if there are diffractive optical elements in the system, the dispersion results from the strong dependence of the grating equation on the wavelength). Dispersion changes the paraxial parameters such as the focal length of a lens. For a thin lens with refractive index n in air we have for example (2.98):

$$\frac{1}{f'} = (n-1) \left(\frac{1}{R_1} - \frac{1}{R_2} \right) . \tag{2.170}$$

If now n depends on the wavelength λ we have

$$\frac{d}{d\lambda}\left(\frac{1}{f'}\right) = -\frac{df'/d\lambda}{f'^2} = \frac{dn}{d\lambda}\left(\frac{1}{R_1} - \frac{1}{R_2}\right)$$
$$= \frac{dn/d\lambda}{n-1}\frac{1}{f'} . \qquad (2.171)$$

By replacing the differentials by finite differences we can write, to a good approximation,

$$\frac{\Delta f'}{f'} = -\frac{\Delta n}{n-1} . \qquad (2.172)$$

To characterize the dispersion of a material the so-called Abbe number V_d is used; it is defined as

$$V_d = \frac{n_d - 1}{n_F - n_C}$$
$$= \frac{n(\lambda_d = 587.6\,\text{nm})}{n(\lambda_F = 486.1\,\text{nm}) - n(\lambda_C = 656.3\,\text{nm})} . \qquad (2.173)$$

So, we have to a good approximation:

$$\frac{f'(\lambda_C = 656.3\,\text{nm}) - f'(\lambda_F = 486.1\,\text{nm})}{f'(\lambda_d = 587.6\,\text{nm})} = \frac{1}{V_d} . \qquad (2.174)$$

For glasses with normal dispersion the Abbe number is a positive constant that has a small value for materials with high dispersion (e.g. materials like SF10) and a large value for materials with small dispersion (like e.g. BK7). The positive sign indicates that the focal length of a lens increases with increasing wavelength.

2.6 Some Important Optical Instruments

In this section some important optical instruments such as the achromatic lens, the camera, the human eye, the telescope and the microscope will be discussed. However, this will be done in some cases quite briefly because there are many text books on geometrical optics which treat these subjects quite amply [2.3, 5, 8].

2.6.1 The Achromatic Lens

In paragraph 2.5.4 the chromatic aberrations of a single lens, i. e. the dependence of the focal length on the wavelength, were treated. An achromatic lens should have, in the ideal case, no chromatic aberrations. However, in practice the most important achromatic lens is an achromatic doublet consisting of two cemented lenses, for which the focal length can be identical for only two different wavelengths. So, in technical optics the term achromatic lens normally means a lens where the focal length is identical for two different wavelengths. For applications in the visible range these two wavelengths are commonly $\lambda_F = 486.1$ nm (blue line of atomic hydrogen) and $\lambda_C = 656.3$ nm (red line of atomic hydrogen), which are near the edge of the visible range. A lens where the focal length is identical for three wavelengths is called an apochromatic lens.

To understand the principle of the achromatic correction of a lens doublet the paraxial matrix M of a combination of two thin lenses (paraxial matrices M_1 and M_2) situated in air with a zero separation is calculated. Of course, this is a simplification because in practice no thin lens really exists and, if the principal points of thick lenses are taken as reference elements, the distance between two lenses will normally be different from zero. But nevertheless, the calculation with two zero-distant thin lenses explains the principle and, according to equation (2.97), the result is

$$M = M_2 M_1 = \begin{pmatrix} 1 & 0 \\ -\frac{1}{f'_2} & 1 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ -\frac{1}{f'_1} & 1 \end{pmatrix}$$
$$= \begin{pmatrix} 1 & 0 \\ -\frac{1}{f'_1} - \frac{1}{f'_2} & 1 \end{pmatrix} , \qquad (2.175)$$

where the focal lengths of the two thin lenses are f'_1 and f'_2. Therefore, the focal length f' of the combination of these two lenses is

$$\frac{1}{f'} = \frac{1}{f'_1} + \frac{1}{f'_2} ; \qquad (2.176)$$

that is, the optical powers of the single lenses are just added.

The refractive index of the first lens is n_1 and that of the second lens is n_2, and both are situated in air. The optical powers $1/f'_i$ ($i \in \{1, 2\}$) of refractive thin lenses are then, according to (2.98),

$$\frac{1}{f'_i(\lambda)} = [n_i(\lambda) - 1]\left(\frac{1}{R_{i,1}} - \frac{1}{R_{i,2}}\right)$$
$$=: [n_i(\lambda) - 1]\,C_i , \qquad (2.177)$$

where the term C_i depends only on the two radii of curvature $R_{i,1}$ and $R_{i,2}$ of the thin lenses and is independent of the wavelength λ, whereas the refractive index n_i depends on the wavelength.

For an achromatic lens the optical powers at the two wavelengths λ_F and λ_C (or for two other wavelengths depending on the application) have to be identical. By using (2.176) and (2.177) this means:

$$\frac{1}{f_1'(\lambda_F)} + \frac{1}{f_2'(\lambda_F)} = \frac{1}{f_1'(\lambda_C)} + \frac{1}{f_2'(\lambda_C)}$$
$$\Rightarrow [n_1(\lambda_F) - 1]\,C_1 + [n_2(\lambda_F) - 1]\,C_2$$
$$= [n_1(\lambda_C) - 1]\,C_1 + [n_2(\lambda_C) - 1]\,C_2\,,$$
$$\Rightarrow [n_1(\lambda_F) - n_1(\lambda_C)]\,C_1$$
$$= -[n_2(\lambda_F) - n_2(\lambda_C)]\,C_2\,.$$

By using (2.177) again the terms C_1 and C_2 can be expressed using the refractive indices at an intermediate wavelength between λ_F and λ_C, in our case $\lambda_d = 587.6\,\text{nm}$ (the yellow line of helium), and the focal lengths at this wavelength, and the result is:

$$\frac{n_1(\lambda_F) - n_1(\lambda_C)}{[n_1(\lambda_d) - 1]\,f_1'(\lambda_d)} = -\frac{n_2(\lambda_F) - n_2(\lambda_C)}{[n_2(\lambda_d) - 1]\,f_2'(\lambda_d)}$$
$$\Rightarrow V_{1,d}\,f_1'(\lambda_d) = -V_{2,d}\,f_2'(\lambda_d)\,. \qquad (2.178)$$

Here, the Abbe numbers $V_{i,d}$ ($i \in \{1, 2\}$) of the materials with refractive indices n_i are defined by (2.173).

Since the Abbe number of a refractive material is always positive one of the refractive thin lenses has to be a negative lens and one a positive lens to fulfill (2.178). However, if one of the two thin lenses is not a refractive but a diffractive lens it formally has a constant negative Abbe number $V_d = -3.453$ ([2.23], Chap. 10). So, in the case of a so-called hybrid achromatic lens, which consists of a refractive and a diffractive lens, both lenses will have the same sign of optical powers, and so a positive hybrid achromatic lens consists of two positive single lenses: a refractive lens with a high optical power and a high Abbe number and a diffractive lens with a small optical power and a negative Abbe number with small modulus.

However, a positive purely refractive achromatic lens consists of a positive lens with high optical power and high Abbe number (made of a crown glass such as BK7) and a negative lens with smaller optical power and smaller Abbe number (made of a highly dispersive flint glass such as SF10), so that in total a positive optical power results.

In our mathematical description only the case of two thin lenses with zero separation is treated. But it is no

problem to use the paraxial matrix theory to calculate the matrix of a real achromatic doublet consisting of two cemented lenses, i. e. three refractive spherical surfaces with finite distances embedding two different materials. However, in this case not only the focal length will depend on the wavelength but also to some degree the position of the principal planes. So, the position of the focus itself can vary a little, although the focal length is identical for the two selected wavelengths λ_F and λ_C.

In practice, refractive achromatic doublets that can be bought do not only correct the chromatic errors but also fulfill the sine condition (2.138). This is possible because there are three surfaces with different radii of curvature, whereas to fulfill the paraxial properties only two of these three parameters are determined.

Examples of Designing Achromatic Doublets

In this paragraph the paraxial properties of different achromatic doublets will be calculated and compared with those of single refractive lenses. It will be assumed as above that the two lenses of the achromatic doublet are thin lenses with zero distance between the two lenses. This is of course a simplification, but nevertheless it is a good approximation for most cases.

Due to (2.178) the focal lengths $f_1'(\lambda_d)$ and $f_2'(\lambda_d)$ of the two lenses of the achromatic doublet at the wavelength $\lambda_d = 587.6\,\text{nm}$ have to fulfill the condition:

$$V_{1,d}\,f_1'(\lambda_d) = -V_{2,d}\,f_2'(\lambda_d)\,,$$
$$\Rightarrow \quad \begin{aligned} f_1'(\lambda_d) &= -\frac{V_{2,d}}{V_{1,d}}\,f_2'(\lambda_d) \quad \text{or} \\ f_2'(\lambda_d) &= -\frac{V_{1,d}}{V_{2,d}}\,f_1'(\lambda_d)\,. \end{aligned}$$

Here, $V_{1,d}$ and $V_{2,d}$ are the Abbe numbers of the materials of the two lenses. Additionally, the focal length f' of the achromatic doublet can be calculated according to (2.176) by

$$\frac{1}{f'} = \frac{1}{f_1'} + \frac{1}{f_2'}\,.$$

By combining both equations the focal lengths of the two single lenses can be expressed as functions of the focal length of the achromatic doublet:

$$f_1'(\lambda_d) = \frac{V_{1,d} - V_{2,d}}{V_{1,d}}\,f'(\lambda_d)\,,$$
$$f_2'(\lambda_d) = \frac{V_{2,d} - V_{1,d}}{V_{2,d}}\,f'(\lambda_d)\,. \qquad (2.179)$$

A refractive achromatic doublet made of BK7 and SF10 has, for example, Abbe numbers of $V_{1,d} = 64.17$ (BK7) and $V_{2,d} = 28.41$ (SF10). Therefore, the focal lengths of

the two single lenses are in this case, due to (2.179),

Lens made of BK7 : $f_1'(\lambda_d) = 0.557 f'(\lambda_d)$,
Lens made of SF10 : $f_2'(\lambda_d) = -1.259 f'(\lambda_d)$.

So, the second lens, made of the highly dispersive material SF10, is a negative lens if the achromatic doublet itself is a positive lens.

As mentioned previously a diffractive lens (DOE) can be described by a negative and material-independent Abbe number $V_d = -3.453$. Therefore, in the following the focal lengths of the two single lenses of a hybrid achromatic doublet made of one refractive lens and one DOE shall be considered. First, the refractive lens with focal length f_1' is made of BK7 and the second lens with focal length f_2' is a DOE. According to equations (2.179) the focal lengths are:

Lens made of BK7 : $f_1'(\lambda_d) = 1.054 f'(\lambda_d)$,
DOE : $f_2'(\lambda_d) = 19.588 f'(\lambda_d)$.

So, as mentioned previously, both lenses are positive lenses if the achromatic doublet has a positive optical power. Of course, most of the optical power is delivered by the refractive lens.

A second hybrid achromatic doublet can be made, for example, by taking a refractive lens made of SF10 and a DOE:

Lens made of SF10 : $f_1'(\lambda_d) = 1.122 f'(\lambda_d)$,
DOE : $f_2'(\lambda_d) = 9.230 f'(\lambda_d)$.
The remaining chromatic aberrations of an achromatic doublet, i. e. the variation of the focal length with the wavelength of the illuminating light, can be calculated by using (2.176). In this equation the optical power of a refractive lens as function of the wavelength is calculated by (2.177) and the optical power of a diffractive lens as a function of the wavelength is [2.23]

$$\frac{1}{f_{DOE}'(\lambda)} = \frac{\lambda}{\lambda_d f_{DOE}'(\lambda_d)} =: C\lambda .$$

Here, $C = 1/[\lambda_d f_{DOE}'(\lambda_d)]$ is a constant value which depends on the focal length $f_{DOE}'(\lambda_d)$ of the DOE at the wavelength $\lambda_d = 587.6$ nm. So, the optical power of the DOE increases linearly with wavelength. This is easy to explain because, due to the paraxial grating equation (2.118), the angle of the diffracted light also increases linearly with the wavelength.

The chromatic aberrations for the different types of achromatic doublets are shown in Fig. 2.46. The chromatic aberrations of a single refractive lens (made of either BK7 or SF10) compared to that of a refractive achromatic doublet (made of BK7 and SF10) are shown in Fig. 2.47. The result is that the best correction of the chromatic aberrations is made by the refractive achromatic doublet. However, the hybrid achromatic doublet made of a BK7 lens and a DOE also has quite small chromatic aberrations. Nevertheless, all types of achromatic doublets (purely refractive or hybrid) have lower chromatic aberrations than a single refractive lens and of course much lower chromatic aberrations than a single DOE, which is not shown in the figures.

Fig. 2.46 The focal length f' of different achromatic doublets (a refractive achromatic doublet made of BK7 and SF10, a hybrid achromatic doublet made of BK7 and a diffractive lens (DOE) and a hybrid achromatic doublet made of SF10 and a DOE) as a function of the wavelength λ normalized by the focal length f_d' at $\lambda_d = 587.6$ nm

Fig. 2.47 The focal length f' of two single lenses (one made of BK7 and the other made of SF10) and a refractive achromatic doublet (made of BK7 and SF10) as a function of the wavelength λ normalized by the focal length f_d' at $\lambda_d = 587.6$ nm

2.6.2 The Camera

One of the simplest optical instruments is the camera [2.1, 8]. Of course, modern cameras are highly sophisticated technical instruments with complex wide-angle or zoom lenses. However, the basic principle of each camera (see Fig. 2.48) is that a lens forms a real inverted picture of an object on a photosensitive surface, which can be a photographic film or an electronic detector such as a charge-coupled device (CCD) chip. Additionally, each camera has a diaphragm near the lens.

The standard camera objective of a miniature camera has a focal length of $f' = 50\,\mathrm{mm}$ so that each object at a distance of several meters can be assumed to be at an infinite distance and the object distance d_O in the lens equation (2.89) can be assumed to be $d_O \to -\infty$. Then, the image is practically formed in the focal plane of the lens, i. e. $d_I \approx f'$. So, the size x of the image of an object is determined by the angular extension φ of the object by

$$x \approx \varphi f' \,. \tag{2.180}$$

The moon has, for example, an angular extension of about half a degree if observed from the earth so that its image on a standard camera would be just $x = 0.44\,\mathrm{mm}$. This is the reason why the moon on a photo made with a miniature camera with a film size of $24\,\mathrm{mm} \times 36\,\mathrm{mm}$ is really small and details cannot be detected. However, this can be changed by using a telescope (Sect. 2.6.4) in front of the camera, which changes the angular extension φ of the object. In astronomical cameras the eyepiece of the telescope is commonly omitted and the detector is positioned directly in the focal plane of the objective lens

or mirror, which has a large focal length f' and which serves as the camera lens. Nevertheless, such a device is still called an astronomical telescope.

The Depth of Field

In geometrical optics an ideal camera lens (without aberrations) images one object plane very sharply onto the photosensitive image plane. But in reality each image point is imperfect for two reasons: firstly, due to the wave nature of light, it is not an ideal mathematical point but an airy disc, and secondly the resolution of the detector is in many cases smaller than the maximum possible resolution given by the wave nature of light. Object points in other planes than the ideal object plane are imaged to planes in front of or behind the detector plane (Fig. 2.49). Therefore, in the detector plane they will form small image discs, and if the diameter of the image discs is smaller than the pixel size p of the detector these other planes will also be imaged without loss of resolution onto the detector, which limits the resolution.

The ideal object plane, which is imaged very sharply onto the detector, has object distance d_O while the detector plane has image distance d_I (where $d_O < 0$ and $d_I > 0$ for a real image in a camera). An object plane that is nearer the camera lens than $|d_O|$ and where the light rays of the object points form small discs in the detector plane with a diameter of exactly p is the nearest object plane which is imaged onto the detector with the maximum resolution, given by the pixel distance p. Its object distance is called $d_{O,N}$ (index "N" for "near") and its image distance is called $d_{I,N}$ (Fig. 2.49). Similarly, that object plane a larger distance than $|d_O|$ from the lens where the rays coming from the object points also form discs in the detector plane with a diameter p is the farthest object plane which is imaged with the maximum resolution given by the detector. It has object

Fig. 2.48 Principle of a camera. The distance from the object to the lens of the camera compared to the focal length of the lens is in the presented case so large that the object can be assumed to be at infinite distance

Fig. 2.49 Calculation of the depth of field for the case of a camera with a thin lens

distance $d_{O,F}$ and corresponding image distance $d_{I,F}$ (the index F indicates "far").

The depth of field is now defined as the axial extension of the object space between the near object plane and the far object plane, which are both just imaged with the maximum resolution of the detector. The depth of field depends of course on the diameter D of the aperture stop and on the resolution of the detector, i.e. the pixel distance p. We assume in the following that we have a thin ideal lens with a focal length f' on the image side and that the aperture stop is directly in the plane of the lens. Then, the aperture stop is also the entrance pupil and the exit pupil. An important quantity is the so called F number, $f\#$, of the lens which is defined as the ratio of the focal length f' of the lens and the diameter D of the entrance pupil

$$f\# = \frac{f'}{D} \ . \tag{2.181}$$

If the image is formed in the focal plane, as is nearly the case for a camera imaging a distant object, and if the diameter D is small compared to the focal length f' the F number and the numerical aperture on the image side defined by (2.136) are connected to a good approximation by:

$$\mathrm{NA_I} = n_I \sin \varphi_I \approx n_I \frac{D}{2f'} = n_I \frac{1}{2f\#} \ . \tag{2.182}$$

Here, φ_I is the half aperture angle of the light cone on the image side and n_I is the refractive index on the image side. In most cases there will be air on the image side, i.e. $n_I = 1$. But for some camera-like systems such as the human eye n_I will be different from 1 (Sect. 2.6.3).

According to the lens equation (2.89), where n_O and n_I are the refractive indices on the object and image side, respectively, we have three equations for the different object and image distances:

$$\frac{n_I}{d_I} - \frac{n_O}{d_O} = \frac{n_I}{f'} \Rightarrow d_I = \frac{n_I f' d_O}{n_O f' + n_I d_O} \ , \tag{2.183}$$

$$\frac{n_I}{d_{I,N}} - \frac{n_O}{d_{O,N}} = \frac{n_I}{f'} \Rightarrow d_{I,N} = \frac{n_I f' d_{O,N}}{n_O f' + n_I d_{O,N}} \ , \tag{2.184}$$

$$\frac{n_I}{d_{I,F}} - \frac{n_O}{d_{O,F}} = \frac{n_I}{f'} \Rightarrow d_{I,F} = \frac{n_I f' d_{O,F}}{n_O f' + n_I d_{O,F}} \ . \tag{2.185}$$

Additionally, according to the theorem on intersecting lines, we have two additional equations (Fig. 2.49):

$$\frac{D}{d_{I,N}} = \frac{p}{d_{I,N} - d_I} \Rightarrow d_{I,N} - d_I = \frac{p}{D} d_{I,N} \ , \tag{2.186}$$

$$\frac{D}{d_{I,F}} = \frac{p}{d_I - d_{I,F}} \Rightarrow d_I - d_{I,F} = \frac{p}{D} d_{I,F} \ . \tag{2.187}$$

By putting (2.183) and (2.184) in (2.186) and solving for $d_{O,N}$ the result is

$$d_{O,N} = \frac{n_O f' d_O}{n_O f' - \frac{p}{D}(n_O f' + n_I d_O)}$$

$$= \frac{d_O}{1 - \frac{p}{D}\left(1 + \frac{n_I d_O}{n_O f'}\right)} \ . \tag{2.188}$$

In the same way by combining (2.183), (2.185) and (2.187) the result for $d_{O,F}$ is

$$d_{O,F} = \frac{n_O f' d_O}{n_O f' + \frac{p}{D}(n_O f' + n_I d_O)}$$

$$= \frac{d_O}{1 + \frac{p}{D}\left(1 + \frac{n_I d_O}{n_O f'}\right)} \ . \tag{2.189}$$

It is common practice in photography to use the lateral magnification β, which was defined by (2.52) as the ratio of the image height x_I and the object height x_O. For a lens which fulfills the sine condition (2.138) the principal planes are in reality principal spheres which are centered around the object and the image point, respectively. The same is valid for the entrance and exit pupil [2.3]. Then, using (2.138), the lateral magnification can be expressed as

$$\beta = \frac{x_I}{x_O} = \frac{n_O \sin \varphi_O}{n_I \sin \varphi_I} = \frac{n_O D/(2d_O)}{n_I D/(2d_I)} = \frac{n_O}{n_I} \frac{d_I}{d_O} \ . \tag{2.190}$$

By multiplying (2.183) with d_O/n_O it holds:

$$\frac{n_I d_O}{n_O d_I} - 1 = \frac{n_I d_O}{n_O f'} \Rightarrow \frac{1}{\beta} = 1 + \frac{n_I d_O}{n_O f'} \ . \tag{2.191}$$

So, (2.188) and (2.189) can be expressed by

$$d_{O,N} = \frac{d_O}{1 - \frac{p}{D\beta}} = \frac{d_O}{1 - \frac{pf\#}{f'\beta}} \ , \tag{2.192}$$

$$d_{O,F} = \frac{d_O}{1 + \frac{p}{D\beta}} = \frac{d_O}{1 + \frac{pf\#}{f'\beta}} \ . \tag{2.193}$$

In the last step, the F number, $f\#$, defined by (2.181) is used.

In the case of a camera the focal length f' is positive and the lateral magnification β is always negative

since a real image is formed, i. e. $\beta < 0$. So, there is the interesting special case that the denominator of (2.193) can be zero:

$$1 + \frac{p}{D\beta} = 0 \Rightarrow \beta = -\frac{p}{D}$$

$$\Rightarrow d_{O,C} = -\frac{n_O f'}{n_I}\left(1 + \frac{D}{p}\right)$$

$$= -\frac{n_O f'}{n_I}\left(1 + \frac{f'}{p f\#}\right). \tag{2.194}$$

On the right-hand side, (2.191) was used and solved for d_O. So, if the camera is focused to the critical object distance $d_{O,C}$ given by (2.194) it holds that $|d_{O,F}| \rightarrow \infty$ and all objects which are farther from the camera lens than $|d_{O,N}| = |d_{O,C}|/2$ (this follows from (2.192)) will be imaged onto the detector with the maximum resolution, i. e. the image will look sharp. Of course, if the modulus $|d_O|$ of the actual object distance is larger than the modulus of the critical value $|d_{O,C}|$ given by (2.194), $d_{O,F}$ will formally be positive. This means that a virtual object behind the lens with distance $d_{O,F}$, which can be produced by some auxiliary optics, can also be imaged sharp onto the detector. In fact, this still means that all real objects farther from the lens than $|d_{O,N}|$ will be imaged sharp onto the detector.

If we have for example a camera with $f' = 50$ mm, a minimum F number $f\# = 2.8$, $n_O = n_I = 1$, and a pixel distance $p = 11\,\mu$m (typical for a CCD chip) the critical object distance $d_{O,C}$ of (2.194) is $d_{O,C} = -81.2$ m. Therefore, all objects at a distance of more than $|d_{O,N}| = |d_{O,C}|/2 = 40.6$ m from the camera will be imaged sharply if the camera is focused to $d_{O,C}$. If the F number is $f\# = 16$ all objects with a distance of more than 7.1 m will be imaged sharp for a focusing distance of $|d_{O,C}| = 14.3$ m. However, for larger F numbers the wave nature of light begins to limit the resolution because the radius r_{diff} of a diffraction limited spot will be $r_{\text{diff}} = 0.61\lambda/\text{NA} \approx 1.22\lambda f\# = 10.7\,\mu$m $\approx p$ for a wavelength $\lambda = 550$ nm and $f\# = 16$.

Of course, a larger F number means that the light intensity on the detector decreases because the light intensity on the detector is proportional to the effective area $\pi D^2/4$ of the light gathering lens and therefore proportional to $1/f\#^2 = D^2/f'^2$. So, a larger F number means that the exposure time has to be increased proportional to $f\#^2$. All these facts are well-known from photography.

If $d_{O,F}$ has a finite value, e.g. if the camera is focused on a near object, it is useful to calculate the axial extension $\Delta d = d_{O,N} - d_{O,F}$ of the sharply imaged object

space. By using (2.192) and (2.193) the result is

$$\Delta d = d_{O,N} - d_{O,F} = 2d_O \frac{\frac{p f\#}{f'\beta}}{1 - \left(\frac{p f\#}{f'\beta}\right)^2}$$

$$= 2\frac{n_O}{n_I} p f\# \frac{\left(\frac{1}{\beta} - 1\right)\frac{1}{\beta}}{1 - \left(\frac{p f\#}{f'\beta}\right)^2}. \tag{2.195}$$

In the last step (2.191) has been used to express the object distance d_O by the lateral magnification β because these two quantities are of course coupled to each other.

Again, we see in (2.195) the limiting case that the denominator can approach zero [if (2.194) is fulfilled] and that therefore the depth of field has an infinite range. But, for near objects (for example $|d_O| \le 1$ m) we normally have the case that $f'|\beta| \gg p f\#$. Then, Δd has first of all a finite positive value and second there is a quite good approximation which is often used for the photography of near objects [2.8]

$$\Delta d = 2\frac{n_O}{n_I} p f\# \frac{\left(\frac{1}{\beta} - 1\right)\frac{1}{\beta}}{1 - \left(\frac{p f\#}{f'\beta}\right)^2}$$

$$\approx 2\frac{n_O}{n_I} p f\# \left(\frac{1}{\beta} - 1\right)\frac{1}{\beta} = 2\frac{n_O}{n_I} p f\# \frac{1-\beta}{\beta^2}. \tag{2.196}$$

As an example we take again a common electronic camera with $f' = 50$ mm, $p = 11\,\mu$m and $n_O = n_I = 1$. The F number is assumed to be $f\# = 10$ and the object is at $d_O = -1$ m. Then, the lateral magnification is, according to (2.191), $\beta = -0.05263$. The extension of the depth of field Δd is according to the exact (2.195) $\Delta d = 83.75$ mm and according to the approximate (2.196) $\Delta d = 83.60$ mm. So, the error of the approximate equation is about 0.2% and the depth of field has an extension of about 8.4 cm, i. e. objects with an axial extension in this range (for a medium object distance $|d_O| = 1$ m) will be imaged without loss of resolution onto the detector.

2.6.3 The Human Eye

The human eye is based on the principle of a camera that builds an inverted real image of the surroundings on the retina [2.1, 8]. However, the actual structure and performance of the human eye is quite complex [2.46–48] so that only the most important features of the normal emmetropic eye can be discussed in this section.

The optical power of the eye is delivered by the cornea and the deformable crystalline lens (Fig. 2.50). The main part of the optical power is delivered by the cornea with about 43 diopters because at the first surface the difference between the refractive indices of air and the cornea (1.376) is quite high. The crystalline lens, with a refractive index between 1.386 in the outer parts and 1.406 in the core, is immersed on one side in the aqueous humour and on the other side in the vitreous body, both of which have a refractive index of 1.336. Therefore, the lens has about 19 diopters in the case of distant vision. The resulting total optical power of the eye is, due to the finite distance between the cornea and the crystalline lens, about 59 diopters for distant vision. The accommodation of the eye for near objects, which is performed by the crystalline lens, can vary between about 14 diopters in young age and nearly 0 diopters above 50 years of age because the crystalline lens loses its flexibility with increasing age. Since the normal distance for reading is about 25–30 cm an accommodation of less than 3–4 diopters has to be corrected by wearing eyeglasses for reading.

The photosensitive surface of the eye is the curved retina and the diaphragm of the eye is the iris, which can change its diameter between about 2 mm and 8 mm to control the irradiance on the retina depending on the intensity of the illuminating light. The effective focal length of the eye, which, as mentioned above, is an immersion system, is $f'/n' \approx 1/(59 \text{ diopters}) \approx 17$ mm ($n' = 1.336$ is the refractive index of the vitreous body between the eye lens and the retina). The so-called least distance of distinct vision of a normal adult eye is about 25 cm, which requires an accommodation of 4 diopters.

The angular resolution $\Delta\varphi$ of a normal eye is about 1' (one arc min) and, under optimal conditions, it can achieve 30". The later corresponds to a distance of $\Delta x = \Delta\varphi f'/n' = 2.5$ µm on the retina. So, the light-sensitive cells (cones) in the fovea (about 200 µm in diameter), which is the central part of the retina, have to be about 2.5 µm or less in diameter and distance. In the fovea there are mainly color-sensitive cones whereas in the outer parts the rods, which are more sensitive to light but which cannot distinct between different colors, dominate.

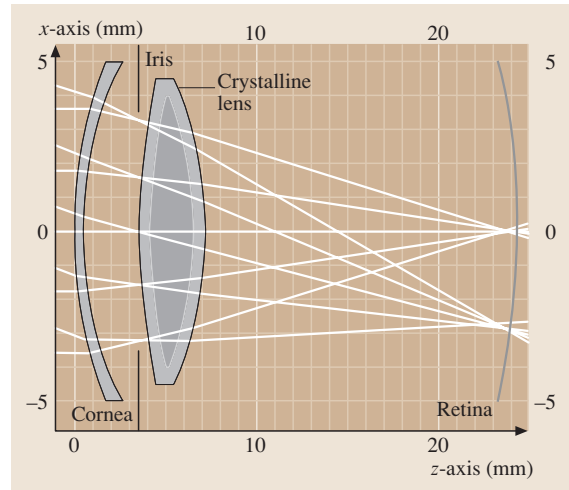
It is interesting to note that a human eye with normal vision is a nearly diffraction-limited optical system for a diameter of the pupil of up to 3 mm (the diameter for sharpest vision). This can be seen because in this case the radius r of the airy disc which limits the resolution according to the Rayleigh criterion (see Sect. 3.4.2) is about $r = 0.61\lambda/\text{NA} = 3.8$ µm for a wavelength of $\lambda = 0.55$ µm and a numerical aperture


Fig. 2.50 Ray tracing of an eye model as used in ophthalmology. Here, the crystalline lens consists of a nucleus with higher refractive index (1.406) and a cortex with lower refractive index (1.386). The first surface of the cornea and all surfaces of the crystalline lens are aspheric surfaces. It can be seen that the foci show aberrations for this large pupil (iris) diameter. The drawn off-axis point with quite high aberrations is of course far out of the fovea so that it is only used in the eye to detect motions and not to image an object

NA ≈ 1.5 mm/17 mm ≈ 0.088. So, the aforementioned value $\Delta x = 2.5$ µm for the smallest resolvable distance on the retina is even slightly smaller than the distance r given by the Rayleigh criterion due to diffraction, which assumes that a drop of 26 percent in irradiance can be detected. The reason is that the Rayleigh criterion is slightly arbitrary and, under optimal conditions, the eye can also detect smaller drops in irradiance between two adjacent points. For larger diameters of the pupil than 3–4 mm spherical aberration and chromatic aberrations of the eye reduce the resolution. Therefore, at night or in badly illuminated rooms the resolution of the eye is reduced and all tasks which need a high resolution, for example reading, are more difficult or impossible if the irradiance on the retina is too low even for the largest pupil diameter.

2.6.4 The Telescope

One of the most important optical instruments is the telescope [2.1, 3, 8]. It has well-known applications in terrestrial and astronomical observations [2.21]. But there are at least as important applications in optics to

expand or compress a collimated (laser) beam, to filter spatial frequencies in an optical system, to transport an intermediate optical image to another plane, and so on.

A telescope consists in principle of two lenses or two other focusing optical elements such as spherical or aspheric mirrors. Here, to demonstrate the principle we assume that it consists of two lenses with focal lengths f'_1 and f'_2 and a distance d between the two lenses. In order to have a telescope the image-sided focus F'_1 of the first lens and the object-sided focus F_2 of the second lens have to coincide (Fig. 2.51). Additionally, we assume that the two lenses are situated in air, so that we have $f'_2 = -f_2$ for the image-and object-sided focal length. So, by taking into account the sign conventions for the focal lengths the condition for the distance between the two lenses of a telescope is

$$d = f'_1 - f_2 = f'_1 + f'_2 . \tag{2.197}$$

The paraxial matrix M of the telescope from the object-sided principal plane $\mathcal{U}_1$ of the first lens to the image-sided principal plane $\mathcal{U}'_2$ of the second lens is

$$M = \begin{pmatrix} 1 & 0 \\ -\frac{1}{f'_2} & 1 \end{pmatrix} \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\frac{1}{f'_1} & 1 \end{pmatrix}$$

$$= \begin{pmatrix} 1 - \frac{d}{f'_1} & d \\ -\frac{1}{f'_1} - \frac{1}{f'_2} + \frac{d}{f'_1 f'_2} & 1 - \frac{d}{f'_2} \end{pmatrix}$$

$$= \begin{pmatrix} -\frac{f'_2}{f'_1} & f'_1 + f'_2 \\ 0 & -\frac{f'_1}{f'_2} \end{pmatrix} . \tag{2.198}$$

So, the coefficient C of the ABCD-matrix M, which is according to (2.68) the negative value of the optical power, is zero and therefore the focal length of the telescope is infinity. Such a system with zero optical power is called an afocal system. So, a telescope can also be defined to be an afocal optical system where the trivial case that all lenses themselves have zero optical power, i.e. $1/f'_1 = 1/f'_2 = 0$, is excluded.

Telescope as a Beam Expander and Imaging System for Far–Distant Objects

An important property of an afocal system is that it transforms a collimated bundle of rays into another collimated bundle of rays. The application as a beam expander for a collimated beam or as an imaging system for far-distant objects can easily be seen from (2.198) by taking two parallel rays with paraxial ray parameters (x_1, φ_1) and (x_2, φ_2) $(\varphi_2 = \varphi_1)$ in front of the telescope. The paraxial ray parameters (x'_1, φ'_1) and (x'_2, φ'_2) of the
Fig. 2.51a,b Principle set ups of an astronomical telescope (**a**) and a Galilean telescope (**b**)

rays behind the telescope are then:

$$\begin{pmatrix} x'_i \\ \varphi'_i \end{pmatrix} = \begin{pmatrix} -\frac{f'_2}{f'_1} & f'_1 + f'_2 \\ 0 & -\frac{f'_1}{f'_2} \end{pmatrix} \begin{pmatrix} x_i \\ \varphi_i \end{pmatrix}$$

$$= \begin{pmatrix} -\frac{f'_2}{f'_1} x_i + (f'_1 + f'_2)\varphi_i \\ -\frac{f'_1}{f'_2} \varphi_i \end{pmatrix} \tag{2.199}$$

with $i \in \{1, 2\}$.

The angular magnification γ, defined by equation (2.53), i.e. the ratio of the angle $\varphi' := \varphi'_1 = \varphi'_2$ between the bundle of rays and the optical axis behind the afocal system to the angle $\varphi_i := \varphi_1 = \varphi_2$ in front of the system, in the paraxial case is

$$\gamma = \frac{\varphi'}{\varphi} = -\frac{f'_1}{f'_2} . \tag{2.200}$$

So, the angular magnification, which determines the size of the image of a far-distant object, only depends on the ratio of the focal lengths of the two lenses.

The beam-expanding property can be seen by calculating the distance Δx between two parallel rays ($\varphi_2 = \varphi_1$) in front of the telescope and the distance $\Delta x'$ behind the telescope:

$$\Delta x' = x'_2 - x'_1 = -\frac{f'_2}{f'_1}(x_2 - x_1) = -\frac{f'_2}{f'_1} \Delta x \tag{2.201}$$

So, the beam expanding ratio $\Delta x'/\Delta x$ is the reciprocal of the angular magnification.

Imaging Property of a Telescope for Finite Distant Objects

Although a telescope has zero optical power it images an object from one plane to another plane. This can be seen by calculating the paraxial matrix M' from an object plane with a distance d_1 to the principal plane $\mathcal{U}_1$ of the first lens (keep in mind that, contrary to the normal sign conventions of paraxial optics, in the paraxial matrix theory d_1 is positive if the object plane is in front of $\mathcal{U}_1$ and negative if it is behind $\mathcal{U}_1$) to an image plane at a distance d_2 behind the principal plane $\mathcal{U}_2'$ of the second lens (d_2 is positive if the image plane is real and behind $\mathcal{U}_2'$ and negative if it is a virtual image plane in front of $\mathcal{U}_2'$). Figure 2.52 shows the parameters to calculate M':

$$M' = \begin{pmatrix} 1 & d_2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} -\frac{f_2'}{f_1'} & f_1' + f_2' \\ 0 & -\frac{f_1'}{f_2'} \end{pmatrix} \begin{pmatrix} 1 & d_1 \\ 0 & 1 \end{pmatrix}$$

$$= \begin{pmatrix} -\frac{f_2'}{f_1'} & f_1' + f_2' - d_1\frac{f_2'}{f_1'} - d_2\frac{f_1'}{f_2'} \\ 0 & -\frac{f_1'}{f_2'} \end{pmatrix} . \quad (2.202)$$

In the case of imaging, the parameter B of the matrix has to be zero. So, the condition for the distances d_1 and d_2 is

$$f_1' + f_2' - d_1\frac{f_2'}{f_1'} - d_2\frac{f_1'}{f_2'} = 0 ,$$

$$\Rightarrow d_2 = f_2' + \frac{(f_2')^2}{f_1'} - d_1\frac{(f_2')^2}{(f_1')^2} . \quad (2.203)$$

As mentioned before, the image is real if d_2 is positive and it is virtual for a negative value d_2. So, a real image

Fig. 2.52 Parameters to calculate the paraxial matrix M' for imaging of an object point to an image point with the help of a telescope

of a real object point (i. e. $d_1 \geq 0$) means

$$d_2 \geq 0 \Rightarrow f_1' + \frac{f_1'^2}{f_2'} \geq d_1 \geq 0 \Rightarrow \frac{1}{f_1'} + \frac{1}{f_2'} \geq 0 . \quad (2.204)$$

It can easily be seen that the Galilean telescope (see next paragraph) cannot deliver a real image of a real object point whereas the astronomical telescope delivers real images as long as $0 \leq d_1 \leq f_1' + f_1'^2/f_2'$.

A quite interesting property of a telescopic imaging system is the lateral magnification β [see (2.52)]. It is, according to equation (2.202) for the imaging case, i. e. matrix element $B = 0$, equal to the matrix element A:

$$\beta = \frac{x'}{x} = -\frac{f_2'}{f_1'} . \quad (2.205)$$

So, the lateral magnification of the telescopic system depends only on the focal lengths of the two lenses and is independent of the axial position of the object point. If we additionally place the aperture stop into the focal plane of the first lens (only for the astronomical telescope) the telescopic imaging system is telecentric (see also page 60).

A very important system is the so-called $4f$-system with $f := f_1' = f_2' > 0$. Then we have, with the help of (2.203),

$$d_2 = f + f - d_1 \quad \Rightarrow \quad d_1 + d_2 = 2f . \quad (2.206)$$

This means that the sum of the two distances d_1 and d_2 is always $2f$ and in total the distance from the object plane to the image plane is $4f$ (in the case of thin lenses where the thickness of the lenses can be neglected compared to $4f$) because the length of the telescope has to be added. This also means that, for a $4f$-system, the shift of the image plane is equal to the shift of the object plane and, therefore, the telescope itself can, for example, be shifted relative to the object and image plane without changing the imaging situation. Of course, in the non-paraxial realm aberrations will change the imaging quality if the telescope of a $4f$-system is moved because the aberrations depend on the actual position of the telescope relative to the object and image plane.

The Astronomical and the Galilean Telescope

There are two different types of telescopes (Fig. 2.51). The astronomical telescope (also called a Kepler telescope) and the Galilean telescope (also called a Dutch telescope).
Astronomical Telescope. The astronomical telescope (Fig. 2.51a or Fig. 2.53) consists of two positive lenses so that the first lens (called the objective) forms a real image of a far-distant object near the focal plane (or exactly in the focal plane for an object with infinite distance). Then, the second lens (called the eyepiece) also forms an infinite-distant image but with an increased or decreased angular magnification. Since the focal lengths f_1' and f_2' are both positive the angular magnification γ is, according to (2.200), $\gamma = -f_1'/f_2' < 0$. Therefore, the image is upside down so that an astronomical telescope without additional optics to reverse the image is not practical for terrestrial inspections. However, for astronomical purposes or for image transfers in optical systems this is no disadvantage. Additionally, the advantage of the astronomical telescope is that the entrance pupil coincides with the objective in the case of imaging infinite-distant objects. This means that the exit pupil, which is the image of the objective formed by the eyepiece, is typically near the focal plane of the eyepiece if $f_1' \gg f_2'$, which is necessary to obtain an image with angular magnification $|\gamma| \gg 1$. Therefore, the pupil of the eye can be positioned at the exit pupil of the telescope and all light rays with the same off-axis angle (i. e. from the same infinite-distant object point) entering the telescope contribute to the image on the retina of the eye. Another advantage of the astronomical telescope is, as mentioned previously, that it can deliver a telecentric real image of objects with a finite distance.

It is quite interesting to think a little bit more about the position of the aperture stop and the field stop for the two cases of imaging infinite-distant objects or finite-distant objects (Fig. 2.53). As mentioned, the aperture stop for the imaging of infinite-distant objects (Fig. 2.53a) is the aperture of the first lens. The field stop lies in this case in the back focal plane of the first lens. For the case of imaging of finite-distant objects (Fig. 2.53b) the situation is different and it is useful to put the aperture stop in the back focal plane of the first lens to have a well-defined numerical aperture for all object points which are not too far away from the optical axis. Then, the aperture of the first lens can act as the field stop. Of course, in this case the field stop has no sharp rim because parts of the light cone of points with a similar distance from the optical axis than the radius of the first lens can pass the system if the aperture stop is large enough. In this case a kind of vignetting occurs. So, an additional stop directly in the object or image plane serving as a field stop would be desirable.
Fig. 2.53a,b The aperture stop and the field stop for the imaging of (**a**) infinite-distant objects or (**b**) finite-distant objects (here shown for the case that the object plane is in the front focal plane of the first lens) with the help of an astronomical telescope

For astronomical observations most modern telescopes use mirrors as focusing elements instead of lenses [2.21]. There are telescopes with a primary mirror with a diameter of $D = 8$ m. From wave optics it is well known that two (infinite-distant) object points can just be resolved by an aberration-free telescope with a diameter D of the primary mirror and a wavelength λ of the observed light if their angular separation is larger or equal to $\Delta\varphi$ with

$$\Delta\varphi = k\frac{\lambda}{D}, \tag{2.207}$$

where k is a constant of approximately $k = 1$ (for a full circular aperture it is $k = 1.22$). The exact value of k depends on the actual design of the instrument because a reflective telescope has in many cases an annular or more complicated aperture because the secondary mirror and the mounting shadow the central and other parts of the primary mirror. So, a telescope with a large-diameter primary mirror has of course an increased light-gathering power and an increased angular resolution.

Galilean Telescope. The Galilean telescope (Fig. 2.51b) consists of a positive lens (the objective) with the focal length $f_1' > 0$ and a negative lens (the eyepiece) with focal length $f_2' < 0$ or $f_2 = -f_2' > 0$ and $|f_2'| < |f_1'|$. Of course, the telescope can also be rotated by 180° so that it reduces the angular magnification. But, in the following we assume that $f_1' > 0$ and $f_2' < 0$. The total length of the Galilean telescope is only $|f_1'| - |f_2'|$ (for thin lenses) compared to $|f_1'| + |f_2'|$ for the astronomical telescope (we use here the absolute values of the focal lengths although f_1' is always positive and only f_2' has a different sign for an astronomical and a Galilean telescope). Another advantage of the Galilean telescope is that the angular magnification γ is, according to (2.200) positive, $\gamma = -f_1'/f_2' > 0$. Therefore, the image is upright and can be directly used for terrestrial inspections. However, a disadvantage of the Galilean telescope is that the image of the objective made by the second lens is between the two lenses. Therefore, the exit pupil of the Galilean telescope is not accessible for the eye and the pupil of the eye works itself as the aperture stop of the complete system whereas the diameter of the objective limits the field. So, Galilean telescopes have a limited field of view and only small magnifications of two to five are useful. Another disadvantage is that the Galilean telescope cannot deliver a real image of a real object. So, a Galilean telescope cannot be used to transport a real intermediate image to another plane in an optical system.

However, the compact overall length and the positive angular magnification provide applications for a Galilean telescope as a beam expander or terrestrial telescope like a lorgnette.

2.6.5 The Microscope

The last important optical instrument that will be discussed here is the microscope [2.1, 3, 8]. Whereas, the telescope, especially an astronomical telescope, is used to achieve an angular magnification of distant objects, a microscope is used to obtain a magnified image of a very small near object.

The Magnifier
If somebody wants to see details of a small object he brings the object as close to the eye as possible since then the image of the object on the retina of the eye is as large as possible. However, a typical human eye can only form a sharp image of an object at a smallest distance of about $d_S = 25$ cm, which is the standard distance for distinct vision. So, it is obvious that a positive lens, called a magnifier, directly in front of the eye can be used

to obtain at the distance $|d_I| = d_S$ a magnified virtual image of an object that has itself a smaller separation $|d_O|$ from the eye than the standard distance d_S. The image at a distance d_I from the image-sided principal plane of the lens with focal length f' has to fulfill the imaging equation (2.89) whereby the refractive index on the image side has to be $n' = 1$ because the human eye is normally used in air and only in this case delivers a sharp image. Then, the imaging equation is

$$\frac{1}{d_I} - \frac{n}{d_O} = \frac{1}{f'} . \tag{2.208}$$

Here, n is the refractive index on the object side, which is often 1 (object in air) but sometimes also larger than 1 if the object is in immersion (for example in water or oil). Due to the sign conventions of geometrical optics d_O is negative since the object is in front of the lens. The image distance d_I is also negative for a virtual image. Then, the lateral magnification β of the image is, according to (2.52), (2.208) and Fig. 2.54,

$$\beta = \frac{x_I}{x_O} = \frac{\varphi_I d_I}{\varphi_O d_O} = n \frac{d_I}{d_O} = 1 - \frac{d_I}{f'} = 1 + \frac{d_S}{f'} . \tag{2.209}$$

Here, we use that, in the paraxial case, the angles φ_I and φ_O have to fulfill the condition $n'\varphi_I = n\varphi_O$, where $n' = 1$ is valid in our case. Additionally, it is used that the virtual image is at the standard distance for distinct

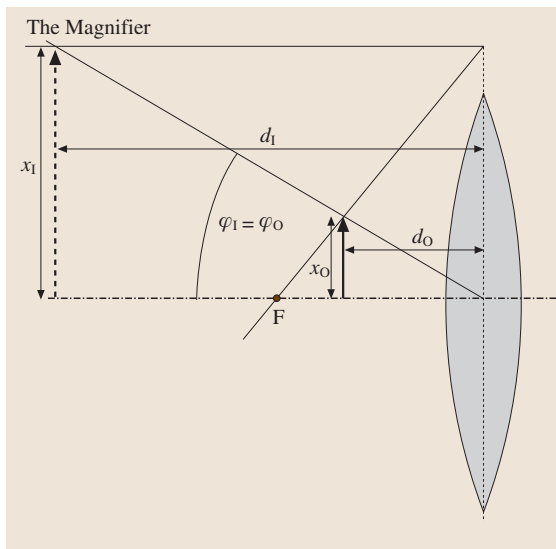

Fig. 2.54 The principle of a magnifier. A thin lens is used and it is assumed that the refractive indices in the object and image space are both equal so that $\varphi_I = \varphi_O$

vision so that the image distance d_I, which is negative, is replaced by $-d_S$, where d_S is the absolute value of the standard distance for distinct vision.

If the lens has, for example, a focal length of $f' = 5$ cm a lateral magnification of $\beta = 1 + 25/5 = 6$ is obtained. In order to have a large field of view without aberrations and especially without chromatic aberrations the magnifier itself is in practice not a single lens but an achromatic combination of different single lenses.

The Two–Stage Microscope

There is of course a limitation to the lateral magnification achievable by using a magnifier because the object has to be very close to the magnifier and therefore also to the eye to achieve large lateral magnifications. Therefore, microscopes have been invented that make a magnification of the object in two stages (Fig. 2.55). First, a magnified real image of the object with magnification $\beta_{\text{objective}}$ is formed by using a lens with a small focal length, called the objective. This real image is of course inverted. Then, a magnifier, called the eyepiece, with a (mostly) larger focal length is used to form a magnified virtual image of the intermediate real image, where the virtual image is at the standard distance of distinct vision of the eye. The lateral magnification for this second operation is β_{eyepiece}. This means, that the lateral magnifications of both operations are multiplied and the total lateral magnification of the microscope $\beta_{\text{microscope}}$ is

$$\beta_{\text{microscope}} = \beta_{\text{objective}}\beta_{\text{eyepiece}} \ . \tag{2.210}$$

In practice, the objective of a microscope is a quite complex lens consisting of many single lenses to correct the aberrations (especially spherical aberration, coma and chromatic aberrations) of the objective and to guarantee a large field of view [2.8]. Moreover, modern microscope objectives are corrected for infinity. This means that their aberrations are only corrected if the object is exactly in the object-sided focal plane. Therefore, the image would be at infinite distance and an additional lens (called the tubus lens) with a fixed focal length (the so-called tubus length, which is often 160 mm) must be used to get the real image with the magnification imprinted on the objective. For biological investigations, where the object is often covered by a thin coverslip, the spherical aberrations, which result from a high-NA spherical wave passing through a plane-parallel plate, also have to be corrected.

Another very important parameter of the objective is its numerical aperture NA (2.135). It determines on the one hand the light-gathering power of the objective and
Fig. 2.55 The principle of a microscope illustrated by using thin lenses. The objective forms a real magnified intermediate image of the object, which is then transformed by the eyepiece into a virtual further-magnified image. The distance of this virtual image from the eyepiece and the eye, which is directly behind the eyepiece, has to be the standard distance of distinct vision

on the other the resolution which is possible. From wave optics we know that the smallest distance Δx between two points which can be resolved by a microscope is

$$\Delta x = k \frac{\lambda}{\text{NA}} \ , \tag{2.211}$$

where λ is the wavelength of the used light and k is a constant (typically about 0.5) that depends on the illumination conditions (coherence) and the exact aperture shape of the objective (mostly circular).

If the image of a microscope has to be on a camera chip (for example a CCD chip) a real image has to be made on the camera chip. Therefore, the eyepiece, which produces a virtual image, cannot be used and indeed it is sufficient just to bring the CCD chip to the position of the real image of the objective (plus the tubus lens). A typical magnification of a high-NA objective in air with, for example, $|\beta| = 50$ is sufficient if a CCD chip with a typical pixel size of 11 μm is used. This would mean that a structure size of 0.22 μm on the object is magnified to the size of a pixel of the CCD chip. However, due to (2.211), 0.22 μm is approximately the resolution of an objective with NA < 1 and a wavelength in the visible spectral range. By bringing an immersion oil between the object and the objective, which has to be a special immersion objective, the NA can be increased up to about 1.4. So, the resolution can be increased accordingly. Another possibility is of course to reduce the wavelength. Modern microscopes for the inspection of integrated circuits use ultraviolet light with a wavelength of 248 nm.

Wave Optics

3. Wave Optics

The quest to understand the nature of light is centuries old and today there can be at least three answers to the single question of what light is depending on the experiment used to investigate light's nature: (i) light consists of rays that propagate, e.g., rectilinear in homogeneous media, (ii) light is an electromagnetic wave, (iii) light consists of small portions of energy, or so-called photons. The first property will be treated in the chapter about geometrical optics, which can be interpreted as a special case of wave optics for very small wavelengths. On the other hand, the interpretation as photons is unexplainable with wave optics and, above all, contradictory to wave optics. Only the theory of quantum mechanics and quantum field theory can simultaneously explain light as photons and electromagnetic waves. The field of optics treating this subject is generally called quantum optics.

In this chapter about wave optics the electromagnetic property of light is treated and the basic equations describing all relevant electromagnetic phenomena are Maxwell's equations. Starting with the Maxwell equations, the wave equation and the Helmholtz equation will be derived. Here, we will try to make a tradeoff between theoretical exactness and a practical approach. For an exact analysis see, e.g., [3.1]. After this, some basic properties of light waves like polarization, interference, and diffraction will be described. The propagation of coherent scalar waves is especially important in optics. Therefore, the section about diffraction will treat several propagation methods like the method of the angular spectrum of plane waves, which can be easily implemented on a computer, or the well-known diffraction integrals of Fresnel–Kirchhoff as well as Fresnel and Fraunhofer. In modern physics and engineering, lasers are very important and therefore the propagation of a coherent laser beam is of special interest. A good approximation for a laser beam is a Hermite–Gaussian mode and the propagation of a fundamental Gaussian beam

can be performed very easily if some approximations of paraxial optics are valid. The formulae for this are treated in the last section of this chapter.

Part A | 3

3.1 Maxwell's Equations and the Wave Equation

3.1.1 The Maxwell Equations

The well known *Maxwell* equations regarding electrodynamics [3.1] are the basis for our considerations and will be presented here in international SI units. The following physical quantities are used:

- E: electric (field) vector, unit $[E] = 1\,\text{V/m}$
- D: electric displacement, unit $[D] = 1\,\text{A s/m}^2$
- H: magnetic (field) vector, unit $[H] = 1\,\text{A/m}$
- B: magnetic induction, unit $[B] = 1\,\text{V s/m}^2 = 1\,\text{T}$
- j: electric current density, unit $[j] = 1\,\text{A/m}^2$
- ρ: electric charge density, unit $[\rho] = 1\,\text{A s/m}^3$

All quantities can be functions of the spatial coordinates with position vector $r = (x, y, z)$ and time t. In the following, this explicit functionality is mostly omitted in the equations if it is clear from the context.

The Maxwell equations are formulated in differential form by using the so-called nabla operator

$$\nabla := \begin{pmatrix} \dfrac{\partial}{\partial x} \\[2mm] \dfrac{\partial}{\partial y} \\[2mm] \dfrac{\partial}{\partial z} \end{pmatrix} . \tag{3.1}$$

The four Maxwell equations and the physical interpretation are

$$\nabla \times E\,(r, t) = -\frac{\partial B\,(r, t)}{\partial t} . \tag{3.2}$$

The vortices of the electric field E are caused by temporal variations of the magnetic induction B.

$$\nabla \times H\,(r, t) = \frac{\partial D\,(r, t)}{\partial t} + j\,(r, t) . \tag{3.3}$$

The vortices of the magnetic field H are either caused by an electric current with density j or by temporal variations of the electric displacement D. The quantity $\partial D/\partial t$ is called the electric displacement current.

$$\nabla \cdot D\,(r, t) = \rho\,(r, t) \tag{3.4}$$

The sources of the electric displacement D are the electric charges with density ρ.

$$\nabla \cdot B\,(r, t) = 0 \tag{3.5}$$

The magnetic field (induction) is solenoidal, i. e., there exist no "magnetic charges".

The Continuity Equation

From (3.3) and (3.4) the conservation of the electric charge can be obtained by using the mathematical identity $\nabla \cdot (\nabla \times H) = 0$,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot j = 0 . \tag{3.6}$$

This equation is called the continuity equation of electrodynamics because it is analogous to the continuity equation of hydrodynamics. By integrating over a volume V with a closed surface A and applying Gauss' theorem the following equation is obtained:

$$\int_V \frac{\partial \rho}{\partial t}\,\mathrm{d}V = -\int_V \nabla \cdot j\,\mathrm{d}V = -\oint_A j \cdot \mathrm{d}A . \tag{3.7}$$

Note that the integral $\int_V f\,\mathrm{d}V$ always indicates a volume integral of a scalar function f over the volume V, whereas the symbol $\oint_A a \cdot \mathrm{d}A$ always indicates a surface integral of the vector function a over the closed surface A, which borders the volume V. The vector $\mathrm{d}A$ always points outwards from the closed surface.

Therefore, the left side of (3.7) is the temporal variation of the total electric charge Q in the volume V and the right-hand side of (3.7) is the net electric current I_{net} (i. e., the current of positive charges flowing out of the surface plus the current of negative charges flowing in the surface minus the current of positive charges flowing in the surface minus the current of negative charges flowing out of the surface), which flows through the closed surface A

$$\frac{\partial Q}{\partial t} = -I_{\text{net}} . \tag{3.8}$$

If the net current I_{net} is positive the total charge in the volume decreases during time, i.e., it becomes "more negative."

Energy Conservation in Electrodynamics

From (3.2) and (3.3) a law of energy conservation of electrodynamics can be deduced by calculating the scalar product of E with (3.3) minus the scalar product of H with (3.2):

$$E \cdot (\nabla \times H) - H \cdot (\nabla \times E)$$
$$= E \cdot \frac{\partial D}{\partial t} + E \cdot j + H \cdot \frac{\partial B}{\partial t} \,.$$

According to the rules of calculating using a nabla operator, the following equation is obtained:

$$\nabla \cdot S = \nabla \cdot (E \times H)$$
$$= -[E \cdot (\nabla \times H) - H \cdot (\nabla \times E)] \,.$$

The quantity S

$$S = E \times H \tag{3.9}$$

is called the Poynting vector and has the physical unit of an intensity: $[S] = 1\,\mathrm{V\,A/m^2} = 1\,\mathrm{W/m^2}$, i.e., power per surface area. The Poynting vector arises due to the property of a cross product of two vectors perpendicular to both the electric and magnetic vector. Its absolute value describes the flow of energy per unit area and unit time through a surface perpendicular to the Poynting vector. It therefore describes the energy transport of the electromagnetic field.

The sources of S are connected with temporal variations of the electric displacement, or of the magnetic induction, or with explicit electric currents.

$$\nabla \cdot S = -\left(E \cdot \frac{\partial D}{\partial t} + E \cdot j + H \cdot \frac{\partial B}{\partial t} \right) \,. \tag{3.10}$$

In the next section it will be shown for the special case of an isotropic dielectric material that this equation can be interpreted as an equation of energy conservation.

Energy Conservation in the Special Case of Isotropic Dielectric Materials

In Sect. 3.1.3 we will see that isotropic dielectric materials are described with the following equations. The charge density and the electric currents are both zero

$$\rho = 0, \quad j = 0 \,. \tag{3.11}$$

Additionally, there are the following linear interrelations between the electric and magnetic quantities

$$D(r, t) = \varepsilon_0 \varepsilon(r) E(r, t) \,,$$
$$B(r, t) = \mu_0 \mu(r) H(r, t) \,, \tag{3.12}$$

where ε is the dielectric function of the material and μ the magnetic permeability. Both are functions of the position r. The dielectric constant of the vacuum $\varepsilon_0 = 8.8542 \times 10^{-12}\,\mathrm{A\,s\,V^{-1}\,m^{-1}}$ and the magnetic permeability of the vacuum $\mu_0 = 4\pi \times 10^{-7}\,\mathrm{V\,s\,A^{-1}\,m^{-1}}$ are related to the speed of light in a vacuum c by:

$$c = \frac{1}{\sqrt{\varepsilon_0 \mu_0}} \tag{3.13}$$

with $c = 2.99792458 \times 10^8\,\mathrm{m/s}$. In fact, the light speed in a vacuum is defined in the SI system as a fundamental constant of nature to exactly this value so that the basic unit of length (1 m) can be connected with the basic unit of time (1 s). The magnetic permeability of the vacuum is also defined in order to connect the basic SI unit of the electric current (1 A) with the mechanical basic SI units of mass (1 kg), length (1 m) and time (1 s). So, only the dielectric constant of the vacuum has to be determined by experiment, whereas c and μ_0 are defined constants in the SI system.

In dielectrics, by using (3.11) and (3.12), (3.10) is reduced to the following equation

$$\nabla \cdot S = -\left(\varepsilon_0 \varepsilon E \cdot \frac{\partial E}{\partial t} + \mu_0 \mu H \cdot \frac{\partial H}{\partial t} \right)$$
$$= -\frac{1}{2} \frac{\partial}{\partial t} (\varepsilon_0 \varepsilon E \cdot E + \mu_0 \mu H \cdot H) \,. \tag{3.14}$$

By integrating both sides of (3.14) over a volume V, which is bounded by a closed surface A (see Fig. 3.1),

Fig. 3.1 Illustration of the quantities used for applying Gauss' theorem. The surface A need not be the surface of a sphere with volume V, but can be an arbitrary closed surface. The *small dotted* vector symbolizes the infinitesimal surface vector $\mathrm{d}A$, whereas the other vectors represent the vector field of the local Poynting vectors S at a fixed time

Gauss' theorem can be applied:

$$P_{\text{net}} := \oint_A \mathbf{S} \cdot \mathrm{d}\mathbf{A} = \int_V \nabla \cdot \mathbf{S} \, \mathrm{d}V$$

$$= \int_V \left[-\frac{1}{2} \frac{\partial}{\partial t} \left(\varepsilon_0 \varepsilon \mathbf{E} \cdot \mathbf{E} + \mu_0 \mu \mathbf{H} \cdot \mathbf{H} \right) \right] \mathrm{d}V$$

$$= -\frac{\partial}{\partial t} \int_V \left(\frac{1}{2} \varepsilon_0 \varepsilon \mathbf{E} \cdot \mathbf{E} + \frac{1}{2} \mu_0 \mu \mathbf{H} \cdot \mathbf{H} \right) \mathrm{d}V$$

$$= -\frac{\partial}{\partial t} \int_V w \, \mathrm{d}V \,. \tag{3.15}$$

The integral $\int_V \nabla \cdot \mathbf{S} \, \mathrm{d}V$ symbolizes the volume integral of $\nabla \cdot \mathbf{S}$ over the volume V, whereas the integral $\oint_A \mathbf{S} \cdot \mathrm{d}\mathbf{A}$ symbolizes the surface integral of the Poynting vector over the closed surface A. The vector $\mathrm{d}\mathbf{A}$ in the integral always points outwards in the case of a closed surface. Therefore, P_{net} is equal to the net amount of the electromagnetic power (difference between the power flowing out of the closed surface and the power flowing in the closed surface), which flows through the closed surface. So, a positive value of P_{net} indicates that more energy flows out of the surface than into the system. Since the right-hand side of (3.15) must therefore also have the physical unit of power (unit $1\,\mathrm{W} = 1\,\mathrm{J/s}$), it is clear that the quantity

$$w := \frac{1}{2} \left(\varepsilon_0 \varepsilon \mathbf{E} \cdot \mathbf{E} + \mu_0 \mu \mathbf{H} \cdot \mathbf{H} \right) = w_{\mathrm{e}} + w_{\mathrm{m}} \tag{3.16}$$

is the energy density of the electromagnetic field in isotropic dielectric materials having the unit $1\,\mathrm{J/m^3}$. The first term,

$$w_{\mathrm{e}} = \frac{1}{2} \varepsilon_0 \varepsilon \mathbf{E} \cdot \mathbf{E} \tag{3.17}$$

is the electric energy density and the second term,

$$w_{\mathrm{m}} = \frac{1}{2} \mu_0 \mu \mathbf{H} \cdot \mathbf{H} \tag{3.18}$$

is the magnetic energy density. The negative sign on the right-hand side of (3.15) just indicates that the amount of energy in the volume decreases over time if the net amount of power P_{net} flowing through the surface is positive, because this means that in total energy flows out of the closed surface. If the net electromagnetic power flow through the surface is zero, i.e., $P_{\text{net}} = 0$, the total amount of electromagnetic energy $\int_V w \, \mathrm{d}V$ in the volume is constant. This again shows that it is useful to interpret w as an energy density.

The Wave Equation in Homogeneous Dielectrics

In this section the behavior of light in homogeneous dielectric materials will be discussed. In homogeneous materials the dielectric function ε and the magnetic permeability μ are both constants. A special case is the vacuum, where both constants are equal to 1 ($\varepsilon = 1$, $\mu = 1$). The conclusion that electromagnetic waves can also exist in a vacuum without any matter was one of the most important discoveries in physics in the 19th century.

In homogeneous dielectrics the Maxwell equations (3.2–3.5) can be simplified by using (3.11) and (3.12) with ε and μ being constant

$$\nabla \times \mathbf{E} (\mathbf{r}, t) = -\mu_0 \mu \frac{\partial \mathbf{H} (\mathbf{r}, t)}{\partial t} \,, \tag{3.19}$$

$$\nabla \times \mathbf{H} (\mathbf{r}, t) = \varepsilon_0 \varepsilon \frac{\partial \mathbf{E} (\mathbf{r}, t)}{\partial t} \,, \tag{3.20}$$

$$\nabla \cdot \mathbf{E} (\mathbf{r}, t) = 0 \,, \tag{3.21}$$

$$\nabla \cdot \mathbf{H} (\mathbf{r}, t) = 0 \,. \tag{3.22}$$

These equations are completely symmetrical to a simultaneous replacement of $\mathbf{E}$ with $\mathbf{H}$ and $\varepsilon_0 \varepsilon$ with $-\mu_0 \mu$.

In the following, the vector identity

$$\nabla \times (\nabla \times \mathbf{E}) = \nabla (\nabla \cdot \mathbf{E}) - (\nabla \cdot \nabla) \mathbf{E}$$
$$= \nabla (\nabla \cdot \mathbf{E}) - \Delta \mathbf{E} \tag{3.23}$$

must be used. Thereby, the Laplacian operator $\Delta = \partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$ has to be applied to each component of $\mathbf{E}$!

Equation (3.19) together with (3.21) then results in

$$\nabla \times (\nabla \times \mathbf{E}) = -\Delta \mathbf{E} = -\mu_0 \mu \nabla \times \frac{\partial \mathbf{H}}{\partial t}$$
$$= -\mu_0 \mu \frac{\partial}{\partial t} (\nabla \times \mathbf{H}) \,. \tag{3.24}$$

Using (3.20) the wave equation for the electric vector in a homogeneous dielectric is obtained

$$-\Delta \mathbf{E} = -\mu_0 \mu \frac{\partial}{\partial t} \left(\varepsilon_0 \varepsilon \frac{\partial \mathbf{E}}{\partial t} \right)$$
$$\Rightarrow \Delta \mathbf{E} - \varepsilon_0 \mu_0 \varepsilon \mu \frac{\partial^2 \mathbf{E}}{\partial t^2} = 0 \,. \tag{3.25}$$

By using (3.13) this is usually written as

$$\Delta \mathbf{E} - \frac{n^2}{c^2} \frac{\partial^2 \mathbf{E}}{\partial t^2} = 0 \,. \tag{3.26}$$

The refractive index n of a homogeneous dielectric is defined as

$$n = \sqrt{\varepsilon \mu} \,. \tag{3.27}$$

Because of the symmetry in E and H of the Maxwell equations (3.19–3.22) in homogeneous dielectrics, the same equation also holds for the magnetic vector

$$\Delta H - \frac{n^2}{c^2}\frac{\partial^2 H}{\partial t^2} = 0 . \tag{3.28}$$

Plane Waves in Homogeneous Dielectrics

By defining the so-called phase velocity

$$v = \frac{c}{n} \tag{3.29}$$

a solution of (3.26) or (3.28) is

$$E(r,t) = f(e \cdot r \mp vt) , \tag{3.30}$$

$$H(r,t) = g(e \cdot r \mp vt) . \tag{3.31}$$

This can be seen by using

$$u := e \cdot r \mp vt = e_x x + e_y y + e_z z \mp vt$$
$$\text{with} \quad e_x^2 + e_y^2 + e_z^2 = 1 \tag{3.32}$$

so that it holds

$$\Delta E = \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix}$$
$$= \left(e_x^2 + e_y^2 + e_z^2 \right) \frac{\partial^2 f(u)}{\partial u^2} = \frac{\partial^2 f(u)}{\partial u^2} ,$$
$$\frac{\partial^2 E}{\partial t^2} = v^2 \frac{\partial^2 f(u)}{\partial u^2} ,$$

and thus the same is valid for H in (3.31). The quantity nu has the physical unit of a path and the first term $ne \cdot r$ is called the optical path difference OPD because it is the product of the geometrical path and the refractive index n.

A solution of type (3.30) or (3.31) is called a plane wave because for the following reason. The value of E remains constant for a constant argument $u = u_0$ defined by (3.32). The same is valid for H. Now, if we consider e.g., $u = u_0 = 0$ and take the negative sign in (3.32) we obtain:

$$u = 0 \quad \Rightarrow \quad e \cdot r = vt . \tag{3.33}$$

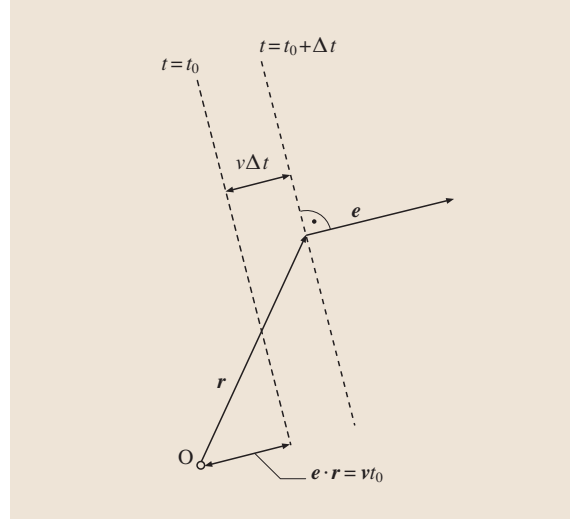
The geometrical path at time $t = 0$ must then also be zero and this means that the plane then passes through the origin of the coordinate system. For a fixed value of t_0, (3.33) describes a plane surface in space (see Fig. 3.2) at a distance vt_0 from the origin. At the time $t_0 + \Delta t$ it again describes a plane surface parallel to the plane at $t = 0$ but with a distance $v(t_0 + \Delta t)$ from the origin. The


Fig. 3.2 The plane surfaces of constant optical path in the case of a plane wave. O is the origin of the coordinate system and the *dashed lines* indicate the planes at two different times for the fixed value $u = 0$

unit vector e is perpendicular to the planes and points in the direction of propagation if the negative sign is used in (3.32) (as done here and in the following) and points in the opposite direction if the positive sign is used.

The Orthogonality Condition for Plane Waves in Homogeneous Dielectrics

The Maxwell equations (3.19–3.22) do not allow all orientations of the electric and magnetic vector relative to the propagation direction e of a plane wave. Equations (3.30) and (3.32) deliver

$$\frac{\partial E}{\partial t} = \mp v \frac{\partial f}{\partial u}$$

and

$$(\nabla \times E)_x = \frac{\partial E_z}{\partial y} - \frac{\partial E_y}{\partial z} = \frac{\partial f_z}{\partial u} e_y - \frac{\partial f_y}{\partial u} e_z$$
$$= \left(e \times \frac{\partial f}{\partial u} \right)_x \quad \Rightarrow \quad \nabla \times E = e \times \frac{\partial f}{\partial u} .$$

An analogous expression is valid for H.

Therefore, the Maxwell equations (3.19) and (3.20) deliver

$$e \times \frac{\partial f}{\partial u} = \pm \mu_0 \mu v \frac{\partial g}{\partial u} , \tag{3.34}$$

$$e \times \frac{\partial g}{\partial u} = \mp \varepsilon_0 \varepsilon v \frac{\partial f}{\partial u} . \tag{3.35}$$

These equations can be integrated with respect to the variable u and by setting the integration constant to zero and using (3.13), (3.27) and (3.29) the result is

$$E = f = \mp\sqrt{\frac{\mu_0\mu}{\varepsilon_0\varepsilon}}e \times H \, , \qquad (3.36)$$

$$H = g = \pm\sqrt{\frac{\varepsilon_0\varepsilon}{\mu_0\mu}}e \times E \, . \qquad (3.37)$$

These two equations show that E is perpendicular to e and H and that H is perpendicular to e and E. This can only be the case if e, E and H form an orthogonal triad of vectors. Therefore, a plane wave in a homogeneous dielectric is always a transversal wave.

The Poynting Vector of a Plane Wave

In this section, the physical interpretation of the Poynting vector will be illustrated for plane waves. The Poynting vector defined in (3.9) is parallel to e

$$S = E \times H = \left(\mp\sqrt{\frac{\mu_0\mu}{\varepsilon_0\varepsilon}}e \times H\right) \times \left(\pm\sqrt{\frac{\varepsilon_0\varepsilon}{\mu_0\mu}}e \times E\right)$$
$$= -\left[(e \times H) \cdot E\right]e + \left[(e \times H) \cdot e\right]E \, . \qquad (3.38)$$

The second scalar product is zero so that only the first term remains. By using (3.36) this finally results in

$$S = -\left[(e \times H) \cdot E\right]e = \pm\sqrt{\frac{\varepsilon_0\varepsilon}{\mu_0\mu}}(E \cdot E)e \, . \qquad (3.39)$$

This means that the energy transport is along the direction of propagation of the plane wave and that the absolute value of the Poynting vector, i.e., the intensity of the light wave, is proportional to $|E|^2$.

By using the vector identity $(a \times b) \cdot c = -(a \times c) \cdot b$ and (3.37) we can also write

$$S = -\left[(e \times H) \cdot E\right]e = \left[(e \times E) \cdot H\right]e$$
$$= \pm\sqrt{\frac{\mu_0\mu}{\varepsilon_0\varepsilon}}(H \cdot H)e \, . \qquad (3.40)$$

This means that the absolute value of the Poynting vector is also proportional to $|H|^2$ and that the following equality holds:

$$\sqrt{\frac{\mu_0\mu}{\varepsilon_0\varepsilon}}|H|^2 = \sqrt{\frac{\varepsilon_0\varepsilon}{\mu_0\mu}}|E|^2$$
$$\Rightarrow \quad \mu_0\mu|H|^2 = \varepsilon_0\varepsilon|E|^2 \, . \qquad (3.41)$$

Comparing this with (3.16), (3.17) and (3.18) for the energy density of the electromagnetic field we have for a plane wave in a homogeneous dielectric

$$w_e = w_m = \frac{1}{2}w$$
$$\Rightarrow \quad w = \varepsilon_0\varepsilon|E|^2 = \mu_0\mu|H|^2 \, . \qquad (3.42)$$

By again using (3.13), (3.27) and (3.29) the equations (3.39) and (3.40) can be transformed to

$$S = \pm v\mu_0\mu|H|^2 e = \pm v\varepsilon_0\varepsilon|E|^2 e = \pm vwe \, . \qquad (3.43)$$

This means that the absolute value of the Poynting vector is, in a homogeneous dielectric, the product of the energy density (energy per volume) of the electromagnetic field and the phase velocity of light. This confirms the interpretation of the Poynting vector as being the vector of the electromagnetic wave transporting the energy of the electromagnetic field with the phase velocity of light. Figure 3.3 illustrates this. In the infinitesimal time interval dt the light covers the infinitesimal distance $dz = v\, dt$. We assume that the distance dz is so small that the local energy density w of the electromagnetic field is constant in the volume $dV = A\, dz$, whereby A is the area of a small surface perpendicular to the Poynting vector. Therefore, all the energy $dW = w\, dV$ that is contained in the infinitesimal volume dV passes the surface area A in the time dt and we have, for the intensity I (electromagnetic power per area),

$$I = \frac{dW}{A\, dt} = \frac{w\, dV}{A\, dt} = \frac{wA\, v\, dt}{A\, dt} = wv = |S| \, . \quad (3.44)$$

This is exactly the absolute value of the Poynting vector S. The light intensity on a surface, which is not perpendicular to the direction of the Poynting vector is calculated by the equation

$$I = S \cdot N \, , \qquad (3.45)$$

where N is a local unit vector perpendicular to the surface.
Fig. 3.3 Illustration of the Poynting vector S as transporting the energy of the electromagnetic field. A is the area of the circular surface

A Time-Harmonic Plane Wave

Up to now a plane wave was defined with (3.30) and (3.31) to be $E(r, t) = f(u)$ and $H(r, t) = g(u)$. The argument u is defined by (3.32) to be $u = e \cdot r - vt$. This means that all points with position vector r at a fixed point t in time lie on a plane surface for a constant value u. Additionally, we saw that e, E and H have to form an orthogonal triad of vectors (3.36, 3.37). But the concrete form of the functions f and g can be quite arbitrary to fulfill these conditions. A wave which is very important in optics because of its simple form is a time-harmonic wave. Furthermore, it should be linearly polarized, i.e., the direction of the electric and magnetic vector are both constant. A linearly polarized time-harmonic plane wave is represented by the equations:

$$E(r, t) = E_0 \cos\left(\frac{2\pi n}{\lambda} u\right)$$

$$= E_0 \cos\left[\frac{2\pi n}{\lambda} (e \cdot r - vt)\right] , \qquad (3.46)$$

$$H(r, t) = H_0 \cos\left(\frac{2\pi n}{\lambda} u\right)$$

$$= H_0 \cos\left[\frac{2\pi n}{\lambda} (e \cdot r - vt)\right] . \qquad (3.47)$$

Here, we have introduced the value λ, which has the physical unit of a length so that the argument of the cosine function has no physical unit. Its meaning will soon become clear.

The characteristic property of a time-harmonic wave is that it has, for a fixed point r, periodically the same value after a certain time interval. The smallest time interval for which this is the case is called period T:

$$E(r, t + T) = E_0 \cos\left\{\frac{2\pi n}{\lambda} [e \cdot r - v(t + T)]\right\}$$

$$= E_0 \cos\left[\frac{2\pi n}{\lambda} (e \cdot r - vt)\right] = E(r, t)$$

$$\Rightarrow \quad \frac{2\pi n}{\lambda} vT = 2\pi$$

$$\Rightarrow \quad vT = \frac{\lambda}{n} \quad \text{or} \quad cT = \lambda . \qquad (3.48)$$

Therefore, λ/n is the distance the light covers in the material in the period T and is called the wavelength of the harmonic wave in the material. The quantity λ itself is the wavelength in a vacuum. The reciprocal of T is called the frequency v of the wave and the term $2\pi v = 2\pi/T$ is called the angular frequency ω of the

wave. Therefore the two following equations are valid

$$cT = \lambda \quad \Rightarrow \quad c = \lambda v , \qquad (3.49)$$

$$\frac{2\pi}{\lambda} c = \frac{2\pi}{T} = 2\pi v = \omega . \qquad (3.50)$$

Additionally, we introduce the wave vector k, which is defined by

$$k = \frac{2\pi n}{\lambda} e . \qquad (3.51)$$

Then (3.46) and (3.47) for E and H can be written as

$$E(r, t) = E_0 \cos(k \cdot r - \omega t) , \qquad (3.52)$$

$$H(r, t) = H_0 \cos(k \cdot r - \omega t) . \qquad (3.53)$$

Because of the orthogonality condition k (or e, which is parallel to k), E_0 and H_0 have to form an orthogonal triad. This can be explicitly seen in this case by using Maxwell's first equation (3.19) in a homogeneous dielectric and the mathematical rules for the nabla operator

$$\nabla \times E = \nabla \times [E_0 \cos(k \cdot r - \omega t)]$$

$$= [\nabla \cos(k \cdot r - \omega t)] \times E_0$$

$$= -k \times E_0 \sin(k \cdot r - \omega t) ,$$

$$-\mu_0 \mu \frac{\partial H}{\partial t} = -\omega \mu_0 \mu H_0 \sin(k \cdot r - \omega t) ;$$

$$\Rightarrow \quad \omega \mu_0 \mu H_0 = k \times E_0$$

$$\Rightarrow \quad H_0 = \frac{1}{\omega \mu_0 \mu} k \times E_0 = \frac{\lambda}{2\pi c \mu_0 \mu} k \times E_0$$

$$= \sqrt{\frac{\varepsilon_0 \varepsilon}{\mu_0 \mu}} e \times E_0 . \qquad (3.54)$$

In the last step (3.50), (3.13) and (3.27) are used and the geometrical interpretation of the result is that H_0 is perpendicular to both e and E_0. The third Maxwell equation (3.21) delivers

$$\nabla \cdot E = \nabla \cdot [E_0 \cos(k \cdot r - \omega t)]$$

$$= E_0 \cdot [\nabla \cos(k \cdot r - \omega t)]$$

$$= -E_0 \cdot k \sin(k \cdot r - \omega t) = 0 ;$$

$$\Rightarrow \quad E_0 \cdot k = 0 . \qquad (3.55)$$

This also means that k (or e) and E_0 are perpendicular to each other. The two other Maxwell equations (3.20) and (3.22) are automatically fulfilled because of the symmetry in E and H.

3.1.2 The Complex Representation of Time–Harmonic Waves

In paragraph "A Time harmonic Plane Wave" of Sect. 3.1.1 a linearly polarized time-harmonic plane wave is expressed with real cosine functions for the electric and the magnetic vector. Because E and H are observable physical quantities, they must, of course, be expressed by real functions. The fact that usual detectors are not fast enough to detect the electric and magnetic vector of light waves directly does not matter here. Nevertheless, the calculation with a complex exponential function is more convenient than the calculation with real cosine or sine functions. Now, the Maxwell equations (3.2–3.5) are linear. Therefore, if the functions E_1, D_1, H_1, B_1, j_1 and ρ_1 on the one hand and E_2, D_2, H_2, B_2, j_2 and ρ_2 on the other are both solutions of the Maxwell equations, then a linear combination of these functions is also a solution:

$$\nabla \times E_1 = -\frac{\partial B_1}{\partial t} \ ,$$

$$\nabla \times H_1 = \frac{\partial D_1}{\partial t} + j_1 \ ,$$

$$\nabla \cdot D_1 = \rho_1 \ ,$$

$$\nabla \cdot B_1 = 0 \ ,$$

$$\nabla \times E_2 = -\frac{\partial B_2}{\partial t} \ ,$$

$$\nabla \times H_2 = \frac{\partial D_2}{\partial t} + j_2 \ ,$$

$$\nabla \cdot D_2 = \rho_2 \ ,$$

$$\nabla \cdot B_2 = 0 \ ;$$

$$\Rightarrow$$

$$\nabla \times (\alpha E_1 + \beta E_2) = -\frac{\partial (\alpha B_1 + \beta B_2)}{\partial t} \ , \tag{3.56}$$

$$\nabla \times (\alpha H_1 + \beta H_2) = \frac{\partial (\alpha D_1 + \beta D_2)}{\partial t} + \alpha j_1 + \beta j_2 \ , \tag{3.57}$$

$$\nabla \cdot (\alpha D_1 + \beta D_2) = \alpha \rho_1 + \beta \rho_2 \ , \tag{3.58}$$

$$\nabla \cdot (\alpha B_1 + \beta B_2) = 0 \ , \tag{3.59}$$

where α and β are arbitrary real or complex constants. The Euler equation delivers:

$$e^{ix} = \cos x + i \sin x \tag{3.60}$$

or

$$\cos x = \frac{e^{ix} + e^{-ix}}{2} = \frac{e^{ix} + (e^{ix})^*}{2} \ . \tag{3.61}$$

Due to the linearity of the Maxwell equations it is obvious that if a function containing a cosine function is a solution of the Maxwell equations the replacement of the cosine function by a complex exponential function will then also be a solution. Therefore, it is quite normal that waves are expressed by using a complex function although only the real part of this function represents the real physical quantity. The addition, subtraction, integration and differentiation of such a complex function is also a linear operation, so that we can in the end build the real part and have the real solution:

$$z_1(x) = a_1(x) + ib_1(x)$$

$$z_2(x) = a_2(x) + ib_2(x)$$

$$\mathrm{Re}\,(z_1 + z_2) = \mathrm{Re}\,(z_1) + \mathrm{Re}\,(z_2)$$

$$\mathrm{Re}\,(z_1 - z_2) = \mathrm{Re}\,(z_1) - \mathrm{Re}\,(z_2)$$

$$\Rightarrow \quad \mathrm{Re}\left(\frac{\mathrm{d}z_1}{\mathrm{d}x}\right) = \frac{\mathrm{d}}{\mathrm{d}x}\mathrm{Re}\,(z_1) \tag{3.62}$$

$$\mathrm{Re}\left(\int z_1\,\mathrm{d}x\right) = \int \mathrm{Re}\,(z_1)\,\mathrm{d}x$$

$$\mathrm{Re}\,(fz_1) = f\mathrm{Re}\,(z_1)$$

Here, f is an arbitrary real function or constant. Only if two complex functions have to be multiplied or divided, or the absolute value has to be built, do we have to be careful:

$$\mathrm{Re}\,(z_1 z_2) = a_1 a_2 - b_1 b_2 \neq a_1 a_2 = \mathrm{Re}\,(z_1)\,\mathrm{Re}\,(z_2) \ ,$$

$$\mathrm{Re}\left(\frac{z_1}{z_2}\right) = \frac{a_1 a_2 + b_1 b_2}{a_2^2 + b_2^2} \neq \frac{a_1}{a_2} = \frac{\mathrm{Re}\,(z_1)}{\mathrm{Re}\,(z_2)} \ ,$$

$$\mathrm{Re}\,(z_1 z_1) = a_1^2 - b_1^2 \neq a_1^2 + b_1^2 = |z_1|^2 \ . \tag{3.63}$$

So, if the Poynting vector or products of the electric or magnetic vectors have to be calculated it is not allowed to just take the complex functions. Nevertheless, there are some useful applications of the complex notation. As we mentioned before, the frequency of a light wave is so high that no usual detector can directly measure the vibrations. For a typical wavelength of visible light of 500 nm the frequency of a wave in vacuum is determined according to (3.49)

$$\nu = \frac{c}{\lambda} = \frac{2.998 \times 10^8\,\mathrm{m\,s^{-1}}}{5.0 \times 10^{-7}\,\mathrm{m}} = 5.996 \times 10^{14}\,\mathrm{s^{-1}} \ ,$$

$$\Rightarrow \quad T = \frac{1}{\nu} = 1.668 \times 10^{-15}\,\mathrm{s} = 1.668\,\mathrm{fs} \ .$$

So, the period is just a little bit more than a femtosecond. This means that in most cases only the time average of the light intensity over many periods is measured.

A general time-harmonic wave with the angular frequency ω has the representation

$$
E(r, t) = \begin{pmatrix} A_x(r) \cos[\Phi_x(r) - \omega t] \\ A_y(r) \cos[\Phi_y(r) - \omega t] \\ A_z(r) \cos[\Phi_z(r) - \omega t] \end{pmatrix}
$$

$$
= \mathrm{Re} \left\{ \begin{pmatrix} A_x(r)\, \mathrm{e}^{\mathrm{i}\Phi_x(r) - \mathrm{i}\omega t} \\ A_y(r)\, \mathrm{e}^{\mathrm{i}\Phi_y(r) - \mathrm{i}\omega t} \\ A_z(r)\, \mathrm{e}^{\mathrm{i}\Phi_z(r) - \mathrm{i}\omega t} \end{pmatrix} \right\}
$$

$$
= \mathrm{Re} \left\{ \mathrm{e}^{-\mathrm{i}\omega t} \begin{pmatrix} A_x(r)\, \mathrm{e}^{\mathrm{i}\Phi_x(r)} \\ A_y(r)\, \mathrm{e}^{\mathrm{i}\Phi_y(r)} \\ A_z(r)\, \mathrm{e}^{\mathrm{i}\Phi_z(r)} \end{pmatrix} \right\}
$$

$$
=: \mathrm{Re} \left\{ \mathrm{e}^{-\mathrm{i}\omega t} \hat{E}(r) \right\} . \tag{3.64}
$$

A_x, A_y, A_z, Φ_x, Φ_y and Φ_z are all real functions that depend only on the position r. Additionally, A_x, A_y and A_z, which are called the components of the amplitude, are slowly varying functions of the position. On the other hand, the exponential terms with the components of the phase Φ_x, Φ_y and Φ_z are rapidly varying functions of the position. The components of the complex vector $\hat{E}(r)$ are often called the complex amplitudes of the electric vector of the wave.

Equation (3.39) gives the relation between the Poynting vector and the electric vector in a homogeneous dielectric

$$
S = \sqrt{\frac{\varepsilon_0 \varepsilon}{\mu_0 \mu}} (E \cdot E)\, e .
$$

Now, the time average $\bar{S}$ of the absolute value of the Poynting vector, i. e., the intensity, which is really measured by a common detector, will be calculated for the general time-harmonic wave. Therefore, we have to integrate the absolute value S of the Poynting vector over one period T and divide it by T

$$
\bar{S}(r) := \frac{1}{T} \int_0^T |S(r, t)|\, \mathrm{d}t
$$

$$
= \sqrt{\frac{\varepsilon_0 \varepsilon}{\mu_0 \mu}} \frac{1}{T} \int_0^T E(r, t) \cdot E(r, t)\, \mathrm{d}t . \tag{3.65}
$$

Using (3.64) for a general time-harmonic wave and (3.13) we obtain

$$
\bar{S} = \frac{\varepsilon_0 c}{T} \sqrt{\frac{\varepsilon}{\mu}} \int_0^T \big[A_x^2 \cos^2(\Phi_x - \omega t)
$$
$$
+ A_y^2 \cos^2(\Phi_y - \omega t)
$$
$$
+ A_z^2 \cos^2(\Phi_z - \omega t) \big]\, \mathrm{d}t
$$
$$
= \sqrt{\frac{\varepsilon}{\mu}} \frac{\varepsilon_0 c}{2} \left(A_x^2 + A_y^2 + A_z^2 \right) . \tag{3.66}
$$

But, if we calculate directly the square of the absolute value of the time-independent vector $\hat{E}$ we also obtain

$$
\left| \hat{E} \right|^2 = \hat{E} \cdot \hat{E}^* = A_x^2 + A_y^2 + A_z^2 . \tag{3.67}
$$

By combining equations (3.66) and (3.67) we finally obtain

$$
\bar{S}(r) = \sqrt{\frac{\varepsilon}{\mu}} \frac{\varepsilon_0 c}{2} \left| \hat{E}(r) \right|^2 = \sqrt{\frac{\varepsilon}{\mu}} \frac{\varepsilon_0 c}{2} \hat{E}(r) \cdot \left[\hat{E}(r) \right]^* . \tag{3.68}
$$

Therefore, the complex representation of time-harmonic waves allows a fast calculation of the time average of the Poynting vector, i. e., of the intensity of the light wave.

3.1.3 Material Equations

In the last two sections we often concentrated on the electromagnetic field in an isotropic and homogeneous dielectric material where the Maxwell equations are simplified to (3.19–3.22). In other materials the general Maxwell equations (3.2–3.5) have to be used and more complex interrelations between the electric displacement and the electric vector on one hand and the magnetic induction and the magnetic vector on the other have to be found. Since the atomic distances are small compared to the wavelength of light, a macroscopic description with smooth functions is possible. To calculate the influence of the material, first of all the interrelations between D and E as well as B and H are considered in vacuum. These equations in a vacuum are obtained from (3.12) for the case $\mu = \varepsilon = 1$. Then, additional terms are added to the equations in a vacuum. The electric polarization P and the magnetization M are introduced by:

$$
D(r, t) = \varepsilon_0 E(r, t) + P(r, t) , \tag{3.69}
$$
$$
B(r, t) = \mu_0 H(r, t) + M(r, t) . \tag{3.70}
$$

The atomic theory goes far beyond our scope. But in a macroscopic theory the effect of the atoms (i. e., mainly

the electrons of the atoms) on the electric polarization is that it is a function of the electric vector. In the same way the magnetization is a function of the magnetic vector. The most general equations are

$$P_i\,(\boldsymbol{r},t) = P_0\,(\boldsymbol{r},t) + \varepsilon_0 \sum_{j=1}^{3} \eta_{ij}^{(1)}\,(\boldsymbol{r},t)\,E_j\,(\boldsymbol{r},t)$$

$$+ \sum_{j=1}^{3}\sum_{k=1}^{3} \eta_{ijk}^{(2)}\,(\boldsymbol{r},t)\,E_j\,(\boldsymbol{r},t)\,E_k\,(\boldsymbol{r},t)$$

$$+ \sum_{j=1}^{3}\sum_{k=1}^{3}\sum_{l=1}^{3} \eta_{ijkl}^{(3)}(\boldsymbol{r},t)E_j(\boldsymbol{r},t)E_k(\boldsymbol{r},t)E_l(\boldsymbol{r},t) + \dots,$$

$$\tag{3.71}$$

$$M_i\,(\boldsymbol{r},t) = M_0\,(\boldsymbol{r},t) + \mu_0 \sum_{j=1}^{3} \chi_{ij}^{(1)}\,(\boldsymbol{r},t)\,H_j\,(\boldsymbol{r},t)$$

$$+ \sum_{j=1}^{3}\sum_{k=1}^{3} \chi_{ijk}^{(2)}\,(\boldsymbol{r},t)\,H_j\,(\boldsymbol{r},t)\,H_k\,(\boldsymbol{r},t)$$

$$+ \sum_{j=1}^{3}\sum_{k=1}^{3}\sum_{l=1}^{3} \chi_{ijkl}^{(3)}(\boldsymbol{r},t)H_j(\boldsymbol{r},t)H_k(\boldsymbol{r},t)H_l(\boldsymbol{r},t) + \dots.$$

$$\tag{3.72}$$

Here, the lower indices running from 1 to 3 indicate the components of the respective electromagnetic vectors, e.g., $E_1 := E_x$, $E_2 := E_y$ and $E_3 := E_z$. The tensor functions $\eta_{ij}^{(1)}$, $\eta_{ijk}^{(2)}$ and so on describe the influence of the electric vector on the electric polarization and the same is valid for the tensor functions $\chi_{ij}^{(1)}$, $\chi_{ijk}^{(2)}$ and so on in the magnetic case. The tensor functions are defined here in such a way that $\eta_{ij}^{(1)}$ and $\chi_{ij}^{(1)}$ have no physical unit and are pure numbers. Nevertheless, the tensor functions of higher degree have different physical units. The tensors $\eta_{ij}^{(1)}$, $\eta_{ijk}^{(2)}$ and so on are called the tensors of dielectric susceptibility. The tensors $\chi_{ij}^{(1)}$, $\chi_{ijk}^{(2)}$ and so on are called the tensors of magnetic susceptibility. In (3.71) a bias P_0 for the polarization is also assumed and the same is made for the magnetization. In our general material equations, the different terms can depend on the position $\boldsymbol{r}$ as well as on the time t. But in most cases the material functions will not depend explicitly on the time t.

Additionally, there have to be equations for the current density $\boldsymbol{j}$ and the charge density ρ. In optics the most important materials are either dielectrics or metals (e.g., for mirrors). In both cases we can assume $\rho = 0$. For the current density we can in most cases take the

equation:

$$\boldsymbol{j} = \sigma \boldsymbol{E}\,. \tag{3.73}$$

The conductivity σ indicates how good an electric current is conducted in a material and has the physical unit $[\sigma] = 1\,\mathrm{A\,V^{-1}\,m^{-1}}$. For ideal dielectric materials σ is zero so that we obtain $\boldsymbol{j} = 0$. In this case the material does not absorb light. For metals, σ is, of course, not zero and for an ideal conductor it would become infinity, so that all light would be absorbed or reflected at once. There are also anisotropic absorbing materials like special crystals where σ is not a scalar but a tensor [3.1]. But this is out of our present scope.

Discussion of the General Material Equations

Polarization. The term $\sum_{j=1}^{3} \eta_{ij}^{(1)} E_j$ in (3.71) is responsible for linear responses of the electric polarization on the electric vector and is the most important effect. The following terms and the bias term are responsible for so-called nonlinear effects and are subject to nonlinear optics [3.2] (e.g., second-harmonic generation or self-focusing effects). In the following, the bias and all tensors with upper index (2) and more of the dielectric susceptibility $\eta_{ijk}^{(2)}$, $\eta_{ijkl}^{(3)}$, ... will be set to zero because only linear optics will be treated in this chapter. In "normal" materials like different glass types the linear case is the normal case. Only if the absolute value of the electric vector of the electromagnetic field is in the range of the atomic electric field nonlinear effects occur in these materials.

An estimation of the electric fields in atoms and in a light wave is helpful. In a typical atom the electric field on an outer electron can be estimated by applying Coulomb's law and assuming an effective charge of the nucleus of one elementary charge and a distance of the electron of $r = 10^{-10}\,\mathrm{m}$

$$E = |\boldsymbol{E}| = \frac{e}{4\pi\varepsilon_0 r^2}\,,$$

$$r = 10^{-10}\,\mathrm{m},\ e = 1.6022 \times 10^{-19}\,\mathrm{A\,s}\,,$$

$$\varepsilon_0 = 8.8542 \times 10^{-12}\,\mathrm{As\,V^{-1}\,m^{-1}}$$

$$\Rightarrow\quad E \approx 1.4 \times 10^{11}\,\mathrm{V\,m^{-1}}\,. \tag{3.74}$$

The electric field oscillates very rapidly in a light wave. Therefore, to estimate the electric field in a light wave (here in a vacuum) the amplitude $|\hat{E}|$ of the modulus of the time-independent complex-valued electric field is calculated. This can be done by using (3.68) for the relation between the time average $\bar{S}$ of the modulus of the Poynting vector and the modulus of the time-independent complex-valued electric

field. Here, the values are calculated in a vacuum ($\varepsilon = \mu = 1$):

$$\bar{S} = \frac{c\varepsilon_0}{2} \left| \hat{E} \right|^2 \quad \Rightarrow \quad \left| \hat{E} \right| = \sqrt{\frac{2\bar{S}}{c\varepsilon_0}} \ . \tag{3.75}$$

The result for the electric field of the light on a sunny day is:

$$\bar{S} \approx 1\,\mathrm{kW/m^2} \quad \Rightarrow \left| \hat{E} \right| \approx 868\,\mathrm{V/m} \ .$$

In the focused spot of a medium-power continuous wave (cw) laser beam we have e.g.,

$$\bar{S} = 1\,\mathrm{W/\mu m^2} = 10^{12}\,\mathrm{W/m^2}$$

$$\Rightarrow \left| \hat{E} \right| \approx 2.74 \times 10^7\,\mathrm{V/m} \ .$$

This shows that in normal materials and with "normal" light intensities the electric field of a light wave is quite small compared to the electric field of the atoms. Therefore, the electrons are only moved a little bit and this results normally in a linear response of the dielectric function to the exciting electric field of the light wave. Of course, there are also so-called nonlinear materials which show for smaller electric fields nonlinear effects. In addition, ultrashort pulsed lasers, e.g., so-called femtosecond lasers, can achieve much higher intensities in their focus so that electric fields, which are comparable to or higher than the electric field in atoms, result. Then the response is, of course, nonlinear.

Magnetization. In practice, there are nearly no materials relevant to optics that show nonlinear magnetic effects, so that $\chi^{(2)}_{ijk}$ and all higher order tensors are zero. In fact, most optically interesting materials are not magnetic at all, so that the remaining tensor of the magnetic susceptibility $\chi^{(1)}_{ij}$ is also zero. In some materials the magnetic susceptibility $\chi^{(1)}_{ij}$ is not zero but it can be written as a scalar constant χ multiplied by a 3×3 unit matrix. χ is a negative constant for diamagnetic materials or a positive constant for paramagnetic materials. The magnetic permeability μ of the material, which is a pure real number without a physical unit, is then defined as

$$\mu := 1 + \chi \ . \tag{3.76}$$

Then we have, due to (3.70) and (3.72)

$$\boldsymbol{B} = \mu\mu_0 \boldsymbol{H} \ . \tag{3.77}$$

This equation, which is also used in (3.12) will be used in the rest of this chapter and in many cases μ will really be a constant that does not depend on the position $\boldsymbol{r}$.

Specialization to the Equations of Linear and Nonmagnetic Materials

For linear materials, only the tensor of lowest degree of the dielectric susceptibility $\eta^{(1)}_{ij}$ is different from zero. It can be expressed as a matrix

$$\begin{pmatrix} \eta^{(1)}_{11} & \eta^{(1)}_{12} & \eta^{(1)}_{13} \\ \eta^{(1)}_{21} & \eta^{(1)}_{22} & \eta^{(1)}_{23} \\ \eta^{(1)}_{31} & \eta^{(1)}_{32} & \eta^{(1)}_{33} \end{pmatrix} \ . \tag{3.78}$$

The dielectric tensor is defined as

$$\begin{pmatrix} \varepsilon_{11} & \varepsilon_{12} & \varepsilon_{13} \\ \varepsilon_{21} & \varepsilon_{22} & \varepsilon_{23} \\ \varepsilon_{31} & \varepsilon_{32} & \varepsilon_{33} \end{pmatrix} := \begin{pmatrix} 1 + \eta^{(1)}_{11} & \eta^{(1)}_{12} & \eta^{(1)}_{13} \\ \eta^{(1)}_{21} & 1 + \eta^{(1)}_{22} & \eta^{(1)}_{23} \\ \eta^{(1)}_{31} & \eta^{(1)}_{32} & 1 + \eta^{(1)}_{33} \end{pmatrix} \ . \tag{3.79}$$

Using (3.69) and (3.71) the relation between the dielectric displacement and the electric vector is

$$\begin{pmatrix} D_x \\ D_y \\ D_z \end{pmatrix} = \varepsilon_0 \begin{pmatrix} \varepsilon_{11} & \varepsilon_{12} & \varepsilon_{13} \\ \varepsilon_{21} & \varepsilon_{22} & \varepsilon_{23} \\ \varepsilon_{31} & \varepsilon_{32} & \varepsilon_{33} \end{pmatrix} \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix} \ . \tag{3.80}$$

In anisotropic materials like noncubic crystals or originally isotropic materials that are subject to mechanical stresses, the dielectric tensor has this general matrix form and the effects that occur are e.g., birefringence [3.1, 3]. It can be shown that the dielectric tensor is symmetric, i.e., $\varepsilon_{ij} = \varepsilon_{ji}$. But the treatment of anisotropic materials is out of the scope of this chapter so that we will have in the following only isotropic materials. Then the dielectric tensor reduces to a scalar ε times a unit matrix whereby ε is in general a function of the position $\boldsymbol{r}$.

Material Equations for Linear and Isotropic Materials

If the material is isotropic the dielectric tensor and all other material quantities are scalars times a unit matrix. Due to (3.80) and (3.77) we have, in this case, the well-known relations between the electric displacement and the electric vector on one hand and between the magnetic induction and the magnetic vector on the other, which we also used in (3.12):

$$\boldsymbol{D}(\boldsymbol{r}, t) = \varepsilon_0 \varepsilon(\boldsymbol{r}) \boldsymbol{E}(\boldsymbol{r}, t) \ ,$$

$$\boldsymbol{B}(\boldsymbol{r}, t) = \mu_0 \mu(\boldsymbol{r}) \boldsymbol{H}(\boldsymbol{r}, t) \ , \tag{3.81}$$

where $\varepsilon(\boldsymbol{r})$, $\mu(\boldsymbol{r})$ means that the material functions will in general depend on the position. An explicit dependence on time is most often not the case so it is omitted here.

Additionally, we assume that the charge density is zero and (3.73) is valid

$$\rho = 0 , \tag{3.82}$$

$$\boldsymbol{j}(\boldsymbol{r}, t) = \sigma(\boldsymbol{r}) \boldsymbol{E}(\boldsymbol{r}, t) . \tag{3.83}$$

If ε, μ and σ are constant, i.e., independent of the position, the material is called homogeneous.

Due to the dispersion theory, which will not be treated here, the material functions will, in general, depend on the frequency of the stimulating electric or magnetic fields. Therefore, the Fourier components of the electric and magnetic field have to be calculated and treated separately. The electric vector and the electric displacement are written as Fourier integrals, i.e., as a superposition of time-harmonic waves with the angular frequency ω:

$$\boldsymbol{E}(\boldsymbol{r}, t) = \frac{1}{\sqrt{2\pi}} \int\limits_{-\infty}^{+\infty} \tilde{\boldsymbol{E}}(\boldsymbol{r}, \omega) \, \mathrm{e}^{-\mathrm{i}\omega t} \, \mathrm{d}\omega ,$$

$$\boldsymbol{D}(\boldsymbol{r}, t) = \frac{1}{\sqrt{2\pi}} \int\limits_{-\infty}^{+\infty} \tilde{\boldsymbol{D}}(\boldsymbol{r}, \omega) \, \mathrm{e}^{-\mathrm{i}\omega t} \, \mathrm{d}\omega . \tag{3.84}$$

The magnetic vector and the magnetic induction are treated in the same way so that we can omit this. If the function $\boldsymbol{E}$ is given $\tilde{\boldsymbol{E}}$ is calculated by

$$\tilde{\boldsymbol{E}}(\boldsymbol{r}, \omega) = \frac{1}{\sqrt{2\pi}} \int\limits_{-\infty}^{+\infty} \boldsymbol{E}(\boldsymbol{r}, t) \, \mathrm{e}^{\mathrm{i}\omega t} \, \mathrm{d}t . \tag{3.85}$$

Since $\boldsymbol{E}$ is a real function the complex Fourier components have to fulfill the condition

$$\tilde{\boldsymbol{E}}(\boldsymbol{r}, -\omega) = \tilde{\boldsymbol{E}}^*(\boldsymbol{r}, \omega) . \tag{3.86}$$

The same is valid for the electric displacement, the magnetic vector and the magnetic induction.

In total, the material equations can be written for isotropic and linear materials with the Fourier components of the four electromagnetic vector quantities:

$$\tilde{\boldsymbol{D}}(\boldsymbol{r}, \omega) = \varepsilon_0 \varepsilon(\boldsymbol{r}, \omega) \tilde{\boldsymbol{E}}(\boldsymbol{r}, \omega)$$

$$\tilde{\boldsymbol{B}}(\boldsymbol{r}, \omega) = \mu_0 \mu(\boldsymbol{r}, \omega) \tilde{\boldsymbol{H}}(\boldsymbol{r}, \omega) . \tag{3.87}$$

In the following the tilde on the different quantities will mostly be omitted to simplify the notation. This is equivalent to just deal with time-harmonic waves of a certain angular frequency ω, where the quantities ε and μ are functions of ω.

3.1.4 The Wave Equations

The Maxwell equations (3.2–3.5) contain the five vector fields $\boldsymbol{E}$, $\boldsymbol{D}$, $\boldsymbol{H}$, $\boldsymbol{B}$ and $\boldsymbol{j}$ and the scalar field ρ. These quantities are related to each other by the material equations. Here, only the case of isotropic, linear and uncharged ($\rho = 0$) materials will be treated. Additionally, all material parameters like ε, μ and σ will be independent of the time t, but functions of the position $\boldsymbol{r}$ (and the frequency or wavelength of the light). In the following the explicit dependence of the functions on $\boldsymbol{r}$ and t will be omitted, but there are the following functionalities: $\boldsymbol{E}(\boldsymbol{r}, t)$, $\boldsymbol{H}(\boldsymbol{r}, t)$, $\mu(\boldsymbol{r})$, $\varepsilon(\boldsymbol{r})$, $\sigma(\boldsymbol{r})$.

Using (3.81) and (3.83) for this case results in the following specialized Maxwell equations

$$\nabla \times \boldsymbol{E} = -\mu_0 \mu \frac{\partial \boldsymbol{H}}{\partial t} , \tag{3.88}$$

$$\nabla \times \boldsymbol{H} = \varepsilon_0 \varepsilon \frac{\partial \boldsymbol{E}}{\partial t} + \sigma \boldsymbol{E} , \tag{3.89}$$

$$\nabla \cdot (\varepsilon \boldsymbol{E}) = 0 , \tag{3.90}$$

$$\nabla \cdot (\mu \boldsymbol{H}) = 0 . \tag{3.91}$$

These equations contain, for given material functions ε, μ and σ, only the electric and the magnetic vector. To eliminate the magnetic vector the cross product of the nabla operator with (3.88) is taken

$$\nabla \times (\nabla \times \boldsymbol{E}) = -\mu_0 \nabla \times \left(\mu \frac{\partial \boldsymbol{H}}{\partial t} \right) \tag{3.92}$$

$$= -\mu_0 \mu \frac{\partial}{\partial t} (\nabla \times \boldsymbol{H}) - \mu_0 (\nabla \mu) \times \frac{\partial \boldsymbol{H}}{\partial t} .$$

By using (3.88), (3.89) and the nabla operator calculus for a double cross product, this results in

$$\nabla (\nabla \cdot \boldsymbol{E}) - \Delta \boldsymbol{E} = -\varepsilon_0 \mu_0 \varepsilon \mu \frac{\partial^2 \boldsymbol{E}}{\partial t^2} - \mu_0 \mu \sigma \frac{\partial \boldsymbol{E}}{\partial t}$$
$$+ [\nabla (\ln \mu)] \times (\nabla \times \boldsymbol{E}) . \tag{3.93}$$

Here, $\Delta = \nabla \cdot \nabla$ is the Laplacian operator, which has to be applied on each component of $\boldsymbol{E}$. Equation (3.90) can be used to eliminate the term $\nabla \cdot \boldsymbol{E}$ from (3.93)

$$\nabla \cdot (\varepsilon \boldsymbol{E}) = \boldsymbol{E} \cdot \nabla \varepsilon + \varepsilon \nabla \cdot \boldsymbol{E} = 0 ;$$

$$\Rightarrow \quad \nabla \cdot \boldsymbol{E} = -\frac{1}{\varepsilon} \boldsymbol{E} \cdot \nabla \varepsilon = -\boldsymbol{E} \cdot \nabla (\ln \varepsilon) .$$

So, (3.93) gives the final so-called wave equation for the electric vector E

$$\Delta E + \nabla\left[E\cdot\nabla\left(\ln\varepsilon\right)\right] - \frac{\varepsilon\mu}{c^2}\frac{\partial^2 E}{\partial t^2} - \mu_0\mu\sigma\frac{\partial E}{\partial t}$$
$$+ \left[\nabla\left(\ln\mu\right)\right]\times\left(\nabla\times E\right) = 0 \, . \tag{3.94}$$

Additionally, (3.13) was used to replace $\varepsilon_0\mu_0$ by $1/c^2$.

An analogue equation for the magnetic vector can be found using (3.88), (3.89) and (3.91):

$$\nabla\times\left(\nabla\times H\right) = \nabla\underbrace{\left(\nabla\cdot H\right)}_{=-H\cdot\nabla(\ln\mu)} - \Delta H$$
$$= -\nabla\left[H\cdot\nabla\left(\ln\mu\right)\right] - \Delta H$$
$$= \varepsilon_0\nabla\times\left(\varepsilon\frac{\partial E}{\partial t}\right) + \nabla\times\left(\sigma E\right)$$
$$= \varepsilon_0\varepsilon\nabla\times\frac{\partial E}{\partial t} + \varepsilon_0\left(\nabla\varepsilon\right)\times\frac{\partial E}{\partial t}$$
$$+ \sigma\nabla\times E + \left(\nabla\sigma\right)\times E$$
$$= -\varepsilon_0\mu_0\varepsilon\mu\frac{\partial^2 H}{\partial t^2} + \varepsilon_0\left(\nabla\varepsilon\right)$$
$$\times\frac{\partial E}{\partial t} - \mu_0\mu\sigma\frac{\partial H}{\partial t} + \left(\nabla\sigma\right)\times E \, . \tag{3.95}$$

Using (3.89) again, this equation can be resolved with respect to $\partial E/\partial t$:

$$\nabla\times H = \varepsilon_0\varepsilon\frac{\partial E}{\partial t} + \sigma E$$
$$\Rightarrow \quad \frac{\partial E}{\partial t} = \frac{1}{\varepsilon_0\varepsilon}\left(\nabla\times H - \sigma E\right) \, .$$

Then, $\partial E/\partial t$ can be eliminated in (3.95) resulting in:

$$\Delta H + \nabla\left[H\cdot\nabla\left(\ln\mu\right)\right] - \frac{\varepsilon\mu}{c^2}\frac{\partial^2 H}{\partial t^2}$$
$$- \mu_0\mu\sigma\frac{\partial H}{\partial t} + \left[\nabla\left(\ln\varepsilon\right)\right]\times\left(\nabla\times H\right)$$
$$+ \left[\nabla\sigma - \sigma\nabla\left(\ln\varepsilon\right)\right]\times E = 0 \, . \tag{3.96}$$

Unfortunately, it is not possible to completely eliminate the electric vector from this wave equation of the magnetic field.

Equations (3.94) and (3.96) are nearly symmetrical for a replacement of E with H and ε with μ. Only the terms containing the conductivity σ are not symmetrical. Nevertheless, there are two important special cases that provide symmetries of the wave equations of the electric and magnetic vector.

Wave Equations for Pure Dielectrics

If the material is a pure dielectric the conductivity σ, which is responsible for absorption is zero. Then (3.94) and (3.96) reduce to:

$$\Delta E + \nabla\left[E\cdot\nabla\left(\ln\varepsilon\right)\right] - \frac{\varepsilon\mu}{c^2}\frac{\partial^2 E}{\partial t^2}$$
$$+ \left[\nabla\left(\ln\mu\right)\right]\times\left(\nabla\times E\right) = 0 \, , \tag{3.97}$$

$$\Delta H + \nabla\left[H\cdot\nabla\left(\ln\mu\right)\right] - \frac{\varepsilon\mu}{c^2}\frac{\partial^2 H}{\partial t^2}$$
$$+ \left[\nabla\left(\ln\varepsilon\right)\right]\times\left(\nabla\times H\right) = 0 \, . \tag{3.98}$$

Here, the equations are really symmetrical for a replacement of E with H and ε with μ. In practice, there are, of course, no materials that are completely transparent to light. But in the visible or infrared region most glasses can be assumed with a good approximation to be dielectrics.

Wave Equations for Homogeneous Materials

The second interesting special case is for homogeneous materials. Here, ε, μ and σ are constants that do not depend on r and their gradients are zero. In this case (3.94) and (3.96) reduce to

$$\Delta E - \frac{\varepsilon\mu}{c^2}\frac{\partial^2 E}{\partial t^2} - \mu_0\mu\sigma\frac{\partial E}{\partial t} = 0 \, , \tag{3.99}$$

$$\Delta H - \frac{\varepsilon\mu}{c^2}\frac{\partial^2 H}{\partial t^2} - \mu_0\mu\sigma\frac{\partial H}{\partial t} = 0 \, . \tag{3.100}$$

These equations are symmetrical to a replacement of E with H. In practice, homogeneous materials are the most important case because all conventional lenses (with the exception of graded index lenses, or GRIN lenses) are made of homogeneous glasses or at least of glasses with a very small inhomogeneity.

3.1.5 The Helmholtz Equations

Assume a time-harmonic wave with angular frequency ω represented in its complex notation (3.64):

$$E\left(r, t\right) = \hat{E}\left(r\right)\mathrm{e}^{-\mathrm{i}\omega t} \, , \tag{3.101}$$

$$H\left(r, t\right) = \hat{H}\left(r\right)\mathrm{e}^{-\mathrm{i}\omega t} \, . \tag{3.102}$$

As long as linear operations are made using this complex representation is permitted. The partial derivatives with respect to t can be calculated directly where again the

functionalities are omitted in our notation:

$$\frac{\partial \boldsymbol{E}}{\partial t} = -\mathrm{i}\omega \hat{\boldsymbol{E}}\mathrm{e}^{-\mathrm{i}\omega t} \,,$$

$$\frac{\partial \boldsymbol{H}}{\partial t} = -\mathrm{i}\omega \hat{\boldsymbol{H}}\mathrm{e}^{-\mathrm{i}\omega t} \,,$$

$$\frac{\partial^2 \boldsymbol{E}}{\partial t^2} = -\omega^2 \hat{\boldsymbol{E}}\mathrm{e}^{-\mathrm{i}\omega t} \,,$$

$$\frac{\partial^2 \boldsymbol{H}}{\partial t^2} = -\omega^2 \hat{\boldsymbol{H}}\mathrm{e}^{-\mathrm{i}\omega t} \,.$$

These equations can be used in the wave equations (3.94) and (3.96) for linear and isotropic materials. The result is

$$\Delta \hat{\boldsymbol{E}} + \nabla \left[\hat{\boldsymbol{E}} \cdot \nabla (\ln \varepsilon) \right] + \omega^2 \frac{\varepsilon \mu}{c^2} \hat{\boldsymbol{E}} + \mathrm{i}\omega \mu_0 \mu \sigma \hat{\boldsymbol{E}}$$
$$+ [\nabla (\ln \mu)] \times \left(\nabla \times \hat{\boldsymbol{E}} \right) = 0 \,, \tag{3.103}$$

$$\Delta \hat{\boldsymbol{H}} + \nabla \left[\hat{\boldsymbol{H}} \cdot \nabla (\ln \mu) \right] + \omega^2 \frac{\varepsilon \mu}{c^2} \hat{\boldsymbol{H}} + \mathrm{i}\omega \mu_0 \mu \sigma \hat{\boldsymbol{H}}$$
$$+ [\nabla (\ln \varepsilon)] \times \left(\nabla \times \hat{\boldsymbol{H}} \right) + [\nabla \sigma - \sigma \nabla (\ln \varepsilon)] \times \hat{\boldsymbol{E}} = 0 \,. \tag{3.104}$$

These two time-independent equations are called the Helmholtz equations for the electric and the magnetic vector. Since only the position-dependent complex electric and magnetic vectors $\hat{\boldsymbol{E}}$ and $\hat{\boldsymbol{H}}$ are used, only time-averaged quantities can be calculated using the Helmholtz equations. Again two special cases are of interest.

Helmholtz Equations for Pure Dielectrics
For pure dielectric materials the conductivity is zero ($\sigma = 0$). In this case (3.103) and (3.104) result in

$$\Delta \hat{\boldsymbol{E}} + \nabla \left[\hat{\boldsymbol{E}} \cdot \nabla (\ln \varepsilon) \right] + \omega^2 \frac{\varepsilon \mu}{c^2} \hat{\boldsymbol{E}}$$
$$+ [\nabla (\ln \mu)] \times \left(\nabla \times \hat{\boldsymbol{E}} \right) = 0 \,, \tag{3.105}$$

$$\Delta \hat{\boldsymbol{H}} + \nabla \left[\hat{\boldsymbol{H}} \cdot \nabla (\ln \mu) \right] + \omega^2 \frac{\varepsilon \mu}{c^2} \hat{\boldsymbol{H}}$$
$$+ [\nabla (\ln \varepsilon)] \times \left(\nabla \times \hat{\boldsymbol{H}} \right) = 0 \,. \tag{3.106}$$

Again, both equations are symmetric with regards to a replacement of $\hat{\boldsymbol{E}}$ with $\hat{\boldsymbol{H}}$ and ε with μ.

Helmholtz Equations for Homogeneous Materials
For homogeneous materials the gradients of ε, μ and σ are zero. In this case (3.103) and (3.104) obtain a quite simple form

$$\Delta \hat{\boldsymbol{E}} + \omega^2 \frac{\varepsilon \mu}{c^2} \hat{\boldsymbol{E}} + \mathrm{i}\omega \mu_0 \mu \sigma \hat{\boldsymbol{E}} = 0 \,, \tag{3.107}$$

$$\Delta \hat{\boldsymbol{H}} + \omega^2 \frac{\varepsilon \mu}{c^2} \hat{\boldsymbol{H}} + \mathrm{i}\omega \mu_0 \mu \sigma \hat{\boldsymbol{H}} = 0 \,. \tag{3.108}$$

Both equations are completely symmetric in $\hat{\boldsymbol{E}}$ and $\hat{\boldsymbol{H}}$. The angular frequency ω is defined as $2\pi\nu$ and the frequency ν and the wavelength in vacuum λ are connected by (3.49): $\nu\lambda = c$. Therefore, (3.107) and (3.108) can be written as

$$\left(\Delta + \hat{k}^2 \right) \hat{\boldsymbol{E}} = 0 \,, \tag{3.109}$$

$$\left(\Delta + \hat{k}^2 \right) \hat{\boldsymbol{H}} = 0 \,, \tag{3.110}$$

with

$$\hat{k}^2 = \omega^2 \frac{\varepsilon \mu}{c^2} + \mathrm{i}\omega \mu_0 \mu \sigma$$
$$= \left(\frac{2\pi}{\lambda} \right)^2 \left(\varepsilon \mu + \mathrm{i} \frac{\lambda}{2\pi c \varepsilon_0} \mu \sigma \right) = \left(\frac{2\pi \hat{n}}{\lambda} \right)^2 \,. \tag{3.111}$$

Here, the refractive index $\hat{n}$ is defined as

$$\hat{n}^2 = \varepsilon \mu + \mathrm{i} \frac{\lambda}{2\pi c \varepsilon_0} \mu \sigma \,. \tag{3.112}$$

This means that $\hat{n}$ is a complex number if the conductivity σ is not zero. Therefore, the real part n and the imaginary part n_I of $\hat{n}$ can be calculated:

$$\hat{n} = n + \mathrm{i} n_\mathrm{I} \quad \Rightarrow \quad \hat{n}^2 = n^2 - n_\mathrm{I}^2 + 2\mathrm{i} n n_\mathrm{I} \,; \tag{3.113}$$

$$\Rightarrow \quad n^2 - n_\mathrm{I}^2 = \varepsilon \mu \quad \text{and} \quad 2 n n_\mathrm{I} = \frac{\lambda}{2\pi c \varepsilon_0} \mu \sigma \,,$$

$$\Rightarrow \quad n_\mathrm{I}^2 = \left(\frac{\lambda}{4\pi c \varepsilon_0 n} \mu \sigma \right)^2 \,,$$

$$\Rightarrow \quad n^4 - \varepsilon \mu n^2 - \left(\frac{\lambda}{4\pi c \varepsilon_0} \mu \sigma \right)^2 = 0 \,.$$

$$\Rightarrow \quad n = \sqrt{\frac{\varepsilon \mu + \sqrt{\varepsilon^2 \mu^2 + \frac{\lambda^2 \mu^2 \sigma^2}{4\pi^2 c^2 \varepsilon_0^2}}}{2}} \,; \tag{3.114}$$

$$n_\mathrm{I} = \frac{\lambda}{4\pi c \varepsilon_0} \mu \sigma \sqrt{\frac{2}{\varepsilon \mu + \sqrt{\varepsilon^2 \mu^2 + \frac{\lambda^2 \mu^2 \sigma^2}{4\pi^2 c^2 \varepsilon_0^2}}}} \,. \tag{3.115}$$

Only the positive solution of the two solutions of the quadratic equation with the variable n^2 is taken since n should be a real number and additionally only the

positive square root of n^2 is taken since n should be a positive real number. For a pure dielectric ($\sigma = 0$) the imaginary part vanishes and the refractive index is a real number like it was defined in (3.27):

$$\sigma = 0 \quad \Rightarrow \quad \hat{n} = n = \sqrt{\varepsilon\mu} \tag{3.116}$$

A Simple Solution of the Helmholtz Equation in a Homogeneous Material

A simple solution of (3.109) is, e.g., a linearly polarized plane wave propagating in the z direction

$$\hat{E} = \hat{E}_0 e^{i\hat{k}z} = \hat{E}_0 e^{i2\pi\hat{n}z/\lambda} . \tag{3.117}$$

Here, $\hat{E}_0$ is a constant vector and its modulus represents the amplitude of the electric vector at $z = 0$. If $\hat{n}$ is complex the effective position-dependent amplitude decreases exponentially

$$\hat{n} = n + in_I \quad \Rightarrow \quad \hat{E} = \hat{E}_0 e^{-2\pi n_I z/\lambda} e^{i2\pi nz/\lambda} . \tag{3.118}$$

So, the extinction of a wave can be formally included in the notation of a wave using complex exponential terms by just assuming a complex refractive index. The real part of this complex refractive index is responsible for the "normal" refractive properties and the imaginary part is responsible for absorption. For metals, n_I can be larger than one so that the wave can enter the metal for only a fraction of a wavelength before the electric (and magnetic) vector vanishes.

Instead of using the imaginary part n_I of the refractive index the so-called absorption coefficient α is often used. It is defined by

$$\alpha := \frac{4\pi}{\lambda} n_I \quad \Rightarrow \quad \hat{E} = \hat{E}_0 e^{-\alpha z/2} e^{i2\pi nz/\lambda} . \tag{3.119}$$

After having propagated a distance $z = 1/\alpha$ the electric energy density of the wave, which is proportional to $|\hat{E}|^2$, decreases to $1/e$ of its starting value.

Whereas α is, according to our definition, always positive in lossy materials there are also active gain media, e.g., in lasers, which have a negative coefficient α. Then α is not an absorption but an amplification or gain coefficient.

Inhomogeneous Plane Waves

The solution of the Helmholtz equation (3.109) in a homogeneous but lossy material defined by (3.118) is the simplest form of a so-called inhomogeneous plane wave [3.1, 4]. The general inhomogeneous plane wave is obtained from (3.109) by the approach

$$\hat{E} = \hat{E}_0 e^{i\hat{k}\cdot r} = \hat{E}_0 e^{-g\cdot r} e^{ik\cdot r}$$

$$\Rightarrow \quad -\hat{k}\cdot\hat{k} + \hat{k}^2 = 0 , \tag{3.120}$$

where $\hat{k} = k + ig$ is a constant but complex wave vector with the real part k and the imaginary part g. In the general case, $\hat{E}_0$ is also a constant but complex electric vector so that all polarization states can be represented (Sect. 3.2.3).

By using the (3.111), (3.113) and (3.119) the complex quantity $\hat{k}$ is defined as

$$\hat{k} = \frac{2\pi}{\lambda}\hat{n} = \frac{2\pi}{\lambda}(n + in_I) = \frac{2\pi n}{\lambda} + i\frac{\alpha}{2} \tag{3.121}$$

$$\Rightarrow \quad \hat{k}^2 = \frac{4\pi^2 n^2}{\lambda^2} - \frac{\alpha^2}{4} + i\frac{2\pi n\alpha}{\lambda} .$$

This means that the two vectors k and g have to fulfill the conditions

$$\hat{k}\cdot\hat{k} = (k + ig)\cdot(k + ig)$$
$$= |k|^2 - |g|^2 + 2ig\cdot k$$
$$= \hat{k}^2$$
$$= \frac{4\pi^2 n^2}{\lambda^2} - \frac{\alpha^2}{4} + i\frac{2\pi n\alpha}{\lambda} . \tag{3.122}$$

A separation of the real and imaginary part gives

$$|k|^2 - |g|^2 = \frac{4\pi^2 n^2}{\lambda^2} - \frac{\alpha^2}{4}, \tag{3.123}$$

$$g\cdot k = \frac{\pi n\alpha}{\lambda} . \tag{3.124}$$

So, the projection of the vector g onto the vector k has to fulfill the second equation. An important and interesting case is that of a lossless material, i. e., $\alpha = 0$. Then g and k have to be perpendicular to each other meaning that the planes of constant phase, which are perpendicular to k, and the planes of constant amplitude, which are perpendicular to g, are also perpendicular to each other.

Inhomogeneous plane waves do not exist in the whole space because the amplitude decreases exponentially along the direction of g, but on the other side it increases exponentially for the direction antiparallel to g and would tend to infinity. Therefore, only the half-space with the exponentially decreasing part can exist in the real world, whereas in the other direction there

has to be a limit. An example of an inhomogeneous plane wave is an evanescent wave in the case of total internal reflection at an interface between two dielectric materials with different refractive indices. There, a plane wave propagating in the material with higher refractive index with an angle of incidence at the interface of more than the critical angle of total internal reflection is reflected. Besides the reflected wave, however, there exists an evanescent wave in the material with the lower refractive index. Its vector k is parallel to the interface between the two materials, while its amplitude decreases exponentially with increasing distance from the interface. The evanescent wave transports no energy into the material with the lower refractive index, but the total energy is in the reflected wave.

In the following sections some basic properties of light waves will be described. For more information see textbooks on optics such as e.g., [3.1, 5–11].

3.2 Polarization

In Sect. 3.1.1 it is shown that a so-called linearly polarized plane wave is a solution of Maxwell's equations. There, the electric vector has a well-defined direction which remains constant during the propagation of the wave. There are other solutions of Maxwell's equations where the direction of the electric vector does not remain constant during the propagation, but nevertheless, it has at a certain point and at a certain time a well-defined direction. All these solutions are called polarized light.

Contrary to this, light that is emitted by an electric bulb is unpolarized. This means that there are many light waves with stochastically distributed phase relations to each other, i. e., incoherent light, and where the polarization varies in time. So, these light waves are added incoherently and there is no preferred direction of the electric vector. In practice, light is often partially polarized, i. e., some of the light is unpolarized and the other is polarized. Natural sun light on the earth is, e.g., partially polarized because of the influence of the atmosphere to the originally unpolarized light of the sun.

Here, only the case of a fully polarized plane wave in a homogeneous dielectric material will be investigated. In the paragraph "The Orthogonality Condition for Plane Waves in Homogeneous Dielectrics" it is shown that the electric vector E and the magnetic vector H of a plane wave in a homogeneous and isotropic linear material are always perpendicular to each other and both are perpendicular to the direction of propagation e of the plane wave. Therefore, for a given direction of propagation e it is sufficient to consider only the electric vector. The magnetic vector is then automatically defined by (3.37)

$$H = \pm \sqrt{\frac{\varepsilon_0 \varepsilon}{\mu_0 \mu}} e \times E .$$

The electric vector E has to fulfill the wave equation (3.99) with $\sigma = 0$

$$\Delta E - \frac{n^2}{c^2} \frac{\partial^2 E}{\partial t^2} = 0 .$$

Without loss of generality, the direction of propagation will be parallel to the z-axis, i. e., $e = (0, 0, 1)$. Because of the orthogonality relation E can then only have a x and a y component. A quite general plane wave solution of the wave equation is in this case

$$\begin{aligned} E(z, t) &= \begin{pmatrix} E_x(z, t) \\ E_y(z, t) \\ E_z(z, t) \end{pmatrix} \\ &= \begin{pmatrix} A_x \cos(kz - \omega t + \delta_x) \\ A_y \cos(kz - \omega t + \delta_y) \\ 0 \end{pmatrix} . \end{aligned} \quad (3.125)$$

Here, $k = 2\pi n/\lambda = \omega n/c$ (3.50) is the modulus of the wave vector $k = 2\pi n e/\lambda$. It holds $A_x \geq 0$ and $A_y \geq 0$. By applying a trigonometric theorem, introducing the parameter $\alpha := kz - \omega t + \delta_x$ and the phase difference $\delta := \delta_y - \delta_x$ this equation can be written as

$$\begin{aligned} \begin{pmatrix} E_x(\alpha) \\ E_y(\alpha) \end{pmatrix} &= \begin{pmatrix} A_x \cos\alpha \\ A_y \cos(\alpha + \delta) \end{pmatrix} \\ &= \begin{pmatrix} A_x \cos\alpha \\ A_y \cos\alpha \cos\delta - A_y \sin\alpha \sin\delta \end{pmatrix} . \end{aligned} \quad (3.126)$$

This equation is the parametric representation of an ellipse, which is formed by the apex of the two-dimensional vector (E_x, E_y) in the xy-plane for different values of the parameter α. Unfortunately, in general, the principal axes of this ellipse will be rotated with respect to the x-axis and y-axis. Therefore, a transformation has to be done to calculate the principal axes of this ellipse with lengths $2a$ and $2b$. To do this, the following quantity is calculated where the argument α of E_x and E_y is

omitted in the notation

$$\left(\frac{E_x}{A_x}\right)^2 + \left(\frac{E_y}{A_y}\right)^2 - 2\frac{E_x E_y}{A_x A_y}\cos\delta$$

$$= \cos^2\alpha + (\cos\alpha\cos\delta - \sin\alpha\sin\delta)^2$$

$$\quad - 2\cos\alpha\cos\delta\,(\cos\alpha\cos\delta - \sin\alpha\sin\delta)$$

$$= \cos^2\alpha + (\cos\alpha\cos\delta - \sin\alpha\sin\delta)$$

$$\quad \times (-\cos\alpha\cos\delta - \sin\alpha\sin\delta)$$

$$= \cos^2\alpha\left(1 - \cos^2\delta\right) + \sin^2\alpha\sin^2\delta = \sin^2\delta;$$

$$\Rightarrow \quad \left(\frac{E_x}{A_x\sin\delta}\right)^2 + \left(\frac{E_y}{A_y\sin\delta}\right)^2$$

$$\quad - 2\frac{E_x E_y}{A_x A_y\sin^2\delta}\cos\delta = 1 . \tag{3.127}$$

This is the implicit representation of an ellipse that is rotated with respect to the x- and y-axis (see Fig. 3.4). On the other side an ellipse with the half-axes a and b parallel to the coordinate axes x' and y' and the coordinates of the electric vector E_x' and E_y' are written as

$$\left(\frac{E_x'}{a}\right)^2 + \left(\frac{E_y'}{b}\right)^2 = 1 . \tag{3.128}$$

This equation is transformed into a coordinate system with axes x and y whereby the system (x', y') is rotated by an angle φ relative to the system (x, y) by applying
Fig. 3.4 The polarization ellipse on which the apex of the electric vector moves if the time t or the coordinate z changes

the well-known rotation matrix to the coordinates

$$\begin{pmatrix} E_x' \\ E_y' \end{pmatrix} = \begin{pmatrix} \cos\varphi & \sin\varphi \\ -\sin\varphi & \cos\varphi \end{pmatrix} \begin{pmatrix} E_x \\ E_y \end{pmatrix}$$

$$= \begin{pmatrix} E_x\cos\varphi + E_y\sin\varphi \\ -E_x\sin\varphi + E_y\cos\varphi \end{pmatrix} .$$

So, the equation of the rotated ellipse in the coordinate system (x, y) indexed by terms in E_x^2, E_y^2 and $E_x E_y$ is

$$E_x^2\left(\frac{\cos^2\varphi}{a^2} + \frac{\sin^2\varphi}{b^2}\right)$$

$$+ E_y^2\left(\frac{\sin^2\varphi}{a^2} + \frac{\cos^2\varphi}{b^2}\right)$$

$$+ E_x E_y\sin(2\varphi)\left(\frac{1}{a^2} - \frac{1}{b^2}\right) = 1 .$$

In the last step the trigonometric equality $\sin(2\varphi) = 2\sin\varphi\cos\varphi$ is used.

By comparing this equation with (3.127) the coefficients of the terms in E_x^2, E_y^2 and $E_x E_y$ have to be equal to calculate the rotation angle φ and the principal axes. This results in three equations

$$\frac{\cos^2\varphi}{a^2} + \frac{\sin^2\varphi}{b^2} = \frac{1}{A_x^2\sin^2\delta},$$

$$\frac{\sin^2\varphi}{a^2} + \frac{\cos^2\varphi}{b^2} = \frac{1}{A_y^2\sin^2\delta},$$

$$\sin(2\varphi)\left(\frac{1}{a^2} - \frac{1}{b^2}\right) = -2\frac{\cos\delta}{A_x A_y\sin^2\delta} .$$

By (1) adding the second equation to the first equation and (2) subtracting the second equation from the first equation and applying the trigonometric equation $\cos(2\varphi) = \cos^2\varphi - \sin^2\varphi$ two new equations are obtained and written together with the old third equation

$$\frac{1}{a^2} + \frac{1}{b^2} = \frac{1}{\sin^2\delta}\left(\frac{1}{A_x^2} + \frac{1}{A_y^2}\right),$$

$$\cos(2\varphi)\left(\frac{1}{a^2} - \frac{1}{b^2}\right) = \frac{1}{\sin^2\delta}\left(\frac{1}{A_x^2} - \frac{1}{A_y^2}\right),$$

$$\sin(2\varphi)\left(\frac{1}{a^2} - \frac{1}{b^2}\right) = -2\frac{\cos\delta}{A_x A_y\sin^2\delta} .$$

Division of the third equation by the second equation gives the tangent of twice the rotation angle φ of the ellipse

$$\tan(2\varphi) = \frac{-2\cos\delta}{A_x A_y \left(\frac{1}{A_x^2} - \frac{1}{A_y^2}\right)} = \frac{-2A_x A_y \cos\delta}{A_y^2 - A_x^2}.$$

(3.129)

So, the rotation angle φ can be calculated from the known variables A_x, A_y and δ. There is a null of the denominator for the case $A_x = A_y$. Then the argument of the tangent is $2\varphi = \pm\pi/2$, i. e., $\varphi = \pm\pi/4$. Only if the numerator is also zero, i. e., $\cos\delta = 0$ and therefore $\delta = (2n+1)\pi/2$, the angle φ is not defined. In this case, the ellipse is degenerated into a circle as we will see later and then the rotation angle is, of course, not defined. It should also be mentioned that the rotation angle φ is only defined between $-\pi/4$ and $\pi/4$ and therefore 2φ between $-\pi/2$ and $\pi/2$ so that the arctangent function is well defined. This is sufficient because first, a rotation of an ellipse by π $(= 180$ degrees) does not change anything. And second, the principal axes of the ellipse can be chosen in such a way that either a is the large axis or b. So, the rotation angle φ has to be defined only in an interval of the length $\pi/2$, i. e., $[-\pi/4; \pi/4]$.

After having calculated φ, the half-axes a and b of the polarization ellipse can also be calculated using the first two of the above equations

(i) $\frac{1}{a^2} + \frac{1}{b^2} = \frac{1}{\sin^2\delta}\left(\frac{1}{A_x^2} + \frac{1}{A_y^2}\right),$

(ii) $\frac{1}{a^2} - \frac{1}{b^2} = \frac{1}{\cos(2\varphi)\sin^2\delta}\left(\frac{1}{A_x^2} - \frac{1}{A_y^2}\right);$

$(i)+(ii) \Rightarrow \frac{1}{a^2}$

$$= \frac{1}{2\sin^2\delta}\left[\frac{1}{A_x^2} + \frac{1}{A_y^2} + \frac{1}{\cos(2\varphi)}\left(\frac{1}{A_x^2} - \frac{1}{A_y^2}\right)\right],$$

(3.130)

$(i)-(ii) \Rightarrow \frac{1}{b^2}$

$$= \frac{1}{2\sin^2\delta}\left[\frac{1}{A_x^2} + \frac{1}{A_y^2} - \frac{1}{\cos(2\varphi)}\left(\frac{1}{A_x^2} - \frac{1}{A_y^2}\right)\right].$$

(3.131)

Using a trigonometric relation and (3.129) it holds that

$$\frac{1}{\cos(2\varphi)} = \sqrt{1 + \tan^2(2\varphi)} = \sqrt{1 + 4\frac{A_x^2 A_y^2 \cos^2\delta}{\left(A_y^2 - A_x^2\right)^2}}$$

$$= \frac{\sqrt{\left(A_y^2 - A_x^2\right)^2 + 4A_x^2 A_y^2 \cos^2\delta}}{\left|A_y^2 - A_x^2\right|}.$$

Remember that 2φ is only defined between $-\pi/2$ and $\pi/2$ so that $\cos(2\varphi) \geq 0$. Defining the value s by

$$s = \begin{cases} +1 \text{ if } A_y^2 - A_x^2 \geq 0 \\ -1 \text{ if } A_y^2 - A_x^2 < 0 \end{cases},$$

(3.132)

the reciprocal values of the squares of the half-axes can be explicitly written as

$$\frac{1}{a^2} = \frac{1}{2A_x^2 A_y^2 \sin^2\delta}$$

$$\times \left[A_y^2 + A_x^2 + s\sqrt{\left(A_y^2 - A_x^2\right)^2 + 4A_x^2 A_y^2 \cos^2\delta}\right],$$

(3.133)

$$\frac{1}{b^2} = \frac{1}{2A_x^2 A_y^2 \sin^2\delta}$$

$$\times \left[A_y^2 + A_x^2 - s\sqrt{\left(A_y^2 - A_x^2\right)^2 + 4A_x^2 A_y^2 \cos^2\delta}\right].$$

(3.134)

Now it is easy to calculate the ratio of the squares of the half-axes, whereby the equality $\cos^2\delta - 1 = -\sin^2\delta$ is used

$$\frac{b^2}{a^2} = \frac{A_y^2 + A_x^2 + s\sqrt{\left(A_y^2 + A_x^2\right)^2 - 4A_x^2 A_y^2 \sin^2\delta}}{A_y^2 + A_x^2 - s\sqrt{\left(A_y^2 + A_x^2\right)^2 - 4A_x^2 A_y^2 \sin^2\delta}}$$

$$= \frac{1 + s\sqrt{1 - 4\sin^2\delta \frac{A_x^2 A_y^2}{\left(A_y^2 + A_x^2\right)^2}}}{1 - s\sqrt{1 - 4\sin^2\delta \frac{A_x^2 A_y^2}{\left(A_y^2 + A_x^2\right)^2}}}.$$

(3.135)

So, for given parameters A_x, A_y and δ the half-axes a and b of the ellipse can be calculated by (3.133) and (3.134). The rotation angle can be calculated by (3.129) and the ratio of the half-axes by (3.135). There are several interesting special cases of polarization states and these will be discussed in the following.

3.2.1 Different States of Polarization

Linear Polarization
An important and quite simple polarization state is the case of linear polarization. In this case the polarization ellipse degenerates to a line and the apex of the electric vector just oscillates on a line. This is the case if either the numerator or the denominator of (3.135) is zero so that a or b is zero. This means

$$1 - \sqrt{1 - 4\sin^2\delta \frac{A_x^2 A_y^2}{\left(A_y^2 + A_x^2\right)^2}} = 0 \Rightarrow \sin\delta = 0$$

or $A_x = 0$ or $A_y = 0$. \hfill (3.136)

The two cases $A_x = 0$ or $A_y = 0$ are obvious because in this case there is only an x or a y component of the electric vector. If both components are different from zero there is nevertheless linear polarization if the phase difference δ between the two components of the electric vector is $\delta = 0$ or $\delta = \pi$.

Circular Polarization
If the apex of the electric vector moves on a circle, the polarization state is called circular polarization. This means that both half-axes have to be equal: $a = b$. Using (3.135) this requires

$$\frac{b^2}{a^2} = 1 \Rightarrow 2\sin\delta \frac{A_x A_y}{A_y^2 + A_x^2} = \pm 1 .$$

Since $|\sin\delta| \leq 1$ this requires (A_x and A_y are both positive)

$$\frac{A_x A_y}{A_y^2 + A_x^2} \geq \frac{1}{2} \Rightarrow 2A_x A_y \geq A_x^2 + A_y^2$$

$$\Rightarrow 0 \geq \left(A_x - A_y\right)^2 .$$

This condition can only be fulfilled for the case $A_x = A_y$ and then there is the additional condition $\sin\delta = \pm 1$. Finally, the conditions for circular polarization are

$$A_x = A_y \wedge \delta = \frac{\pm\pi}{2} . \hfill (3.137)$$

Using the original (3.125) this means for the electric vector

$$\begin{pmatrix} E_x(z,t) \\ E_y(z,t) \end{pmatrix} = \begin{pmatrix} A_x \cos(kz - \omega t + \delta_x) \\ A_x \cos\left(kz - \omega t + \delta_x \pm \frac{\pi}{2}\right) \end{pmatrix}$$

$$= \begin{pmatrix} A_x \cos(kz - \omega t + \delta_x) \\ \mp A_x \sin(kz - \omega t + \delta_x) \end{pmatrix} .$$

\hfill (3.138)

So, the two different signs of the phase difference δ correspond to different directions of rotation of the apex of the electric vector. These two cases are called right-handed circular polarization ($\delta = \pi/2$) and left-handed circular polarization ($\delta = -\pi/2$). The definition of right-handed and left-handed is not always identical in textbooks so that we use the definition of [3.1].

Elliptic Polarization
The general polarization state is, of course, the so-called elliptic polarization. In this case the apex of the electric vector moves on an ellipse if the time t or the position z is changed. This state is the case if neither $\delta = 0$ or $\delta = \pi$ nor $\delta = \pm\pi/2$. Also if $\delta = \pm\pi/2$ the light is elliptically polarized if $A_x \neq A_y$. There, we have to again distinguish between right-handed and left-handed elliptic polarization.

3.2.2 The Poincaré Sphere

A method to visualize the different states of polarization is the so-called Poincaré sphere, which was introduced by H. Poincaré in 1892. By using (3.126) as the definition of the electric field, the so-called Stokes parameters of a plane monochromatic wave can be defined [3.1]

$$s_0 := A_x^2 + A_y^2 ,$$
$$s_1 := A_x^2 - A_y^2 ,$$
$$s_2 := 2A_x A_y \cos\delta ,$$
$$s_3 := 2A_x A_y \sin\delta . \hfill (3.139)$$

It is obvious that the four quantities are connected by the relation

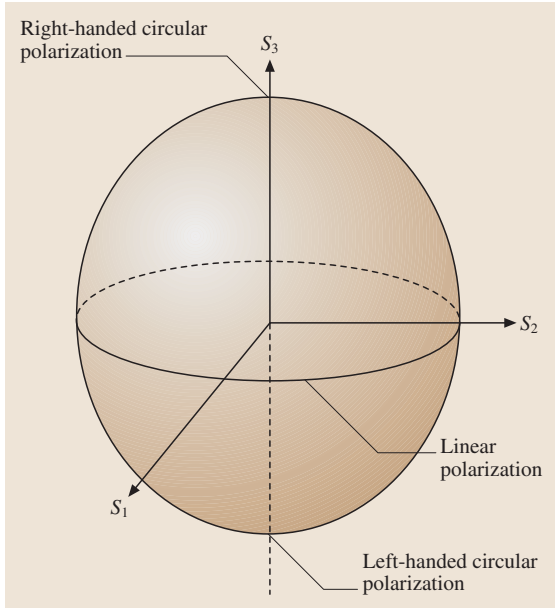
$$s_1^2 + s_2^2 + s_3^2 = A_x^4 + A_y^4 - 2A_x^2 A_y^2 + 4A_x^2 A_y^2$$
$$= A_x^4 + A_y^4 + 2A_x^2 A_y^2 = s_0^2 . \hfill (3.140)$$


Fig. 3.5 The Poincaré sphere and the visualization of the different states of polarization

So, only three of the parameters are independent and the parameter s_0 is proportional to the intensity of the wave. If s_1, s_2 and s_3 are now used as the cartesian coordinates of a point in space, all allowed combinations will be situated according to (3.140) on a sphere with radius s_0. The radius s_0 is proportional to the intensity of the wave and the sphere is called the Poincaré sphere (Fig. 3.5).

The different polarization states correspond to different positions on the Poincaré sphere. For linearly polarized light it is, e.g., either $A_x = 0$ or $A_y = 0$ or $\delta = 0$ or $\delta = \pi$. In all four cases the parameter s_3 will be zero. This means that points lying in the equatorial plane of the Poincaré sphere represent linear polarization. Another interesting case is circular polarization. In this case the conditions are according to (3.137): $A_x = A_y$ and $\delta = \pm\pi/2$. Therefore, s_1 and s_2 are both zero and circular polarization corresponds to the poles of the Poincaré sphere. At the north pole ($s_1 = s_2 = 0$ and $s_3 = s_0$) the light is right-handed circularly polarized ($\delta = \pi/2$). At the south pole ($s_1 = s_2 = 0$ and $s_3 = -s_0$) the light is left-handed circularly polarized ($\delta = -\pi/2$). All other states of polarization (elliptic polarization) correspond to points somewhere else on the Poincaré sphere. In the upper hemisphere of the Poincaré sphere ($s_3 > 0$) the light is always right-handed polarized and in the lower hemisphere ($s_3 < 0$) the light is left-handed polarized.

3.2.3 Complex Representation of a Polarized Wave

In (3.125) the electric vector is expressed as a real quantity. As we have seen in other sections it is in many cases useful to take a complex notation, where only the real part has a physical meaning

$$
\begin{aligned}
\boldsymbol{E}(z, t) &= \begin{pmatrix} E_x(z, t) \\ E_y(z, t) \\ E_z(z, t) \end{pmatrix} \\
&= \begin{pmatrix} A_x \cos(kz - \omega t + \delta_x) \\ A_y \cos(kz - \omega t + \delta_y) \\ 0 \end{pmatrix} \\
&= \mathrm{Re}\left[\begin{pmatrix} A_x \mathrm{e}^{\mathrm{i}\delta_x} \\ A_y \mathrm{e}^{\mathrm{i}\delta_y} \\ 0 \end{pmatrix} \mathrm{e}^{\mathrm{i}kz} \mathrm{e}^{-\mathrm{i}\omega t} \right] \\
&= \mathrm{Re}\left(\hat{\boldsymbol{A}} \mathrm{e}^{\mathrm{i}kz} \mathrm{e}^{-\mathrm{i}\omega t} \right).
\end{aligned}
\tag{3.141}
$$

In this case the vector $\hat{\boldsymbol{A}}$ is a constant but complex vector in order to represent all possible states of polarization. With a real vector only a linear polarization state could be represented. The complex notation has the advantage that it is quite easy to calculate the time average of the intensity. According to (3.68) the time average of the intensity I is proportional to the square of the absolute value of the time-independent complex electric vector $\hat{\boldsymbol{E}}$:

$$
\hat{\boldsymbol{E}}(z) = \hat{\boldsymbol{A}} \mathrm{e}^{\mathrm{i}kz} \Rightarrow I \propto \hat{\boldsymbol{E}} \cdot \hat{\boldsymbol{E}}^* = A_x^2 + A_y^2 . \tag{3.142}
$$

Therefore, it is clear that a detector sensitive only to the intensity of a light wave cannot distinguish between different polarization states.

3.2.4 Simple Polarizing Optical Elements and the Jones Calculus

There are, of course, optical elements that influence the polarization state like polarizers, quarter-wave plates, half-wave plates and many others. Here, only the basic idea of their effects can be discussed. For more information about the treatment of polarizing optical elements see, e.g., [3.12–14]. In this section only fully polarized light is treated. This can be produced from natural unpolarized light with the help of a polarizer. In the following the word *polarizer* is always used for a po-

larization filter whereas other polarizing elements are simply called *polarizing elements* or *polarizing optical elements*. The case of partially polarized light will not be treated.

A quite useful algorithm for the treatment of fully polarized light is the so-called Jones calculus, which was invented by *Jones* [3.15]. If we again have a plane wave propagating in the z direction the polarization state can be described by a two-dimensional vector J in the x and y direction containing the x and y components of the vector $\hat{A}$ of (3.141):

$$J = \begin{pmatrix} J_x \\ J_y \end{pmatrix} = \begin{pmatrix} A_x e^{i\delta_x} \\ A_y e^{i\delta_y} \end{pmatrix} . \tag{3.143}$$

This vector is called the Jones vector.

Now each polarizing optical element can be represented by a 2×2 matrix, the Jones matrix. The resulting Jones vector of the light that has passed such a polarizing optical element is calculated by multiplying the Jones vector of the incident light with the Jones matrix. Several polarizing optical elements can be passed by simply multiplying the Jones matrices of these elements.

Polarizer
A polarizer is, e.g., a device that produces linearly polarized light from an arbitrary polarization state. If the polarizer passes only light polarized in x direction its Jones matrix is

$$P_x = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} . \tag{3.144}$$

Similarly Jones matrices of polarizers in other directions (y direction, 45° or −45°) can be represented by

$$P_y = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} ; P_{45°} = \frac{1}{2} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} ;$$

$$P_{-45°} = \frac{1}{2} \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} . \tag{3.145}$$

As an example consider a plane wave linearly polarized in the x direction, which first passes a polarizer in the x direction and then in the direction 45°. The resulting vector is:

$$J_{\text{final}} = \frac{1}{2} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} E_0 \\ 0 \end{pmatrix}$$

$$= \frac{1}{2} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} E_0 \\ 0 \end{pmatrix} = \frac{1}{2} \begin{pmatrix} E_0 \\ E_0 \end{pmatrix} .$$

Of course, the first polarizer in the x direction has no effect and the second polarizer selects the component of the electric vector in the 45° direction. The resulting intensity of the wave is then proportional to $|J_{\text{final}}|^2 = E_0^2/2$, i.e., half of the intensity is absorbed. Another well-known effect is the combination of two crossed polarizers (e.g., in the x and y directions). Their matrix is, of course,

$$P_{\text{crossed}} = P_y P_x = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix} .$$

This means that no light passes this combination. Only if other polarizing elements are between the two crossed polarizers can light pass. If, e.g., a polarizer with direction 45° is inserted between the two crossed polarizers light can pass this combination if it originally has a component in the x direction. The resulting light will, of course, only have a y component:

$$P_{\text{crossed}+45°} = P_y P_{45°} P_x$$

$$= \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \frac{1}{2} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$$

$$= \frac{1}{2} \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} .$$

Though this is a well-known example it is nevertheless a typical example that polarizing optical elements can produce quite astonishing results by inserting additional elements.

Quarter–Wave Plate
Another elementary polarizing optical element is a quarter-wave plate ($\lambda/4$-plate), which consists of a birefringent material. If the axes of the material are correctly oriented the refractive index for light polarized in x direction is, e.g., different from the refractive index for polarized light in y direction. The resulting effect is a phase difference between the two components of the Jones vector of $\pi/2$. The Jones matrix for a higher phase velocity in the y direction is, e.g.,

$$P_{\lambda/4} = e^{i\pi/4} \begin{pmatrix} 1 & 0 \\ 0 & i \end{pmatrix} . \tag{3.146}$$

This means that linearly polarized light with components in only the x or y direction remains linearly polarized

and the intensity is unchanged (in practice some light is, of course, absorbed). But for light that is linearly polarized and has equal components in the x and y direction (i. e., linearly polarized with a direction of 45°) the resulting polarization state is circularly polarized light

$$J_{\text{final}} = e^{i\pi/4} \begin{pmatrix} 1 & 0 \\ 0 & i \end{pmatrix} \frac{1}{\sqrt{2}} \begin{pmatrix} E_0 \\ E_0 \end{pmatrix}$$

$$= \frac{1}{\sqrt{2}} e^{i\pi/4} \begin{pmatrix} E_0 \\ iE_0 \end{pmatrix} .$$

Again, the intensity of the light is unchanged, only the polarization state has changed. Linearly polarized incident light with other directions of polarization will result in elliptically polarized light.

Half–Wave Plate

A third interesting case is when the circularly polarized light passes an identical quarter-wave plate a second time. Then the Jones vector is

$$J_{\text{final}} = e^{i\pi/4} \begin{pmatrix} 1 & 0 \\ 0 & i \end{pmatrix} \frac{1}{\sqrt{2}} e^{i\pi/4} \begin{pmatrix} E_0 \\ iE_0 \end{pmatrix}$$

$$= \frac{1}{\sqrt{2}} e^{i\pi/2} \begin{pmatrix} E_0 \\ -E_0 \end{pmatrix} .$$

The result is again linearly polarized light, but with a rotation of the direction of polarization of 90°. The effect of two identical quarter-wave plates is, of course, the effect of a half-wave plate ($\lambda/2$-plate). So, a half-wave plate rotates the direction of polarization of linearly polarized light by 90° if the incident light is polarized in the 45° direction. If the incident light is polarized in the x or y direction nothing happens. The matrix of a half-wave plate is

$$P_{\lambda/2} = e^{i\pi/4} \begin{pmatrix} 1 & 0 \\ 0 & i \end{pmatrix} e^{i\pi/4} \begin{pmatrix} 1 & 0 \\ 0 & i \end{pmatrix}$$

$$= e^{i\pi/2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} . \tag{3.147}$$

3.3 Interference

Interference is the property of all types of waves to form characteristic stationary variations of the intensity by the superposition of two or more waves. Of course, in the case of light some conditions have to be fulfilled because with natural light from the sun or light from a bulb it is quite difficult to get interference effects. On the other hand it is no problem to obtain interference effects with the help of a laser. In fact, the condition is that the light has to be coherent or at least partially coherent[3.16]. There are complete books about interference effects and the application of these optical effects in the field of interferometry [3.17–20]. So, in this section only the basic ideas can be treated.

3.3.1 Interference of Two Plane Waves

First, the interference of two monochromatic plane waves in a homogeneous and isotropic material will be treated. The two plane waves with the angular frequency ω are propagating in the direction of their wave vectors k_1 and k_2. The corresponding unit vectors in the direction of propagation are $e_1 = k_1/|k_1|$ and $e_2 = k_2/|k_2|$. Their polarization state shall be arbitrary. In Sect. 3.2 we investigated the different polarization states and used the fact that for one plane wave the coordinate system can be chosen so conveniently that

the direction of propagation is in the z direction and the electric vector can only have x and y components because of the orthogonality condition. For two plane waves, which are not propagating parallel, a more generalized description has to be found. Therefore, the unit vector $e_\perp$, which is perpendicular to the plane formed by the two propagation vectors e_1 and e_2 is defined as

$$e_\perp := \frac{e_1 \times e_2}{|e_1 \times e_2|} . \tag{3.148}$$

Only for the case that e_1 and e_2 are parallel or antiparallel, i. e., $e_2 = \pm e_1$, $e_\perp$ is not defined and we define in this case $e_1 := (0, 0, 1)$ and $e_\perp = (0, 1, 0)$. But in the following, it is sufficient to assume that $e_\perp$ is well defined via (3.148) or otherwise. So, for each wave we can define a unit vector $e_{\parallel,1}$ or $e_{\parallel,2}$, which lies in the plane defined by the directions of propagation of the two waves but perpendicular to the respective propagation vector

$$e_{\parallel,1} := e_\perp \times e_1 , \tag{3.149}$$

$$e_{\parallel,2} := e_\perp \times e_2 . \tag{3.150}$$

Now, each plane wave will only have components along $e_\perp$ and the respective vector $e_{\parallel,1}$ or $e_{\parallel,2}$. The components along $e_\perp$ are called transversal electric (TE) components. The components along $e_{\parallel,1}$ or $e_{\parallel,2}$

are called transversal magnetic (TM) components, because in this case the corresponding component of the magnetic vector is perpendicular to the plane of propagation.

Therefore, using a generalization of (3.141) the electric vectors of both plane waves can be represented as:

$$
\begin{aligned}
\mathbf{E}_1(\mathbf{r}, t) &= \mathrm{Re}\Big[\Big(A_{\parallel,1}\mathrm{e}^{\mathrm{i}\delta_{\parallel,1}}\mathbf{e}_{\parallel,1} + A_{\perp,1}\mathrm{e}^{\mathrm{i}\delta_{\perp,1}}\mathbf{e}_{\perp}\Big) \\
&\quad \times \mathrm{e}^{\mathrm{i}\mathbf{k}_1\cdot\mathbf{r}}\mathrm{e}^{-\mathrm{i}\omega t}\Big] \\
&= \mathrm{Re}\Big[\Big(\hat{\mathbf{A}}_{\parallel,1} + \hat{\mathbf{A}}_{\perp,1}\Big)\mathrm{e}^{\mathrm{i}\mathbf{k}_1\cdot\mathbf{r}}\mathrm{e}^{-\mathrm{i}\omega t}\Big],
\end{aligned}
$$

(3.151)

$$
\begin{aligned}
\mathbf{E}_2(\mathbf{r}, t) &= \mathrm{Re}\Big[\Big(A_{\parallel,2}\mathrm{e}^{\mathrm{i}\delta_{\parallel,2}}\mathbf{e}_{\parallel,2} + A_{\perp,2}\mathrm{e}^{\mathrm{i}\delta_{\perp,2}}\mathbf{e}_{\perp}\Big) \\
&\quad \times \mathrm{e}^{\mathrm{i}\mathbf{k}_2\cdot\mathbf{r}}\mathrm{e}^{-\mathrm{i}\omega t}\Big] \\
&= \mathrm{Re}\Big[\Big(\hat{\mathbf{A}}_{\parallel,2} + \hat{\mathbf{A}}_{\perp,2}\Big)\mathrm{e}^{\mathrm{i}\mathbf{k}_2\cdot\mathbf{r}}\mathrm{e}^{-\mathrm{i}\omega t}\Big].
\end{aligned}
$$

(3.152)

The quantities with a hat are complex, the others are real. Using this representation the orthogonality condition for electromagnetic waves is automatically fulfilled. The magnetic vector is not explicitly noted here because it is automatically defined by (3.37). Moreover, the interaction of an electromagnetic wave with matter is normally due to an electric field. Therefore, the electric vector is used in our calculation.

The interference of these two plane waves just means that the electric vectors have to be added. Since this is a linear operation and we are, in the end, only interested in the time average of the intensity it is sufficient to add the time-independent complex electric vectors $\hat{\mathbf{E}}_1$ and $\hat{\mathbf{E}}_2$. The resulting electric vector $\hat{\mathbf{E}}_{1+2}$ is

$$
\begin{aligned}
\hat{\mathbf{E}}_{1+2} = \hat{\mathbf{E}}_1 + \hat{\mathbf{E}}_2 &= \Big(\hat{\mathbf{A}}_{\parallel,1} + \hat{\mathbf{A}}_{\perp,1}\Big)\mathrm{e}^{\mathrm{i}\mathbf{k}_1\cdot\mathbf{r}} \\
&\quad + \Big(\hat{\mathbf{A}}_{\parallel,2} + \hat{\mathbf{A}}_{\perp,2}\Big)\mathrm{e}^{\mathrm{i}\mathbf{k}_2\cdot\mathbf{r}}.
\end{aligned}
$$

(3.153)

The intensity of a plane wave measured on a surface perpendicular to the direction of propagation is, according to (3.68), proportional to $|\hat{\mathbf{E}}|^2$. The proportionality factor is $\sqrt{\varepsilon/\mu}\,\varepsilon_0 c/2$. The intensity of the plane wave on a plane surface that is not perpendicular to the direction of the energy flow is decreased by the cosine of the angle of incidence. In the following, the plane on which we define the intensity of our interference pattern is perpendicular to the effective direction of the energy flow, i.e., perpendicular to $\mathbf{k}_1 + \mathbf{k}_2$ if the two waves are not antiparallel or perpendicular to $\mathbf{k}_1$ if $\mathbf{k}_1 = -\mathbf{k}_2$. The co-

sine factors are then identical for both waves and the intensity I_{1+2} and the square of the modulus of the resulting electric vector $|\hat{\mathbf{E}}_{1+2}|^2$ are really proportional to each other with a constant of proportionality a. So, for the interference pattern the following holds true:

$$
\begin{aligned}
\Big|\hat{\mathbf{E}}_{1+2}\Big|^2 &= \hat{\mathbf{E}}_{1+2}\cdot\hat{\mathbf{E}}_{1+2}^* \\
&= \Big[\Big(\hat{\mathbf{A}}_{\parallel,1} + \hat{\mathbf{A}}_{\perp,1}\Big)\mathrm{e}^{\mathrm{i}\mathbf{k}_1\cdot\mathbf{r}} \\
&\quad + \Big(\hat{\mathbf{A}}_{\parallel,2} + \hat{\mathbf{A}}_{\perp,2}\Big)\mathrm{e}^{\mathrm{i}\mathbf{k}_2\cdot\mathbf{r}}\Big] \\
&\quad \times\Big[\Big(\hat{\mathbf{A}}_{\parallel,1}^* + \hat{\mathbf{A}}_{\perp,1}^*\Big)\mathrm{e}^{-\mathrm{i}\mathbf{k}_1\cdot\mathbf{r}} \\
&\quad + \Big(\hat{\mathbf{A}}_{\parallel,2}^* + \hat{\mathbf{A}}_{\perp,2}^*\Big)\mathrm{e}^{-\mathrm{i}\mathbf{k}_2\cdot\mathbf{r}}\Big] \\
&= \hat{\mathbf{A}}_{\parallel,1}\cdot\hat{\mathbf{A}}_{\parallel,1}^* + \hat{\mathbf{A}}_{\perp,1}\cdot\hat{\mathbf{A}}_{\perp,1}^* \\
&\quad + \hat{\mathbf{A}}_{\parallel,2}\cdot\hat{\mathbf{A}}_{\parallel,2}^* + \hat{\mathbf{A}}_{\perp,2}\cdot\hat{\mathbf{A}}_{\perp,2}^* \\
&\quad + \Big(\hat{\mathbf{A}}_{\parallel,1}\cdot\hat{\mathbf{A}}_{\parallel,2}^* + \hat{\mathbf{A}}_{\perp,1}\cdot\hat{\mathbf{A}}_{\perp,2}^*\Big) \\
&\quad \times\mathrm{e}^{\mathrm{i}(\mathbf{k}_1-\mathbf{k}_2)\cdot\mathbf{r}} \\
&\quad + \Big(\hat{\mathbf{A}}_{\parallel,1}^*\cdot\hat{\mathbf{A}}_{\parallel,2} + \hat{\mathbf{A}}_{\perp,1}^*\cdot\hat{\mathbf{A}}_{\perp,2}\Big) \\
&\quad \times\mathrm{e}^{-\mathrm{i}(\mathbf{k}_1-\mathbf{k}_2)\cdot\mathbf{r}}.
\end{aligned}
$$

(3.154)

All other terms vanish because of the orthogonality of the respective vectors. To evaluate this equation further, the scalar product of $\mathbf{e}_{\parallel,1}$ and $\mathbf{e}_{\parallel,2}$ has to be calculated. It is

$$
\begin{aligned}
\mathbf{e}_{\parallel,1}\cdot\mathbf{e}_{\parallel,2} &= (\mathbf{e}_\perp\times\mathbf{e}_1)\cdot(\mathbf{e}_\perp\times\mathbf{e}_2) \\
&= [\mathbf{e}_1\times(\mathbf{e}_\perp\times\mathbf{e}_2)]\cdot\mathbf{e}_\perp \\
&= [(\mathbf{e}_1\cdot\mathbf{e}_2)\mathbf{e}_\perp - (\mathbf{e}_1\cdot\mathbf{e}_\perp)\mathbf{e}_2]\cdot\mathbf{e}_\perp \\
&= \mathbf{e}_1\cdot\mathbf{e}_2.
\end{aligned}
$$

(3.155)

This relation is, of course, obvious and we can use it to evaluate the interference pattern. To abbreviate the notation the phase differences between the two waves are defined as $\delta_\parallel := \delta_{\parallel,1} - \delta_{\parallel,2}$ and $\delta_\perp := \delta_{\perp,1} - \delta_{\perp,2}$

$$
\begin{aligned}
\Big|\hat{\mathbf{E}}_{1+2}\Big|^2 &= A_{\parallel,1}^2 + A_{\perp,1}^2 + A_{\parallel,2}^2 + A_{\perp,2}^2 \\
&\quad + \Big[A_{\parallel,1}A_{\parallel,2}\mathrm{e}^{\mathrm{i}\delta_\parallel}(\mathbf{e}_1\cdot\mathbf{e}_2) \\
&\quad + A_{\perp,1}A_{\perp,2}\mathrm{e}^{\mathrm{i}\delta_\perp}\Big]\mathrm{e}^{\mathrm{i}(\mathbf{k}_1-\mathbf{k}_2)\cdot\mathbf{r}} \\
&\quad + \Big[A_{\parallel,1}A_{\parallel,2}\mathrm{e}^{-\mathrm{i}\delta_\parallel}(\mathbf{e}_1\cdot\mathbf{e}_2) \\
&\quad + A_{\perp,1}A_{\perp,2}\mathrm{e}^{-\mathrm{i}\delta_\perp}\Big]\mathrm{e}^{-\mathrm{i}(\mathbf{k}_1-\mathbf{k}_2)\cdot\mathbf{r}}
\end{aligned}
$$

$$= A_{\parallel,1}^2 + A_{\parallel,2}^2 + 2A_{\parallel,1}A_{\parallel,2}\,(\boldsymbol{e}_1 \cdot \boldsymbol{e}_2)$$
$$\times \cos\left[(\boldsymbol{k}_1 - \boldsymbol{k}_2)\cdot\boldsymbol{r} + \delta_{\parallel}\right]$$
$$+ A_{\perp,1}^2 + A_{\perp,2}^2 + 2A_{\perp,1}A_{\perp,2}$$
$$\times \cos\left[(\boldsymbol{k}_1 - \boldsymbol{k}_2)\cdot\boldsymbol{r} + \delta_{\perp}\right]. \qquad (3.156)$$

The two terms that depend on the parameters of both waves and are functions of the position are called interference terms. These interference terms distinguish the superposition of coherent waves and incoherent waves. In the case of incoherent waves the interference terms vanish and the resulting intensity is just the sum of the single intensities of both waves.

It can be seen that the interference pattern resolves into terms that depend only on TM components and those that depend only on TE components. Since both are perpendicular to each other, the intensities of both waves can also be divided into the sum of a "TM intensity" and a "TE intensity"

$$I_1 = a\left(A_{\parallel,1}^2 + A_{\perp,1}^2\right) = I_{\parallel,1} + I_{\perp,1}\,,$$
$$I_2 = a\left(A_{\parallel,2}^2 + A_{\perp,2}^2\right) = I_{\parallel,2} + I_{\perp,2}\,. \qquad (3.157)$$

Here, the constant of proportionality a is used, which was explained above. Then, the intensity of the interference pattern is

$$I_{1+2} = I_{\parallel,1} + I_{\parallel,2}$$
$$+ 2\sqrt{I_{\parallel,1}I_{\parallel,2}}\,(\boldsymbol{e}_1 \cdot \boldsymbol{e}_2)\cos\left[(\boldsymbol{k}_1 - \boldsymbol{k}_2)\cdot\boldsymbol{r} + \delta_{\parallel}\right]$$
$$+ I_{\perp,1} + I_{\perp,2}$$
$$+ 2\sqrt{I_{\perp,1}I_{\perp,2}}\cos\left[(\boldsymbol{k}_1 - \boldsymbol{k}_2)\cdot\boldsymbol{r} + \delta_{\perp}\right]. \quad (3.158)$$

The Grating Period and the Fringe Period

Equation (3.158) shows that the surfaces of constant intensity are plane surfaces with

$$(\boldsymbol{k}_1 - \boldsymbol{k}_2)\cdot\boldsymbol{r} = \text{constant}\,. \qquad (3.159)$$

The planes are perpendicular to the so-called grating vector $\boldsymbol{G}$ (Fig. 3.6) with

$$\boldsymbol{G} = \boldsymbol{k}_1 - \boldsymbol{k}_2\,. \qquad (3.160)$$

Since the cosine function is periodic the distance between the two neighboring planes of equal intensity is called the grating period Λ of the interference pattern. It can be calculated by taking a point $\boldsymbol{r}_1$ on the first plane and a point $\boldsymbol{r}_2$ on the neighboring second plane, so that the vector $\Delta\boldsymbol{r} := \boldsymbol{r}_2 - \boldsymbol{r}_1$ is parallel to $\boldsymbol{G}$ and
Fig. 3.6 Interference of two plane waves. The *solid lines* indicate the planes of constant phase of the two plane waves at a fixed time having the distance λ/n, respectively, whereas the *dashed lines* indicate the interference planes with constant intensity having a distance Λ. The planes themselves are perpendicular to the drawing plane

simultaneously perpendicular to the planes. Its modulus is the grating period

$$\cos\left[(\boldsymbol{k}_1 - \boldsymbol{k}_2)\cdot\boldsymbol{r}_2\right] = \cos\left[(\boldsymbol{k}_1 - \boldsymbol{k}_2)\cdot\boldsymbol{r}_1\right];$$
$$\Rightarrow (\boldsymbol{k}_1 - \boldsymbol{k}_2)\cdot\boldsymbol{r}_2 = (\boldsymbol{k}_1 - \boldsymbol{k}_2)\cdot\boldsymbol{r}_1 + 2\pi$$
$$\Rightarrow \boldsymbol{G}\cdot\Delta\boldsymbol{r} = |\boldsymbol{G}|\,|\Delta\boldsymbol{r}| = 2\pi$$
$$\Rightarrow \Lambda = |\Delta\boldsymbol{r}| = \frac{2\pi}{|\boldsymbol{G}|} = \frac{2\pi}{\frac{2\pi n}{\lambda}|\boldsymbol{e}_1 - \boldsymbol{e}_2|} = \frac{\lambda}{n|\boldsymbol{e}_1 - \boldsymbol{e}_2|}\,. \qquad (3.161)$$

Here, n is the refractive index of the material in which the waves propagate and $\lambda = 2\pi c/\omega$ would be the wavelength in vacuum. So, the grating period is infinity if both waves are propagating parallel, i.e., $\boldsymbol{e}_1 = \boldsymbol{e}_2$, and the smallest grating period can be obtained if both waves are propagating antiparallel, i.e., $\boldsymbol{e}_1 = -\boldsymbol{e}_2$. Then the grating period $\Lambda_{\min}$ is

$$\Lambda_{\min} = \frac{\lambda}{2n}\,.$$

In the general case the grating period can be expressed by using the angle φ between the two wave vectors (Fig. 3.6)

$$|\boldsymbol{e}_1 - \boldsymbol{e}_2| = \sqrt{(\boldsymbol{e}_1 - \boldsymbol{e}_2)\cdot(\boldsymbol{e}_1 - \boldsymbol{e}_2)}$$
$$= \sqrt{2 - 2\boldsymbol{e}_1 \cdot \boldsymbol{e}_2}$$
$$\Rightarrow \Lambda = \frac{\lambda}{n\sqrt{2\,(1 - \cos\varphi)}}\,. \qquad (3.162)$$

This can also be seen in Fig. 3.6 using the trigonometric identity $\sqrt{2(1 - \cos\varphi)} = 2\sin(\varphi/2)$.

What is really observed are the lines of intersection of the planes of constant intensity with a detector plane. The resulting lines are called the interference fringes. In the case of the interference of two plane waves the interference fringes are straight, parallel and equidistant lines with the distance p, called the period of the fringes. Only in the case when the grating vector G is parallel to the detector plane is the fringe period p equal to the grating period Λ. In the general case, only the component of the grating vector parallel to the detector plane has to be used to calculate the fringe period. This relation can be easily seen by taking the plane with $z = 0$ as detector plane. Then the fringes in the xy-plane are described in analogy to (3.159) by

$$\left(k_{x,1} - k_{x,2}\right) x + \left(k_{y,1} - k_{y,2}\right) y = G_{\parallel} \cdot r = \text{constant} . \tag{3.163}$$

In analogy to (3.161) the result is

$$p = \frac{2\pi}{|G_{\parallel}|} = \frac{2\pi}{|G - (G \cdot N)\, N|} , \tag{3.164}$$

where N is a unit vector perpendicular to the detector plane. By defining the two angles of incidence β_1 and β_2 of the plane waves onto the detector plane as

$$\cos \beta_1 := e_1 \cdot N; \quad \cos \beta_2 := e_2 \cdot N;$$

the fringe period p can be written as:

$$
\begin{aligned}
p &= \frac{2\pi}{\sqrt{[G - (G \cdot N)\, N]^2}} = \frac{2\pi}{\sqrt{|G|^2 - (G \cdot N)^2}} \\
&= \frac{2\pi}{\sqrt{|k_1 - k_2|^2 - [(k_1 - k_2) \cdot N]^2}} \\
&= \frac{\lambda}{n\sqrt{2\,(1 - \cos\varphi) - (\cos\beta_1 - \cos\beta_2)^2}}
\end{aligned}
$$

or

$$
\begin{aligned}
p &= \frac{2\pi}{\sqrt{|G|^2 - (G \cdot N)^2}} = \frac{\Lambda}{\sqrt{1 - \cos^2 \alpha}} \\
&= \frac{\Lambda}{\sin\alpha} = \frac{\lambda}{n\sqrt{2\,(1 - \cos\varphi)}\,\sin\alpha} .
\end{aligned}
\tag{3.165}
$$

In the last equation the angle α between the grating vector G and the surface normal N, i.e., the angle α between the grating planes and the detector plane, is defined as $\cos\alpha = (G \cdot N)/|G|$. From (3.165) it can be seen that the fringe period is infinity if the grating planes are parallel to the detector plane and that the fringe period is minimal if the grating planes are perpendicular

to the detector plane, i. e., if G is parallel to the detector plane. Then the fringe period p is equal to the grating period Λ.

3.3.2 Interference Effects for Plane Waves with Different Polarization States

In the calculation of the grating period and the fringe period we assumed that the interference terms in (3.158) are different from zero so that interference occurs. But, this is not always the case as we will now discuss.

A quite interesting quantity in interferometry is the visibility V of the interference fringes. It is defined as

$$V := \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}} , \tag{3.166}$$

where $I_{\max}$ is the maximum intensity and $I_{\min}$ the minimum intensity at a point in the interference pattern when the phase (i. e., the argument of the cosine function) of the interference terms is varied in a range of 2π. For the interference of plane waves the maximum and minimum intensity can also be taken at different points because the intensity of the two single waves is then independent of the position. The visibility can vary between 0 for $I_{\min} = I_{\max}$, i. e., no interference occurs, and 1 for $I_{\min} = 0$.

Linearly Polarized Plane Waves
For the case of linearly polarized plane waves the phase constants of each wave $\delta_{\parallel,1}$ and $\delta_{\perp,1}$ on the one hand and $\delta_{\parallel,2}$ and $\delta_{\perp,2}$ on the other are equal or differ only by π. There are, in fact, effectively two different cases:

$$
\left.
\begin{aligned}
\delta_{\parallel,1} &= \delta_{\perp,1} \ \wedge\ \delta_{\parallel,2} = \delta_{\perp,2} \\
\delta_{\parallel,1} &= \delta_{\perp,1} + \pi \ \wedge\ \delta_{\parallel,2} = \delta_{\perp,2} + \pi
\end{aligned}
\right\}
$$

$$
\begin{aligned}
\delta_{\perp} &= \delta_{\perp,1} - \delta_{\perp,2} \\
\Rightarrow\ &= \delta_{\parallel,1} - \delta_{\parallel,2} = \delta_{\parallel} \\
&=: \delta \text{ and } s := +1
\end{aligned}
\tag{3.167}
$$

$$
\left.
\begin{aligned}
\delta_{\parallel,1} &= \delta_{\perp,1} + \pi \ \wedge\ \delta_{\parallel,2} = \delta_{\perp,2} \\
\delta_{\parallel,1} &= \delta_{\perp,1} \ \wedge\ \delta_{\parallel,2} = \delta_{\perp,2} + \pi
\end{aligned}
\right\}
$$

$$
\begin{aligned}
\delta_{\perp} &= \delta_{\perp,1} - \delta_{\perp,2} \\
\Rightarrow\ \delta_{\parallel,1} - \delta_{\parallel,2} \mp \pi &= \delta_{\parallel} \mp \pi \\
&=: \delta \mp \pi \text{ and } s := -1
\end{aligned}
\tag{3.168}
$$

The parameter s characterizes the different cases and is either $+1$ or -1. Then the intensity of the interference

pattern (see (3.158)) can be expressed as

$$I_{1+2} = I_{\parallel,1} + I_{\parallel,2}$$
$$+ 2\sqrt{I_{\parallel,1} I_{\parallel,2}} \cos\varphi \cos[(k_1 - k_2) \cdot r + \delta]$$
$$+ I_{\perp,1} + I_{\perp,2}$$
$$+ 2s\sqrt{I_{\perp,1} I_{\perp,2}} \cos[(k_1 - k_2) \cdot r + \delta] . \quad (3.169)$$

Here, the angle φ between the directions of propagation of the two waves is used. So, there are several interesting special cases of (3.169):

- Both waves have only TE components, i. e., $I_{\parallel,1} = I_{\parallel,2} = 0$, $I_{\perp,1} \neq 0$ and $I_{\perp,2} \neq 0$. Then, we obtain

$$I_{\text{TE,TE}} = I_{\perp,1} + I_{\perp,2}$$
$$+ 2s\sqrt{I_{\perp,1} I_{\perp,2}} \cos[(k_1 - k_2) \cdot r + \delta] . \quad (3.170)$$

This is the well-known interference equation that is also used for scalar waves where an arbitrary component of the electric vector, but for a small angle φ between the two wave vectors of the waves, is regarded. In this case the visibility $V_{\text{TE,TE}}$ (defined with (3.166)) of the interference pattern is

$$V_{\text{TE,TE}} = \frac{2\sqrt{I_{\perp,1} I_{\perp,2}}}{I_{\perp,1} + I_{\perp,2}} . \quad (3.171)$$

If the intensities of both waves are equal the visibility is 1.

- One wave has only a TE component, i. e., $I_{\parallel,1} = 0$ and $I_{\perp,1} \neq 0$, and the other wave has only a TM component, i. e., $I_{\parallel,2} \neq 0$ and $I_{\perp,2} = 0$. Then the interference terms vanish and the intensity is constant

$$I_{\text{TE,TM}} = I_{\perp,1} + I_{\parallel,2} = \text{constant} . \quad (3.172)$$

This just means that orthogonally polarized waves cannot interfere.

- Both waves have only TM components, i. e., $I_{\perp,1} = I_{\perp,2} = 0$, $I_{\parallel,1} \neq 0$ and $I_{\parallel,2} \neq 0$. Then, we obtain

$$I_{\text{TM,TM}} = I_{\parallel,1} + I_{\parallel,2}$$
$$+ 2\sqrt{I_{\parallel,1} I_{\parallel,2}} \cos\varphi \cos[(k_1 - k_2) \cdot r + \delta] . \quad (3.173)$$

The visibility $V_{\text{TM,TM}}$ is in this case:

$$V_{\text{TM,TM}} = \frac{2\sqrt{I_{\parallel,1} I_{\parallel,2}} \cos\varphi}{I_{\parallel,1} + I_{\parallel,2}} . \quad (3.174)$$
Fig. 3.7a,b The different possibilities for the interference of linearly polarized waves. (**a**) $s = +1$, i. e., the two electric vectors are oscillating in the same quadrant; (**b**) $s = -1$, i. e. the two electric vectors are oscillating in different quadrants. The *dashed line* indicates the plane in which the wave vectors of both waves are situated

So, the visibility is always smaller than 1 and the interference term vanishes if both waves are propagating perpendicular to each other, i. e., $e_1 \cdot e_2 = \cos\varphi = 0$. For the case $I_{\parallel,1} = I_{\parallel,2}$, where the visibility is 1 in the TE polarized case, the visibility in the TM polarized case is $V_{\text{TM,TM}} = \cos\varphi$. Only for small angles between the directions of propagation of the two plane waves the visibility is high. Of course, for small angles there is in fact no real difference between TE- and TM-polarized light and for $\varphi = 0$ or $\varphi = \pi$ the difference between TE and TM exists no longer.

- TE and TM components of both waves are present. Then the value of the constant s is important. For $s = +1$ the interference terms have identical signs and add. But for $s = -1$ the interference terms have different signs and cancel each other out if

$$\sqrt{I_{\parallel,1} I_{\parallel,2}} \cos\varphi = \sqrt{I_{\perp,1} I_{\perp,2}} . \quad (3.175)$$

The meaning of this is that for $s = -1$ the electric vectors of both waves are oscillating in different quadrants. If the above equation is fulfilled they are again perpendicular to each other and cannot interfere. This is explained in Fig. 3.7.

Circularly Polarized Plane Waves

Circularly polarized plane waves exist according to (3.137) only if

$$I_{\parallel,1} = I_{\perp,1} = \frac{1}{2} I_1 ; \quad \delta_{\parallel,1} - \delta_{\perp,1} = \pm\frac{\pi}{2} ,$$
$$I_{\parallel,2} = I_{\perp,2} = \frac{1}{2} I_2 ; \quad \delta_{\parallel,2} - \delta_{\perp,2} = \pm\frac{\pi}{2} .$$

Then, the intensity of the interference pattern is determined according to (3.158)

$$
\begin{aligned}
I_{1+2} = \frac{1}{2} \Big\{ & I_1 + I_2 + 2\sqrt{I_1 I_2} \\
& \times \cos\varphi \cos\left[(\boldsymbol{k}_1 - \boldsymbol{k}_2) \cdot \boldsymbol{r} + \delta_\parallel \right] \Big\} \\
+ \frac{1}{2} \Big\{ & I_1 + I_2 + 2\sqrt{I_1 I_2} \\
& \times \cos\left[(\boldsymbol{k}_1 - \boldsymbol{k}_2) \cdot \boldsymbol{r} + \delta_\perp \right] \Big\} \\
= & I_1 + I_2 + \sqrt{I_1 I_2} \\
& \times \Big\{ \cos\varphi \cos\left[(\boldsymbol{k}_1 - \boldsymbol{k}_2) \cdot \boldsymbol{r} + \delta_\parallel \right] \\
& + \cos\left[(\boldsymbol{k}_1 - \boldsymbol{k}_2) \cdot \boldsymbol{r} + \delta_\perp \right] \Big\} .
\end{aligned}
$$
(3.176)

Now, we have to differentiate between several cases:

- Both waves have the same chirality, i.e., either $\delta_{\parallel,1} - \delta_{\perp,1} = \pi/2$ and $\delta_{\parallel,2} - \delta_{\perp,2} = \pi/2$ or $\delta_{\parallel,1} - \delta_{\perp,1} = -\pi/2$ and $\delta_{\parallel,2} - \delta_{\perp,2} = -\pi/2$. Then, the phase differences are

$$
\delta_\parallel = \delta_{\parallel,1} - \delta_{\parallel,2}; \quad \delta_\perp = \delta_{\perp,1} - \delta_{\perp,2} = \delta_\parallel =: \delta
$$

and (3.176) reduces to

$$
\begin{aligned}
I_{\uparrow\uparrow} = & I_1 + I_2 + \sqrt{I_1 I_2} \\
& \times (\cos\varphi + 1) \cos\left[(\boldsymbol{k}_1 - \boldsymbol{k}_2) \cdot \boldsymbol{r} + \delta \right] .
\end{aligned}
$$
(3.177)

The visibility (3.166) is

$$
V_{\uparrow\uparrow} = \frac{\sqrt{I_1 I_2} \, (\cos\varphi + 1)}{I_1 + I_2} .
$$
(3.178)

For small angles φ between the directions of propagation of the two waves the intensity is identical to the interference pattern of two linearly TE-polarized waves and the visibility can reach 1 for equal intensities in both waves. If both waves are propagating perpendicular to each other the interference term has only half the size and the visibility is for equal intensities only $1/2$. If the angle φ is larger than $\pi/2$ and approaches π the interference term and the visibility vanish. This means that waves propagating antiparallel and with the same chirality cannot interfere.

- Both waves have different chirality, i.e., either $\delta_{\parallel,1} - \delta_{\perp,1} = \pi/2$ and $\delta_{\parallel,2} - \delta_{\perp,2} = -\pi/2$ or $\delta_{\parallel,1} - \delta_{\perp,1} = -\pi/2$ and $\delta_{\parallel,2} - \delta_{\perp,2} = \pi/2$. Then, the phase differences are

$$
\delta_\parallel = \delta_{\parallel,1} - \delta_{\parallel,2} =: \delta;
$$
$$
\delta_\perp = \delta_{\perp,1} - \delta_{\perp,2} = \delta_\parallel \pm \pi = \delta \pm \pi
$$

and (3.176) reduces to

$$
\begin{aligned}
I_{\uparrow\downarrow} = & I_1 + I_2 + \sqrt{I_1 I_2} \\
& \times (\cos\varphi - 1) \cos\left[(\boldsymbol{k}_1 - \boldsymbol{k}_2) \cdot \boldsymbol{r} + \delta \right] .
\end{aligned}
$$
(3.179)

The visibility (3.166) is

$$
V_{\uparrow\downarrow} = \frac{\sqrt{I_1 I_2} \, (1 - \cos\varphi)}{I_1 + I_2} .
$$
(3.180)

So, for different chirality the behavior is reverse to that of equal chirality. Waves that are propagating parallel ($\varphi = 0$) and have different chirality cannot interfere, whereas waves that are propagating antiparallel ($\varphi = \pi$) and have different chirality interfere very well.

The Application of Two-Beam Interference for an Electron Accelerator

A quite interesting modern application of the interference of two waves is the laser-driven electron accelerator [3.21],[3.22]. This accelerator can in principle also be used for any other charged particle whereby the efficiency increases if the velocity of the particle is nearly identical to the speed of light. So, heavy particles need a lot of kinetic energy (at best a multiple of their rest energy $m_0 c^2$) if they shall be accelerated by laser light with a good efficiency. Here, only the basic principle can be discussed.

Figure 3.8 shows two interfering waves both with linear TM polarization, equal amplitudes and a phase

Fig. 3.8 The interference of two linearly polarized waves with TM polarization and π phase difference results in a longitudinal component $\boldsymbol{E}_z$ of the electric field

difference of π on points along the z-axis. First of all, we assume that the waves are plane. The z-axis bisects the angle 2θ between the wave vectors $\mathbf{k}_1$ and $\mathbf{k}_2$ of both waves so that θ is the angle between the z-axis and one of the wave vectors. Then, the electric vectors $\mathbf{E}_1$ and $\mathbf{E}_2$ are oriented as indicated and the components perpendicular to the z-axis, i.e., parallel to the x-axis, cancel each other. The magnetic vectors of both waves, which are perpendicular to the drawing plane, i.e., parallel to the y-axis, also cancel each other out on points along the z-axis because they are antiparallel. However, due to the configuration of the two interfering waves there is a resulting longitudinal component $\mathbf{E}_z$ of the electric vector for points on the z-axis. From a mathematical point of view, we have for the electric vectors using the coordinate system of Fig. 3.8

$$\mathbf{E}_1 (x, z, t)$$

$$= \begin{pmatrix} E_0 \cos\theta \cos\left[\frac{2\pi}{\lambda}(-x\sin\theta + z\cos\theta) - \omega t\right] \\ 0 \\ E_0 \sin\theta \cos\left[\frac{2\pi}{\lambda}(-x\sin\theta + z\cos\theta) - \omega t\right] \end{pmatrix},$$

$$\mathbf{E}_2 (x, z, t)$$

$$= \begin{pmatrix} -E_0 \cos\theta \cos\left[\frac{2\pi}{\lambda}(x\sin\theta + z\cos\theta) - \omega t\right] \\ 0 \\ E_0 \sin\theta \cos\left[\frac{2\pi}{\lambda}(x\sin\theta + z\cos\theta) - \omega t\right] \end{pmatrix};$$

$$\Rightarrow \mathbf{E}_z (x = 0, z, t)$$

$$= \mathbf{E}_1 (x = 0, z, t) + \mathbf{E}_2 (x = 0, z, t)$$

$$= \begin{pmatrix} 0 \\ 0 \\ 2E_0 \sin\theta \cos\left(\frac{2\pi}{\lambda} z \cos\theta - \omega t\right) =: E_z (0, z, t) \end{pmatrix}.$$

$$(3.181)$$

Here, E_0 is the maximum amplitude of the electric vector of one of the two interfering waves ($E_0 = \max|\mathbf{E}_1| = \max|\mathbf{E}_2|$), λ is the wavelength of the waves and ω is their angular frequency. So, we see that along the z-axis with $x = 0$ there exists only a component of the electric field parallel to the z-axis and by using the relations $\lambda \nu = c$ and $\omega = 2\pi\nu = 2\pi c/\lambda$ (ν is the frequency) for our waves, which are situated in a vacuum, we obtain

$$E_z (x = 0, z, t)$$

$$= 2E_0 \sin\theta \cos\left[2\pi \frac{c}{\lambda}\left(z\frac{\cos\theta}{c} - t\right)\right]. \quad (3.182)$$

Now, a relativistic electron, i.e., the speed v of the electron should be nearly the speed of light c, travels along the z-axis from left to right. It should pass the regarded point at that time where $E_z = -2E_0 \sin\theta$. Then, the electron will be maximally accelerated along the z-axis due to its negative electric charge. But, the interference maximum with $E_z = -2E_0 \sin\theta$ seems to propagate along the z-axis with the phase velocity $c/\cos\theta$, which is faster than the speed of light for $\theta > 0$. Of course, this is in no contradiction to special relativity because no information nor energy is transported with this speed. So, for a small angle θ the relativistic electron with $v \approx c$ (but nevertheless $v < c$) travels a certain distance nearly in phase with the accelerating electric field before it comes out of phase because of $c/\cos\theta > c > v$. The distance after which the electron is out of phase can also be calculated very easily. The electron travels in the laboratory framework in the time interval t, a distance $z = vt$, i.e., $t = z/v$. The velocity v can be assumed to be constant during the acceleration process because it should be nearly the speed of light and therefore it does not change considerably although the electron may gain a lot of kinetic energy. By introducing this into (3.182) the argument Φ of the cosine function as a function of the position z on the z-axis is:

$$\Phi(z) = 2\pi \frac{c}{\lambda}\left(z\frac{\cos\theta}{c} - t\right) = 2\pi \frac{c}{\lambda} z\left(\frac{\cos\theta}{c} - \frac{1}{v}\right). \quad (3.183)$$

If the phase Φ of the electric field, which affects the electron changes by $\pm\pi$, the electric field that first accelerated the electron will now slow it down. So, the distance Δz on the z-axis between being accelerated and decelerated by the electric field is

$$\Delta\Phi = 2\pi \frac{c}{\lambda} \Delta z\left(\frac{\cos\theta}{c} - \frac{1}{v}\right)$$

$$= \pm\pi \Rightarrow \Delta z = \pm\frac{\lambda}{2(\cos\theta - c/v)}. \quad (3.184)$$

For $v \approx c$ the longest distance for being in phase would be achieved by $\theta = 0$. But then, the accelerating electric field itself would be zero because of the factor $\sin\theta$ in (3.182). So, in practice, a tradeoff has to be found between a big value $\sin\theta$ and another big value $\cos\theta$. Additionally, the velocity of the electron (or other charged particle) should be nearly the speed of light.

However, we see that for the interference of two infinitely extended plane waves the electron would be accelerated and slowed down periodically. But, we can

replace the plane waves by focused laser beams, i. e., Gaussian beams (Sect. 3.5), so that the region with a high electric field has a quite limited length smaller than Δz. The beam waist of each laser beam should be at the crossing point of the two Gaussian beams on the z-axis to achieve a high amplitude of the electric vector. Then, the electric field amplitude E_0 is not constant along the z-axis but decreases outside of the beam waist like a Gaussian curve. So, it is possible to achieve a net acceleration of the electron if it is harmonized with the phase of the electric field of the laser beams when it crosses the beam waist. If the electron is not harmonized with the phase of the laser beams it can also be slowed down. The concrete calculation in the case of Gaussian beams is, of course, a little bit more complex than with plane waves because the wave vector and therefore the direction of the electric vector changes locally in the case of a Gaussian beam. By using ultrashort and focused laser pulses the resulting electric field in the beam waist, which accelerates the electron can be as high as $1\,\text{GV/m}$ or higher. Of course, the acceleration distance is only as long as the beam waist, i. e., several µm for a strongly focused laser beam. So, some keV of kinetic energy can be gained by the electron. But, by repeating many acceleration devices in series (and, of course, harmonized in phase) the effective acceleration distance can be increased so that the laser-driven electron accelerator may become an alternative to conventional particle accelerators in the future.

3.3.3 Interference of Arbitrary Scalar Waves

The interference phenomena are, of course, not restricted to plane waves but can occur for arbitrary waves. Since for arbitrary waves the polarization can change locally we will neglect the polarization in this section and concentrate on so-called scalar waves.

Some Notes on Scalar Waves

In the case of scalar waves only one Cartesian component of the electric (or magnetic) vector is regarded and the complete polarization state is neglected. Nevertheless, for two linearly polarized interfering waves, which are both TE polarized, the result of the scalar calculation is identical to the exact result. Since the orthogonality condition is neglected for scalar waves the result of the scalar wave equation is not automatically a solution of the Maxwell equations.

A scalar wave, which is often used in optics, is a spherical wave with its center of curvature at the point r_0 with the complex amplitude

$$u(r) = a \frac{e^{ik|r-r_0|}}{|r-r_0|} \tag{3.185}$$

and the modulus of the wave vector $k = 2\pi n/\lambda$, which is also called a wave number. a is a constant. It should be mentioned that a spherical wave is a solution of the scalar Helmholtz equation of homogeneous materials (Sect. 3.1.5), where only one component of the electric or magnetic vector is regarded. But, a spherical wave is not a solution of the Maxwell equations itself because this would violate the orthogonality conditions of an electromagnetic wave. But, in the far field and in the plane perpendicular to its dipole axis, a dipole radiation is a good approximation for a spherical wave.

Here, the scalar complex amplitude u was introduced, which can stand, apart from a constant of proportionality, for one component of the electric or magnetic vector. Again, the intensity of this scalar wave is at least proportional to the square of the modulus of u and in the following we just define for scalar waves

$$I := uu^* . \tag{3.186}$$

A general scalar wave can be described by

$$u(r) = A(r)\,e^{i\Phi(r)} . \tag{3.187}$$

In this case, A is a real function, which changes only slowly with the position r, where Φ is also a real function but the complex exponential factor $\exp(i\Phi)$ varies rapidly with the position r.

The Interference Equation for Scalar Waves

By using two general scalar waves (3.187)

$$u_1(r) = A_1(r)\,e^{i\Phi_1(r)} , \quad u_2(r) = A_2(r)\,e^{i\Phi_2(r)}$$

instead of using plane waves in (3.158) or (3.170) the interference equation of scalar waves is obtained by

$$I_{1+2} = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos\Phi \tag{3.188}$$

with $I_1 = A_1^2$, $I_2 = A_2^2$ and $\Phi = \Phi_1 - \Phi_2$. In some cases it is more convenient to write this equation as

$$I_{1+2} = I_0\,(1 + V\cos\Phi) . \tag{3.189}$$

Here, $I_0 = I_1 + I_2$ is defined as the resulting intensity for incoherent light, where only the intensities of the single waves have to be added. The visibility V is defined in (3.166) and is here

$$V = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}} = \frac{2\sqrt{I_1 I_2}}{I_1 + I_2} = \frac{2\sqrt{I_1 I_2}}{I_0} . \tag{3.190}$$

For general scalar waves the fringe period in the detector plane with coordinates (x, y) is not constant but will vary. But at a point (x, y) in the neighborhood of a fixed point (x_0, y_0) the phase function Φ can be written as a Taylor expansion neglecting all terms of second and higher order:

$$\Phi(x, y) \approx \Phi(x_0, y_0) + \begin{pmatrix} \frac{\partial \Phi(x_0, y_0)}{\partial x} \\ \frac{\partial \Phi(x_0, y_0)}{\partial y} \end{pmatrix} \cdot \begin{pmatrix} x - x_0 \\ y - y_0 \end{pmatrix}$$

$$= \Phi(x_0, y_0) + \nabla_\perp \Phi(x_0, y_0) \cdot \Delta r \ .$$
(3.191)

Here, the two-dimensional nabla operator $\nabla_\perp$ is introduced. The local fringe period p is defined as the distance between two fringes, i. e., the distance where the phase function increases or decreases by 2π taken along a path parallel to the local phase gradient. Therefore, we have for the vector Δr pointing from one fringe to the next neighboring fringe at the position (x_0, y_0)

$$\Delta r = p \frac{\nabla_\perp \Phi}{|\nabla_\perp \Phi|} \ \Rightarrow \ \nabla_\perp \Phi \cdot \Delta r = p |\nabla_\perp \Phi| = 2\pi;$$

$$\Rightarrow \ p = \frac{2\pi}{|\nabla_\perp \Phi|} = \frac{2\pi}{\sqrt{\left(\frac{\partial \Phi}{\partial x}\right)^2 + \left(\frac{\partial \Phi}{\partial y}\right)^2}} \ .$$
(3.192)

All quantities have to be calculated at the point (x_0, y_0). By comparing this equation with (3.164) it is clear that the component $G_\parallel$ of the grating vector in the xy-plane is defined by

$$G_\parallel = \begin{pmatrix} \frac{\partial \Phi}{\partial x} \\ \frac{\partial \Phi}{\partial y} \\ 0 \end{pmatrix} \ .$$
(3.193)

The grating vector G itself is defined as

$$G = \nabla \Phi = \begin{pmatrix} \frac{\partial \Phi}{\partial x} \\ \frac{\partial \Phi}{\partial y} \\ \frac{\partial \Phi}{\partial z} \end{pmatrix} \ ,$$
(3.194)

with Φ defined as a function of (x, y, z).

The local fringe frequency ν is defined as the reciprocal of the local fringe period

$$\nu = \frac{1}{p} = \frac{\sqrt{\left(\frac{\partial \Phi}{\partial x}\right)^2 + \left(\frac{\partial \Phi}{\partial y}\right)^2}}{2\pi}$$
(3.195)

and describes the number of fringes per length unit. If the fringe frequency is too high the interference pattern

cannot be resolved in practice since common detector arrays like a CCD camera only have a limited number of pixels per length unit and integrate the light intensity over the area of one pixel.

Interference of Scalar Spherical and Plane Waves

The interference of two plane waves is investigated in detail in the last section for general polarization states. Simple examples of the interference of two scalar waves are the interference of a spherical wave and a plane wave or the interference of two spherical waves. In principle, the general statements to the effects of different polarization states also hold for spherical waves as long as the numerical aperture is not too high. So, the investigation of scalar waves is not really a restriction.

Two spherical waves with the wavelength λ and the corresponding wave number $k = 2\pi n / \lambda$ having their center of curvature at the points $r_1 = (x_1, y_1, z_1)$ and $r_2 = (x_2, y_2, z_2)$ have the complex amplitude functions

$$u_1(r) = a_1 \frac{e^{ik|r - r_1|}}{|r - r_1|} \ ,$$

$$u_2(r) = a_2 \frac{e^{ik|r - r_2|}}{|r - r_2|} \ .$$

In the following, only the interference pattern in the xy-plane at $z = 0$ in an area centered around the origin of the coordinate system at $x = y = z = 0$ is evaluated. Additionally, the distances $|r_i|$ $(i = 1, 2)$ of the centers of curvature of both spherical waves from the origin of the coordinate system shall be large compared to the maximum distance $|r| = \sqrt{x^2 + y^2}$ of the origin of the coordinate system from a point lying in the evaluated aperture of the interference pattern. Then the amplitude of the spherical waves can be assumed to be constant because of

$$|r_i| \gg |r| \Rightarrow$$

$$|r - r_i| = \sqrt{(r - r_i) \cdot (r - r_i)}$$

$$= \sqrt{|r_i|^2 + |r|^2 - 2|r_i||r|\cos\alpha} \approx |r_i| \ .$$

Here, α is the angle between the two vectors r and r_i. Therefore, the two spherical waves are written as

$$u_1(r) = A_1 e^{ik|r - r_1|} \ ,$$

$$u_2(r) = A_2 e^{ik|r - r_2|}$$

with constant amplitudes $A_1 = a_1 / |r_1|$ and $A_2 = a_2 / |r_2|$. The arguments of the complex exponential func-

tions can, of course, not be replaced by the constant terms $|r_i|$ because these are very fast oscillating functions. Then, the intensity I_{1+2} of the interference pattern is, according to (3.188),

$$I_{1+2}(x, y) = I_1 + I_2 + 2\sqrt{I_1 I_2} \cos \Phi(x, y)$$

with $I_1 = A_1^2; \; I_2 = A_2^2$

and

$$\Phi(x, y) = k(|r - r_1| - |r - r_2|)$$
$$= k \left(|r_1| \sqrt{1 + \frac{x^2 + y^2 - 2xx_1 - 2yy_1}{|r_1|^2}} \right.$$
$$\left. - |r_2| \sqrt{1 + \frac{x^2 + y^2 - 2xx_2 - 2yy_2}{|r_2|^2}} \right).$$
$$(3.196)$$

The square roots can be developed into a Taylor series according to $\sqrt{1+x} \approx 1 + x/2 - x^2/8$ for $x \ll 1$. Since $|r_i| \gg |r|$, the most important terms are

$$|r_i| \sqrt{1 + \frac{x^2 + y^2 - 2xx_i - 2yy_i}{|r_i|^2}}$$
$$\approx |r_i| + \frac{x^2 + y^2}{2|r_i|} - \frac{xx_i + yy_i}{|r_i|}$$
$$- \frac{(x^2 + y^2 - 2xx_i - 2yy_i)^2}{8|r_i|^3}. \qquad (3.197)$$

The last term can be neglected for

$$k \frac{(x^2 + y^2 - 2xx_i - 2yy_i)^2}{8|r_i|^3} \ll 1$$
$$\Rightarrow \frac{(x^2 + y^2 - 2xx_i - 2yy_i)^2}{8|r_i|^3} \ll \frac{\lambda}{2\pi n}. \qquad (3.198)$$

By using spherical coordinates $r_i, \vartheta_i, \varphi_i$ for r_i, where r_i is the distance from the origin, ϑ_i is the polar angle and φ_i is the azimuthal angle,

$$x_i = r_i \cos \varphi_i \sin \vartheta_i, \qquad (3.199)$$
$$y_i = r_i \sin \varphi_i \sin \vartheta_i, \qquad (3.200)$$
$$z_i = r_i \cos \vartheta_i, \qquad (3.201)$$

the condition for neglecting the last term is

$$\frac{(x^2 + y^2)^2}{4r_i^3} - \frac{(x^2 + y^2)(x \cos \varphi_i + y \sin \varphi_i) \sin \vartheta_i}{r_i^2}$$
$$+ \frac{(x \cos \varphi_i + y \sin \varphi_i)^2 \sin^2 \vartheta_i}{r_i} \ll \frac{\lambda}{\pi n}. \qquad (3.202)$$

If this condition is fulfilled for both spherical waves the phase function of the interference pattern can be written as

$$\Phi(x, y) \approx \delta + \frac{\pi n}{\lambda} \left(\frac{1}{r_1} - \frac{1}{r_2} \right) \left(x^2 + y^2 \right)$$
$$- \frac{2\pi n}{\lambda} (\cos \varphi_1 \sin \vartheta_1 - \cos \varphi_2 \sin \vartheta_2) x$$
$$- \frac{2\pi n}{\lambda} (\sin \varphi_1 \sin \vartheta_1 - \sin \varphi_2 \sin \vartheta_2) y.$$
$$(3.203)$$

The phase constant δ is defined as $\delta = 2\pi n(r_1 - r_2)/\lambda$.

The term dependent on $x^2 + y^2$ is called defocus and is proportional to the difference of the curvatures of both spherical waves. The linear terms in x and y are called tilts and are only present if the centers of curvature of the two spherical waves and the origin do not lie on a common line. In the interferometric testing of spherical surfaces or in the measurement of the wave aberrations of lenses there often appears defocus and tilts due to an axial ($\Rightarrow$ defocus) or lateral ($\Rightarrow$ tilts) misalignment of the test object. Then the coefficients of these terms are determined by a least-squares fit of the function

$$\Phi_{\text{misalign}} = a + bx + cy + d \left(x^2 + y^2 \right) \qquad (3.204)$$

to the measured phase function Φ_{measured}. Afterwards, the phase function Φ_{reduced}, which is freed from misalignment aberrations is calculated by

$$\Phi_{\text{reduced}} = \Phi_{\text{measured}} - \Phi_{\text{misalign}} \qquad (3.205)$$

using the fitted coefficients a, b, c and d. The phase function Φ_{reduced} then only contains the desired wave aberrations or the desired surface deviations from the ideal surface plus systematic errors of the experimental setup.

A special case of (3.203) is that one of the waves is a plane wave. Without loss of generality the second wave shall be plane. This means that the parameter r_2 is infinity. Then (3.203) reduces to:

$$\Phi(x, y) \approx \delta + \frac{\pi n}{\lambda r_1} \left(x^2 + y^2 \right)$$
$$- \frac{2\pi n}{\lambda} (\cos \varphi_1 \sin \vartheta_1 - e_{x,2}) x$$
$$- \frac{2\pi n}{\lambda} (\sin \varphi_1 \sin \vartheta_1 - e_{y,2}) y, \qquad (3.206)$$

where $e_{x,2} := \cos \varphi_2 \sin \vartheta_2$ and $e_{y,2} := \sin \varphi_2 \sin \vartheta_2$ are the x and y components of the unit vector $e_2 = k_2/|k_2|$ parallel to the wave vector k_2 of the plane wave. Of course, the phase constant δ, which is only defined modulus 2π, is therefore not infinity, but has a certain value

that depends on r_1 and the phase offset of the plane wave at $(x = 0, y = 0, z = 0)$. In the case of the interference of a spherical and a plane wave the defocus term is directly proportional to the curvature of the spherical wave. The tilt terms again depend on both waves but for the case that either the spherical wave has its center of curvature at $x = y = 0$ ($\Rightarrow \sin \vartheta_1 = 0$) or the plane wave is perpendicular to the xy-plane ($\Rightarrow e_{x,2} = e_{y,2} = 0$) the tilt terms depend only on the parameters of one wave.

Two Examples of Interference Patterns

Assume that we have two interfering monochromatic waves with a wavelength $\lambda = 0.5\,\mu m$. Additionally, we know that the first of the waves is a plane wave that propagates parallel to the optical axis, which is defined to be parallel to the surface normal of the detector and to intersect the detector in its center. So, the parameters of the first wave in (3.203) are $r_1 \to \infty$, $\vartheta_1 = 0$ and $\varphi_1 = 0$

and the phase function Φ of the interference pattern depends only on the parameters of the second wave

$$\Phi(x, y) \approx \delta - \frac{\pi}{\lambda r_2}\left(x^2 + y^2\right) + \frac{2\pi}{\lambda}\cos\varphi_2 \sin\vartheta_2\, x$$
$$+ \frac{2\pi}{\lambda}\sin\varphi_2 \sin\vartheta_2\, y\,. \tag{3.207}$$

The refractive index n has been set to 1 because the measurements should be made in air.

Let us now assume that we detect the interference pattern, which is displayed in Fig. 3.9. Such an interference pattern is often called an interferogram. In this case it has straight, parallel and equidistant fringes parallel to the y-axis. Therefore, the second wave also has to be a plane wave ($r_2 \to \infty$), which can be described by the two angles φ_2 and ϑ_2. The interference pattern only changes along the x-axis and there the period p is 0.2 mm. Therefore, the phase function Φ has to be of the form $\Phi(x, y) = ax$ with $a = 2\pi/p = 10\pi/\text{mm}$. Comparing this with (3.207) results in

$$\delta + \frac{2\pi}{\lambda}\cos\varphi_2 \sin\vartheta_2\, x + \frac{2\pi}{\lambda}\sin\varphi_2 \sin\vartheta_2\, y = ax;$$
$$\Rightarrow \quad \delta = 0 \wedge \varphi_2 = 0 \wedge \sin\vartheta_2 = \frac{a\lambda}{2\pi} = 0.0025\,. \tag{3.208}$$

By looking at the intensity pattern it can also be seen that the visibility has the maximum value of $V = (I_{max} - I_{min})/(I_{max} + I_{min}) = (2-0)/(2+0) = 1$. Therefore, the second plane wave has the same intensity as the first wave.

In a second (simulated) measurement the interferogram of Fig. 3.10 is obtained. It can be estimated that the local fringe frequency increases linearly with the distance from the center and that we therefore have a defocus term with a quadratic phase function. No linear phase function is present and therefore the tilt angle ϑ_2 of the second wave has to be zero. A more detailed evaluation of the intensity pattern using the interference equation (3.188) confirms the estimation that the phase function is $\Phi(x, y) = b(x^2 + y^2)$ with $b = 20\pi/\text{mm}^2$. Additionally, it can be seen that the visibility is $V = (1.28 - 0.72)/(1.28 + 0.72) = 0.28$.

Using (3.207) to calculate the radius of curvature r_2 of the second wave results in

$$\Phi(x, y) = -\frac{\pi}{\lambda r_2}\left(x^2 + y^2\right) = b\left(x^2 + y^2\right)$$
$$\Rightarrow |r_2| = \frac{\pi}{b\lambda} = 100\,\text{mm}\,. \tag{3.209}$$

Fig. 3.9 Example of an interference pattern (interferogram) with straight, parallel and equidistant fringes. *Top:* (simulated) camera picture as also seen directly with the eye. *Bottom:* section through the intensity function

Fig. 3.10 Example of an interference pattern showing a defocus term with a low contrast. *Top:* (simulated) camera picture as also seen directly with the eye. *Bottom:* section through the intensity function

This means that the intensity of the second wave is either about 50 times higher than that of the first wave or about 50 times smaller. Which one of these two values is valid can be determined by measuring first the intensity I_1 of the first wave alone and then the intensity of the interference pattern and therefore also $I_1 + I_2$. The example also shows that the visibility decreases quite slowly if the intensity difference factor α increases. This is the reason why, e.g., a scattered spherical wave of a dust particle, which has quite a small intensity compared to the intensity of the illuminating coherent wave, produces in many cases quite high-contrast fringes that disturb the measurement.

These two examples are, of course, quite simple and can be evaluated manually. However, already in the second example it can be seen that it is not so easy to decide whether it is really a pure defocus term or mixed with some other terms. Therefore, in practice, an automated evaluation of the interference pattern has to be made [3.20]. One step to this is the phase shifting technique which will be discussed briefly on page 121.

3.3.4 Some Basic Ideas of Interferometry

The basic principle of an interferometer is that an incident wave is divided into two waves, which can then interfere with each other. In most interferometers, like, e.g., a Michelson or a Mach–Zehnder interferometer, there exists a so-called reference arm and an object arm. The object arm often contains an object to be tested that changes the object wave. Together with the unchanged wave of the reference arm the interference pattern is formed and carries information about the test object. Nevertheless, there are also interferometers, like, e.g., shearing interferometers, which do not have an object and a reference arm but two copies of an object wave that interfere.

The sign of r_2 cannot be detected in this case where only one interferogram without a carrier frequency is known. This is quite clear because the cosine function is an even function and so $\cos \Phi = \cos(-\Phi)$.

By using (3.190) and the approach $I_2 = \alpha I_1$ the coefficient α can be calculated using the visibility V

$$V = \frac{2\sqrt{\alpha}}{1+\alpha}$$

$$\Rightarrow \alpha = \frac{2}{V^2} - 1 \pm \sqrt{\left(\frac{2}{V^2} - 1\right)^2 - 1} = \begin{cases} 49 \\ 0.02 \end{cases}.$$

(3.210)

The applications of interferometers are the measurement of surface deviations or aberrations of optical elements and wavefront characterization. Another application is the high-precision length measurement. In the following, the principles of the most important two-beam interferometers with monochromatic light are described. Other types of interferometers, which are not treated here, are interferometers with two or more wavelengths and so-called white-light interferometers with a broad spectrum of wavelengths. Additionally, there are multiple beam interferometers where three or more light beams interfere, e.g., a Fabry–Perot interferometer. For more information about interferometry we refer to [3.17–20, 23–28].

Michelson Interferometer

One of the simplest interferometers is the Michelson interferometer (Fig. 3.11). A plane wave is divided by a beam splitter into two plane waves. One of these plane waves hits the reference mirror and the other hits the object mirror. Both waves are then reflected back and each wave is again divided into two plane waves. Therefore, the Michelson interferometer has two exits, where one is identical to the entrance so that only the other can really be used. If the beam splitter is exactly oriented at 45° relative to the incoming plane wave and both mirrors are exactly perpendicular to the plane waves the wave vectors k_1 and k_2 of the two plane waves at the exit are parallel, i. e., $k_1 = k_2$. Then, according to (3.170), which is also valid for scalar waves, the intensity in the whole space behind the exit, e.g., in the detector plane, which shall be perpendicular to the z-axis, depends only on the phase difference δ, which is constant over the whole exit pupil:

$$I_{1+2} = I_1 + I_2 + 2\sqrt{I_1 I_2} \cos\left[(k_1 - k_2) \cdot r + \delta\right]$$
$$= I_1 + I_2 + 2\sqrt{I_1 I_2} \cos\delta . \tag{3.211}$$

In this case one speaks of fluffed out fringes because no interference fringes are present. Depending on the optical path difference δ between object and reference arm the intensity can have a maximum or a minimum. If the object mirror is axially shifted the intensity on the detector changes periodically and one period corresponds to an axial shift Δz of half a wavelength in the material with refractive index n, in which the light propagates (normally air), because of the double pass arrangement

$$\Delta z = \frac{\lambda}{2n} . \tag{3.212}$$

If the beam splitter or one of the mirrors are tilted, there are interference fringes on the detector. An axial shift of the object mirror then causes a lateral movement of the fringes. Again, the fringes move by one period if the axial shift is $\lambda/(2n)$. A typical application of a Michelson interferometer is the length measurement whereby the relative shift of the object mirror can be measured.
There are several variations of the Michelson interferometer. One is a Twyman–Green interferometer, where a lens is placed in the object arm and instead of using a plane object mirror a spherical mirror is used. In the case of the ideal adjustment of the interferometer the focus of the lens and the center of curvature of the spherical mirror have to coincide. If the quality of either the lens or the spherical mirror (and of all other components of the interferometer) is known, the resulting interference pattern can be used to determine the errors of the other component.

Mach–Zehnder Interferometer

Another very important interferometer is a Mach–Zehnder interferometer (Fig. 3.12). There the light of an incoming plane wave is again divided by a beam splitter into two waves. Then the transmitted plane wave is reflected at the upper mirror and passes the second beam splitter or is reflected at it. The plane wave reflected at the first beam splitter is reflected at the lower mirror and can pass an optional transmissive object to be tested. At the second beam splitter this wave can be transmitted or reflected. So, the Mach–Zehnder interferometer has two exits, which can both be used. Similarly to the case of the Michelson interferometer there are fluffed out fringes if all mirrors and beam splitters are oriented by exactly 45° relative to the incoming plane wave. If one of the mirrors or beam splitters is tilted there are fringes on the detector.

Fig. 3.11 Basic principle of a Michelson interferometer
Fig. 3.12 Basic principle of a Mach–Zehnder interferometer

A Mach–Zehnder interferometer can be used to detect inhomogeneities of an optional object in the object arm. A special type is, e.g., an interferometer where the object is a tube filled with gas. By changing the pressure or the temperature in the tube the refractive index n is changed. Then the optical path difference between the object and the reference arm also changes and the fringes move or, in the case of fluffed out fringes, the overall intensity changes. So, the dependence of the refractive index of the gas on the pressure and temperature can be measured. In another type of Mach–Zehnder interferometer the object is a combination of a well-known lens and a lens to be tested, which together form a telescope. Using phase shifting interferometry (see later) by shifting one of the mirrors the errors of the lens to be tested can be determined. Of course, in practice there are always so-called adjustment errors that have to be eliminated from the measurement results and there are also systematic errors of the other components in the setup. Additionally, a very important fact is that the object to be tested has to be imaged onto the detector using auxiliary optics. Then, it is possible to say that the measured errors correspond to errors of the object at a certain point. This is, of course, also valid for the Twyman–Green interferometer and all other interferometers used for the measurement of an optical object with a limited depth. In an interferometer for the measurement of refractive index changes where the object is very long, it is not possible to image the complete object sharply onto the detector.

Shearing Interferometer

An interesting interferometer that needs no external reference arm is a shearing interferometer. There, by some means, a copy of the object wave is generated, which is either laterally or radially sheared [3.19, 29]. Here, only the case of lateral shearing will be discussed. The coordinate system is chosen in such a way that the shearing is along the x-axis by a distance Δx. Then, the phases of the two copies are $\Phi_1(x, y) = \Phi_\mathrm{o}(x + \Delta x, y)$ and $\Phi_2(x, y) = \Phi_\mathrm{o}(x, y)$, whereby Φ_o is the phase of the object wave itself. The phase difference Φ, which appears in the interference term of the interference (3.188), is then

$$\begin{aligned}\Phi(x, y) &= \Phi_1(x, y) - \Phi_2(x, y) \\ &= \Phi_\mathrm{o}(x + \Delta x, y) - \Phi_\mathrm{o}(x, y) \\ &\approx \Delta x \frac{\partial \Phi_\mathrm{o}(x, y)}{\partial x} \, .\end{aligned} \tag{3.213}$$

The approximation of taking the first partial derivative at the point (x, y) is valid for small shearing distances Δx. The shearing interferometer can be similarly evaluated as other interferometers with phase shifting techniques and phase unwrapping, whereby a continuous function for $\Phi \approx \Delta x \partial \Phi_\mathrm{o}/\partial x$ results. To obtain the phase Φ_o of the wavefront itself a kind of integration has to be made [3.19], [3.30]. To obtain an unambiguous wavefront both partial derivatives of Φ_o in the x and y directions have to be determined before the integration can be performed.

Phase–Shifting Interferometry

A typical technique to extract the object phase from the measured intensity values is phase-shifting interferometry [3.25, 31]. There, the reference mirror (or the object) is axially shifted by a well-known small distance and at least three different intensity distributions with different but well-known reference phases have to be observed, whereby there are also other possibilities to shift the phase [3.32]. By shifting the reference phase by $\delta\phi$, which is a well-defined integer multiple m of $\pi/2$ the intensity of the interference pattern $I_{1+2}^{(m)}$ changes according to (3.188) as

$$\begin{aligned}I_{1+2}^{(m)} &= I_1 + I_2 + 2\sqrt{I_1 I_2} \cos(\Phi + \delta\phi) \\ &= I_1 + I_2 + 2\sqrt{I_1 I_2} \cos\left(\Phi + m\frac{\pi}{2}\right). \end{aligned} \tag{3.214}$$

Three measurements with different reference phases are in principle enough because (3.214) contains the three unknowns I_1, I_2 and the desired phase Φ. It is quite simple to combine the three measured intensity distributions $I_{1+2}^{(0)}$, $I_{1+2}^{(1)}$ and $I_{1+2}^{(2)}$ with different values m in order to calculate Φ:

$$\begin{aligned}I_{1+2}^{(0)} &= I_1 + I_2 + 2\sqrt{I_1 I_2} \cos\Phi \, , \\ I_{1+2}^{(1)} &= I_1 + I_2 + 2\sqrt{I_1 I_2} \cos\left(\Phi + \frac{\pi}{2}\right) \\ &= I_1 + I_2 - 2\sqrt{I_1 I_2} \sin\Phi \, , \\ I_{1+2}^{(2)} &= I_1 + I_2 + 2\sqrt{I_1 I_2} \cos(\Phi + \pi) \\ &= I_1 + I_2 - 2\sqrt{I_1 I_2} \cos\Phi \, ; \\ \Rightarrow I_{1+2}^{(0)} + I_{1+2}^{(2)} &= 2(I_1 + I_2) \, , \\ I_{1+2}^{(0)} - I_{1+2}^{(2)} &= 4\sqrt{I_1 I_2} \cos\Phi \, , \\ I_{1+2}^{(0)} + I_{1+2}^{(2)} - 2I_{1+2}^{(1)} &= 4\sqrt{I_1 I_2} \sin\Phi \, , \\ \Rightarrow \tan\Phi &= \frac{I_{1+2}^{(0)} + I_{1+2}^{(2)} - 2I_{1+2}^{(1)}}{I_{1+2}^{(0)} - I_{1+2}^{(2)}} \, . \end{aligned} \tag{3.215}$$

However, this simple phase shifting algorithm with only three measurements is quite sensitive to phase shifting

errors, i. e., if the phase shifts are not integer multiples of $\pi/2$. If more measurements are made, the correction of phase shifting errors is possible [3.20, 26, 31].

A principal problem of two beam interferometry is that the phase values obtained with a phase shifting algorithm, like, e.g., with (3.215), are only defined modulo 2π. (Note: The arctangent function itself is only unambiguously defined between $-\pi/2$ and $+\pi/2$. But by evaluating the signs of the numerator and denominator of (3.215) the phase Φ can be unambiguously calculated between $-\pi$ and $+\pi$.) Therefore, so-called phase unwrapping algorithms [3.20] have to be used in order to obtain a continuous phase profile of, e.g., the surface deviations or wave aberrations of a lens.

Some Ideas on the Energy Conservation in Interferometers

Here, some principal ideas to the conservation of energy in an interferometer shall be given because the laws of energy conservation have to be fulfilled everywhere in optics.

Let us consider, e.g., the Mach–Zehnder interferometer of Fig. 3.12. We assume that each beam splitter has a splitting ratio of 1:1, i. e., half of the light power is transmitted and half is reflected. So, if the intensity of the incoming plane wave is I_0 at the entrance, the intensities of the transmitted and reflected plane waves are each $I_0/2$. The two mirrors are assumed to reflect all light without losses and diffraction effects at apertures are also neglected because we use plane waves. So, at the second beam splitter each of the plane waves is again divided into two waves with equal intensity, i. e., each of the four waves now has the intensity $I_0/4$. At exit 1, two of these waves interfere and we assume that the phase difference Φ between these two waves shall be zero or an integer number times 2π. Then, the resulting intensity I_{1+2} is, according to (3.188),

$$I_{1+2} = I_1 + I_2 + 2\sqrt{I_1 I_2} \cos \Phi$$
$$= \frac{I_0}{4} + \frac{I_0}{4} + 2\sqrt{\frac{I_0^2}{16}} = I_0 . \tag{3.216}$$

This, however, means that all of the incoming light power has to be at exit 1. Therefore, the intensity I'_{1+2} at exit 2 has to automatically be zero. Since the intensities of the two single waves, which interfere at exit 2 are also $I_0/4$, this is only possible if the phase difference Φ' is an odd-numbered multiple of π

$$I'_{1+2} = \frac{I_0}{4} + \frac{I_0}{4} + 2\sqrt{\frac{I_0^2}{16}} \cos \Phi'$$
$$= 0 \;\Rightarrow\; \Phi' = (2m+1)\,\pi \tag{3.217}$$

with an integer number m. So, if we take the basic solution $\Phi' = \pi$ this requires that the phase shift between the transmitted and the reflected wave at each beam splitter is half of this value, i. e., $\pi/2$. Then, the law of energy conservation is fulfilled. To explain this further consider Fig. 3.12 regarded.

The phase differences between the two waves interfering at exits 1 and 2, respectively, due to the geometrical path are identical for both exits. The same is valid for reflections at the mirrors because each wave is exactly reflected once at a mirror. So, there has to be a phase shift between a reflected and a transmitted wave at a beam splitter in order to fulfill the law of energy conservation. The two waves that interfere at exit 1 (symmetrical exit) are each reflected one time a a beam splitter and transmitted one time by a beam splitter. So, the assumed phase shifts of $\pi/2$ due to a reflection at a beam splitter cancel out each other because the phase difference between both interfering waves is taken. But, at the exit 2 (antisymmetric exit) the first wave is transmitted by both beam splitters and the other wave is reflected at both beam splitters. Therefore, the phase difference between the two interfering waves is in this case

$$\Phi' = \Phi + 2\frac{\pi}{2} = \Phi + \pi . \tag{3.218}$$

This guarantees that the sum of the intensities $I_{1+2} + I'_{1+2}$ at both exits is equal to the intensity at the entrance:

$$I_{1+2} + I'_{1+2} = \left(\frac{I_0}{4} + \frac{I_0}{4} + 2\sqrt{\frac{I_0^2}{16}} \cos \Phi \right)$$
$$+ \left(\frac{I_0}{4} + \frac{I_0}{4} + 2\sqrt{\frac{I_0^2}{16}} \cos \Phi' \right)$$
$$= \frac{I_0}{2} (1+\cos \Phi) + \frac{I_0}{2} (1-\cos \Phi) = I_0 . \tag{3.219}$$

So, the energy is conserved if the phase shift of a wave, which is reflected at a beam splitter, is $\pi/2$ compared to the phase of the transmitted wave.

3.4 Diffraction

Up to now we have mostly investigated the propagation of plane waves and other waves that are not affected by any limiting apertures. A plane wave has, e.g., an infinite spatial extension and therefore it does not exist in the real world. Nevertheless, if the diameter of the limiting aperture is very large compared to the wavelength of the light, a plane wave can be a quite good approximation if the propagation distance is not very large. But also in this case there are disturbances at the rim of the wave which are called diffraction effects. In this section diffraction theory will mostly be treated for scalar waves and only at the end of this section will the influence of polarization effects on the electric energy density in the focal region of a lens be treated [3.33, 34]. In contrast to most textbooks on optics like [3.1, 35], we will not start historically with the Huygens–Fresnel principle or with the integral theorem of Helmholtz and Kirchhoff, but with the angular spectrum of plane waves. Only Kirchhoff's boundary conditions will be used, i.e., a wave that is incident on an absorbing screen with a hole will be undisturbed in the area of the hole and completely absorbed in the other parts of the screen. Starting from the angular spectrum of plane waves the Fresnel–Kirchhoff diffraction integral will be derived and it will be shown that both formulations are nearly equivalent [3.36–38]. The approximations of Fresnel diffraction and Fraunhofer diffraction will be discussed afterwards. A quite interesting application of Fraunhofer diffraction is, e.g., the calculation of the intensity distribution in the focal region of a lens [3.1, 39]. Afterwards, some ideas to the numerical implementation of scalar diffraction formula are given [3.38]. At the end of this section we will briefly reflect on the combination of polarization and diffraction by using the superposition of plane waves taking into account their polarization states. This is used to calculate the influence of polarization effects to the electric energy density in the focal region of a lens.

There are many modern applications of diffraction and interference effects in optical holography [3.40–43] and computer-generated diffractive optics [3.44–50]. But, there is no space to cover these fields in this chapter and we refer therefore to the literature.

3.4.1 The Angular Spectrum of Plane Waves

The knowledge of the angular spectrum of plane waves allows the exact propagation of a complex amplitude function u from one plane (which is chosen perpendicular to the z-axis) to another parallel plane in the distance z_0 in a homogeneous and isotropic material with the refractive index n. The only approximation here is that u is assumed to be a scalar function. But, since a plane wave can easily be defined by taking into account polarization (Sect. 3.2) an extension of this formalism is possible, but will not be treated here.

According to (3.52) a scalar plane wave

$$u(\boldsymbol{r}) = u_0 e^{i\boldsymbol{k}\cdot\boldsymbol{r}} \tag{3.220}$$

fulfills the Helmholtz equation (3.109), which is written for scalar waves as

$$\left(\nabla^2 + k^2\right) u(x, y, z) = 0 . \tag{3.221}$$

The condition for the modulus $|\boldsymbol{k}| = k$ of the wave vector is

$$|\boldsymbol{k}| = \sqrt{k_x^2 + k_y^2 + k_z^2} = \frac{2\pi n}{\lambda} . \tag{3.222}$$

According to the linearity of the Helmholtz equation a sum of plane waves with different directions of propagation is also a solution of the Helmholtz equation and in the limit a continuous spectrum of plane waves is a solution (Fig. 3.13). There, the integration has to be done over two angles or more exactly over two components of the wave vector. The third component is then automatically defined by (3.222) as long as only plane waves propagating in the positive z direction are taken into account, which will be the case here. Since the complex amplitude is always regarded in a plane perpendicular to the z-axis, the two components of the wave

Fig. 3.13 Arbitrary scalar wave as superposition of plane waves

vector used for the integration will be the x and y components. To obtain a symmetrical formulation the vector $\boldsymbol{v}$ of the spatial frequencies is introduced by

$$\boldsymbol{v} = \frac{1}{2\pi}\boldsymbol{k} = \begin{pmatrix} v_x \\ v_y \\ v_z \end{pmatrix} \quad \text{with}$$

$$|\boldsymbol{v}| = \sqrt{v_x^2 + v_y^2 + v_z^2} = \frac{n}{\lambda} . \tag{3.223}$$

The complex amplitude $u(\boldsymbol{r})$ of a wave can then be written as a superposition of plane waves

$$u(\boldsymbol{r}) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \tilde{u}\left(v_x, v_y\right) e^{2\pi i \boldsymbol{v} \cdot \boldsymbol{r}} \, dv_x \, dv_y . \tag{3.224}$$

The integration takes into account arbitrary spatial frequencies v_x and v_y so that later the mathematical formalism of the Fourier transformation [3.51, 52] can be used. To fulfill (3.222) the z component of the vector of the spatial frequencies is defined by the x and y components since we allow only waves propagating in the positive z direction

$$v_z = \sqrt{\frac{n^2}{\lambda^2} - v_x^2 - v_y^2} . \tag{3.225}$$

Nevertheless, the square root only delivers a real solution for a positive argument. Therefore, two cases have to be distinguished

$$v_x^2 + v_y^2 \leq \frac{n^2}{\lambda^2} \Rightarrow e^{2\pi i v_z z} = e^{2\pi i z \sqrt{\frac{n^2}{\lambda^2} - v_x^2 - v_y^2}} , \tag{3.226}$$

$$v_x^2 + v_y^2 > \frac{n^2}{\lambda^2} \Rightarrow e^{2\pi i v_z z} = e^{-2\pi z \sqrt{v_x^2 + v_y^2 - \frac{n^2}{\lambda^2}}} , \tag{3.227}$$

where in both cases the result of the square root is a real number. The second case corresponds to an exponentially decreasing amplitude and so the waves with such high spatial frequencies propagate only along very small distances z of the range of some wavelengths and are called evanescent waves.

If the complex amplitude u_0 of a wave is known in a plane and the coordinate system is chosen such that this plane is perpendicular to the z-axis at $z = 0$ according

to (3.224) it holds that

$$u_0(x, y, 0) \tag{3.228}$$

$$= \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \tilde{u}_0\left(v_x, v_y, 0\right) e^{2\pi i (v_x x + v_y y)} \, dv_x \, dv_y ,$$

where $\tilde{u}_0(v_x, v_y, 0)$ is the Fourier transform of u_0 in the plane at $z = 0$ and can be calculated using the Fourier relation

$$\tilde{u}_0\left(v_x, v_y, 0\right) \tag{3.229}$$

$$= \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} u_0(x, y, 0) e^{-2\pi i (v_x x + v_y y)} \, dx \, dy .$$

Since $\tilde{u}_0$ is now known the complex amplitude u in another parallel plane at $z = z_0$ can be calculated with (3.224) and (3.225):

$$u(x, y, z_0)$$

$$= \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \tilde{u}_0\left(v_x, v_y, 0\right) e^{2\pi i \left(v_x x + v_y y\right)}$$

$$\times e^{2\pi i v_z z_0} \, dv_x \, dv_y ; \tag{3.230}$$

$$\Rightarrow u(x, y, z_0)$$

$$= \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \tilde{u}_0\left(v_x, v_y, 0\right)$$

$$\times e^{2\pi i \frac{n z_0}{\lambda}\sqrt{1 - \frac{\lambda^2}{n^2}\left(v_x^2 + v_y^2\right)}}$$

$$\times e^{2\pi i \left(v_x x + v_y y\right)} \, dv_x \, dv_y . \tag{3.231}$$

So, this is an inverse Fourier transformation where the function

$$\tilde{u}\left(v_x, v_y, z_0\right)$$

$$= \tilde{u}_0\left(v_x, v_y, 0\right) e^{2\pi i \frac{n z_0}{\lambda}\sqrt{1 - \frac{\lambda^2}{n^2}\left(v_x^2 + v_y^2\right)}} \tag{3.232}$$

has to be Fourier transformed. In total, by using a Fourier transformation (3.229), multiplying $\tilde{u}_0$ with the propagation factor $\exp(2\pi i v_z z_0)$, and applying an inverse Fourier transformation ((3.231) for both operations) the complex amplitude in a plane parallel to the original

plane in the distance z_0 can be calculated. Hereby, it must be taken into account that according to (3.226) and (3.227) the propagation factor $\exp(2\pi i \nu_z z_0)$ can either be a pure phase factor (for $\nu_x^2 + \nu_y^2 \leq n^2/\lambda^2$) or an exponentially decreasing real term.

The propagation factor is also known as the transfer function of free space H

$$H\left(\nu_x, \nu_y, z_0\right) = e^{2\pi i \frac{nz_0}{\lambda}\sqrt{1 - \frac{\lambda^2}{n^2}\left(\nu_x^2 + \nu_y^2\right)}}.$$

(3.233)

Then, (3.231) can be written as

$$u(x, y, z_0) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \tilde{u}_0\left(\nu_x, \nu_y, 0\right) H\left(\nu_x, \nu_y, z_0\right)$$

$$\times e^{2\pi i\left(\nu_x x + \nu_y y\right)} d\nu_x d\nu_y.$$

(3.234)

3.4.2 The Equivalence of the Rayleigh–Sommerfeld Diffraction Formula and the Angular Spectrum of Plane Waves

According to the convolution theorem of Fourier mathematics, (3.234) can be written as a convolution of two functions, whereby these two functions are the inverse Fourier transforms of $\tilde{u}_0$ and H. The inverse Fourier transform of $\tilde{u}_0$ is, due to (3.228), the complex amplitude distribution u_0 at $z = 0$. The other term is not so obvious. But in [3.36] and [3.37] it is shown that the following relation is valid

$$\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} e^{2\pi i \frac{nz_0}{\lambda}\sqrt{1 - \frac{\lambda^2}{n^2}\left(\nu_x^2 + \nu_y^2\right)}}$$

$$\times e^{2\pi i\left(\nu_x x + \nu_y y\right)} d\nu_x d\nu_y$$

$$= -\frac{1}{2\pi} \frac{\partial}{\partial z_0}\left(\frac{e^{2\pi i \frac{nr}{\lambda}}}{r}\right) = -\frac{1}{2\pi} \frac{\partial}{\partial z_0}\left(\frac{e^{ikr}}{r}\right)$$

$$= -\frac{1}{2\pi}\left(ik - \frac{1}{r}\right)\frac{z_0}{r}\frac{e^{ikr}}{r},$$

(3.235)

whereby $r := \sqrt{x^2 + y^2 + z_0^2}$ and $k := 2\pi n/\lambda$.

So, in total (3.231) can be written as

$$u(x, y, z_0) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \tilde{u}_0\left(\nu_x, \nu_y, 0\right)$$

$$\times e^{ikz_0\sqrt{1 - \frac{\lambda^2}{n^2}\left(\nu_x^2 + \nu_y^2\right)}}$$

$$\times e^{2\pi i\left(\nu_x x + \nu_y y\right)} d\nu_x d\nu_y$$

$$= -\frac{1}{2\pi}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} u_0\left(x', y', 0\right)\left(ik - \frac{1}{l}\right)$$

$$\times \frac{z_0}{l}\frac{e^{ikl}}{l} dx' dy'$$

(3.236)

with

$$l := \sqrt{(x - x')^2 + (y - y')^2 + z_0^2}.$$

(3.237)

The right-hand side of (3.236) is known as the general Rayleigh–Sommerfeld diffraction formula. So, the complex amplitude $u(x, y, z_0)$ can either be expressed as a superposition of plane waves or as a convolution of the original complex amplitude $u_0(x, y, 0)$ with a spherical Huygens wavelet h of the form

$$h\left(x, y, z_0\right) = -\frac{1}{2\pi}\left(ik - \frac{1}{r}\right)\frac{z_0}{r}\frac{e^{ikr}}{r},$$

(3.238)

which is the inverse Fourier transform of the transfer function of free space H; h is also called the impulse response since it results if the stimulating complex amplitude $u_0(x, y, 0)$ has the form of a δ function. Equation (3.236) is a mathematical expression of the Huygens–Fresnel principle. The term z_0/l is the cosine obliquity factor. By using (3.236) and (3.238) the complex amplitude can be written as

$$u(x, y, z_0)$$

(3.239)

$$= \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} u_0\left(x', y', 0\right) h\left(x - x', y - y', z_0\right) dx' dy',$$

i. e., as a convolution of the original complex amplitude u_0 in the first plane and the impulse response h.

In most cases the term r is much larger than the wavelength in the medium λ/n. Then the relation $k \gg$

$1/r$ is valid and the impulse response of (3.238) can be written as

$$h(x, y, z_0) = -\frac{1}{2\pi}\left(ik - \frac{1}{r}\right)\frac{z_0}{r}\frac{e^{ikr}}{r}$$

$$\approx -i\frac{n}{\lambda}\frac{z_0}{r}\frac{e^{ikr}}{r} \ . \qquad (3.240)$$

Then (3.236) results in the more familiar but less general Rayleigh–Sommerfeld diffraction formula

$$u(x, y, z_0)$$

$$\approx -i\frac{n}{\lambda}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} u_0\left(x', y', 0\right)\frac{z_0}{l}\frac{e^{ikl}}{l}\, dx'\, dy' \ . \ (3.241)$$

In the case that the complex amplitude u_0 is different from zero inside an aperture A and zero outside of the aperture A (3.241) is also known as the Fresnel–Kirchhoff diffraction integral [3.1]. Then, the effective integration is not carried out from minus infinity to plus infinity but on the area of the aperture A.

It has to be mentioned that (3.236) can also be written in a similar form that does not explicitly assume that the original complex amplitude, which is now named $u_0(\mathbf{r}')$ has to be known in a plane and that the complex amplitude $u(\mathbf{r})$, which has to be calculated, is also defined in a plane. The generalization is

$$u(\mathbf{r}) = -\frac{1}{2\pi}\iint\limits_{A} u_0\left(\mathbf{r}'\right)\left(ik - \frac{1}{l}\right)$$

$$\times \frac{\mathbf{N}\cdot(\mathbf{r} - \mathbf{r}')}{l}\frac{e^{ikl}}{l}\, dS \ . \qquad (3.242)$$

Here, $\mathbf{r}' = (x', y', z')$ defines an arbitrary point on a curved surface (the aperture A) where the original complex amplitude u_0 is defined and $\mathbf{r} = (x, y, z)$ is an arbitrary point on the second curved surface on which the complex amplitude u has to be calculated. Additionally, $\mathbf{N}$ is a unit vector perpendicular to the aperture A at the point $\mathbf{r}'$. The integration is done over the aperture A and the integration element dS indicates a two-dimensional integration. Additionally, the distance l is then defined by:

$$l := \sqrt{|\mathbf{r} - \mathbf{r}'|^2} \ . \qquad (3.243)$$

Nevertheless, in the following we will always assume that both complex amplitudes u_0 and u are defined in parallel planes. This allows, as we will see in the next section, that approximate integrals like the Fresnel diffraction integral can be numerically calculated using the efficient fast Fourier transformation.

3.4.3 The Fresnel and the Fraunhofer Diffraction Integral

In the following, we always assume that the plane aperture A on which the integration of the diffraction integral is carried out is limited and has a maximum diameter of D. There is no other restriction on the form of the aperture, which can be circular, rectangular or irregularly formed. The parameter D is therefore the diameter of a circle, which contains the aperture and which is centered around the z-axis. Again, we have the complex amplitude $u_0(x', y', 0)$ in a first plane at $z = 0$, which is zero outside of the aperture. Additionally, the distance z_0 of the second plane to the first parallel plane is much larger than the diameter D of the aperture A, i.e., $D \ll z_0$.

Then, the distance l (see (3.237)) of a point $P' = (x', y', 0)$ in the first plane and a point $P = (x, y, z_0)$ in the second plane can be written as (Fig. 3.14)

$$l = \sqrt{(x - x')^2 + (y - y')^2 + z_0^2}$$

$$= \sqrt{x^2 + y^2 + z_0^2 + x'^2 + y'^2 - 2xx' - 2yy'}$$

$$= \sqrt{x^2 + y^2 + z_0^2}\sqrt{1 + \frac{x'^2 + y'^2 - 2xx' - 2yy'}{x^2 + y^2 + z_0^2}} \ . $$

$$(3.244)$$

We define the term l_0 as

$$l_0 := \sqrt{x^2 + y^2 + z_0^2} \gg D \Rightarrow \frac{D}{l_0} \ll 1 \ . \qquad (3.245)$$

Because of $x' \leq D/2$, $y' \leq D/2$ and (3.245) all terms on the order of x'^3/l_0^3, y'^3/l_0^3 and higher can be neglected. Then l can be approximated by the first terms of its

Fig. 3.14 Coordinate systems used in the calculation of the different diffraction integrals

Taylor expansion:

$$l = l_0 \sqrt{1 + \frac{x'^2 + y'^2 - 2xx' - 2yy'}{l_0^2}}$$

$$\approx l_0 \left(1 + \frac{x'^2 + y'^2}{2l_0^2} - \frac{xx' + yy'}{l_0^2} \right.$$

$$\left. - \frac{\left(x'^2 + y'^2 - 2xx' - 2yy' \right)^2}{8l_0^4} \right)$$

$$= l_0 + \frac{x'^2 + y'^2}{2l_0} - \frac{xx' + yy'}{l_0} - \frac{(xx' + yy')^2}{2l_0^3}$$

$$+ \frac{\left(x'^2 + y'^2 \right)(xx' + yy')}{2l_0^3} - \frac{\left(x'^2 + y'^2 \right)^2}{8l_0^3} .$$

(3.246)

The last two terms are on the order of x'^3/l_0^3, y'^3/l_0^3 or higher. Therefore, they can be neglected and the result is

$$l \approx l_0 + \frac{x'^2 + y'^2}{2l_0} - \frac{xx' + yy'}{l_0} - \frac{(xx' + yy')^2}{2l_0^3} ,$$

(3.247)

where l in the denominator of the Huygens wavelet of (3.241) can then be replaced with a good approximation by only the first term of the Taylor expansion, i. e., l_0, and the cosine obliquity factor z_0/l can be replaced by the term z_0/l_0. This means that the Fresnel–Kirchhoff diffraction integral (3.241) can be approximated by

$$u(x, y, z_0)$$

$$\approx -\mathrm{i} \frac{n}{\lambda l_0} \frac{z_0}{l_0} \int\limits_{-\infty}^{+\infty} \int\limits_{-\infty}^{+\infty} u_0 \left(x', y', 0 \right) \mathrm{e}^{\mathrm{i}kl} \, \mathrm{d}x' \, \mathrm{d}y' ,$$

(3.248)

where l is defined via (3.247). This equation is valid as long as the last two terms of (3.246) can be neglected in the exponential factor $\exp(\mathrm{i}kl)$. Therefore, two conditions have to be valid:

$$k \frac{\left(x'^2 + y'^2 \right)(xx' + yy')}{2l_0^3} \ll \pi$$

$$\Rightarrow n \frac{\left(x'^2 + y'^2 \right)(xx' + yy')}{\lambda l_0^3} \ll 1 ,$$

(3.249)

$$k \frac{\left(x'^2 + y'^2 \right)^2}{8l_0^3} \ll \pi \Rightarrow n \frac{\left(x'^2 + y'^2 \right)^2}{4\lambda l_0^3} \ll 1 .$$

(3.250)

There are two especially interesting approximations of the Fresnel–Kirchhoff diffraction integral. The first is the Fresnel diffraction integral where only points P in the neighborhood of the axis, i. e., in the paraxial regime, are considered and the second is the Fraunhofer diffraction integral where only points in the far field or in the focal plane of a lens are considered.

The Fresnel Diffraction Integral

In the paraxial regime, i. e., $x^2 + y^2 \leq D^2$, we can write

$$x^2 + y^2 \leq D^2 \ll z_0^2$$

$$\Rightarrow l_0 = z_0 \sqrt{1 + \frac{x^2 + y^2}{z_0^2}} \approx z_0 + \frac{x^2 + y^2}{2z_0} . \quad (3.251)$$

The second term is only interesting in the rapidly oscillating exponential factor $\exp(\mathrm{i}kl_0)$. In the other cases we can write $l_0 \approx z_0$ and $z_0/l_0 \approx 1$. Additionally, we have to approximate $1/l_0$ in some terms in the exponential factor

$$\frac{1}{l_0} = \frac{1}{z_0} \left(1 + \frac{x^2 + y^2}{z_0^2} \right)^{-1/2} \approx \frac{1}{z_0} - \frac{x^2 + y^2}{2z_0^3} .$$

(3.252)

Since the term $1/l_0$ appears only in terms that are themselves on the order of x'^2, y'^2 or xx', yy', the second term $(x^2 + y^2)/(2z_0^3)$ can be neglected because it would lead to terms of higher order. In the paraxial regime the last term in (3.247) can also be neglected. Finally, we obtain from (3.248):

$$u(x, y, z_0)$$

$$= -\mathrm{i} \frac{n}{\lambda z_0} \mathrm{e}^{\mathrm{i} \frac{2\pi n z_0}{\lambda}} \mathrm{e}^{\mathrm{i}\pi n \frac{x^2 + y^2}{\lambda z_0}}$$

$$\times \int\int\limits_{A} u_0 \left(x', y', 0 \right) \mathrm{e}^{\mathrm{i}\pi n \frac{x'^2 + y'^2}{\lambda z_0}}$$

$$\times \mathrm{e}^{-2\pi \mathrm{i} n \frac{xx' + yy'}{\lambda z_0}} \, \mathrm{d}x' \, \mathrm{d}y' . \quad (3.253)$$

This is the Fresnel diffraction integral, where the integration is made over the aperture A. The condition for the

validity of the Fresnel diffraction integral is, according to (3.249) and (3.250),

$$n \frac{\left(x'^2 + y'^2\right)\left(xx' + yy'\right)}{\lambda l_0^3} \ll 1$$

and

$$n \frac{\left(x'^2 + y'^2\right)^2}{4\lambda l_0^3} \ll 1$$

$$\Rightarrow Q_{\text{Fresnel}} := \frac{n(D/2)^4}{\lambda z_0^3} = \frac{n D^4}{16\lambda z_0^3} \ll 1 . \tag{3.254}$$

As an example, we take $n = 1$, $\lambda = 0.5\,\mu\text{m}$, $D = 10\,\text{mm}$ and $z_0 = 1\,\text{m}$. Then the term Q_{Fresnel} has the value $Q_{\text{Fresnel}} = 0.00125$ and the condition for the validity of the Fresnel diffraction integral is very well fulfilled. If the distance z_0 is only 0.1 m the term Q_{Fresnel} is 1.25 and the Fresnel approximation is at the limit of its validity. This shows that the Fresnel diffraction integral is a good approximation in a distance between the near and the far field. In the near field (which ranges from $z_0 = 0$ up to a distance z_0 of several times D) the Fresnel–Kirchhoff diffraction integral or the angular spectrum of plane waves has to be used. In the far field there is another more simple approximation, the Fraunhofer diffraction formula, which will be discussed in the next section. But before doing this the Fresnel diffraction integral of (3.253) will be discussed a little further.

Equation (3.253) shows that the integral itself is formally the Fourier transformation of the function

$$f\left(x', y'\right)$$

$$= \begin{cases} u_0\left(x', y', 0\right) \exp\left(i\pi n \frac{x'^2 + y'^2}{\lambda z_0}\right) \\ \qquad\qquad \text{if } (x', y') \in A \\ 0 \qquad\qquad \text{if } (x', y') \notin A \end{cases} . \tag{3.255}$$

This gives the quite efficient possibility of calculating the integral numerically by using a fast Fourier transformation (FFT) [3.52]. But (3.253) can also be written in a different form

$$u(x, y, z_0) = -i \frac{n}{\lambda z_0} e^{i\frac{2\pi n z_0}{\lambda}}$$

$$\times \iint_A u_0\left(x', y', 0\right) e^{i\pi n \frac{(x-x')^2 + (y-y')^2}{\lambda z_0}} dx'\, dy' . \tag{3.256}$$

So, this form shows the Fresnel diffraction integral as a convolution of the functions u_0 and $\exp[i\pi n(x'^2 +$

$y'^2)/(\lambda z_0)]$. According to the convolution theorem the Fresnel diffraction integral can then formally be written as

$$u(x, y, z_0) \tag{3.257}$$

$$= -i\frac{n}{\lambda z_0} e^{i\frac{2\pi n z_0}{\lambda}} \text{FT}^{-1}$$

$$\times \left\{ \text{FT}\left\{u_0(x', y', 0)\right\} \cdot \text{FT}\left\{ e^{i\pi n \frac{x'^2 + y'^2}{\lambda z_0}} \right\} \right\} .$$

Now, according to (3.229) we have

$$\tilde{u}_0\left(\nu_x, \nu_y, 0\right)$$

$$= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} u_0(x', y', 0) e^{-2\pi i(\nu_x x' + \nu_y y')} dx'\, dy'$$

$$= \text{FT}\left\{u_0(x', y', 0)\right\} . \tag{3.258}$$

The second Fourier pair is

$$\text{FT}\left\{ e^{i\pi n \frac{x'^2 + y'^2}{\lambda z_0}} \right\}$$

$$= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} e^{i\pi n \frac{x'^2 + y'^2}{\lambda z_0}} e^{-2\pi i(\nu_x x' + \nu_y y')} dx'\, dy'$$

$$= i\frac{\lambda z_0}{n} e^{-i\pi \frac{\lambda z_0}{n}\left(\nu_x^2 + \nu_y^2\right)} . \tag{3.259}$$

In total, (3.257) results in

$$u(x, y, z_0)$$

$$= e^{i\frac{2\pi n z_0}{\lambda}} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \tilde{u}_0\left(\nu_x, \nu_y, 0\right)$$

$$\times e^{-i\pi \frac{\lambda z_0}{n}\left(\nu_x^2 + \nu_y^2\right)}$$

$$\times e^{2\pi i(\nu_x x + \nu_y y)} d\nu_x\, d\nu_y . \tag{3.260}$$

This is the Fresnel diffraction integral expressed in the Fourier domain. The same equation can also be obtained from the angular spectrum of plane waves (3.231) by

expanding the square root of the transfer function of free space in a Taylor series

$$\sqrt{1 - \frac{\lambda^2}{n^2}\left(v_x^2 + v_y^2\right)} \approx 1 - \frac{\lambda^2}{2n^2}\left(v_x^2 + v_y^2\right);$$

$$\Rightarrow e^{2\pi i \frac{nz_0}{\lambda}\sqrt{1 - \frac{\lambda^2}{n^2}\left(v_x^2 + v_y^2\right)}}$$

$$\approx e^{2\pi i \frac{nz_0}{\lambda}} e^{-i\pi \frac{\lambda z_0}{n}\left(v_x^2 + v_y^2\right)} .$$

(3.261)

This approximation is valid as long as the higher-order terms do not contribute to a considerable variation of the exponential factor. The condition for this is

$$2\pi \frac{nz_0}{\lambda} \frac{\lambda^4}{8n^4}\left(v_x^2 + v_y^2\right)^2 = \pi \frac{\lambda^3 z_0}{4n^3}\left(v_x^2 + v_y^2\right)^2 \ll \pi;$$

$$\Rightarrow Q_{\text{Fresnel, Fourier}} := \frac{\lambda^3 z_0}{4n^3}\left(v_x^2 + v_y^2\right)^2 \ll 1 .$$

(3.262)

To give an estimation of this term a spherical wave with the half-aperture angle φ is regarded. Then, the maximum spatial frequency of the spherical wave will be $n \sin\varphi/\lambda$. The function $\tilde{u}_0$ will be considerably different from zero only for spatial frequencies with $v_x^2 + v_y^2 < n^2 \sin^2 \varphi/\lambda^2$. Therefore, the condition (3.262) can be transformed to

$$Q_{\text{Fresnel, Fourier}} = \frac{nz_0}{4\lambda} \sin^4 \varphi \ll 1 .$$

(3.263)

It is obvious that the error term $Q_{\text{Fresnel, Fourier}}$ increases with increasing distance z_0 whereas the error term Q_{Fresnel} of (3.254) decreases with increasing z_0.

So, the formulation of the Fresnel diffraction integral in the Fourier domain (3.260) is better used for the near field whereas the Fresnel diffraction integral of (3.253) is better used for the medium or far field. So, both formulations are contrary. The numerical evaluation of both diffraction integrals can be done using FFT's whereas only one FFT is necessary in the formulation of (3.253) and two FFT's (one for calculating $\tilde{u}_0$ and one for the integral itself) in the formulation of (3.260).

The Fraunhofer Diffraction Formula
An approximation of the Fresnel–Kirchhoff diffraction integral for the far field can be obtained from (3.247) and (3.248). First, we define the direction cosines α and β as

$$\alpha := \frac{x}{l_0} ; \quad \beta := \frac{y}{l_0}$$

(3.264)

so that (3.247) can be written as

$$l \approx l_0 + \frac{x'^2 + y'^2}{2l_0} - \left(\alpha x' + \beta y'\right) - \frac{\left(\alpha x' + \beta y'\right)^2}{2l_0} .$$

(3.265)

With increasing l_0 the second and fourth term decrease more and more and only the first and the third term remain. The condition that only these two terms have to be considered is that the contribution of the other terms does not remarkably vary the exponential factor in (3.248). This is fulfilled if

$$\pi n \frac{x'^2 + y'^2}{\lambda l_0} \ll \pi \Rightarrow Q_{\text{Fraunhofer}} := \frac{nD^2}{4\lambda z_0} \ll 1 .$$

(3.266)

In the last step it is required that all points in the aperture A fulfill the condition $x'^2 + y'^2 \le (D/2)^2$, where D is again the maximum diameter of the aperture. We also used that according to (3.245) $l_0 \ge z_0$.

Then, (3.248) can be written as

$$u(\alpha, \beta, z_0)$$

$$= -i\frac{n}{\lambda l_0} \frac{z_0}{l_0} e^{ikl_0}$$

$$\times \int\int_A u_0\left(x', y', 0\right) e^{-2\pi i \frac{n}{\lambda}\left(\alpha x' + \beta y'\right)} dx' dy'.$$

(3.267)

This is the well-known Fraunhofer diffraction integral. It means that the complex amplitude in the far field is the Fourier transform of the complex amplitude at $z = 0$.

The importance of (3.267) would be quite marginal if it is only valid for the far field. This can be seen by the following example. We assume $n = 1$, $\lambda = 0.5\,\mu m$, $D = 10\,mm$. Then (3.266) would require

$$z_0 \gg \frac{nD^2}{4\lambda} = 50\,m .$$

(3.268)

But, there is another quite important case: the complex amplitude in the focal plane of a lens.

The Complex Amplitude in the Focal Plane of a Lens
We assume a complex amplitude u_0 in the starting plane that is defined as different from zero in the aperture A and zero outside of the aperture. The influence of an ideal thin lens which is positioned in the starting plane would be that u_0 has to be multiplied by the transmission

function $t_{\text{lens, ideal}}$ of the lens, which is an exponential phase factor of the form

$$
t_{\text{lens, ideal}}\left(x', y'\right) = e^{-ik\left(f\sqrt{1+\dfrac{x'^2+y'^2}{f^2}}-f\right)}
$$

$$
=: e^{-ikl_{\text{lens}}} . \tag{3.269}
$$

Here, f is the focal length of the lens and a positive value f corresponds to a positive lens, whereas in our case we will only have a positive lens. Of course, an ideal lens does not exist in reality and a more adapted transmission function is

$$
t_{\text{lens}}\left(x', y'\right) = e^{-ikl_{\text{lens}} + iW\left(x', y'\right)} , \tag{3.270}
$$

where W are the wave aberrations of the lens. However, in reality the wave aberrations of a lens will depend on the incident wavefront and a wave-optical simulation of a lens including aberrations is not so easy. But here, we assume that W is known for a given complex amplitude u_0. For an ideal lens we just have to put W equal to zero.

So, the new complex amplitude u'_0 behind the lens is defined by

$$
u'_0\left(x', y', 0\right) = u_0\left(x', y', 0\right) t_{\text{lens}}\left(x', y'\right) \tag{3.271}
$$

and the complex amplitude in a parallel plane at the distance z_0 is, according to the Fresnel–Kirchhoff diffraction integral (3.241),

$$
u(x, y, z_0) = -i\frac{n}{\lambda} \iint\limits_A u'_0\left(x', y', 0\right) \frac{z_0}{l} \frac{e^{ikl}}{l} \, dx' \, dy' , \tag{3.272}
$$

with l defined by (3.237) as

$$
l = \sqrt{(x-x')^2 + (y-y')^2 + z_0^2} .
$$

Now, we are only interested in points in the neighborhood of the Gaussian focus of the lens at $(0, 0, f)$ and since the radius $D/2$ of the aperture shall be several times smaller than the focal length f of the lens we have the following conditions and approximations

$$
f = z_0(1+\varepsilon) \quad \text{with}
$$

$$
|\varepsilon| \ll 1, \quad f \gg \frac{D}{2} \gg \frac{\lambda}{n};
$$

$$
x'^2 + y'^2 \le \frac{D^2}{4} \ll z_0^2,
$$

$$
\frac{x}{z_0} \ll \frac{D/2}{z_0} \ll 1 \quad \text{and} \quad \frac{y}{z_0} \ll \frac{D/2}{z_0} \ll 1 .
$$

Then, similar to the case of the Fresnel diffraction integral the cosine obliquity factor z_0/l is one and the distance l in the denominator of (3.272) can be replaced by z_0. Only l in the exponential phase factor of (3.272) has to be considered carefully since the phase factor will rapidly oscillate if l varies by more than one wavelength λ/n. So, using (3.270), (3.272) and the approximations the intermediate result is

$$
u(x, y, z_0)
$$
$$
= -i\frac{n}{\lambda z_0} \iint\limits_A u_0\left(x', y', 0\right) e^{iW\left(x', y'\right)}
$$
$$
\times e^{ik\left(l - l_{\text{lens}}\right)} \, dx' \, dy' . \tag{3.273}
$$

The term $l - l_{\text{lens}}$ has to be evaluated:

$$
l - l_{\text{lens}}
$$
$$
= z_0\sqrt{1 + \frac{x^2+y^2+x'^2+y'^2-2(xx'+yy')}{z_0^2}}
$$
$$
- f\sqrt{1 + \frac{x'^2+y'^2}{f^2}} + f
$$
$$
\approx z_0 + \frac{x^2+y^2}{2z_0} + \frac{x'^2+y'^2}{2z_0} - \frac{xx'+yy'}{z_0} - \frac{x'^2+y'^2}{2f}
$$
$$
= z_0 + \frac{x^2+y^2}{2z_0} + \frac{\Delta z}{fz_0}\frac{x'^2+y'^2}{2} - \frac{xx'+yy'}{z_0}
$$
$$
\tag{3.274}
$$

with

$$
\Delta z := f - z_0 .
$$

As in the case of the Fresnel diffraction integral the terms of higher than second order in x, y, x' or y' have been neglected because of our conditions. Nevertheless, it should be pointed out that the restrictions on the sine of the half-aperture angle φ of the lens ($\sin\varphi \approx D/(2f)$) are not so severe as in the case of the Fresnel diffraction integral since only points in the neighborhood of the Gaussian focus, i.e., when x, y and Δz are small, are interesting. To make this clear the higher-order terms have to be estimated whereby only one section along x and x' is considered. But this is no restriction if the aperture is circular or if the section along x, x' has a larger diameter than along y, y'. The maximum value of x' is $D/2$ and the maximum interesting value of x is just some wavelengths if we are near the focal plane of the lens. Additionally, we can replace the term $D/(2z_0)$ with a good approximation by $\sin\varphi$ because of $f \approx z_0$. For the same reason

we also have $1/z_0^3 - 1/f^3 \approx 3\Delta z/f^4$. The fourth-order terms of $k(l - l_{\text{lens}})$ are therefore of the following form

$$k\left(\frac{\left(x^2 + x'^2 - 2xx'\right)^2}{8z_0^3} - \frac{x'^4}{8f^3}\right)$$

$$= 2\pi n\left[\frac{x^4}{8\lambda z_0^3} + \left(\frac{1}{8\lambda z_0^3} - \frac{1}{8\lambda f^3}\right)x'^4\right.$$

$$\left. + \frac{3x^2 x'^2}{4\lambda z_0^3} - \frac{x^3 x'}{2\lambda z_0^3} - \frac{xx'^3}{2\lambda z_0^3}\right]$$

$$\le \pi n\left(\frac{x_{\text{max}}^4}{4\lambda f^3} + \frac{3\Delta z}{4\lambda}\sin^4\varphi + \frac{3x_{\text{max}}^2 \sin^2\varphi}{2\lambda f}\right.$$

$$\left. - \frac{x_{\text{max}}^3 \sin\varphi}{\lambda f^2} - \frac{x_{\text{max}}\sin^3\varphi}{\lambda}\right) . \quad (3.275)$$

Again, these terms have to be much smaller than π so that they can be neglected. A numerical example can illustrate this: A lens with a focal length of $f = 100$ mm and $D/2 = 30$ mm, i.e., $\sin\varphi = 0.29$, is illuminated with light of the wavelength $\lambda = 0.5\,\mu$m. The refractive index for the light propagation is $n = 1$. The propagation distance behind the lens is $z_0 = 99.9$ mm and the maximum value of x, which is interesting for us, is $x_{\text{max}} = 10\,\mu$m. Later, in (3.294), we will see that the radius of the diffraction-limited Airy disc of a lens with $\sin\varphi = 0.29$ and $\lambda = 0.5\,\mu$m is $\rho_0 = 0.61\,\lambda/\text{NA} = 0.61\lambda/(n\sin\varphi) \approx 1\,\mu$m. Therefore, an area with radius $x_{\text{max}} = 10\,\mu$m contains all interesting structures of the intensity distribution of the focus. Using these values, the higher-order terms are

$$\pi n\frac{x_{\text{max}}^4}{4\lambda f^3} = 5\times 10^{-12}\pi ,$$

$$\pi n\frac{3\Delta z}{4\lambda}\sin^4\varphi = 1.1\,\pi ,$$

$$\pi n\frac{3x_{\text{max}}^2 \sin^2\varphi}{2\lambda f} = 2.5\times 10^{-4}\pi ,$$

$$\pi n\frac{x_{\text{max}}^3 \sin\varphi}{\lambda f^2} = 6\times 10^{-8}\pi ,$$

$$\pi n\frac{x_{\text{max}}\sin^3\varphi}{\lambda} = 0.49\pi .$$

We see that the "defocus" term of higher order is $1.1\,\pi$ and cannot be neglected. But if we go directly in the focal plane, i.e., $z_0 = f$, this term will completely vanish. The second term that cannot be neglected is the last term $(0.49\,\pi)$, which is proportional to x_{max}/λ and the third power of the $\sin\varphi$. But in the direct neighborhood of

the Airy disc, which has in the diffraction-limited case a radius of about 1 μm this term will be a factor of 10 smaller. This means that for $\sin\varphi$ of 0.3 (and the given other parameters) the higher order terms can only be neglected in the direct neighborhood of the focus and the complex amplitude calculated outside may have some errors. But by decreasing the numerical aperture of the lens the accuracy of the calculation increases.

So, finally we have the following result for the complex amplitude in the neighborhood of the Gaussian focus by neglecting higher-order terms

$$u(x, y, z_0)$$

$$= -\mathrm{i}\frac{n}{\lambda z_0}\,\mathrm{e}^{\mathrm{i}kz_0}\mathrm{e}^{\mathrm{i}k\frac{x^2+y^2}{2z_0}}$$

$$\times \iint\limits_A u_0\left(x', y', 0\right)\mathrm{e}^{\mathrm{i}W\left(x', y'\right)}\mathrm{e}^{\mathrm{i}k\frac{\Delta z}{z_0 f}\frac{x'^2+y'^2}{2}}$$

$$\times \mathrm{e}^{-\mathrm{i}k\frac{xx'+yy'}{z_0}}\,\mathrm{d}x'\,\mathrm{d}y' . \quad (3.276)$$

This integral is similar to the Debye integral. In [3.1] a slightly different but in fact nearly identical form of this integral is evaluated for an ideal lens, i.e., $W = 0$, using the Lommel functions (E. Lommel invented these functions when he was a professor of physics at the University of Erlangen in 1868–1886). For us it is especially interesting that (3.276) expresses the complex amplitude in the neighborhood of the Gaussian focus as a Fourier transformation of the pupil function G

$$G\left(x', y'\right) =$$

$$\begin{cases} u_0(x', y', 0)\exp\left[\mathrm{i}W(x', y')\right]\exp\left(\mathrm{i}k\frac{\Delta z}{f z_0}\frac{x'^2+y'^2}{2}\right) \\ 0 \end{cases}$$

$$\begin{aligned} &\text{if } (x', y') \in A \\ &\text{if } (x', y') \notin A . \end{aligned} \quad (3.277)$$

Here, u_0 is the complex amplitude of the incident wave, the term $\exp(\mathrm{i}W)$ describes the influence of the wave aberrations of the lens and the third term is a defocus term. In the focal plane itself the defocus term vanishes since then $z_0 = f$. So, in fact we see that in the focal plane of an ideal lens (i.e., $W = 0$ and $\Delta z = 0$) we again have a kind of Fraunhofer diffraction and the complex amplitude u is calculated by a Fourier transformation of u_0.

The intensity distribution I in the focal plane for an incident plane on-axis wave, i.e., $u_0(x', y', 0) =$

$a = $ constant with $I_0 = a^2$, is according to (3.276)

$$I(x, y, z_0 = f) = I_0 \frac{n^2}{\lambda^2 f^2}$$ (3.278)

$$\times \left| \iint_A e^{iW(x', y')} e^{-2\pi i n \frac{xx' + yy'}{\lambda f}} dx' dy' \right|^2 ,$$

where I_0 is the intensity of the incident plane wave. The intensity distribution in the focal plane is also called the point spread function (PSF) of the lens. It is often usual to normalize the PSF by dividing it by the intensity I_F of an nonaberrated lens of the same type at the Gaussian focus. Using (3.278) I_F is obtained by setting $W = 0$ and $(x, y) = (0, 0)$:

$$I_F(0, 0, f) = I_0 \frac{n^2}{\lambda^2 f^2} \left| \iint_A dx' dy' \right|^2 = I_0 \frac{n^2}{\lambda^2 f^2} S^2 .$$ (3.279)

Here, $S = \iint_A dx' dy'$ is the surface area of the aperture A. Then, the normalized point spread function PSF is

$$PSF(x, y) = \frac{I(x, y, f)}{I_F(0, 0, f)}$$ (3.280)

$$= \frac{1}{S^2} \left| \iint_A e^{iW(x', y')} e^{-2\pi i n \frac{xx' + yy'}{\lambda f}} dx' dy' \right|^2 .$$

The dimensionless number $\sigma = PSF(0, 0)$ of the aberrated lens at the Gaussian focus is called the Strehl ratio of the lens and is defined by

$$\sigma = PSF(0, 0) = \frac{1}{S^2} \left| \iint_A e^{iW(x', y')} dx' dy' \right|^2 .$$ (3.281)

In this section we calculated the PSF and the Strehl ratio only for a thin lens with the aperture in the plane of the lens. For general optical systems the same concept and the same equations are used but then the aperture A is the exit pupil of the optical system and f is the distance of the Gaussian focus from the exit pupil of the system.

Two Examples of Fraunhofer Diffraction

Two simple examples that can be solved analytically are the Fraunhofer diffraction at a rectangular aperture or at a circular aperture.

Fig. 3.15 Parameters of a rectangular transparent aperture in an opaque screen

Fraunhofer Diffraction at a Rectangular Aperture. The intensity distribution in the focal plane of an ideal lens (focal length f) with a rectangular aperture of the diameter $2a$ in x direction and $2b$ in y direction has to be calculated (Fig. 3.15). The wavelength of the light is λ and the refractive index of the material in which the wave propagates is n. The lens itself is illuminated with a uniform plane on-axis wave with the intensity I_0. Then, according to (3.278) the intensity in the focal plane of the ideal lens (i. e., $W = 0$) is

$$I(x, y, z_0 = f)$$

$$= I_0 \frac{n^2}{\lambda^2 f^2} \left| \iint_A e^{-2\pi i n \frac{xx' + yy'}{\lambda f}} dx' dy' \right|^2$$

$$= I_0 \frac{n^2}{\lambda^2 f^2} \left| \int_{-a}^{a} e^{-2\pi i n \frac{xx'}{\lambda f}} dx' \right|^2$$

$$\times \left| \int_{-b}^{b} e^{-2\pi i n \frac{yy'}{\lambda f}} dy' \right|^2 .$$ (3.282)

The first integral is

$$\int_{-a}^{a} e^{-2\pi i n \frac{xx'}{\lambda f}} dx' = \left[\frac{-\lambda f}{2\pi i n x} e^{-2\pi i n \frac{xx'}{\lambda f}} \right]_{x'=-a}^{x'=a}$$

$$= \frac{2\lambda f}{2\pi n x} \sin\left(2\pi n \frac{xa}{\lambda f}\right) .$$ (3.283)

Fig. 3.16 Normalized intensity distribution along the x-axis in the focal plane of a lens for a rectangular aperture. Shown is the function $\left[\sin(\pi\hat{x})/(\pi\hat{x})\right]^2$. The function $\left[\sin(\pi\hat{y})/(\pi\hat{y})\right]^2$ along the y-axis is identical

Fig. 3.17 Parameters of a circular transparent aperture in an opaque screen

The second integral is analogous and so the intensity in the focal plane is

$$I(x, y, z_0 = f) = I_0 \left(\frac{n\,2a\,2b}{\lambda f}\right)^2 \left(\frac{\sin\left(\pi\frac{nx\,2a}{\lambda f}\right)}{\pi\frac{nx\,2a}{\lambda f}}\right)^2$$

$$\times \left(\frac{\sin\left(\pi\frac{ny\,2b}{\lambda f}\right)}{\pi\frac{ny\,2b}{\lambda f}}\right)^2 . \qquad (3.284)$$

By introducing the variables $\hat{x} = nx\,2a/(\lambda f)$ and $\hat{y} = ny\,2b/(\lambda f)$, which are pure numbers without a physical unit, the normalized intensity distribution along one of the axes (along the x- or y-axis) can be easily calculated and is shown in Fig. 3.16. The minima of the intensity distribution along the x-axis are at

$$\hat{x} = m \text{ with } m = 1, 2, 3 \ldots \Rightarrow x = m\frac{\lambda f}{2na}$$

$$\approx m\frac{\lambda}{2\mathrm{NA}_x} . \qquad (3.285)$$

Here, the numerical aperture $\mathrm{NA}_x := n\sin\varphi \approx na/f$ with the half-aperture angle $\varphi \ll 1$ of the lens in the x direction has been used.

Fraunhofer Diffraction at a Circular Aperture. The intensity distribution in the focal plane of an ideal lens (focal length f) with a circular aperture of the radius a can also be calculated using (3.278) (Fig. 3.17). The wavelength of the light is again λ and the refractive index of the material in which the wave propagates is n. The lens itself is again illuminated with a uniform plane on-axis wave with intensity I_0. Because of the circular symmetry it is useful to introduce polar coordinates

$$\left.\begin{array}{ll} x' = \rho'\cos\phi'; & x = \rho\cos\phi \\ y' = \rho'\sin\phi'; & y = \rho\sin\phi \end{array}\right\} \Rightarrow xx' + yy'$$

$$= \rho\rho'\cos\left(\phi' - \phi\right) . \qquad (3.286)$$

Then, according to (3.278) the intensity in the focal plane of the ideal lens (i.e., $W = 0$) is written in polar coordinates

$$I(\rho, \phi, z_0 = f)$$

$$= I_0 \frac{n^2}{\lambda^2 f^2} \left|\int\int_A e^{-2\pi i n \frac{xx' + yy'}{\lambda f}} \,\mathrm{d}x'\,\mathrm{d}y'\right|^2$$

$$= I_0 \frac{n^2}{\lambda^2 f^2} \left|\int_0^a \int_0^{2\pi} e^{-2\pi i n \frac{\rho\rho'\cos\left(\phi' - \phi\right)}{\lambda f}} \rho'\,\mathrm{d}\rho'\mathrm{d}\phi'\right|^2$$

$$= I_0 \frac{n^2}{\lambda^2 f^2} \left|\int_0^a \int_0^{2\pi} e^{-2\pi i n \frac{\rho\rho'\cos\phi'}{\lambda f}} \rho'\,\mathrm{d}\rho'\,\mathrm{d}\phi'\right|^2 .$$

$$(3.287)$$

To solve the double integral the well-known Bessel functions [3.51] of the first kind $J_m(x)$ are introduced by the integral representation

$$J_m(x) = \frac{i^{-m}}{2\pi} \int_0^{2\pi} e^{ix\cos\alpha} e^{im\alpha} \, d\alpha \, . \tag{3.288}$$

For $m = 0$ we obtain

$$J_0(x) = \frac{1}{2\pi} \int_0^{2\pi} e^{ix\cos\alpha} \, d\alpha \, . \tag{3.289}$$

Therefore, the intensity is

$$I(\rho, \phi, z_0 = f)$$

$$= I_0 \left(\frac{2\pi n}{\lambda f}\right)^2 \left| \int_0^a J_0\left(-2\pi n \frac{\rho\rho'}{\lambda f}\right) \rho' \, d\rho' \right|^2 \, . \tag{3.290}$$

There is another integral relation which connects the two Bessel functions J_0 and J_1:

$$x J_1(x) = \int_0^x x' J_0(x') \, dx' \, . \tag{3.291}$$

By substituting $x' = -2\pi n \rho \rho'/(\lambda f)$ and $dx' = -2\pi n \rho/(\lambda f) \, d\rho'$ we obtain

$$I(\rho, \phi, z_0 = f)$$

$$= I_0 \left(\frac{2\pi n}{\lambda f}\right)^2 \left| \frac{\lambda^2 f^2}{4\pi^2 n^2 \rho^2} \int_0^{-2\pi n \frac{\rho a}{\lambda f}} x' J_0(x') \, dx' \right|^2$$

$$= I_0 \left(\frac{2\pi n}{\lambda f}\right)^2 \left[-\frac{\lambda f a}{2\pi n \rho} J_1\left(-2\pi n \frac{\rho a}{\lambda f}\right) \right]^2$$

$$= I_0 \left(\frac{2\pi n a^2}{\lambda f}\right)^2 \left(\frac{J_1\left(2\pi n \frac{\rho a}{\lambda f}\right)}{2\pi n \frac{\rho a}{\lambda f}} \right)^2 \, . \tag{3.292}$$

Here, the symmetry of the Bessel function $J_1(-x) = J_1(x)$ has been used. By defining the variable $\hat\rho := 2n\rho a/(\lambda f)$, which is a pure number without a physical unit, the intensity in the focal plane of the ideal lens

**Fig. 3.18** Normalized intensity distribution in the focal plane of a lens. Shown is the function $\left[2J_1(\pi\hat\rho)/(\pi\hat\rho)\right]^2$

can be written as

$$I(\hat\rho, z_0 = f) = I_0 \left(\frac{n\pi a^2}{\lambda f}\right)^2 \left(2\frac{J_1(\pi\hat\rho)}{\pi\hat\rho}\right)^2 \, . \tag{3.293}$$

The function $\left[2J_1(\pi\hat\rho)/(\pi\hat\rho)\right]^2$ is shown in Fig. 3.18. The first minimum is at the value $\hat\rho_0 = 1.22$, i. e., at the radius ρ_0 with

$$\rho_0 = 1.22\frac{\lambda f}{2na} = 0.61\frac{\lambda f}{na} = 0.61\frac{\lambda}{\mathrm{NA}} \, . \tag{3.294}$$

Here, again the numerical aperture of the lens $\mathrm{NA} \approx na/f$ is used. The area inside the first minimum of the diffraction limited focus is called the Airy disc. It is also interesting to compare the maximum intensity $I(\hat\rho = 0, z_0 = f)$ in the central peak of the focus with the intensity I_0 of the incident plane wave. The ratio is

$$\frac{I(\hat\rho = 0, z_0 = f)}{I_0} = \left(\frac{n\pi a^2}{\lambda f}\right)^2 \, . \tag{3.295}$$

For a lens with a focal lens of $f = 10\,\mathrm{mm}$, an aperture radius of $a = 1\,\mathrm{mm}$ and a wavelength of $\lambda = 0.5\,\mathrm{\mu m}$ and $n = 1$ we obtain, e.g., $I(\hat\rho = 0, z_0 = f)/I_0 = (200\pi)^2 \approx 4 \times 10^5$. The quantity $na^2/(\lambda f)$ is also known as the Fresnel number F of a lens, which is the number of Fresnel zones of the lens in the paraxial case. This can be easily seen by calculating the optical path difference OPD between

a ray from the center of the lens to the focus and a ray from the rim of the lens to the focus. It is

$$\text{OPD} = n\left(\sqrt{a^2 + f^2} - f\right) = n\left(f\sqrt{1 + \frac{a^2}{f^2}} - f\right)$$

$$\approx \frac{na^2}{2f} = F\frac{\lambda}{2};$$

$$\Rightarrow F = \frac{na^2}{\lambda f}. \tag{3.296}$$

This means that the intensity in the central peak of the focus of an ideal lens is proportional to the square of the Fresnel number of this lens.

3.4.4 Numerical Implementation of the Different Diffraction Methods

Many of the proposed diffraction integrals can be solved by performing one or two Fourier transformations (Table 3.1). For a numerical implementation, a discrete Fourier transformation is necessary and to increase the speed of the calculation it makes sense to take a fast Fourier transformation (FFT) [3.52]. Of course, it has to be noted that the sampling theorem is fulfilled and that the size of the field is large enough. In practice, large field sizes of, e.g., more than 2048×2048 samples need a lot of computer memory and computing time. To use a FFT the field of the complex amplitude u_0 is in each spatial direction x and y uniformly sampled at $N_x \times N_y$ points, where N_x and N_y are powers of two. The diameters of the field in the spatial domain are called D_x in the x and D_y in the y direction. In most cases the field will be quadratic and sampled with equal number of points, i. e., $N_x = N_y$ and $D_x = D_y$. Nevertheless, there are cases (e.g., systems with cylindrical or toric optical elements) where it is useful to have different sampling rate and number of sampling points along x and y. Then, the sampling interval Δx and Δy in the x and y direction between two neighboring sampling points in the spatial

Fig. 3.19 Discrete fields for solving diffraction integrals using a FFT

domain are (Fig. 3.19)

$$\Delta x = \frac{D_x}{N_x},$$

$$\Delta y = \frac{D_y}{N_y}. \tag{3.297}$$

We call the conjugated variables in the Fourier domain ν_x and ν_y, where these can be really the spatial frequencies defined in (3.223) or other variables like in the Fresnel diffraction integral, which just have the physical dimension of a spatial frequency. Table 3.1 shows the conjugated variables for the different diffraction integrals. The diameters of the fields in the Fourier domain are called $D_{\nu x}$ and $D_{\nu y}$ along the ν_x- and ν_y direction. The associated sampling intervals between two neighboring sampling points in the Fourier domain are

$$\Delta \nu_x = \frac{D_{\nu x}}{N_x},$$

$$\Delta \nu_y = \frac{D_{\nu y}}{N_y}. \tag{3.298}$$

For a FFT the product of the respective diameters in the spatial domain and in the Fourier domain is equal to the number of sampling points. Therefore, the two relations are valid

$$D_x D_{\nu x} = N_x,$$

$$D_y D_{\nu y} = N_y. \tag{3.299}$$

Table 3.1 Conjugated variables and number of FFTs for calculating the different diffraction integrals

Diffraction method	Spectrum of plane waves	Fresnel (Fourier domain)	Fresnel (convolution)	Fraunhofer, Debye integral
Equation	(3.231)	(3.260)	(3.253)	(3.267), (3.276)
Conjugated variables	$(x, y) \leftrightarrow (\nu_x, \nu_y)$	$(x, y) \leftrightarrow (\nu_x, \nu_y)$	$(x', y') \leftrightarrow \left(\frac{nx}{\lambda z_0}, \frac{ny}{\lambda z_0}\right)$	$(x', y') \leftrightarrow \left(\frac{n\alpha}{\lambda}, \frac{n\beta}{\lambda}\right)$, $(x', y') \leftrightarrow \left(\frac{nx}{\lambda z_0}, \frac{ny}{\lambda z_0}\right)$
Number of FFTs	2	2	1	1

By using (3.297) and (3.298) it is clear that for the product of the sampling intervals in the spatial and in the Fourier domain the following equations apply

$$\Delta x \Delta \nu_x = \frac{1}{N_x} \Rightarrow \Delta \nu_x = \frac{1}{D_x}; \quad \Delta x = \frac{1}{D_{\nu x}},$$

$$\Delta y \Delta \nu_y = \frac{1}{N_y} \Rightarrow \Delta \nu_y = \frac{1}{D_y}; \quad \Delta y = \frac{1}{D_{\nu y}} \quad (3.300)$$

The variables are in our case always symmetrical around the origin of the coordinate system. Therefore, the minimum and maximum values of the respective variables are

$$
\begin{aligned}
x_{\min} &= -\frac{D_x}{2}, & x_{\max} &= \frac{D_x}{2}; \\
y_{\min} &= -\frac{D_y}{2}, & y_{\max} &= \frac{D_y}{2}; \\
\nu_{x,\min} &= -\frac{N_x}{2}\Delta \nu_x = -\frac{N_x}{2D_x}, \\
\nu_{x,\max} &= +\frac{N_x}{2}\Delta \nu_x = +\frac{N_x}{2D_x}; \\
\nu_{y,\min} &= -\frac{N_y}{2}\Delta \nu_y = -\frac{N_y}{2D_y}, \\
\nu_{y,\max} &= +\frac{N_y}{2}\Delta \nu_y = +\frac{N_y}{2D_y} .
\end{aligned}
\quad (3.301)
$$

Since a discrete Fourier transformation has periodic boundary conditions the function values at the left boundary will be equal to those at the right boundary, i.e., $u(x_{\min}, y) = u(x_{\max}, y)$, $u(x, y_{\min}) = u(x, y_{\max})$, and so on. This fact is important because it generates aliasing effects if the field size and the sampling are not correct. In the following some special aspects of the different diffraction integrals, which can be calculated using one or two FFTs are presented.

Numerical Implementation of the Angular Spectrum of Plane Waves or the Fresnel Diffraction in the Fourier Domain

To solve the diffraction integrals (3.231) and (3.260) two FFTs are necessary. The first is to transform the complex amplitude u_0 into the Fourier domain with the spatial frequencies ν_x and ν_y. In order to represent all propagating waves the maximum spatial frequencies have to fulfill the conditions

$$\nu_{x,\max} \geq \frac{n}{\lambda} \Rightarrow N_x \geq \frac{2nD_x}{\lambda},$$

$$\nu_{y,\max} \geq \frac{n}{\lambda} \Rightarrow N_y \geq \frac{2nD_y}{\lambda}. \quad (3.302)$$

Here, (3.223) and (3.301) have been used. However, it is in general not necessary that all spatial frequencies belonging to propagating waves can be represented. Es-

pecially, in the case of the Fresnel diffraction integral (3.260) formulated in the Fourier domain high spatial frequencies will in most cases not be allowed because the equation is, depending on the propagation distance z_0, only valid for small spatial frequencies (3.262). Let us assume that the angular spectrum of plane waves has a maximum tilt angle φ for which the Fourier transform $\tilde{u}_0$ of u_0 has a function value that is noticeably different from zero. Then, it is sufficient that instead of (3.302) the following conditions are used

$$\nu_{x,\max} \geq \frac{n}{\lambda}\sin\varphi \Rightarrow N_x \geq \frac{2nD_x}{\lambda}\sin\varphi,$$

$$\nu_{y,\max} \geq \frac{n}{\lambda}\sin\varphi \Rightarrow N_y \geq \frac{2nD_y}{\lambda}\sin\varphi. \quad (3.303)$$

If these conditions are not fulfilled aliasing effects occur and the numerical result is wrong. It is clear that only for microoptical elements the condition (3.302), i.e., $\sin\varphi$ is allowed to be 1, can be fulfilled. For a wavelength of $\lambda = 0.5\,\mu\text{m}$, refractive index $n = 1$ and a field diameter in the x direction of $D_x = 1\,\text{mm}$, we obtain, e.g., $N_x \geq 2nD_x/\lambda = 4000$. For a two-dimensional FFT a field size of 4096×4096 samples is at the upper limit of modern personal computers.

Also in the case of the second (inverse) FFT, which calculates u using (3.231) or (3.260) aliasing effects can occur. Graphically, this means that parts of a diverging propagating wave leave the border of the field. Because of the periodic boundary conditions these parts of the waves will then enter the field at the opposite boundary. Figure 3.20 illustrates this effect for a diverging spherical wave that has a diameter D_0 at the starting plane and would have a diameter $D_{z_0} > D_x$ in the distance z_0. If the half-aperture angle of the spherical wave is φ, where we assume that φ is so small that $\sin\varphi \approx \tan\varphi$,

Fig. 3.20 Illustration of aliasing effects. The parts of the wave that leave the field at a boundary enter the field at the opposite boundary and interfere with the other parts of the wave

the diameter D_{z_0} will be

$$D_{z_0} \approx D_0 + 2z_0 \sin\varphi \, . \tag{3.304}$$

If $D_{z_0} > D_x$ aliasing effects will appear. This effect can be useful to numerically simulate the self-imaging Talbot effect for infinitely extended periodic structures [3.53]. However, in most cases aliasing effects are disturbing and have to be avoided. For converging waves, aliasing effects will not appear as long as the propagation distance is not so large that the wave passes the focus and becomes diverging. In practice, the limitations on the number of samples will limit the application of the propagation of a wave using the angular spectrum of plane waves. It is also very interesting to note that the field diameters D_x and D_y normally do not change between the two planes at $z = 0$ and $z = z_0$ in the case of the propagation using the angular spectrum of plane waves or the Fresnel integral in the Fourier domain formulation. Only, if the field size in the Fourier domain is manipulated will the field size in the spatial domain change. This is only possible by taking each second sampling point and embedding the new field with so many zeros that the total number of sampling points remains unchanged. Then the effective diameters in the Fourier domain $D_{\nu x}$ and $D_{\nu y}$ are doubled and therefore, according to (3.299) the diameters D_x and D_y in the spatial domain will be halved. But this manipulation reduces the sampling density in the Fourier domain and is therefore a kind of high-pass filtering operation suppressing the long-periodic spatial structures.

Numerical Implementation of the Fresnel (Convolution Formulation) and the Fraunhofer Diffraction

Using the method of the angular spectrum of plane waves guarantees that the field sizes D_x and D_y do not change during the propagation as long as no manipulations are made in the Fourier domain. The reason for this is that two FFTs are used, one "normal" and one inverse FFT. If the Fresnel diffraction integral of (3.253) or the Fraunhofer diffraction integrals (3.267) or (3.276) are used, only one FFT is made. Therefore, the field size changes because the conjugated variables are now, according to Table 3.1, (x', y') and $[nx/(\lambda z_0), ny/(\lambda z_0)]$ or $[(n\alpha/\lambda, n\beta/\lambda)$, where $\alpha = x/z_0$ and $\beta = y/z_0]$. This means that according to (3.299) the following relations are valid if we introduce the field diameters $D_{x,0} = D_x$ and $D_{y,0} = D_y$ in the first plane and the field

diameters D_{x,z_0} and D_{y,z_0} in the second plane, where $D_{\nu x} = n D_{x,z_0}/(\lambda z_0)$ and $D_{\nu y} = n D_{y,z_0}/(\lambda z_0)$

$$D_x D_{\nu x} = N_x \Rightarrow D_{x,z_0} = N_x \frac{\lambda z_0}{n D_{x,0}},$$

$$D_y D_{\nu y} = N_y \Rightarrow D_{y,z_0} = N_y \frac{\lambda z_0}{n D_{y,0}} \, . \tag{3.305}$$

Of course, the sampling densities Δx_{z_0} and Δy_{z_0} in the second plane are then

$$\Delta x_{z_0} = \frac{\lambda z_0}{n D_{x,0}},$$

$$\Delta y_{z_0} = \frac{\lambda z_0}{n D_{y,0}} \, . \tag{3.306}$$

Let us calculate the intensity distribution in the focal plane of a lens with focal length f ($z_0 = f$) using (3.276). The aperture of the lens shall be quadratic with diameters $2a = 2b$. Then, it is enough to just consider one dimension, e.g., the x direction. If the field size $D_{x,0}$ would now only be $2a$ the sampling interval would be

$$\Delta x_{z_0} = \frac{\lambda f}{n 2a} \approx \frac{\lambda}{2\mathrm{NA}} \, , \tag{3.307}$$

where, the numerical aperture of the lens $\mathrm{NA} := n \sin\varphi \approx na/f$ has been used. But by comparing this result with (3.285) it is clear that the sampling density is so low that the secondary maxima are not observed because the sampling is only in the minima. Therefore, it is necessary that the aperture of the lens is embedded into a field of zeros so that the effective field diameter $D_{x,0}$ is at least doubled $D_{x,0} \geq 4a$. So, by embedding the aperture of the lens by more and more zeros the effective sampling density in the focal plane is increased. Increasing the field size by a factor m and filling the new area with zeros reduces the sampling interval by a factor m to $\Delta x_{z_0} = \lambda/(2m\mathrm{NA})$. In other words we can say: the total field size D_{x,z_0} in the focal plane is proportional to the number N_x/m of samples with which the lens aperture is sampled whereas the sampling density is proportional to the factor m of the zero embedding.

Of course, there is also another reason for embedding the lens aperture with zeros: the aliasing effects. A quadratic lens aperture with $D_{x,0} = 2a$ would, due to the periodic boundary conditions, mean that the aperture is repeated periodically without spaces in between and fills the whole space. Therefore, no diffraction at all would occur and the focus would be a delta peak as in geometrical optics.

3.4.5 The Influence of Polarization Effects to the Intensity Distribution Near the Focus

In the previous cases of diffraction we considered only the scalar case. But, in this section we want to discuss the influence of polarization effects to the intensity distribution in the focal region of a lens. However, we will only discuss a simple numerical simulation method, which is in fact identical to the semi-analytical vectorial Debye integral formulation discussed, e.g., in [3.54] or [3.34]. *Richards* and *Wolf* [3.34] were one of the first who calculated that the light distribution in the focus of a lens, which is illuminated by a linearly polarized plane wave, is asymmetrical for a high numerical aperture of the lens.

Some Elementary Qualitative Explanations

To illustrate the influence of polarization effects to the focus refer to Fig. 3.21. Assume a plane wave with linear polarization (electric vector in the y direction), which is focused by a lens. Then, there is one plane (xz-plane) where the electric vectors are perpendicular to the plane of refraction of the rays (Fig. 3.21a). There, the electric vectors in the focus add like scalars and a quite large transversal component is obtained. But, there is also the yz-plane, where the electric vectors change their direction after being refracted by the lens. Then, they add in the focus like real vectors and a smaller transversal component than in the xz-plane is obtained (Fig. 3.21b). Especially, for very steep rays corresponding to high numerical aperture rays the electric vectors nearly cancel each other in the focus. Due to the broken symmetry of

Fig. 3.22a,b Local polarization vectors in the aperture in front of the lens for **(a)** linearly polarized light and **(b)** a radially polarized doughnut mode

this problem the intensity distribution in the focus will also be nonrotationally symmetric. Of course, this effect is only visible for very high numerical apertures, because otherwise the vector character of the electric field is not so obvious. It is especially visible for annular apertures and a high numerical aperture lens.

But there is a rotationally symmetric polarization pattern, called the doughnut mode [3.33], where the direction of the electric vector varies locally, so that it always points away from the optical axis in radial direction. Figure 3.22 shows in (a) the electric vectors in the aperture of the lens at a certain time for linearly polarized light, i.e., they all point in the same direction. In (b) the electric vectors for the radially polarized doughnut mode are drawn at a certain time. They all point radially away from the optical axis. Of course, in the case of the doughnut mode there has to be the intensity zero on the optical axis due to the symmetry of the problem. So, the intensity distribution in the aperture of the lens is not homogeneous in the case of the radially symmetric doughnut mode but in fact it is the superposition of a Hermite–Gaussian TEM_{10} and a TEM_{01} mode (Fig. 3.32) with relative phase difference zero. Then, the time-independent complex-valued electric vector E_{rad} before the lens has the value

$$E_{rad}(x, y, z = 0) = E_0 \begin{pmatrix} x \\ y \\ 0 \end{pmatrix} e^{-\left(x^2 + y^2\right)/w_0^2}.$$

(3.308)

Here, w_0 is the beam waist of the Gaussian function and E_0 is a constant. The maximum of the amplitude of the electric vector is at $\sqrt{x^2 + y^2} = w_0/\sqrt{2}$ as can be easily calculated.

But now, for the radially polarized doughnut mode in all planes containing the optical axis, the electric vectors are oriented as in Fig. 3.23. Then, the electric vectors add

Fig. 3.21a,b Addition of the electric vectors in the focus of a lens for linearly polarized light. **(a)** The electric vectors are perpendicular to the xz-plane, i.e., they add arithmetically like scalars; **(b)** the electric vectors lie in the yz-plane and add vectorially to a transversal component
Fig. 3.23 Orientation of the electric vectors in front of and behind a lens for the radially symmetric doughnut mode. The electric vectors add to a longitudinal component parallel to the optical axis

in the focus to a longitudinal component and this is the case for all planes containing the optical axis. Therefore, the focus is completely rotationally symmetric.

Numerical Calculation Method

To calculate the electric energy density in the focal region of a lens the vectorial Debye integral of [3.34] or the method of [3.55] can be used. Both say that the electric vector in the focal region can be written as a superposition of plane waves, which propagate along the direction of the rays running from the exit pupil of the lens to the geometrical focus. In this model, diffraction effects at the rim of the aperture are neglected, as is also done in the scalar formulation of the Debye integral. But this is a quite good approximation as long as the diameter of the aperture of the lens is large compared to the wavelength ($2r_{\text{aperture}} \gg \lambda$) and as long as the numerical aperture of the lens is sufficiently high (which is always the case here because polarization effects are only interesting for high numerical apertures).

For the numerical calculation we make a uniform sampling of rays in the planar entrance pupil of the lens, e.g., $N \times N$ rays in an orthogonal pattern, where the rays outside of the aperture (e.g., circular or annular aperture) have zero amplitude. The optical axis shall be the z-axis. Each ray number (i, j) at the coordinate (x_i, y_j, z_0) in the entrance pupil has a wave vector $\mathbf{k}_{i,j} = (0, 0, k) = (0, 0, 2\pi/\lambda)$ and a generally complex polarization vector $\mathbf{P}_{i,j} = (P_{x,i,j}, P_{y,i,j}, 0)$, which is in fact proportional to the electric vector $\mathbf{E}$ at this point if the sampling is uniform. Of course, $\mathbf{P}_{i,j}$ is orthogonal to $\mathbf{k}_{i,j}$ because of

the orthogonality condition of plane waves (Sect. 3.1.1) (see the paragraph on page 91). Examples of different polarization states are (see Sect. 3.2.4):

- A linearly polarized homogeneous plane wave (polarization in the y direction) with the polarization vector $\mathbf{P}_{i,j} = (0, P_0, 0)$ with a constant real value P_0.
- A circularly polarized homogeneous plane wave with the polarization vector $\mathbf{P}_{i,j} = (P_0/\sqrt{2}, \mathrm{i}P_0/\sqrt{2}, 0)$, where the factor $1/\sqrt{2}$ is introduced to have $|\mathbf{P}_{i,j}|^2 = P_0^2$.
- The radially polarized doughnut mode with the polarization vectors according to (3.308).

The lens itself fulfills the sine condition so that we have for the refracted ray behind the lens

$$ h = \sqrt{x^2 + y^2} = f \sin\vartheta \quad \Rightarrow \quad \sin\vartheta = \frac{\sqrt{x^2 + y^2}}{f}, \tag{3.309} $$

where, f is the focal length of the lens and ϑ the polar angle (Fig. 3.24). By defining the azimuthal angle φ we have the following relations for the rays in front of the lens and behind the lens

$$ \begin{aligned} x &= h\cos\varphi \\ y &= h\sin\varphi \end{aligned} \quad \Rightarrow \quad \varphi = \arctan\frac{y}{x} \tag{3.310} $$

and

$$ \mathbf{k}' = k \begin{pmatrix} -\cos\varphi\sin\vartheta \\ -\sin\varphi\sin\vartheta \\ \cos\vartheta \end{pmatrix}. \tag{3.311} $$

Fig. 3.24 Principal scheme of the distribution of rays used to calculate the electric energy density in the focus. The lens has to fulfill the sine condition so that the ray height $h = \sqrt{x^2 + y^2}$ is $h = f \sin\vartheta$

The polarization vector P of each ray has to be separated into a component lying in the plane of refraction and a component perpendicular to it. The unit vector $e_\parallel$ along the component in the plane of refraction in front of the lens is

$$e_\parallel = \begin{pmatrix} \cos \varphi \\ \sin \varphi \\ 0 \end{pmatrix} . \tag{3.312}$$

Behind the lens the new unit vector $e'_\parallel$ along the component in the plane of refraction is

$$e'_\parallel = \begin{pmatrix} \cos \varphi \cos \vartheta \\ \sin \varphi \cos \vartheta \\ \sin \vartheta \end{pmatrix} . \tag{3.313}$$

So, the polarization vector P' behind the lens can be calculated by keeping in mind that the component perpendicular to the plane of refraction remains unchanged and that the component in the plane of refraction keeps its amplitude but is now parallel to $e'_\parallel$. In total this means for P'

$$P' = \frac{1}{\sqrt{\cos \vartheta}} \left[P - (P \cdot e_\parallel) e_\parallel + (P \cdot e_\parallel) e'_\parallel \right]$$

$$= \frac{P - \left(P_x \cos \varphi + P_y \sin \varphi \right) \begin{pmatrix} \cos \varphi (1 - \cos \vartheta) \\ \sin \varphi (1 - \cos \vartheta) \\ -\sin \vartheta \end{pmatrix}}{\sqrt{\cos \vartheta}} . \tag{3.314}$$

Here, the factor $1/\sqrt{\cos \vartheta}$ is necessary in order to conserve the energy of the tilted plane wave [3.56]. In other words, behind the lens the density of the numerical sampling by the polarization vectors $P'_{i,j}$ depends on the angle ϑ whereas in front of the lens the sampling of $P_{i,j}$ is selected to be uniform. So, the electric vector E behind the lens is no longer proportional to the polarization vector P' alone, but to the ratio of P' and the small surface element dA perpendicular to P' which is assigned to each ray by the distance of the ray sampling, and which is itself depending on the angle ϑ. So, the factor $1/\sqrt{\cos \vartheta}$ corrects the non uniform numerical sampling of the polarization vectors behind the lens. If the lens does not fulfill the sine condition but another equation the correction factor will of course change.

For an ideal lens the plane waves along the rays have to be all in phase at the focus. So, we just can set the focus to the coordinate $r' = (x' = 0, y' = 0, z' = 0)$. To calculate the electric vector E at a point r' near the focus the plane waves have to be summarized according to

$$E (r') \propto \sum_{i,j} P'_{i,j} e^{i k'_{i,j} \cdot r'} . \tag{3.315}$$

Small wave aberrations $W(x, y)$ of the lens can also be taken into account by just adding them to the phase term of each plane wave, i. e., $k'_{i,j} \cdot r' \rightarrow k'_{i,j} \cdot r' + W_{i,j}$ with $W_{i,j} := W(x_i, y_j)$. Then we have:

$$E (r') \propto \sum_{i,j} P'_{i,j} e^{i k'_{i,j} \cdot r' + i W_{i,j}} . \tag{3.316}$$

It can be seen that in the focal plane $z' = 0$ and for linearly polarized light with a small numerical aperture, this sum reduces to a discretized formulation of the scalar diffraction integral of (3.276) for calculating the light distribution near the focus of a lens.

By just changing the polarization vectors of the field distribution in front of the lens the effects of a quite arbitrary state of polarization to the focus can be investigated. The squares of the x, y, or z components of the electric field E can also be calculated separately. Of course, the electric energy density w_e, which is the physical quantity normally detected by a light detector, can then be calculated by

$$w_e (r') \propto |E|^2 = E \cdot E^* . \tag{3.317}$$

The proportionality factors are omitted because we are only interested in relative energy distributions and not in absolute values.

Some Simulation Results

Figures 3.25, 3.26 and 3.27 show the results of some simulations for the electric energy density in the focal plane (xy-plane) of an ideal lens. In all cases the numerical aperture of the lens is assumed to be 1.0 and the wavelength of the illuminating light is $\lambda = 632.8$ nm. The typical number of plane waves used to sample the aperture of the lens is $N \times N = 100 \times 100$ (or 200×200), whereby in the case of a circular aperture (normal case) and especially in the case of an annular aperture (see later) the effective number of plane waves is smaller (factor $\pi/4$ smaller for a circular aperture) because the sampling is made in an orthogonal and uniformly sampled xy-pattern and plane waves outside of the aperture just have zero amplitude. The number of sampling points in the focal plane is 200×200 and so a simulation on a modern 1 GHz Pentium PC takes less than two minutes.

In Fig. 3.25 the lens is illuminated by a linearly polarized plane wave (polarization in y direction). The squares of the different components of the electric vector in the focal plane are displayed. The x component in Fig. 3.25a is quite small and vanishes in the center of the geometrical focus (pay attention to the scale). The biggest component is the y component in Fig. 3.25b, i. e., along the direction in which the light is polarized

in front of the lens. But, there is also a z component (Fig. 3.25c) for points besides the geometrical focus. This component is mainly responsible for the asymmetric shape of the total electric energy density, which is displayed in Fig. 3.25d. Figure 3.26 shows sections along the x- and y-axis of the total electric energy density. It can be seen that the diameter of the central maximum along the y-axis is increased whereas the diameter along the x-axis has nearly the value of the scalar calculation $d_{focus} = 1.22\lambda/NA = 0.77$ μm. All quantities are normalized in such a way that the total energy density has a maximum value of 1.

In Fig. 3.27 the lens is illuminated by a radially polarized doughnut mode, whereby the beam waist w_0 is at 95% of the lens aperture radius. Then, there are radial, i.e., transversal components of the electric field in Fig. 3.27a, which are of course rotationally symmetric due to the symmetry of the field. But, the strongest com-
ponent is the longitudinal z component in Fig. 3.27b, which is also rotationally symmetric and has a central maximum with a diameter slightly smaller than the value of the scalar calculation. The total electric energy density in Fig. 3.27c is also rotationally symmetric but the diameter of the central maximum is increased due to the transversal components of the electric field. However, the surface area S, which is covered in the focus by a total electric energy density of more than half the maximum value is $S = 0.29\lambda^2$ in the linearly polarized case and only $S = 0.22\lambda^2$ for the radially polarized doughnut mode. So, if the light spot is used to write into a nonlinear material, which is only sensitive to a total electric energy density beyond a certain threshold a tighter spot can be obtained using the radially polarized doughnut mode.

Figure 3.28 shows for the same parameters as in Figs. 3.26 and 3.27 the total electric energy density near the focus in planes containing the optical axis (z-axis) and one of the lateral coordinates. In Figs. 3.28a,b the xz-plane and the yz-plane are shown for the case of an illumination of the lens with linearly polarized homogeneous light (polarization in the y direction). Figure 3.28c shows the same for the case of the radially polarized doughnut mode, where here the focal region is completely rotationally symmetric so that only one section has to be shown. It can again be seen that in the case of linear polarization the lateral diameter of the focus is broader in the yz-plane than in the xz-plane. The focus of the radially polarized doughnut mode has a lateral diameter nearly that of the small axis of the linearly polarized case focus.

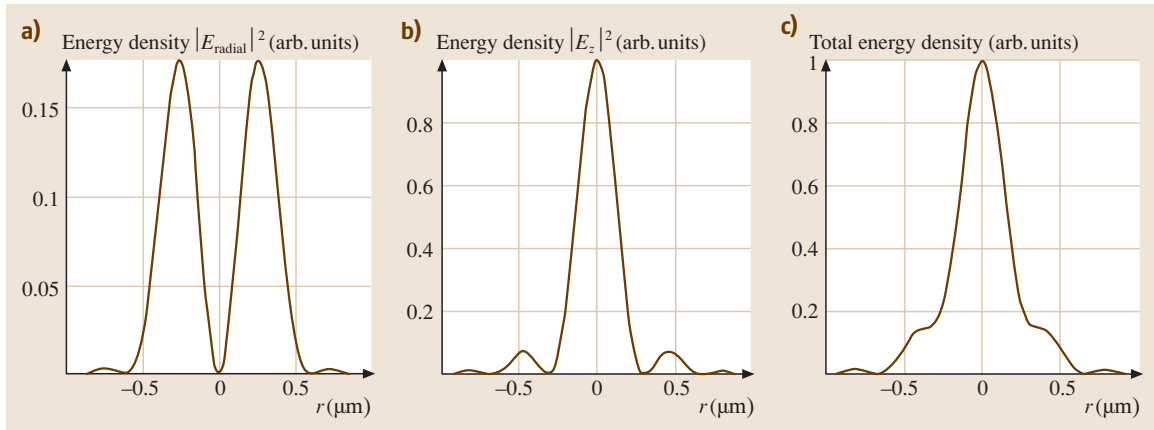
From the scalar theory it is well-known that the diameter of the central maximum of the focus is decreased if an annular aperture is used instead of a circular one. It is


Fig. 3.27a–c Squares of the components of the electric vector in the focal plane of an ideal lens with NA = 1.0, which is illuminated by a radially polarized doughnut mode with $\lambda = 632.8$ nm. The beam waist w_0 of the Gaussian function is $w_0 = 0.95 r_{\mathrm{aperture}}$, whereby r_{aperture} is the illuminated aperture radius of the lens. (**a**) Radial components, i. e., $|E_x|^2 + |E_y|^2$, (**b**) z component, (**c**) sum of all components, i. e., total electric energy density

Fig. 3.28a–c Simulation of the total electric energy density in the focal region by using a circular aperture (NA = 1.0, $\lambda = 632.8$ nm). (**a**) Linearly polarized homogeneous light (xz-plane), (**b**) linearly polarized homogeneous light (yz-plane), (**c**) radially polarized doughnut mode with $w_0 = 0.95 r_{\mathrm{aperture}}$ (xz-plane or yz-plane because of rotational symmetry)

also well-known from the scalar theory that in this case, the secondary maxima increases compared to a circular aperture. So, by using an annular aperture a smaller focus should be reached and this should especially be the case for the radially polarized doughnut mode. The reason is that in this case the transversal components in the focus of the doughnut mode decrease so that the total energy density is more and more dominated by the longitudinal

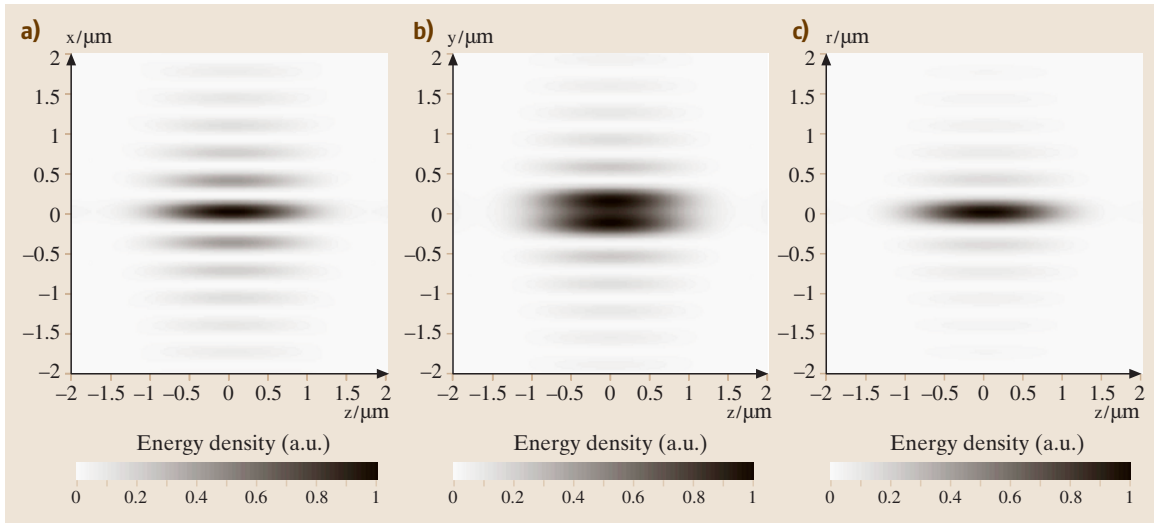
z component, which has a small diameter. So, by using a radially symmetric doughnut mode, an annular aperture (e.g., $r_{\mathrm{annulus}} = 0.9 r_{\mathrm{aperture}}$), and a high numerical aperture lens (NA > 0.9) a very tight rotationally symmetric spot with a small surface area can be obtained. This effect can be used to achieve a higher resolution in optical data storage or in optical lithography where a mask is written spot by spot by a so-called laser pattern


Fig. 3.29a–c Simulation of the total electric energy density in the focal region by using an annular aperture with an inner radius of 90% of the full aperture (NA = 1.0, λ = 632.8 nm). **(a)** linearly polarized homogeneous light (xz-plane), **(b)** linearly polarized homogeneous light (yz-plane), **(c)** radially polarized doughnut mode with $w_0 = 0.95 r_{aperture}$ (xz-plane or yz-plane because of rotational symmetry)

generator. Figure 3.29 shows the simulation results of the electric energy density in the focal region for an annular aperture with $r_{annulus} = 0.9 r_{aperture}$. As in the former cases, the numerical aperture itself is NA = 1.0 and the wavelength is $\lambda = 632.8$ nm. Figures 3.29a and b show the xz-plane and yz-plane, respectively, for the case of linear polarization and Fig. 3.29c shows the same for the doughnut mode ($w_0 = 0.95 r_{aperture}$), where the result is rotationally symmetric so that only one section is shown. It can be seen that in the case of an annular aperture the lateral diameter of the focus is decreased but on the other side the depth of focus along the optical axis is increased compared to the full aperture case. Besides the central maximum there are also, as expected, some secondary maxima with increased height. Nevertheless, a comparison of the cases of linear polarization and the doughnut mode shows that the lateral diameter of the focus is decreased for the doughnut mode, especially in the yz-plane. By calculating the surface area S again, which is covered in the focus by a total electric energy density of more than half the maximum value, the result is $S = 0.29 \lambda^2$ for the linearly polarized light and only $S = 0.12 \lambda^2$ for the radially polarized doughnut mode. Moreover, the height of the secondary maxima is not as high for the doughnut mode as for the linear polarization. In some applications these secondary maxima can be disturbing, but in applications where a certain threshold value of the energy density has to be reached in order to obtain an effect, these secondary maxima have no influence. So, the annular aperture, especially combined with the radially polarized doughnut mode, allows a high lateral resolution. Experiments verify the simulation results for linearly polarized light [3.57] and for the radially polarized doughnut mode [3.33, 54].

3.5 Gaussian Beams

Gaussian beams are a paraxial solution of the scalar Helmholtz equation and are suitable to describe the propagation of coherent laser beams [3.10, 11, 58]. However, the influence of apertures on the laser beam is not considered in this description because apertures would generally disturb the Gaussian beam. The transformation of laser beams at a lens is, of course, also only treated in a paraxial sense and aberrations of the lens are not taken into account.

3.5.1 Derivation of the Basic Equations

The typical property of a collimated laser beam is that it propagates straight on in a homogeneous material.

Nevertheless, because of diffraction effects, the laser beam diverges during the propagation. Depending on the diameter of the laser beam this effect will be quite small or large. However, the laser beam will behave along the direction of propagation (z-axis) nearly as a plane wave. But instead of having a constant amplitude, as for a plane wave, the amplitude will be a function of the transversal coordinates (x and y) and also a slowly varying function of the propagation distance along the z-axis. Mathematically, this means that the scalar complex amplitude $u(x, y, z)$ of a laser beam can be described by the product of a (generally) complex function $\Psi(x, y, z)$, which changes only slowly along the z-axis, and the complex amplitude of a plane wave propagating in the z direction $\exp(\mathrm{i}kz)$

$$u(x, y, z) = \Psi(x, y, z)\mathrm{e}^{\mathrm{i}kz} . \tag{3.318}$$

The constant k is again defined as $2\pi n/\lambda$. n is the refractive index of the homogeneous material in which the Gaussian beam propagates and λ is the wavelength in a vacuum. To simplify the notation the wavelength $\lambda_n = \lambda/n$ in the material is used in the following.

By using the scalar Helmholtz equation (3.221)

$$\left(\nabla^2 + k^2\right) u(x, y, z) = 0 \tag{3.319}$$

the following equation for u is obtained

$$\begin{aligned} \frac{\partial u}{\partial x} &= \frac{\partial \Psi}{\partial x}\mathrm{e}^{\mathrm{i}kz} , \\ \frac{\partial^2 u}{\partial x^2} &= \frac{\partial^2 \Psi}{\partial x^2}\mathrm{e}^{\mathrm{i}kz} , \\ \frac{\partial u}{\partial z} &= \frac{\partial \Psi}{\partial z}\mathrm{e}^{\mathrm{i}kz} + \mathrm{i}k\Psi\mathrm{e}^{\mathrm{i}kz} , \\ \frac{\partial^2 u}{\partial z^2} &= \frac{\partial^2 \Psi}{\partial z^2}\mathrm{e}^{\mathrm{i}kz} + 2\mathrm{i}k\frac{\partial \Psi}{\partial z}\mathrm{e}^{\mathrm{i}kz} - k^2\Psi\mathrm{e}^{\mathrm{i}kz} ; \\ \Rightarrow \left(\nabla^2 + k^2\right) u &= \left(\frac{\partial^2 \Psi}{\partial x^2} + \frac{\partial^2 \Psi}{\partial y^2}\right)\mathrm{e}^{\mathrm{i}kz} \\ &\quad + \frac{\partial^2 \Psi}{\partial z^2}\mathrm{e}^{\mathrm{i}kz} + 2\mathrm{i}k\frac{\partial \Psi}{\partial z}\mathrm{e}^{\mathrm{i}kz} = 0 . \end{aligned} \tag{3.320}$$

According to our assumption that Ψ changes only slowly along the z direction the term $\partial^2\Psi/\partial z^2$ is assumed to be so small that it can be neglected. This is the case if the relative variation of $\partial\Psi/\partial z$ during the propagation by one wavelength is much smaller than one. In a mathematical formulation this means

$$\left|\frac{\partial^2 \Psi}{\partial z^2}\right| \ll \left|2k\frac{\partial \Psi}{\partial z}\right| = \frac{4\pi}{\lambda_n}\left|\frac{\partial \Psi}{\partial z}\right|$$

$$\Rightarrow \quad \frac{|\Delta(\partial\Psi/\partial z)|}{|\partial\Psi/\partial z|}\bigg|_{\Delta z = \lambda_n} \ll 4\pi . \tag{3.321}$$

Using this simplification the following equation for Ψ is obtained

$$\frac{\partial^2 \Psi}{\partial x^2} + \frac{\partial^2 \Psi}{\partial y^2} + 2\mathrm{i}k\frac{\partial \Psi}{\partial z} = 0 . \tag{3.322}$$

This equation is called the paraxial Helmholtz equation because it corresponds to the case of Fresnel diffraction (Sects. 3.4.3 and 3.5.2). To solve it we first use a quite simple approach for Ψ, which corresponds to a fundamental mode Gaussian beam

$$\Psi(x, y, z) = \Psi_0\exp\left[\mathrm{i}\left[P(z) + \frac{k\left(x^2 + y^2\right)}{2q(z)}\right]\right] \tag{3.323}$$

with the two complex functions P and q, which are both functions of z. Ψ_0 is a constant that depends on the amplitude of the Gaussian beam and is determined by the boundary conditions. Using the notations $P' := \mathrm{d}P/\mathrm{d}z$ and $q' := \mathrm{d}q/\mathrm{d}z$ our approach gives

$$\begin{aligned} \frac{\partial \Psi}{\partial z} &= \left(\mathrm{i}P' - \frac{\mathrm{i}k\left(x^2 + y^2\right)}{2q^2}q'\right)\Psi , \\ \frac{\partial \Psi}{\partial x} &= \mathrm{i}\frac{kx}{q}\Psi, \\ \frac{\partial^2 \Psi}{\partial x^2} &= \frac{\mathrm{i}k}{q}\Psi - \frac{k^2x^2}{q^2}\Psi . \end{aligned}$$

Inserting these equations in (3.322) results in the following conditions for P and q

$$\frac{2\mathrm{i}k}{q} - \frac{k^2\left(x^2 + y^2\right)}{q^2} - 2kP' + \frac{k^2\left(x^2 + y^2\right)}{q^2}q' = 0 . \tag{3.324}$$

This equation has to be fulfilled for arbitrary values of x and y. Therefore, the equation finally gives two equations

$$P' = \frac{\mathrm{i}}{q} \quad \text{and} \quad q' = 1 . \tag{3.325}$$

By integration we obtain

$$q(z) = q_0 + z, \tag{3.326}$$

$$P(z) = \mathrm{i}\ln\left(1 + \frac{z}{q_0}\right) . \tag{3.327}$$

The integration constant of P has been put to zero because it would just introduce a constant phase factor in Ψ.

Equation (3.323) has a similar form like a paraxial spherical wave, i. e., a parabolic wave, if q is interpreted as a kind of complex radius of curvature. Therefore, it is useful to split $1/q$ into a real and an imaginary part

$$\frac{1}{q(z)} = \frac{1}{R(z)} + \mathrm{i}\frac{\lambda_n}{\pi w^2(z)} \, . \tag{3.328}$$

The real part is the curvature of the wave and R is the real radius of curvature. The selection of the imaginary part of $1/q$ becomes obvious by inserting (3.328) into (3.323). It shows that the real function w describes the distance $\sqrt{x^2 + y^2}$ from the z-axis at which the amplitude decreases to $1/\mathrm{e}$ of the maximum value. Therefore, w is called the beam radius; w and R are both real functions of z.

A further simplification can be made by choosing $q_0 = q(0)$ as an imaginary number. This means that the radius of curvature R is infinity at $z = 0$, i. e., the curvature of the wave is zero at $z = 0$

$$\frac{1}{q_0} = \mathrm{i}\frac{\lambda_n}{\pi w_0^2} \quad \Rightarrow \quad q_0 = -\mathrm{i}\frac{\pi w_0^2}{\lambda_n} \, . \tag{3.329}$$

The propagation constant w_0, which corresponds to the curvature $1/R_0 = 0$, is called the beam waist. Later it will be shown (3.337) that the beam waist is the smallest beam radius of a Gaussian beam during its propagation.

In summary by using (3.323), (3.326), (3.327), (3.328), and (3.329) the function Ψ of a fundamental mode Gaussian beam can be written as:

$$\Psi(x, y, z) = \Psi_0 \frac{1}{1 + \mathrm{i}\frac{\lambda_n z}{\pi w_0^2}} \mathrm{e}^{-\frac{x^2 + y^2}{w^2(z)}} \mathrm{e}^{\mathrm{i}\frac{k(x^2 + y^2)}{2R(z)}} \, . \tag{3.330}$$

3.5.2 The Fresnel Diffraction Integral and the Paraxial Helmholtz Equation

In Sect. 3.4.3 the Fresnel diffraction integral is derived as a paraxial solution of the Fresnel–Kirchhoff diffraction formula. Here, it will be shown that the Fresnel diffraction integral describes the propagation of waves with complex amplitudes that fulfill the paraxial Helmholtz equation (3.322). So, the name "paraxial Helmholtz equation" is appropriate.

The Fresnel diffraction integral is determined according to (3.256), where the argument z_0 is substituted by z, because this equation is not only valid in a plane, and k is defined as usual as $k = 2\pi n/\lambda$

$$u(x, y, z) = -\frac{\mathrm{i}k}{2\pi z}\mathrm{e}^{\mathrm{i}kz} \tag{3.331}$$
$$\times \iint\limits_A u_0(x', y', 0)\, \mathrm{e}^{\mathrm{i}k\frac{(x-x')^2 + (y-y')^2}{2z}}\, \mathrm{d}x'\, \mathrm{d}y'$$
$$= \Psi(x, y, z)\mathrm{e}^{\mathrm{i}kz};$$

$$\Rightarrow \Psi(x, y, z) = -\frac{\mathrm{i}k}{2\pi z}$$
$$\times \iint\limits_A u_0(x', y', 0)\, \mathrm{e}^{\mathrm{i}k\frac{(x-x')^2 + (y-y')^2}{2z}}\, \mathrm{d}x'\, \mathrm{d}y' \, .$$

So, the function Ψ is defined in accordance with (3.318) and it has to be shown that this function Ψ is a solution of the paraxial Helmholtz equation (3.322). We have the following equations for the partial derivatives of Ψ

$$\frac{\partial \Psi}{\partial x} = \frac{k^2}{2\pi z^2} \iint\limits_A u_0(x', y', 0)(x - x') \tag{3.332}$$
$$\times \mathrm{e}^{\mathrm{i}k\frac{(x-x')^2 + (y-y')^2}{2z}}\, \mathrm{d}x'\, \mathrm{d}y' \, ,$$

$$\frac{\partial^2 \Psi}{\partial x^2} = \mathrm{i}\frac{k^3}{2\pi z^3} \iint\limits_A u_0(x', y', 0)(x - x')^2$$
$$\times \mathrm{e}^{\mathrm{i}k\frac{(x-x')^2 + (y-y')^2}{2z}}\, \mathrm{d}x'\, \mathrm{d}y'$$
$$+ \frac{k^2}{2\pi z^2} \iint\limits_A u_0(x', y', 0)$$
$$\times \mathrm{e}^{\mathrm{i}k\frac{(x-x')^2 + (y-y')^2}{2z}}\, \mathrm{d}x'\, \mathrm{d}y' \, ,$$

$$\frac{\partial^2 \Psi}{\partial y^2} = \mathrm{i}\frac{k^3}{2\pi z^3} \iint\limits_A u_0(x', y', 0)(y - y')^2$$
$$\times \mathrm{e}^{\mathrm{i}k\frac{(x-x')^2 + (y-y')^2}{2z}}\, \mathrm{d}x'\, \mathrm{d}y'$$
$$+ \frac{k^2}{2\pi z^2} \iint\limits_A u_0(x', y', 0)$$
$$\times \mathrm{e}^{\mathrm{i}k\frac{(x-x')^2 + (y-y')^2}{2z}}\, \mathrm{d}x'\, \mathrm{d}y' \, ,$$

$$\frac{\partial \Psi}{\partial z} = \frac{ik}{2\pi z^2} \int\int_A u_0\left(x', y', 0\right)$$

$$\times e^{ik\frac{(x-x')^2 + (y-y')^2}{2z}} \, dx' \, dy'$$

$$- \frac{k^2}{4\pi z^3} \int\int_A u_0\left(x', y', 0\right)$$

$$\times \left[\left(x-x'\right)^2 + \left(y-y'\right)^2\right]$$

$$\times e^{ik\frac{(x-x')^2 + (y-y')^2}{2z}} \, dx' \, dy' \, .$$

So, it is clear that the function Ψ of (3.331) fulfills the paraxial Helmholtz equation

$$\frac{\partial^2 \Psi}{\partial x^2} + \frac{\partial^2 \Psi}{\partial y^2} + 2ik\frac{\partial \Psi}{\partial z} = 0 \, .$$

Therefore, the Fresnel diffraction integral and the paraxial Helmholtz equation correspond to each other. The propagation of a Gaussian beam can be made either by calculating the Fresnel diffraction integral if the complex amplitude u_0 is given in a plane, or the propagation rules can be directly derived from the paraxial Helmholtz equation as has been done to obtain (3.326) and (3.327) [3.10].

3.5.3 Propagation of a Gaussian Beam

The parameters w and R of a Gaussian beam change during the propagation of the beam along the z-axis. An explicit representation of w and R can be obtained by combining (3.326), (3.328), and (3.329)

$$\frac{1}{R} + i\frac{\lambda_n}{\pi w^2} = \frac{1}{z - i\frac{\pi w_0^2}{\lambda_n}} = \frac{z + i\frac{\pi w_0^2}{\lambda_n}}{z^2 + \left(\frac{\pi w_0^2}{\lambda_n}\right)^2} \, .$$

To simplify the notation the so-called Rayleigh length is defined as

$$z_R := \frac{\pi w_0^2}{\lambda_n} \, . \tag{3.333}$$

So, by separating the real and the imaginary part, two equations are obtained

$$\frac{1}{R} = \frac{z}{z^2 + z_R^2} \, , \tag{3.334}$$

$$\frac{\lambda_n}{\pi w^2} = \frac{z_R}{z^2 + z_R^2} \, ; \tag{3.335}$$

$$R(z) = z + \frac{z_R^2}{z} = z + \frac{\pi^2 w_0^4}{\lambda_n^2 z} \, , \tag{3.336}$$

$$\Rightarrow$$

$$w^2(z) = \frac{\lambda_n}{\pi} \frac{z^2 + z_R^2}{z_R} = w_0^2 + \frac{\lambda_n^2 z^2}{\pi^2 w_0^2} \, . \tag{3.337}$$

The last equation shows that the beam waist w_0 is indeed the smallest value of the beam radius w and that it is obtained at $z = 0$. Simultaneously, the radius of curvature R is infinity at $z = 0$. The equation also shows that the beam radius of the Gaussian beam has the value $w = \sqrt{2} w_0$ at the distance $z = z_R$ (Rayleigh length) from the beam waist.

Another interesting limiting case is the far field, i. e., $z \to \pm\infty$. Then we have

$$R(z) = z, \tag{3.338}$$

$$w(z) = \frac{\lambda_n |z|}{\pi w_0} \, . \tag{3.339}$$

The far field angle θ of a Gaussian beam is

$$\theta \approx \tan\theta = \frac{w(z)}{|z|} = \frac{\lambda_n}{\pi w_0} \, . \tag{3.340}$$

So, by measuring the far field angle θ and the wavelength λ_n of a laser diode its beam waist w_0 can be calculated if we assume that the fundamental Gaussian beam is a good description for the wavefront of a laser diode.

By using (3.337) the function Ψ (3.330) can be written in a more illustrating way

$$\frac{1}{1 + i\frac{\lambda_n z}{\pi w_0^2}} = \frac{w_0}{w_0 + i\frac{\lambda_n z}{\pi w_0}} = \frac{w_0\left(w_0 - i\frac{\lambda_n z}{\pi w_0}\right)}{w_0^2 + \frac{\lambda_n^2 z^2}{\pi^2 w_0^2}} \, .$$

The term in parentheses of the numerator can be expressed as

$$w_0 - i\frac{\lambda_n z}{\pi w_0} = A \, e^{i\Phi} = A\cos\Phi + iA\sin\Phi$$

with

$$A = \sqrt{w_0^2 + \frac{\lambda_n^2 z^2}{\pi^2 w_0^2}} = w(z)$$

and

$$\cos\Phi = \frac{w_0}{w(z)} \, ,$$

$$\sin\Phi = -\frac{\lambda_n z}{\pi w_0 w(z)} \, ;$$

$$\Rightarrow \quad \tan\Phi = -\frac{\lambda_n z}{\pi w_0^2} \, .$$

In summary we have

$$\frac{1}{1+\mathrm{i}\frac{\lambda_n z}{\pi w_0^2}} = \frac{w_0}{w(z)}\mathrm{e}^{\mathrm{i}\Phi(z)} \quad \text{with} \quad \tan\Phi(z) = -\frac{\lambda_n z}{\pi w_0^2} .$$

(3.341)

The complex amplitude u of a Gaussian beam can then be expressed using (3.318), (3.330), and (3.341)

$$u(x, y, z)$$
$$= \Psi_0 \frac{w_0}{w(z)} \mathrm{e}^{-\frac{x^2+y^2}{w^2(z)}} \mathrm{e}^{\mathrm{i}\Phi(z)} \mathrm{e}^{\mathrm{i}\frac{k(x^2+y^2)}{2R(z)}} \mathrm{e}^{\mathrm{i}kz} .$$

(3.342)

This means that a Gaussian beam has a Gaussian profile for a constant value z (Fig. 3.30). The term $w_0/w(z)$ ensures that the total power P_G of the beam is conserved during the propagation along the z direction:

$$P_G(z) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} |u(x, y, z)|^2 \,\mathrm{d}x\,\mathrm{d}y$$
$$= \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \Psi_0^2 \frac{w_0^2}{w^2(z)} \mathrm{e}^{-2\frac{x^2+y^2}{w^2(z)}} \,\mathrm{d}x\,\mathrm{d}y$$
$$= \Psi_0^2 \frac{w_0^2}{w^2(z)} \frac{\pi w^2(z)}{2} = \Psi_0^2 \frac{\pi w_0^2}{2} = \text{constant} .$$

(3.343)

By interpreting the beam radius w as lateral extension of the Gaussian beam it can be graphically symbolized as in Fig. 3.31. At the beam waist the local curvature of the Gaussian beam is zero. In the far field, the radius of curvature R increases proportional to z like the radius of curvature of a spherical wave.

Fig. 3.30 Amplitude of a Gaussian beam at a constant value z

Fig. 3.31 Scheme showing the propagation of a Gaussian beam along the z-axis. The Gaussian beam is laterally limited by the beam radius w and its wavefront has the local radius of curvature R

3.5.4 Higher-Order Modes of Gaussian Beams

In (3.323) a quite simple approach has been selected for the function Ψ, which mainly describes the lateral variation of the Gaussian beam. This approach is the fundamental mode in the case of rotational symmetry. In the following a more general approach is made. The beam can now have two different principal curvatures along the local x and y direction and also higher order modes are taken into account. The different principal curvatures are useful to describe the radiation of laser diodes (e.g., edge emitter), which often have different beam radii and radii of curvature in the x and y directions. Therefore, the following approach is taken for Ψ [3.58]:

$$\Psi(x, y, z) = g\left(\sqrt{2}\frac{x}{w_x(z)}\right) h\left(\sqrt{2}\frac{y}{w_y(z)}\right) \quad (3.344)$$
$$\times \mathrm{e}^{\mathrm{i}\left[P(z) + \frac{kx^2}{2q_x(z)} + \frac{ky^2}{2q_y(z)}\right]} .$$

The functions g and h have to describe the lateral variations of the amplitude of the different modes and therefore it is useful to take the normalized quantities x/w_x and y/w_y, which are pure numbers without a physical unit. Here, w_x and w_y are again the beam radii in the x and y directions, respectively. The factor $\sqrt{2}$ in the arguments of g and h seems to be quite arbitrary at the moment. But it will be shown in the following that this leads to a well-known differential equation for g and h. This approach for Ψ has to fulfill (3.322). The functions are written without arguments in the following to simplify the notation. Additionally, the first or second derivative of a function $f(\eta)$ with respect to its argument η is written as f' or f'', respectively. However, it should be kept in mind that, e.g., g is in fact a function of x and z (since w_x is a function of z) and therefore the

derivative $g'(\eta) := \mathrm{d}g(\eta)/\mathrm{d}\eta$ with $\eta := \sqrt{2}x/w_x(z)$ remains a function of x and z. On the other hand, q_x is, e.g., only a function of z so that the derivative $q'_x(z)$ is just defined as $\mathrm{d}q_x(z)/\mathrm{d}z$. So, using these notations, we have:

$$\frac{\partial \Psi}{\partial z} = \left[gh \left(iP' - \frac{ikx^2}{2q_x^2}q'_x - \frac{iky^2}{2q_y^2}q'_y \right) \right.$$
$$\left. + \left(-gh'\sqrt{2}\frac{y}{w_y^2}w'_y - g'h\sqrt{2}\frac{x}{w_x^2}w'_x \right) \right]$$
$$\times e^{i\left(P + \frac{kx^2}{2q_x} + \frac{ky^2}{2q_y} \right)},$$

$$\frac{\partial \Psi}{\partial x} = \left(gh\frac{ikx}{q_x} + \sqrt{2}\frac{g'}{w_x}h \right) e^{i\left(P + \frac{kx^2}{2q_x} + \frac{ky^2}{2q_y} \right)},$$

$$\frac{\partial^2 \Psi}{\partial x^2} = \left(\frac{ik}{q_x}gh - \frac{k^2x^2}{q_x^2}gh + \sqrt{2}\frac{ikx}{q_xw_x}g'h \right.$$
$$\left. + 2\frac{g''}{w_x^2}h + \sqrt{2}\frac{ikx}{q_xw_x}g'h \right)$$
$$\times e^{i\left(P + \frac{kx^2}{2q_x} + \frac{ky^2}{2q_y} \right)},$$

$$\frac{\partial^2 \Psi}{\partial y^2} = \left(\frac{ik}{q_y}gh - \frac{k^2y^2}{q_y^2}gh + \sqrt{2}\frac{iky}{q_yw_y}gh' \right.$$
$$\left. + 2\frac{h''}{w_y^2}g + \sqrt{2}\frac{iky}{q_yw_y}gh' \right)$$
$$\times e^{i\left(P + \frac{kx^2}{2q_x} + \frac{ky^2}{2q_y} \right)}.$$

By inserting these functions in (3.322) and dividing by gh the following equation is obtained

$$\frac{ik}{q_x} + \frac{ik}{q_y} - 2kP' + \frac{k^2x^2}{q_x^2}(q'_x - 1) + \frac{k^2y^2}{q_y^2}(q'_y - 1)$$
$$+ 2\frac{g''}{gw_x^2} - 2\sqrt{2}\frac{ikx}{w_x^2}\frac{g'}{g}\left(w'_x - \frac{w_x}{q_x} \right)$$
$$+ 2\frac{h''}{hw_y^2} - 2\sqrt{2}\frac{iky}{w_y^2}\frac{h'}{h}\left(w'_y - \frac{w_y}{q_y} \right) = 0. \quad (3.345)$$

This equation also has to be fulfilled for $x \to \infty$ and $y \to \infty$. Then, the terms proportional to x^2 and y^2 are very large compared to the other terms and, similarly to the case of the fundamental mode, the following two

conditions have to be fulfilled:

$$q'_x = 1 \quad \Rightarrow \quad q_x = q_{x,0} + z$$
and
$$q'_y = 1 \quad \Rightarrow \quad q_y = q_{y,0} + z. \quad (3.346)$$

Additionally, q_x and q_y are analogous to the fundamental mode split up into real and imaginary parts

$$\frac{1}{q_x} = \frac{1}{R_x} + i\frac{\lambda_n}{\pi w_x^2} \quad \text{and} \quad \frac{1}{q_y} = \frac{1}{R_y} + i\frac{\lambda_n}{\pi w_y^2}. \quad (3.347)$$

Calculating the derivative with respect to z delivers for the first equation

$$-\frac{q'_x}{q_x^2} = -\frac{1}{q_x^2} = -\frac{R'_x}{R_x^2} - 2i\frac{\lambda_n w'_x}{\pi w_x^3}. \quad (3.348)$$

This equation is added to the square of (3.347). Then, the real and the imaginary part are split resulting in two equations

$$R'_x = 1 - \frac{\lambda_n^2 R_x^2}{\pi^2 w_x^4} \quad \text{and} \quad w'_x = \frac{w_x}{R_x}. \quad (3.349)$$

Analogous results are obtained for R'_y and w'_y. Inserting these results into (3.345) finally delivers

$$\frac{ik}{q_x} + \frac{ik}{q_y} - 2kP'$$
$$+ 2\frac{g''}{gw_x^2} - 4\sqrt{2}\frac{x}{w_x^3}\frac{g'}{g}$$
$$+ 2\frac{h''}{hw_y^2} - 4\sqrt{2}\frac{y}{w_y^3}\frac{h'}{h} = 0. \quad (3.350)$$

Now, the terms in the first row depend only on z, whereas the terms in the second row depend on x and z and the terms in the third row on y and z. Therefore, a separation approach has to be made

$$\frac{ik}{q_x} + \frac{ik}{q_y} - 2kP' = -f_x(z) - f_y(z), \quad (3.351)$$

$$2\frac{g''}{gw_x^2} - 4\sqrt{2}\frac{x}{w_x^3}\frac{g'}{g} = f_x(z), \quad (3.352)$$

$$2\frac{h''}{hw_y^2} - 4\sqrt{2}\frac{y}{w_y^3}\frac{h'}{h} = f_y(z), \quad (3.353)$$

where f_x and f_y are functions that only depend on z. The solution of the differential equation for g (and analogously for h) shall be described briefly because it is a quite general solution scheme, which is often applied in optics and physics. First, the differential equation

is written by using $\eta = \sqrt{2}x/w_x$ and the abbreviation $\alpha := f_x w_x^2$ as

$$\frac{d^2 g(\eta)}{d\eta^2} - 2\eta \frac{dg(\eta)}{d\eta} - \frac{1}{2}\alpha g(\eta) = 0 . \tag{3.354}$$

The usual approach to solve such a differential equation is to write g as a polynomial

$$g(\eta) = \sum_{m=0}^{\infty} a_m \eta^m ,$$

$$\frac{dg(\eta)}{d\eta} = \sum_{m=1}^{\infty} m a_m \eta^{m-1} ,$$

$$\frac{d^2 g(\eta)}{d\eta^2} = \sum_{m=2}^{\infty} m(m-1) a_m \eta^{m-2} . \tag{3.355}$$

Inserting of this approach into the differential (3.354) and arranging for equal powers of η gives

$$\sum_{m=2}^{\infty} m(m-1) a_m \eta^{m-2}$$

$$- 2\sum_{m=1}^{\infty} m a_m \eta^m - \frac{1}{2}\alpha \sum_{m=0}^{\infty} a_m \eta^m$$

$$= \sum_{m=0}^{\infty} \left[(m+2)(m+1) a_{m+2} \right.$$

$$\left. - \left(2m + \frac{1}{2}\alpha \right) a_m \right] \eta^m = 0 . \tag{3.356}$$

This equation can only be fulfilled for all possible values of η if each coefficient in front of η^m is zero, i. e.,

$$(m+2)(m+1) a_{m+2} - \left(2m + \frac{1}{2}\alpha \right) a_m = 0$$

$$\Rightarrow \quad a_{m+2} = \frac{2m + \frac{1}{2}\alpha}{(m+2)(m+1)} a_m . \tag{3.357}$$

Now, if there would be no stop criterion for the progression of coefficients a_m this equation would tend towards very large values of m to

$$\lim_{m \to \infty} a_{m+2} = \frac{2}{m} a_m \tag{3.358}$$

because α has a finite value. But this is the same progression of coefficients as for $\exp(\eta^2)$

$$e^{\eta^2} = \sum_{m=0}^{\infty} \frac{(\eta^2)^m}{m!} = \sum_{m=0}^{\infty} \frac{\eta^{2m}}{m!}$$

$$= \sum_{m=0,2,4,\ldots}^{\infty} \frac{1}{\left(\frac{m}{2}\right)!} \eta^m = \sum_{m=0,2,4,\ldots}^{\infty} b_m \eta^m . \tag{3.359}$$

So, the progression of coefficients will in this case be:

$$b_m = \frac{1}{\left(\frac{m}{2}\right)!}$$

$$\Rightarrow \quad b_{m+2} = \frac{1}{\left(\frac{m+2}{2}\right)!} = \frac{2}{m+2} b_m . \tag{3.360}$$

Therefore, for very large values m the progression of coefficients b_m will have the same behavior as the coefficients a_m and the amplitude $|\Psi|$ of the higher-order mode Gaussian beam would tend to infinity for large values η because the compensating term [(3.344), (3.347)] only has the form $\exp(-x^2/w_x^2) = \exp(-\eta^2/2)$. But, for physical reasons, $|\Psi|$ has to tend to zero for large values of η. Therefore, there has to be a stop criterion for the progression of coefficients, which just means that the variable α has to fulfill the following equation

$$\alpha = f_x w_x^2 = -4j; \quad j = 0, 1, 2, \ldots$$

$$\Rightarrow \quad f_x = -\frac{4j}{w_x^2} . \tag{3.361}$$

By inserting this into (3.354) the well-known differential equation for the Hermite polynomials H_j is obtained

$$\frac{d^2 g(\eta)}{d\eta^2} - 2\eta \frac{dg(\eta)}{d\eta} + 2j g(\eta) = 0 . \tag{3.362}$$

The progression of coefficients of the Hermite polynomials fulfill, according to (3.357) and (3.361), the condition

$$a_{m+2} = \frac{2m + \frac{1}{2}\alpha}{(m+2)(m+1)} a_m$$

$$= \frac{2(m-j)}{(m+2)(m+1)} a_m . \tag{3.363}$$

But, we have two progressions of coefficient, one for odd numbers m and one for even numbers m. So, if j is odd, only the odd coefficient progression will stop and vice versa with even values of j. Therefore, one of the coefficients a_0 or a_1, which are the two integration constants of our second-order differential equation, must additionally be zero. So, we now have the possibility to calculate the Hermite polynomials H_j, which are the solutions of g and h. The Hermite polynomials are, in most textbooks, normalized but by using (3.363) it is only possible to calculate the unnormalized Hermite polynomials. But this is no problem since we do not need the normalized polynomials.

If we take $a_0 \neq 0$ and $a_1 = 0$ for the even Hermite polynomials H_j and $a_0 = 0$ and $a_1 \neq 0$ for the odd Hermite polynomials we obtain up to the third order apart from the normalization constant

$$H_0(\eta) = 1,$$

$$H_1(\eta) = \eta,$$

$$H_2(\eta) = -2\eta^2 + 1,$$

$$H_3(\eta) = -\frac{2}{3}\eta^3 + \eta. \tag{3.364}$$

Equation (3.351) for P' results, together with (3.361) (taking m instead of j) and the analogous equation for

Fig. 3.32 Simulation of the intensity distributions of some Hermite–Gaussian modes using the normalized coordinates x/w_x and y/w_y

f_y (taking n instead of j), in

$$\frac{\mathrm{d}P}{\mathrm{d}z} = \frac{\mathrm{i}}{2}\left(\frac{1}{q_x} + \frac{1}{q_y}\right) - m\frac{\lambda_n}{\pi w_x^2} - n\frac{\lambda_n}{\pi w_y^2}$$

$$= \frac{\mathrm{i}}{2}\left(\frac{1}{q_x} + \frac{1}{q_y}\right) - m\mathrm{Im}\left(\frac{1}{q_x}\right) - n\mathrm{Im}\left(\frac{1}{q_y}\right). \tag{3.365}$$

Using (3.346) and

$$\frac{1}{q_x} = \frac{1}{q_{x,0} + z} = \frac{1}{\mathrm{Re}(q_{x,0}) + \mathrm{i}\mathrm{Im}(q_{x,0}) + z}$$

$$= \frac{z + \mathrm{Re}(q_{x,0}) - \mathrm{i}\mathrm{Im}(q_{x,0})}{z^2 + 2z\mathrm{Re}(q_{x,0}) + |q_{x,0}|^2} \tag{3.366}$$

finally gives

$$P(z) = \mathrm{i}\ln\left(\sqrt{1 + \frac{z}{q_{x,0}}}\sqrt{1 + \frac{z}{q_{y,0}}}\right)$$

$$- m\arctan\left(\frac{z + \mathrm{Re}(q_{x,0})}{-\mathrm{Im}(q_{x,0})}\right)$$

$$- n\arctan\left(\frac{z + \mathrm{Re}(q_{y,0})}{-\mathrm{Im}(q_{y,0})}\right). \tag{3.367}$$

Note that $-\mathrm{Im}(q_{x,0})$ and $-\mathrm{Im}(q_{y,0})$ are used because these quantities are positive as will be seen in (3.369). In summary, the function Ψ of the higher-order mode Gaussian beams (Hermite–Gaussian modes) in the case of a cartesian coordinate system can be written by using (3.344)–(3.367)

$$\Psi(x, y, z) = H_m\left(\sqrt{2}\frac{x}{w_x(z)}\right) H_n\left(\sqrt{2}\frac{y}{w_y(z)}\right)$$

$$\times \frac{1}{\sqrt{\left(1 + \frac{z}{q_{x,0}}\right)\left(1 + \frac{z}{q_{y,0}}\right)}}$$

$$\times e^{-\mathrm{i}\left[m\arctan\left(\frac{z + \mathrm{Re}(q_{x,0})}{-\mathrm{Im}(q_{x,0})}\right) + n\arctan\left(\frac{z + \mathrm{Re}(q_{y,0})}{-\mathrm{Im}(q_{y,0})}\right)\right]}$$

$$\times e^{\mathrm{i}\pi\left(\frac{x^2}{\lambda_n R_x(z)} + \frac{y^2}{\lambda_n R_y(z)}\right)}$$

$$\times e^{-\left(\frac{x^2}{w_x^2(z)} + \frac{y^2}{w_y^2(z)}\right)}. \tag{3.368}$$

The functions w_x and R_x are obtained by comparing the real and imaginary parts of (3.347) and (3.366)

$$w_x^2(z) = \frac{\lambda_n}{\pi} \frac{z^2 + 2z \mathrm{Re}(q_{x,0}) + |q_{x,0}|^2}{-\mathrm{Im}(q_{x,0})} \,, \qquad (3.369)$$

$$R_x(z) = \frac{z^2 + 2z \mathrm{Re}(q_{x,0}) + |q_{x,0}|^2}{z + \mathrm{Re}(q_{x,0})} \,. \qquad (3.370)$$

Analogous equations are, of course, valid for w_y and R_y, which are obtained by substituting the index x for y.

Figure 3.32 shows the typical intensity distribution $|\Psi|^2$ of some lower-order Hermite–Gaussian modes with

$$|\Psi(x, y, z)|^2 = \left[H_m \left(\sqrt{2} \frac{x}{w_x(z)} \right) H_n \left(\sqrt{2} \frac{y}{w_y(z)} \right) \right]^2$$

$$\times \left| \frac{1}{\sqrt{\left(1 + \frac{z}{q_{x,0}}\right)\left(1 + \frac{z}{q_{y,0}}\right)}} \right|^2$$

$$\times e^{-2\left(\frac{x^2}{w_x^2(z)} + \frac{y^2}{w_y^2(z)} \right)} \,. \qquad (3.371)$$

They are named TEM$_{mn}$, where m is the index of the Hermite polynomial H_m with the argument $\sqrt{2}x/w_x$ and n is the index of the Hermite polynomial H_n with the argument $\sqrt{2}y/w_y$. The number of zeros is equal to the mode number and the area covered by the modes increases with the mode number.

So, the complete behavior of the higher order Gaussian beam is well defined if the complex quantities $q_{x,0}$ and $q_{y,0}$ at the plane $z = 0$ are known. This is the case if the beam radii $w_{x,0}$ and $w_{y,0}$ and the radii of curvature $R_{x,0}$ and $R_{y,0}$ of the wavefront at the plane $z = 0$ are known. Hereby, the beam waists in x and y direction can be in different planes. If both beam waists are in the same plane the coordinate system can be chosen such that the beam waists are in the plane $z = 0$ and $q_{x,0} = -i\pi w_{x,0}^2/\lambda_n$ with the beam waist $w_{x,0}$ in the x direction. Then a simplification similar to the case of the fundamental mode of a Gaussian beam can be made and (3.369) and (3.370) reduce to (3.336) and (3.337). Also, (3.368) can then be simplified.

3.5.5 Transformation of a Fundamental Gaussian Beam at a Lens

The transformation of a fundamental Gaussian beam at a (thin) lens is performed using a paraxial approx-

Fig. 3.33 Transformation of a Gaussian beam at a thin ideal lens

imation. This means that it is assumed that the beam radius immediately in front of the lens is identical to the beam radius immediately behind the lens. Additionally, the radius of curvature of the Gaussian beam changes in the same way as that of a spherical wave. The sign convention is that a positive lens has a positive focal length $f > 0$ and that a divergent spherical wave coming from the negative z direction (i. e., from "left" using the optical agreement) has a positive radius of curvature $R > 0$. R_1 is the radius of curvature immediately in front of the lens and R_2 is the radius of curvature immediately behind the lens. Then, a lens with focal length f transforms the radii of curvature according to the paraxial imaging equation of geometrical optics (Fig. 3.33)

$$\frac{1}{R_2} = \frac{1}{R_1} - \frac{1}{f} \,. \qquad (3.372)$$

Since the beam radius remains constant, the complex beam parameters q_1 immediately in front of the lens and q_2 immediately behind the lens transform also with

$$\frac{1}{q_2} = \frac{1}{q_1} - \frac{1}{f} \,. \qquad (3.373)$$

In the case of a thick lens or a lens system the two principal planes of the lens system have to be taken as reference planes for q_1 and q_2 according to the laws of paraxial geometrical optics. If the q parameters are different in x and y direction as in (3.347) both sets of parameters just have to be treated separately using (3.373).

To calculate the relation between the q parameter q_1 in the distance d_1 in front of a lens with the focal length f and q_2 in the distance d_2 behind the lens, (3.326) and (3.373) have to be combined. We call q_L the Gaussian beam parameter immediately in front of the lens and q_R the beam parameter immediately behind the lens, where
Fig. 3.34 Scheme showing the complex beam parameters for the transformation of a Gaussian beam from a plane in the distance d_1 in front of a lens (with focal length f) to a plane in the distance d_2 behind the lens

the parameters are illustrated in Fig. 3.34. Then we have

$$q_L = q_1 + d_1 \,,$$

$$\frac{1}{q_R} = \frac{1}{q_L} - \frac{1}{f} = \frac{1}{q_1 + d_1} - \frac{1}{f} \,,$$

$$\Rightarrow q_R = \frac{f(q_1 + d_1)}{f - q_1 - d_1} \,;$$

$$q_2 = q_R + d_2 = \frac{fq_1 + fd_1 + fd_2 - d_2 q_1 - d_1 d_2}{f - q_1 - d_1} \,,$$

$$\Rightarrow q_2 = \frac{q_1\left(1 - \frac{d_2}{f}\right) + \left(d_1 + d_2 - \frac{d_1 d_2}{f}\right)}{-\frac{q_1}{f} + \left(1 - \frac{d_1}{f}\right)} \,. \quad (3.374)$$

3.5.6 ABCD Matrix Law for Gaussian Beams

The propagation through an optical system can be described in the paraxial geometrical optics by an ABCD matrix (see the chapter about geometrical optics or [3.11, 58–60]). We compare the terms of (3.374) with the paraxial ABCD matrix for the propagation from a plane with the distance d_1 in front of a lens with focal length f to a plane with distance d_2 behind the lens

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} 1 - \frac{d_2}{f} & d_1 + d_2 - \frac{d_1 d_2}{f} \\ -\frac{1}{f} & 1 - \frac{d_1}{f} \end{pmatrix} \,. \quad (3.375)$$

We see that the Gaussian-beam parameter transforms as

$$q_2 = \frac{Aq_1 + B}{Cq_1 + D} \,. \quad (3.376)$$

It can be shown that this ABCD matrix law is valid quite generally as long as the paraxial approximation holds. In the following it will be shown for a sequence of (thin) lenses and free space propagation.

Free Space Propagation
The free space propagation in a homogeneous material with refractive index n is described by (3.326): $q_2 = q_1 + z$. On the other hand the paraxial matrix for free space propagation between two planes with a distance z is

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} 1 & z \\ 0 & 1 \end{pmatrix}$$

$$\Rightarrow q_2 = q_1 + z = \frac{1 \cdot q_1 + z}{0 \times q_1 + 1} = \frac{Aq_1 + B}{Cq_1 + D} \,. \quad (3.377)$$

So, the free space propagation fulfills the ABCD matrix law of Gaussian beams (3.376).

Thin Lens
For the transformation of a Gaussian beam at a thin lens, (3.373) is valid. The paraxial matrix of a thin lens with focal length f is

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ -\frac{1}{f} & 1 \end{pmatrix}$$

$$\Rightarrow q_2 = \frac{fq_1}{f - q_1} = \frac{1 \times q_1 + 0}{-\frac{q_1}{f} + 1} = \frac{Aq_1 + B}{Cq_1 + D} \,. \quad (3.378)$$

So, the transformation of a Gaussian beam at a thin lens also fulfills the ABCD matrix law of (3.376).

A Sequence of Lenses and Free Space Propagation
We assume that M_1 and M_2 are the paraxial matrices for two subsequent operations like free space propagation or transformation at a thin lens. The Gaussian beam has the q parameters q_0 before the first operation, q_1 after the first operation and q_2 after the second operation. Both (3.377) and (3.378) fulfill (3.376). Therefore, we have the relations

$$q_1 = \frac{A_1 q_0 + B_1}{C_1 q_0 + D_1} \quad \text{and} \quad q_2 = \frac{A_2 q_1 + B_2}{C_2 q_1 + D_2} \,. \quad (3.379)$$

Substitution of q_1 into q_2 gives

$$q_2 = \frac{A_2 \frac{A_1 q_0 + B_1}{C_1 q_0 + D_1} + B_2}{C_2 \frac{A_1 q_0 + B_1}{C_1 q_0 + D_1} + D_2} \quad (3.380)$$

$$= \frac{(A_2 A_1 + B_2 C_1)q_0 + (A_2 B_1 + B_2 D_1)}{(C_2 A_1 + D_2 C_1)q_0 + (C_2 B_1 + D_2 D_1)} \,.$$

However, the paraxial matrix M of both operations is

$$M = \begin{pmatrix} A & B \\ C & D \end{pmatrix} = M_2 M_1$$

$$= \begin{pmatrix} A_2 & B_2 \\ C_2 & D_2 \end{pmatrix} \cdot \begin{pmatrix} A_1 & B_1 \\ C_1 & D_1 \end{pmatrix}$$

$$= \begin{pmatrix} A_2 A_1 + B_2 C_1 & A_2 B_1 + B_2 D_1 \\ C_2 A_1 + D_2 C_1 & C_2 B_1 + D_2 D_1 \end{pmatrix} . \quad (3.381)$$

Summarizing, the relation between q_2 and q_0 is

$$q_2 = \frac{A q_0 + B}{C q_0 + D} . \quad (3.382)$$

This shows that the ABCD matrix law is valid for two subsequent operations of free space propagation or transformation at a thin lens. Therefore, it also has to be valid for an arbitrary number of those operations. Geometrical optics shows that a thick lens can be replaced by a thin lens and free space propagation. Therefore, the ABCD matrix law can also be applied for thick lenses or a system consisting of many lenses. We assume that the paraxial ABCD matrix of such a system is known for describing the propagation between two planes with the optical system in between. The transformation of the Gaussian beam parameter q_1 at the first plane to the parameter q_2 at the second plane is then described by (3.376). Of course, it is always assumed that no apertures are in the system and that the paraxial approximation is valid, i.e., the optical system is ideal and does not introduce any aberrations.

3.5.7 Some Examples of the Propagation of Gaussian Beams

Transformation in the Case of Geometrical Imaging

A Gaussian beam with beam parameter q_1 at the distance d_1 in front of the first principal plane of a lens (or a lens system) with focal length f is examined at the distance d_2 behind the second principal plane of the lens. There, the Gaussian beam has the beam parameter q_2. Additionally, it is assumed that the distances d_1 and d_2 and the focal length of the lens fulfill the imaging equation of paraxial geometrical optics

$$\frac{1}{d_1} + \frac{1}{d_2} = \frac{1}{f} \Rightarrow \quad (3.383)$$

$$1 - \frac{d_2}{f} = -\frac{d_2}{d_1} = \beta , \quad (3.384)$$

$$d_1 + d_2 - \frac{d_1 d_2}{f} = 0 , \quad (3.385)$$

$$1 - \frac{d_1}{f} = -\frac{d_1}{d_2} = \frac{1}{\beta} . \quad (3.386)$$

By using (3.374) we obtain

$$q_2 = \frac{\beta q_1}{-\frac{q_1}{f} + \frac{1}{\beta}} \Rightarrow \frac{1}{q_2} = -\frac{1}{\beta f} + \frac{1}{\beta^2 q_1} . \quad (3.387)$$

Using (3.328) to split the complex q parameters into their real variables delivers

$$\frac{1}{R_2} + i \frac{\lambda_n}{\pi w_2^2} = -\frac{1}{\beta f} + \frac{1}{\beta^2 R_1} + i \frac{\lambda_n}{\beta^2 \pi w_1^2} ;$$

$$\Rightarrow \quad \frac{1}{R_2} = \frac{1}{\beta^2 R_1} - \frac{1}{\beta f} \quad \text{and} \quad w_2 = |\beta| w_1 .$$

$$(3.388)$$

The result is that the beam radius transforms from one plane to another plane with the lateral magnification β if the imaging equation is fulfilled for these two planes, i.e., if the first plane is imaged by the lens onto the second plane.

Position and Size of the Beam Waist Behind a Lens

It is assumed that a Gaussian beam has its beam waist w_0 at the distance d_1 in front of a lens with focal length f so that the beam parameter in the first plane is, according to (3.329), $q_1 = -i\pi w_0^2/\lambda_n$. The position and size of the beam waist behind the lens has to be calculated. The desired parameters are the size w_2 of the beam waist and its distance d_2 from the lens (Fig. 3.35).

Fig. 3.35 Scheme showing the parameters to calculate the position and the size of the beam waist of a Gaussian beam behind a lens
Fig. 3.36 Special case of the transformation of a Gaussian beam at a lens where the beam waist lies in the front focal plane of the lens

Using (3.328) and (3.374) results in

$$\frac{1}{q_2} = \frac{1}{R_2} + i\frac{\lambda_n}{\pi w_2^2}$$

$$= \frac{i\frac{\pi w_0^2}{\lambda_n f} + \left(1 - \frac{d_1}{f}\right)}{-i\left(1 - \frac{d_2}{f}\right)\frac{\pi w_0^2}{\lambda_n} + \left(d_1 + d_2 - \frac{d_1 d_2}{f}\right)} \; ;$$

$$\Rightarrow \frac{1}{R_2} + i\frac{\lambda_n}{\pi w_2^2}$$

$$= \frac{\left\{ \begin{array}{l} i\frac{\pi w_0^2}{\lambda_n} - \left(1 - \frac{d_2}{f}\right)\frac{\pi^2 w_0^4}{\lambda_n^2 f} + \\ \left(1 - \frac{d_1}{f}\right)\left(d_1 + d_2 - \frac{d_1 d_2}{f}\right) \end{array} \right\}}{\left(1 - \frac{d_2}{f}\right)^2 \frac{\pi^2 w_0^4}{\lambda_n^2} + \left(d_1 + d_2 - \frac{d_1 d_2}{f}\right)^2} \; .$$

(3.389)

At the position of the beam waist the real part $1/R_2$ of this equation has to vanish. This gives a condition for calculating d_2:

$$-\left(1 - \frac{d_2}{f}\right)\frac{\pi^2 w_0^4}{\lambda_n^2 f}$$
$$+ \left(1 - \frac{d_1}{f}\right)\left(d_1 + d_2 - \frac{d_1 d_2}{f}\right) = 0 \; ;$$

$$\Rightarrow d_2 = \frac{\frac{\pi^2 w_0^4}{\lambda_n^2 f} - d_1\left(1 - \frac{d_1}{f}\right)}{\frac{\pi^2 w_0^4}{\lambda_n^2 f^2} + \left(1 - \frac{d_1}{f}\right)^2} \; .$$

(3.390)

In the limiting case of geometrical optics, i. e., $w_0 \rightarrow 0$, this equation is equal to the paraxial imaging equation.

The beam waist w_2 can be determined using the imaginary part of (3.389) and replacing then the term $d_1 + d_2 - d_1 d_2/f$ with the help of the first part of (3.390)

$$\frac{\lambda_n}{\pi w_2^2} = \frac{\frac{\pi w_0^2}{\lambda_n}}{\left(1 - \frac{d_2}{f}\right)^2 \frac{\pi^2 w_0^4}{\lambda_n^2}\left(1 + \frac{\frac{\pi^2 w_0^4}{\lambda_n^2 f^2}}{\left(1 - \frac{d_1}{f}\right)^2}\right)} \; ;$$

(3.391)

$$\Rightarrow w_2^2 = w_0^2\left(1 - \frac{d_2}{f}\right)^2\left(1 + \frac{\frac{\pi^2 w_0^4}{\lambda_n^2 f^2}}{\left(1 - \frac{d_1}{f}\right)^2}\right) \; .$$

Equation (3.390) delivers

$$1 - \frac{d_2}{f} = \frac{1 - \frac{d_1}{f}}{\frac{\pi^2 w_0^4}{\lambda_n^2 f^2} + \left(1 - \frac{d_1}{f}\right)^2}$$

(3.392)

so that the final result for w_2 is

$$w_2^2 = \frac{w_0^2}{\frac{\pi^2 w_0^4}{\lambda_n^2 f^2} + \left(1 - \frac{d_1}{f}\right)^2} \; .$$

(3.393)

Of special interest is the case that the beam waist w_0 in front of the lens lies in the front focal plane of the lens, i. e., $d_1 = f$. Equations (3.390) and (3.393) reduce in this special case to

$$d_2 = f \quad \text{and} \quad w_2 = \frac{\lambda_n f}{\pi w_0} \; .$$

(3.394)

So, if the beam waist of the incident Gaussian beam lies in the front focal plane of the lens, the beam waist of the transformed Gaussian beam lies in the back focal plane of the lens (Fig. 3.36). Additionally, its size w_2 will be the product of the focal length f of the lens and the far field angle (3.340) of the incident Gaussian beam. This result shows that the transformation of Gaussian beams should not be confused with the transformation of paraxial spherical waves of geometrical optics.

4. Nonlinear Optics

This chapter provides a brief introduction into the basic nonlinear-optical phenomena and discusses some of the most significant recent advances and breakthroughs in nonlinear optics, as well as novel applications of nonlinear-optical processes and devices.

Nonlinear optics is the area of optics that studies the interaction of light with matter in the regime where the response of the material system to the applied electromagnetic field is nonlinear in the amplitude of this field. At low light intensities, typical of non-laser sources, the properties of materials remain independent of the intensity of illumination. The superposition principle holds true in this regime, and light waves can pass through materials or be reflected from boundaries and interfaces without interacting with each other. Laser sources, on the other hand, can provide sufficiently high light intensities to modify the optical properties of materials. Light waves can then interact with each other, exchanging momentum and energy, and the superposition principle is no longer valid. This interaction of light waves can result in the generation of optical fields at new frequencies, including optical harmonics of incident radiation or sum- or difference-frequency signals.

Although the observation of most nonlinear-optical phenomena requires laser radiation, some classes of nonlinear-optical effects were known long before the invention of the laser. The most prominent examples of such phenomena include Pockels and Kerr electrooptic effects [4.1], as well as light-induced resonant absorption saturation, described by *Vavilov* [4.2, 3]. It was, however, only with the advent of lasers that systematic studies of optical nonlinearities and the observation of a vast catalog of spectacular nonlinear-optical phenomena became possible.

In the first nonlinear-optical experiment of the laser era, performed by *Franken* et al. in 1961 [4.4], a ruby-laser radiation with a wavelength of 694.2 nm was used to generate the second harmonic in a quartz crystal at the wavelength of 347.1 nm. This seminal work was followed by the discovery of a rich diversity of nonlinear-optical effects, including sum-frequency generation, stimulated Raman scattering, self-focusing, optical rectification, four-wave mixing, and many others. While in the pioneering work by Franken the efficiency of second-harmonic generation (SHG) was on the order of 10^{-8}, optical frequency doublers created by early

1963 provided 20%–30% efficiency of frequency conversion [4.5, 6]. The early phases of the development and the basic principles of nonlinear optics have been reviewed in the most illuminating way in the classical books by *Bloembergen* [4.7] and *Akhmanov* and *Khokhlov* [4.8], published in the mid 1960s.

Over the following four decades, the field of nonlinear optics has witnessed an enormous growth, leading to the observation of new physical phenomena and giving rise to novel concepts and applications. A systematic introduction into these effects along with a comprehensive overview of nonlinear-optical concepts and devices can be found in excellent textbooks by *Shen* [4.9], *Boyd* [4.1], *Butcher* and *Cotter* [4.10], *Reintjes* [4.11] and others. One of the most recent up-to-date reviews of the field of nonlinear optics with an in-depth discussion of the fundamental physics underlying nonlinear-optical interactions was provided by *Flytzanis* [4.12]. This chapter provides a brief introduction into the main nonlinear-optical phenomena and discusses some of the most significant recent advances in nonlinear optics, as well as novel applications of nonlinear-optical processes and devices.

4.1 Nonlinear Polarization and Nonlinear Susceptibilities

Nonlinear-optical effects belong to a broader class of electromagnetic phenomena described within the general framework of macroscopic Maxwell equations. The Maxwell equations not only serve to identify and classify nonlinear phenomena in terms of the relevant nonlinear-optical susceptibilities or, more generally, nonlinear terms in the induced polarization, but also govern the nonlinear-optical propagation effects. We assume the absence of extraneous charges and currents and write the set of Maxwell equations for the electric, $E(r, t)$, and magnetic, $H(r, t)$, fields in the form

$$\nabla \times E = -\frac{1}{c}\frac{\partial B}{\partial t} , \tag{4.1}$$

$$\nabla \times B = \frac{1}{c}\frac{\partial D}{\partial t} , \tag{4.2}$$

$$\nabla \cdot D = 0 , \tag{4.3}$$

$$\nabla \cdot B = 0 . \tag{4.4}$$

Here, $B = H + 4\pi M$, where M is the magnetic dipole polarization, c is the speed of light, and

$$D = E + 4\pi \int_{-\infty}^{t} J(\zeta)\, d\zeta , \tag{4.5}$$

where J is the induced current density. Generally, the equation of motion for charges driven by the electromagnetic field has to be solved to define the relation between the induced current J and the electric and magnetic fields. For quantum systems, this task can be fulfilled by solving the Schrödinger equation. In Sect. 4.5 of this chapter, we provide an example of such a self-consistent analysis of nonlinear-optical phenomena in a model two-level system. Very often a phenomenological approach based on the introduction of field-independent or local-field-corrected nonlinear-optical susceptibilities can provide an adequate description of nonlinear-optical processes.

Formally, the current density J can be represented as a series expansion in multipoles:

$$J = \frac{\partial}{\partial t}(P - \nabla \cdot Q) + c\, (\nabla \times M) , \tag{4.6}$$

where P and Q are the electric dipole and electric quadrupole polarizations, respectively. In the electric dipole approximation, we keep only the first term on the right-hand side of (4.6). In view of (4.5), this gives the following relation between the D, E, and P vectors:

$$D = E + 4\pi P . \tag{4.7}$$

We now represent the polarization P as a sum

$$P = P_L + P_{nl} , \tag{4.8}$$

where P_L is the part of the electric dipole polarization linear in the field amplitude and P_{nl} is the nonlinear part of this polarization.

The linear polarization governs linear-optical phenomena, i.e., it corresponds to the regime where the optical properties of a medium are independent of the field intensity. The relation between P_L and the electric field E is given by the standard formula of linear optics:

$$P_L = \int \chi^{(1)}(t - t') E(t')\, dt', \tag{4.9}$$

where $\chi^{(1)}(t)$ is the time-domain linear susceptibility tensor. Representing the field E and polarization P_L in the form of elementary monochromatic plane waves,

$$E = E(\omega) \exp(ikr - \omega t) + c.c. \tag{4.10}$$

and

$$P_L = P_L(\omega) \exp\left(ikr - \omega t\right) + c.c. , \tag{4.11}$$

we take the Fourier transform of (4.9) to find

$$P_L(\omega) = \chi^{(1)}(\omega) E(\omega) , \tag{4.12}$$

where

$$\chi^{(1)}(\omega) = \int \chi^{(1)}(t) \exp(i\omega t)\, dt . \tag{4.13}$$

In the regime of weak fields, the nonlinear part of the polarization P_{nl} can be represented as a power-series expansion in the field E:

$$P_{nl} = \iint \chi^{(2)}(t - t_1, t - t_2) : E(t_1)E(t_2)\, dt_1\, dt_2$$
$$+ \iiint \chi^{(3)}(t - t_1, t - t_2, t - t_3)$$
$$\vdots E(t_1)E(t_2)E(t_3)\, dt_1\, dt_2\, dt_3 + \dots , \tag{4.14}$$

where $\chi^{(2)}$ and $\chi^{(3)}$ are the second- and third-order nonlinear susceptibilities.

Representing the electric field in the form of a sum of plane monochromatic waves,

$$E = \sum_i E_i(\omega_i) \exp(ik_i r - \omega_i t) + c.c. , \tag{4.15}$$

we take the Fourier transform of (4.14) to arrive at

$$P_{nl}(\omega) = P^{(2)}(\omega) + P^{(3)}(\omega) + \dots , \tag{4.16}$$

where

$$\boldsymbol{P}^{(2)}(\omega) = \chi^{(2)}(\omega; \omega_i, \omega_j) : \boldsymbol{E}(\omega_i)\boldsymbol{E}(\omega_j) , \quad (4.17)$$

$$\boldsymbol{P}^{(3)}(\omega) = \chi^{(3)}(\omega; \omega_i, \omega_j, \omega_k) \vdots \boldsymbol{E}(\omega_i)\boldsymbol{E}(\omega_j)\boldsymbol{E}(\omega_k) , \quad (4.18)$$

$$\chi^{(2)}(\omega; \omega_i, \omega_j) = \chi^{(2)}(\omega = \omega_i + \omega_j)$$
$$= \iint \chi^{(2)}(t_1, t_2) \exp[\mathrm{i}(\omega_i t_1 + \omega_j t_2)] \, \mathrm{d}t_1 \, \mathrm{d}t_2 \quad (4.19)$$

is the second-order nonlinear-optical susceptibility and

$$\chi^{(3)}(\omega; \omega_i, \omega_j, \omega_k) = \chi^{(3)}(\omega = \omega_i + \omega_j + \omega_k)$$
$$= \iint \chi^{(3)}(t_1, t_2, t_3)$$
$$\exp[\mathrm{i}(\omega_i t_1 + \omega_j t_2 + \omega_k t_3)] \, \mathrm{d}t_1 \, \mathrm{d}t_2 \, \mathrm{d}t_3 \quad (4.20)$$

is the third-order nonlinear-optical susceptibility.

The second-order nonlinear polarization defined by (4.17) gives rise to three-wave mixing processes, optical rectification and linear electrooptic effect. In particular, setting $\omega_i = \omega_j = \omega_0$ in (4.17) and (4.19), we arrive at $\omega = 2\omega_0$, which corresponds to second-harmonic generation, controlled by the nonlinear susceptibility $\chi_{\mathrm{SHG}}^{(2)} = \chi^{(2)}(2\omega_0; \omega_0, \omega_0)$. In a more general case of three-wave mixing process with $\omega_i = \omega_1 \neq \omega_j = \omega_2$, the second-order polarization defined by (4.17) can describe sum-frequency generation (SFG) $\omega_{\mathrm{SF}} = \omega_1 + \omega_2$ Fig. 4.1 or difference-frequency generation (DFG) $\omega_{\mathrm{DF}} = \omega_1 - \omega_2$, governed by the

Fig. 4.1 Sum-frequency generation $\omega_1 + \omega_2 = \omega_3$ in a medium with a quadratic nonlinearity. The case of $\omega_1 = \omega_2$ corresponds to second-harmonic generation

nonlinear susceptibilities $\chi_{\mathrm{SFG}}^{(2)} = \chi^{(2)}(\omega_{\mathrm{SF}}; \omega_1, \omega_2)$ and $\chi_{\mathrm{DFG}}^{(2)} = \chi^{(2)}(\omega_{\mathrm{DF}}; \omega_1, -\omega_2)$, respectively.

The third-order nonlinear polarization defined by (4.18) is responsible for four-wave mixing (FWM), stimulated Raman scattering, two-photon absorption, and Kerr-effect-related phenomena, including self-phase modulation (SPM) and self-focusing. For the particular case of third-harmonic generation, we set $\omega_i = \omega_j = \omega_k = \omega_0$ in (4.18) and (4.20) to obtain $\omega = 3\omega_0$. This type of nonlinear-optical interaction, in accordance with (4.18) and (4.20), is controlled by the cubic susceptibility $\chi_{\mathrm{THG}}^{(3)} = \chi^{(3)}(3\omega_0; \omega_0, \omega_0, \omega_0)$. A more general, frequency-nondegenerate case can correspond to a general type of an FWM process. These and other basic nonlinear-optical processes will be considered in greater details in the following sections.

4.2 Wave Aspects of Nonlinear Optics

In the electric dipole approximation, the Maxwell equations (4.1–4.4) yield the following equation governing the propagation of light waves in a weakly nonlinear medium:

$$\nabla \times (\nabla \times \boldsymbol{E}) - \frac{1}{c^2}\frac{\partial^2 \boldsymbol{E}}{\partial t^2} - \frac{4\pi}{c^2}\frac{\partial^2 \boldsymbol{P}_{\mathrm{L}}}{\partial t^2} = \frac{4\pi}{c^2}\frac{\partial^2 \boldsymbol{P}_{\mathrm{nl}}}{\partial t^2}. \quad (4.21)$$

The nonlinear polarization, appearing on the right-hand side of (4.21), plays the role of a driving source, inducing an electromagnetic wave with the same frequency ω as the nonlinear polarization wave $\boldsymbol{P}_{\mathrm{nl}}(\boldsymbol{r}, t)$. Dynamics of a nonlinear wave process can be then thought as a result of the interference of induced and driving (pump) waves, controlled by the dispersion of the medium.

Assuming that the fields have the form of quasi-monochromatic plane waves propagating along the z-

axis, we represent the field $\boldsymbol{E}$ in (4.21) by

$$\boldsymbol{E}(\boldsymbol{r}, t) = \mathrm{Re}\left[\boldsymbol{e} A(z, t) \exp(\mathrm{i}kz - \omega t)\right] \quad (4.22)$$

and write the nonlinear polarization as

$$\boldsymbol{P}_{\mathrm{nl}}(\boldsymbol{r}, t) = \mathrm{Re}\left[\boldsymbol{e}_{\mathrm{p}} P_{\mathrm{nl}}(z, t) \exp\left(\mathrm{i}k_{\mathrm{p}}z - \omega t\right)\right], \quad (4.23)$$

where k and $A(z, t)$ are the wave vector and the envelope of the electric field, k_p and $P_{\mathrm{nl}}(z, t)$ are the wave vector and the envelope of the polarization wave.

If the envelope $A(z, t)$ is a slowly varying function over the wavelength, $|\partial^2 A/\partial z^2| \ll |k\partial A/\partial z|$, and $\partial^2 \boldsymbol{P}_{\mathrm{nl}}/\partial t^2 \approx -\omega^2 \boldsymbol{P}_{\mathrm{nl}}$, (4.21) is reduced to [4.9]

$$\frac{\partial A}{\partial z} + \frac{1}{u}\frac{\partial A}{\partial t} = \frac{2\pi \mathrm{i}\omega^2}{kc^2} P_{\mathrm{nl}} \exp(\mathrm{i}\Delta kz) , \quad (4.24)$$

where $u = (\partial k/\partial \omega)^{-1}$ is the group velocity and $\Delta k = k_p - k$ is the wave-vector mismatch.

In the following sections, this generic equation of slowly varying envelope approximation (SVEA) will be employed to analyze the wave aspects of the basic second- and third-order nonlinear-optical phenomena.

4.3 Second-Order Nonlinear Processes

4.3.1 Second-Harmonic Generation

In second-harmonic generation, a pump wave with a frequency of ω generates a signal at the frequency 2ω as it propagates through a medium with a quadratic nonlinearity (Fig. 4.1). Since all even-order nonlinear susceptibilities $\chi^{(n)}$ vanish in centrosymmetric media, SHG can occur only in media with no inversion symmetry.

Assuming that diffraction and second-order dispersion effects are negligible, we use (4.24) for a quadratically nonlinear medium with a nonlinear SHG susceptibility $\chi_{SHG}^{(2)} = \chi^{(2)}(2\omega; \omega, \omega)$ to write a pair of coupled equations for the slowly varying envelopes of the pump and second-harmonic fields $A_1 = A_1(z, t)$ and $A_2 = A_2(z, t)$:

$$\frac{\partial A_1}{\partial z} + \frac{1}{u_1}\frac{\partial A_1}{\partial t} = i\gamma_1 A_1^* A_2 \exp(i\Delta kz), \quad (4.25)$$

$$\frac{\partial A_2}{\partial z} + \frac{1}{u_2}\frac{\partial A_2}{\partial t} = i\gamma_2 A_1^2 \exp(-i\Delta kz), \quad (4.26)$$

where

$$\gamma_1 = \frac{2\pi\omega_1^2}{k_1 c^2}\chi^{(2)}(\omega; 2\omega, -\omega) \quad (4.27)$$

and

$$\gamma_2 = \frac{4\pi\omega_1^2}{k_2 c^2}\chi_{SHG}^{(2)} \quad (4.28)$$

are the nonlinear coefficients, u_1 and u_2 are the group velocities of the pump and second-harmonic pulses, respectively, and $\Delta k = 2k_1 - k_2$ is the wave-vector mismatch for the SHG process.

If the difference between the group velocities of the pump and second-harmonic pulses can be neglected for a nonlinear medium with a given length and if the intensity of the pump field in the process of SHG remains much higher than the intensity of the second-harmonic field, we set $u_1 = u_2 = u$ and $|A_1|^2 = |A_{10}|^2 = $ const. in (4.25) and (4.26) to derive in the retarded frame of reference with $z' = z$ and $\eta = t - z/u$

$$A_2(L) = i\gamma_2 A_{10}^2 \frac{\sin\left(\frac{\Delta kL}{2}\right)}{\frac{\Delta kL}{2}} L \exp\left(\frac{i\Delta kL}{2}\right), \quad (4.29)$$

where L is the length of the nonlinear medium.

The intensity of the second-harmonic field is then given by

$$I_2(L) \propto \gamma_2^2 I_{10}^2 \left(\frac{\sin\left(\frac{\Delta kL}{2}\right)}{\frac{\Delta kL}{2}}\right)^2 L^2, \quad (4.30)$$

where I_{10} is the intensity of the pump field.

Second-harmonic intensity I_2, as can be seen from (4.30) oscillates as a function of L Fig. 4.2 with a period $L_c = \pi/|\Delta k| = \lambda_1(4|n_1 - n_2|)^{-1}$, where λ_1 is the pump wavelength and n_1 and n_2 are the values of the refractive index at the frequencies of the pump field and its second harmonic, respectively. The parameter L_c, defining the length of the nonlinear medium providing the maximum SHG efficiency, is referred to as the coherence length.

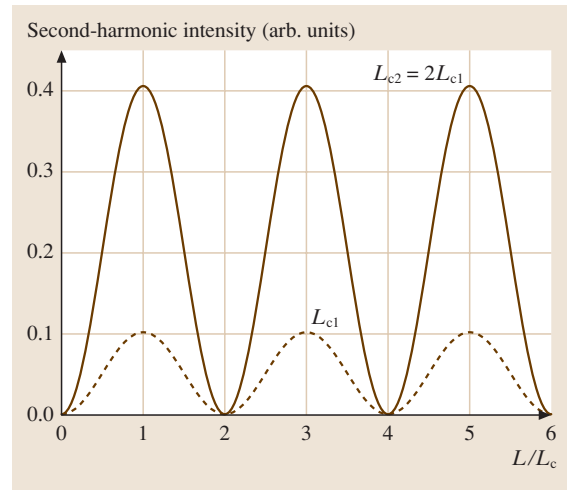

Fig. 4.2 Second-harmonic intensity as a function of the length L of the nonlinear medium normalized to the coherence length L_c for two values of L_c: (dashed line) L_{c1} and (solid line) $L_{c2} = 2L_{c1}$

Although the solution (4.29) describes the simplest regime of SHG, it is very instructive as it visualizes the significance of reducing the wave-vector mismatch Δk for efficient SHG. Since the wave vectors k_1 and k_2 are associated with the momenta of the pump and second-harmonic fields, $p_1 = \hbar k_1$ and $p_2 = \hbar k_2$, with $\hbar$ being the Planck constant, the condition $\Delta k = 0$, known as the phase-matching condition in nonlinear optics, in fact, represents momentum conservation for the SHG process, where two photons of the pump field are requited to generate a single photon of the second harmonic.

Several strategies have been developed to solve the phase-matching problem for SHG. The most practically significant solutions include the use of birefringent nonlinear crystals [4.13, 14], quasi-phase-matching in periodically poled nonlinear materials [4.15, 16] and waveguide regimes of nonlinear interactions with the phase mismatch related to the material dispersion compensated for by waveguide dispersion [4.7]. Harmonic generation in the gas phase, as demonstrated by *Miles* and *Harris* [4.17], can be phase-matched through an optimization of the content of the gas mixture. Figure 4.3 illustrates phase matching in a birefringent crystal. The circle represents the cross section of the refractive-index sphere $n_0(\omega)$ for an ordinary wave at the pump frequency ω. The ellipse is the cross section of the refractive-index ellipsoid $n_e(2\omega)$ for an extraordinary wave at the frequency of the second harmonic 2ω. Phase matching is achieved in the direction where $n_0\omega = n_e(2\omega)$, corresponding to an angle θ_{pm} with respect to the optical axis c of the crystal in Fig. 4.3.

When the phase-matching condition $\Delta k = 0$ is satisfied, (4.29) and (4.30) predict a quadratic growth of the

Fig. 4.4 The amplitudes of the pump and second-harmonic fields as functions of the normalized propagation distance z/z_{sh} with $z_{sh} = [\gamma\rho_{10}(0)]^{-1}$

second-harmonic intensity as a function of the length L of the nonlinear medium. This scaling law holds true, however, only as long as the second-harmonic intensity remains much less than the pump intensity. As $|A_2|$ becomes comparable with $|A_1|$, depletion of the pump field has to be taken into consideration. To this end, we introduce the real amplitudes ρ_j and phases φ_j of the pump and second-harmonic fields, $A_j = \rho_j \exp(i\varphi_j)$, with $j = 1, 2$. Then, assuming that $u_1 = u_2 = u$ and $\gamma_1 = \gamma_2 = \gamma$, we derive from (4.25) and (4.26)

$$\rho_1(\eta, z) = \rho_{10}(\eta)\,\text{sech}\,[\gamma\rho_{10}(\eta)\,z]\;, \tag{4.31}$$

$$\rho_2(\eta, z) = \rho_{10}(\eta)\,\text{tanh}\,[\gamma\rho_{10}(\eta)\,z]\;. \tag{4.32}$$

The solutions (4.31) and (4.32) show that the entire energy of the pump field in the phase-matching regime can be transferred to the second harmonic. As the pump field becomes depleted Fig. 4.4, the growth of the second-harmonic field saturates.

Effects related to the group-velocity mismatch become significant when the length of the nonlinear medium L exceeds the length $L_g = \tau_1/|u_2^{-1} - u_1^{-1}|$, where τ_1 is the pulse width of the pump field. The length L_g characterizes the walk-off between the pump and second-harmonic pulses caused by the group-velocity mismatch. In this nonstationary regime of SHG, the amplitude of the second harmonic in the constant-pump-

Fig. 4.3 Phase-matching second-harmonic generation in a birefringent crystal

field approximation is given by

$$A_2(z,t) = i\gamma_2 \int_0^z A_{10}^2 \left[t - z/u_2 + \xi \left(u_2^{-1} - u_1^{-1} \right) \right]$$
$$\times \exp(-i\Delta k \xi)\, d\xi\, . \qquad (4.33)$$

Group-velocity mismatch may lead to a considerable increase in the pulse width of the second harmonic τ_2. For $L \gg L_g$, the second harmonic pulse width, $\tau_2 \approx |u_2^{-1} - u_1^{-1}|z$, scales linearly with the length of the nonlinear medium and is independent of the pump pulse width.

4.3.2 Sum- and Difference-Frequency Generation and Parametric Amplification

In sum-frequency generation Fig. 4.1, two laser fields with frequencies ω_1 and ω_2 generate a nonlinear signal at the frequency $\omega_3 = \omega_1 + \omega_2$ in a quadratically nonlinear medium with a nonlinear susceptibility $\chi_{SFG}^{(2)} = \chi^{(2)}(\omega_3; \omega_1, \omega_2)$. In the first order of dispersion theory, the coupled equations for slowly varying envelopes of the laser fields $A_1 = A_1(z,t)$ and $A_2 = A_2(z,t)$ and the nonlinear signal $A_3 = A_3(z,t)$ are written as

$$\frac{\partial A_1}{\partial z} + \frac{1}{u_1}\frac{\partial A_1}{\partial t} = i\gamma_1 A_3 A_2^* \exp(i\Delta kz)\, , \qquad (4.34)$$

$$\frac{\partial A_2}{\partial z} + \frac{1}{u_2}\frac{\partial A_2}{\partial t} = i\gamma_2 A_3 A_1^* \exp(i\Delta kz)\, , \qquad (4.35)$$

$$\frac{\partial A_3}{\partial z} + \frac{1}{u_3}\frac{\partial A_3}{\partial t} = i\gamma_3 A_1 A_2 \exp(-i\Delta kz)\, , \qquad (4.36)$$

where

$$\gamma_1 = \frac{2\pi\omega_1^2}{k_1 c^2}\chi^{(2)}(\omega_1; \omega_3, -\omega_2)\, , \qquad (4.37)$$

$$\gamma_2 = \frac{2\pi\omega_2^2}{k_2 c^2}\chi^{(2)}(\omega_2; \omega_3, -\omega_1)\, , \qquad (4.38)$$

$$\gamma_3 = \frac{2\pi\omega_3^2}{k_3 c^2}\chi_{SFG}^{(2)} \qquad (4.39)$$

are the nonlinear coefficients, u_1, u_2, and u_3 and k_1, k_2, and k_3 are the group velocities and the wave vectors of the fields with frequencies ω_1, ω_2, and ω_3, respectively, and $\Delta k = k_1 + k_2 - k_3$ is the wave-vector mismatch for the SFG process.

As long as the intensity of the sum-frequency field remains much less than the intensities of the laser fields, the amplitudes of the laser fields can be can be assumed to be given functions of t, $A_1(z,t) = A_{10}(t)$ and

$A_2(z,t) = A_{20}(t)$, and the solution of (4.36) yields

$$A_3(z,t) = i\gamma_3 \int_0^z A_{10}\left[t - z/u_3 + \xi\left(u_3^{-1} - u_1^{-1}\right)\right]$$
$$\times A_{20}\left[t - z/u_3 + \xi\left(u_3^{-1} - u_2^{-1}\right)\right]$$
$$\times \exp(-i\Delta k\xi)\, d\xi\, . \qquad (4.40)$$

The efficiency of frequency conversion, as can be seen from (4.40) is controlled by the group delays $\Delta_{21} \approx |u_2^{-1} - u_1^{-1}|L$, $\Delta_{31} \approx |u_3^{-1} - u_1^{-1}|L$, and $\Delta_{32} \approx |u_3^{-1} - u_2^{-1}|L$ between the pulses involved in the SFG process. In particular, the laser fields cease to interact with each other when the group delay Δ_{21} starts to exceed the pulse width of the faster laser pulse.

In difference-frequency generation (DFG), two input fields with frequencies ω_1 and ω_2 generate a nonlinear signal at the frequency $\omega_3 = \omega_1 - \omega_2$. This process is of considerable practical significance as it can give rise to intense coherent radiation in the infrared range. In the limiting case of $\omega_1 \approx \omega_2$, this type of nonlinear-optical interaction corresponds to optical rectification, which has been intensely used over the past two decades for the generation of terahertz radiation.

If the field at the frequency ω_1 is strong and remains undepleted in the process of nonlinear-optical interaction, $A_1(z,t) = A_{10}(t)$, the set of coupled equations governing the amplitudes of the remaining two fields in the stationary regime is written as

$$\frac{\partial A_2}{\partial z} + \frac{1}{u_2}\frac{\partial A_2}{\partial t} = i\gamma_2 A_1 A_3^* \exp(i\Delta kz)\, , \qquad (4.41)$$

$$\frac{\partial A_3}{\partial z} + \frac{1}{u_3}\frac{\partial A_3}{\partial t} = i\gamma_3 A_1 A_2^* \exp(-i\Delta kz)\, , \qquad (4.42)$$

where,

$$\gamma_2 = \frac{2\pi\omega_2^2}{k_2 c^2}\chi^{(2)}(\omega_2; \omega_1, -\omega_3)\, , \qquad (4.43)$$

$$\gamma_3 = \frac{2\pi\omega_3^2}{k_3 c^2}\chi^{(2)}(\omega_3; \omega_1, -\omega_2) \qquad (4.44)$$

are the nonlinear coefficientsm and $\Delta k = k_1 - k_2 - k_3$ is the wave-vector mismatch for the DFG process.

With no signal at ω_3 applied at the input of the nonlinear medium, $A_3(0,t) = 0$, the solution to (4.41) and (4.42) in the stationary regime is given by [4.12]

$$A_2(z) = A_2(0)\left[\cosh(\kappa z) + i\frac{\Delta k}{2\kappa}\sinh(\kappa z)\right]\, , \qquad (4.45)$$

$$A_3(z) = iA_2(0)\sinh(\kappa z)\, , \qquad (4.46)$$

where

$$\kappa^2 = 4\gamma_2\gamma_3^* |A_1|^2 - (\Delta k)^2 . \tag{4.47}$$

Away from the phase-matching condition, the amplification of a weak signal is achieved only when the intensity of the pump field exceeds a threshold,

$$I_1 > I_{\text{th}} = \frac{n_1 n_2 n_3 c^3 (\Delta k)^2}{32\pi^3 \left|\chi_{\text{DFG}}^{(2)}\right|^2 \omega_2\omega_3} , \tag{4.48}$$

where we took

$$\chi^{(2)}(\omega_2; \omega_1, -\omega_3) \approx \chi^{(2)}(\omega_3; \omega_1, -\omega_2) = \chi_{\text{DFG}}^{(2)} .$$

Above, this threshold, the growth in the intensity I_2 of a weak input signal is governed by

$$I_2(z) = I_2(0) \left[\frac{\gamma_2\gamma_3^* |A_{10}|^2}{\kappa^2} \sin^2(\kappa z) + 1 \right]. \tag{4.49}$$

This type of three-wave mixing is often referred to as optical parametric amplification. A weak input field, referred to as the signal field (the field with the amplitude A_2 in our case), becomes amplified in this type of process through a nonlinear interaction with a powerful pump field (the undepleted field with the amplitude A_1 in the case considered here). In such a scheme of optical parametric amplification, the third field (the field with the amplitude A_3) is called the idler field.

We now consider the regime of optical parametric amplification $\omega_1 = \omega_2 + \omega_3$ where the pump, signal and idler pulses are matched in their wave vectors and group velocities. Introducing the real amplitudes ρ_j and phases φ_j of the pump, signal, and idler fields, $A_j = \rho_j \exp(i\varphi_j)$, where $j = 1, 2, 3$, assuming that $\gamma_2 = \gamma_3 = \gamma$ in (4.35) and (4.36), $A_1(z, t) = A_{10}(t)$ and $A_3(0, t) = 0$, we write the solution for the amplitude of the signal field as [4.18]

$$A_2(\eta, z) = A_{20}(\eta) \cosh[\gamma\rho_{10}(\eta) z] . \tag{4.50}$$

The idler field then builds up in accordance with

$$A_3(\eta, z) = A_{20}^*(\eta) \exp[i\varphi_{10}(\eta)] \sinh[\gamma\rho_{10}(\eta) z] . \tag{4.51}$$

As can be seen from (4.50), optical parametric amplification preserves the phase of the signal pulse. This property of optical parametric amplification lies at the heart of the principle of optical parametric chirped-pulse amplification [4.19], allowing ultrashort laser pulses to be amplified to relativistic intensities. It also suggests a method of efficient frequency conversion of few-cycle field waveforms without changing the phase offset between their carrier frequency and temporal envelope, making few-cycle laser pulses a powerful tool for the investigation of ultrafast electron dynamics in atomic and molecular systems.

In the nonstationary regime of optical parametric amplification, when the pump, signal, and idler fields propagate with different group velocities, useful and important qualitative insights into the phase relations between the pump, signal, and idler pulses can be gained from energy and momentum conservation, $\omega_1 = \omega_2 + \omega_3$ and $k_1 = k_2 + k_3$. These equalities dictate the following relations between the frequency deviations $\delta\omega_j$ in the pump, signal, and idler fields ($j = 1, 2, 3$):

$$\delta\omega_1 = \delta\omega_2 + \delta\omega_3 \tag{4.52}$$

and

$$\delta\omega_1/u_1 = \delta\omega_2/u_2 + \delta\omega_3/u_3 . \tag{4.53}$$

In view of (4.52) and (4.53), we find

$$\delta\omega_2 = q_2\delta\omega_1 \tag{4.54}$$

and

$$\delta\omega_3 = q_3\delta\omega_1, \tag{4.55}$$

where $q_2 = (u_1^{-1} - u_3^{-1})/(u_2^{-1} - u_3^{-1})$, $q_3 = 1 - q_2$.

In the case of a linearly chirped pump, $\varphi_1(t) = \alpha_1 t^2/2$, the phases of the signal and idler pulses are given by $\varphi_m(t) = \alpha_m t^2/2$, where $\alpha_m = q_m\alpha_1$, $m = 2, 3$. With $q_m \gg 1$, the chirp of the signal and idler pulses can thus considerably exceed the chirp of the pump field.

4.4 Third-Order Nonlinear Processes

Optical nonlinearity of the third order is a universal property, found in any material regardless of its spatial symmetry. This nonlinearity is the lowest-order nonvanishing nonlinearity for a broad class of centrosymmetric materials, where all the even-order nonlinear susceptibilities are identically equal to zero

for symmetry reasons. Third-order nonlinear processes include a vast variety of four-wave mixing processes, which are extensively used for frequency conversion of laser radiation and as powerful methods of nonlinear spectroscopy. Frequency-degenerate, Kerr-effect-type phenomena constitute another important class of third-

order nonlinear processes. Such effects lie at the heart of optical compressors, mode-locked femtosecond lasers, and numerous photonic devices, where one laser pulse is used to switch, modulate, or gate another laser pulse. In this section, we provide a brief overview of the main third-order nonlinear-optical phenomena and discuss some of their practical applications.

4.4.1 Self–Phase Modulation

The third-order nonlinearity gives rise to an intensity-dependent additive to the refractive index:

$$n = n_0 + n_2 I(t) \ , \tag{4.56}$$

where n_0 is the refractive index of the medium in the absence of light field, $n_2 = (2\pi/n_0)^2 \chi^{(3)}(\omega; \omega, \omega, -\omega)$ is the nonlinear refractive index, $\chi^{(3)}(\omega; \omega, \omega, -\omega)$ is the third-order nonlinear-optical susceptibility, referred to as the Kerr-type nonlinear susceptibility, and $I(t)$ is the intensity of laser radiation. Then, the nonlinear (intensity-dependent) phase shift of a pulse at a distance L is given by

$$\Phi(t) = \frac{\omega}{c} n_2 I(t) L \ . \tag{4.57}$$

Due to the time dependence of the radiation intensity within the light pulse, the nonlinear phase shift is also time-dependent, giving rise to a generally time-dependent frequency deviation:

$$\Delta\omega(t) = \frac{\omega}{c} n_2 L \frac{\partial I}{\partial t} \ . \tag{4.58}$$

The resulting spectral broadening of the pulse can be estimated in the following way:

$$\Delta\omega = \frac{\omega}{c} n_2 L \frac{I_0}{\tau} \ , \tag{4.59}$$

where I_0 is the peak intensity of the light pulse and τ is the pulse duration.

The first-order dispersion-theory equation for the slowly varying envelope $A(t, z)$ of a laser pulse propagating in a medium with a Kerr-type nonlinearity is written as [4.9]

$$\frac{\partial A}{\partial z} + \frac{1}{u} \frac{\partial A}{\partial t} = i\tilde{\gamma} |A|^2 A \ , \tag{4.60}$$

where u is the group velocity of the laser pulse and

$$\tilde{\gamma} = \frac{3\pi\omega}{2n_0^2 c} \chi^{(3)}(\omega; \omega, -\omega, \omega) \ . \tag{4.61}$$

is the nonlinear coefficient.

In the retarded frame of reference, $z' = z$ and $\eta = t - z/u$, the solution to (4.60) is written as

$$A(\eta, z) = A_0(\eta) \exp\left[i\tilde{\gamma} |A_0(\eta)|^2 z \right] \ , \tag{4.62}$$

where $A_0(\eta)$ is the initial field envelope.

Since the group-velocity dispersion was not included in (4.60), the shape of the pulse envelope remains unchanged as the pulse propagates through the nonlinear medium. The intensity-dependent change in the refractive index gives rise to a nonlinear phase shift

$$\varphi_{nl}(\eta, z) = \gamma_{SPM} I_0(\eta) z \ , \tag{4.63}$$

where $\gamma_{SPM} = 2\pi n_2/\lambda$ and $I_0(\eta)$ is the initial intensity envelope.

The deviation of the instantaneous frequency of the pulse is given by

$$\delta\omega(\eta, z) = -\frac{\partial \varphi_{nl}(\eta, z)}{\partial t} = -\gamma_{SPM} \frac{\partial I_0(\eta)}{\partial \eta} z \ . \tag{4.64}$$

A quadratic approximation of the pulse envelope,

$$I_0(\eta) \approx I_0(0) \left(1 - \frac{\eta^2}{\tau_0^2} \right) \ , \tag{4.65}$$

where τ_0 is the pulse width, which is valid around the maximum of the laser pulse, gives a linear chirp of the

Fig. 4.5 Self-phase-modulation-induced spectral broadening of a laser pulse with a central wavelength of $1.03\,\mu m$ (an input spectrum is shown by *curve 1*) in a fused-silica optical fiber with $n_2 = 3.2 \times 10^{-16}\,cm^2/W$: $\gamma_{SPM} I_0(0)z = 1.25$ (*curve 2*), 2.50 (*curve 3*), and 6.25 (*curve 4*)

pulse

$$\delta\omega\,(\eta, z) \approx -2\gamma_{\mathrm{SPM}} \frac{I_0\,(0)}{\tau_0^2}\,\eta z\,. \tag{4.66}$$

The spectrum of a self-phase-modulated pulse is given by

$$S\,(\omega) = \left| \int_0^\infty I\,(\eta) \exp\left[\mathrm{i}\omega\eta + \mathrm{i}\varphi_{\mathrm{nl}}\,(\eta) \right]\,\mathrm{d}\eta \right|^2\,. \tag{4.67}$$

Figure 4.5 illustrates SPM-induced spectral broadening of a short laser pulse with a central wavelength of $1.03\,\mu\mathrm{m}$, typical of ytterbium fiber lasers, in a fused-silica optical fiber with nonlinear refractive index $n_2 = 3.2 \times 10^{-16}\,\mathrm{cm}^2/\mathrm{W}$.

Thus, self-phase modulation results in spectral broadening of a light pulse propagating through a hollow fiber. This effect allows compression of light pulses through the compensation of the phase shift acquired by the pulse in a hollow fiber. Compensation of a linear chirp, corresponding to a linear time dependence of the instantaneous frequency, is straightforward from the technical point of view. Such a chirp arises around the maximum of a light pulse, where the temporal pulse envelope can be approximated with a quadratic function of time [see (4.65, 4.66)].

It is physically instructive to consider the compression of chirped light pulses in the time domain. Since the frequency of a chirped pulse changes from its leading edge to its trailing edge, dispersion of our compressor should be designed in such a way as to slower down the leading edge of the pulse with respect to the trailing edge of the pulse. In other words, the group velocities for the frequencies propagating with the leading edge of the pulse should be lower than the group velocities for the frequencies propagating with the trailing edge of the pulse. This can be achieved by designing a dispersive element with the required sign of dispersion and appropriate dispersion relation. Systems of diffraction gratings and, recently, multilayer chirped mirrors [4.20] are now widely used for the purposes of pulse compression. In certain regimes of pulse propagation, self-phase modulation and pulse compression may take place in the same medium.

4.4.2 Temporal Solitons

The nonlinear phase shift acquired by a laser pulse propagating through a medium with a Kerr nonlinearity can be balanced by group-velocity dispersion, giving rise to pulses propagating through the nonlinear dispersive medium with an invariant or periodically varying shape: optical solitons.

Optical solitons is a special class of solutions to the nonlinear Schrödinger equation (NLSE)

$$\mathrm{i}\frac{\partial q}{\partial\xi} + \frac{1}{2}\frac{\partial^2 q}{\partial\tau^2} + |q|^2\,q = 0\,. \tag{4.68}$$

The NLSE can describe the evolution of optical wave packets including the dispersion $\beta(\omega)$ of optical waves in a bulk material or in a waveguide structure through the power series expansion

$$\beta\,(\omega) \approx \beta\,(\omega_0) + \frac{1}{u}\,(\omega - \omega_0)$$
$$+ \frac{1}{2}\beta_2\,(\omega - \omega_0)^2 + \ldots\,, \tag{4.69}$$

where ω_0 is the central frequency of the wave packet, $u = (\partial\beta/\partial\omega|_{\omega=\omega_0})^{-1}$ is the group velocity, and $\beta_2 = \partial^2\beta/\partial\omega^2|_{\omega=\omega_0}$. Thus, with the NLSE (4.68) projected on laser pulses propagating in a nonlinear medium, q is understood as the normalized pulse envelope, $q = A/(P_0)^{1/2}$, with ξ being the normalized propagation coordinate, $\xi = z/L_\mathrm{d}$, $L_\mathrm{d} = \tau_0^2/|\beta_2|$ being the dispersion length, P_0 and τ_0 defined as the pulse width and the pulse peak power, respectively, and $\tau = (t - z/u)/\tau_0$.

The canonical form of the fundamental soliton solution to (4.68) is [20]

$$q\,(\xi, \tau) = \mathrm{sech}\,(\tau) \exp\left(\mathrm{i}\frac{\xi}{2} \right)\,. \tag{4.70}$$

The radiation peak power required to support such a soliton is given by

$$P_0 = |\beta_2|\,/(\gamma\tau_0^2)\,. \tag{4.71}$$

Solitons retain their stable shape as long as their spectrum lies away from the spectrum of dispersive waves that can propagate in the medium. High-order dispersion perturbs solitons, inducing Cherenkov-type wave-matching resonances between solitons and dispersive waves [4.21, 22]. Under these conditions solitons tend to lose a part of their energy in the form of blue-shifted dispersive-wave emission. For low pump-field powers, the generic wave-matching condition for such soliton–dispersive wave resonances is written [4.22] $\Omega = 1/2\varepsilon$, where Ω is the frequency difference between the soliton and the resonant dispersive wave and ε is the parameter controlling the smallness of perturbation of the nonlinear Schrödinger equation, which can be represented as $\varepsilon = |\beta_3/6\beta_2|$ for photonic-crystal fibers

(PCFs) with second-order dispersion $\beta_2 = \partial^2\beta/\partial\omega^2$ and third-order dispersion $\beta_3 = \partial^3\beta/\partial\omega^3$. This dispersive-wave emission of solitons is an important part of supercontinuum generation in nonlinear optical fibers, including photonic-crystal fibers.

4.4.3 Cross–Phase Modulation

Cross-phase modulation (XPM) is a result of nonlinear-optical interaction of at least two physically distinguishable light pulses (i. e., pulses with different frequencies, polarizations, mode structures, etc.) related to the phase modulation of one of the pulses (a probe pulse) due to the change in the refractive index of the medium induced by another pulse (a pump pulse).

The cross-action of a pump pulse with a frequency ω_1 on a probe pulse with a frequency ω_2 gives rise to a phase shift of the probe pulse, which can be written as [4.23].

$$\Phi_{\mathrm{XPM}}(\eta, z) = \frac{3\pi\omega_2^2}{c^2 k_2}\chi^{(3)}\left(\omega_{\mathrm{s}}; \omega_{\mathrm{s}}, \omega_{\mathrm{p}}, -\omega_{\mathrm{p}}\right)$$
$$\times \int_0^z \left|A_{\mathrm{p}}\left(\eta - \frac{\zeta}{\sigma}, 0\right)\right|^2 \mathrm{d}\zeta , \qquad (4.72)$$

where $\chi^{(3)}(\omega_{\mathrm{s}}; \omega_{\mathrm{s}}, \omega_{\mathrm{p}}, -\omega_{\mathrm{p}})$ is the third-order nonlinear-optical susceptibility of the medium; $1/\sigma = 11/u_1 - 1/u_2$; u_1 and u_2 are the group velocities of the pump and probe pulses, respectively; and k_2 is the wave number of the pump pulse. Taking the time derivative of the non-linear phase shift, we arrive at the following expression for the frequency deviation of the probe pulse

$$\delta\omega_{\mathrm{XPM}}(\eta, z) = -\frac{3\pi\omega_2^2}{c^2 k_2}\chi^{(3)}\left(\omega_{\mathrm{s}}; \omega_{\mathrm{s}}, \omega_{\mathrm{p}}, -\omega_{\mathrm{p}}\right)$$
$$\times \sigma\left[\left|A_{\mathrm{p}}(\eta, 0)\right|^2 - \left|A_{\mathrm{p}}\left(\eta - \frac{z}{\sigma}, 0\right)\right|^2\right] . \qquad (4.73)$$

Similarly to self-phase modulation, cross-phase modulation can be employed for pulse compression. The dependence of the chirp of the probe pulse on the pump pulse intensity can be used to control the parameters of ultrashort pulses [4.24]. Cross-phase modulation also opens the ways to study the dynamics of ultrafast nonlinear processes, including multiphoton ionization, and to characterize ultrashort light pulses through phase measurements on a short probe pulse [4.25].

4.4.4 Self–Focusing

Self-focusing is a spatial counterpart of self-phase modulation. While SPM originates from the time-dependent change in the refractive index induced by a laser pulse with an intensity envelope $I(t)$ varying in time, self-focusing is related to a nonlinear lens induced by a laser beam with a spatially nonuniform intensity distribution $I(r)$. Given a transverse intensity profile $I(r)$, the nonlinear additive to the refractive index is written as

$$n(r) = n_0 + n_2 I(r) . \qquad (4.74)$$

If the field intensity peaks at the center of the beam at $r = 0$, the nonlinear change in the refractive index also reaches its maximum at $r = 0$, yielding a focusing or defocusing lens, depending on the sign of n_2.

The stationary regime of self-focusing is governed by [4.9]

$$2\mathrm{i}k\frac{\partial A}{\partial z} + \Delta_\perp A = -2k^2\frac{\Delta n}{n_0}A , \qquad (4.75)$$

where $\Delta n = n_2 I = \tilde{n}_2|E|^2$, $\Delta_\perp$ is the transverse part of the Laplacian.

We consider a Gaussian beam and assume that this beam retains its profile as it propagates through the nonlinear medium,

$$A(r, z) = \frac{A_0}{f(z)}\exp\left[-\frac{r^2}{2a_0^2 f^2(z)} + \mathrm{i}\psi(z)\right] , \qquad (4.76)$$

where a_0 is the initial beam size, $f(z)$ characterizes the evolution of the beam size along the propagation coordinate z [$f(0) = 1$], and the function $\psi(z)$ describes the spatial phase modulation of the field.

In the paraxial approximation, $r \ll a_0 f(z)$, (4.75) and (4.76) give [4.18]

$$\frac{\mathrm{d}^2 f}{\mathrm{d}z^2} = \frac{\left(L_{\mathrm{df}}^{-2} - L_{\mathrm{nl}}^{-2}\right)}{f^3(z)} , \qquad (4.77)$$

where $L_{\mathrm{df}} = 2\pi a_0^2/\lambda$ and $L_{\mathrm{nl}} = a_0[2n_0/(n_2|A|^2)]^{1/2}$ are the characteristic diffraction and nonlinear lengths, respectively.

Solving (4.77), we arrive at

$$f^2(z) = 1 + \left(\frac{z}{L_{\mathrm{df}}}\right)^2\left(1 - \frac{P_0}{P_{\mathrm{cr}}}\right) , \qquad (4.78)$$

where P_0 is the total power of the laser beam and

$$P_{\mathrm{cr}} = \frac{c\lambda^2}{16\pi^2 n_2} \qquad (4.79)$$

is the critical power of self-focusing. The focal length of the nonlinear lens is given by

$$L_{\mathrm{sf}} = \frac{L_{\mathrm{df}}}{\left(\frac{P_0}{P_{\mathrm{cr}}} - 1\right)^{1/2}} . \qquad (4.80)$$

With $P_0 > P_{cr}$, the nonlinear lens leads to a beam collapse. In reality, beam collapse can be arrested by the saturation of optical nonlinearity occurring at high field intensities.

Beyond the paraxial approximation, the scenario of self-focusing is much more complicated. The beam does not collapse as a whole, as the focal length of the nonlinear lens for peripheral beams differs from the one for paraxial beams. In the quasistationary regime, i.e., when the pulse duration τ_0 is much larger than the characteristic response time of optical nonlinearity τ_{nl}, the length of self-focusing is a function of time, giving rise to moving foci [4.26]. In the nonstationary regime, i.e., on time scales less than τ_{nl}, the leading edge of the pulse experiences no focusing, but induces a nonlinear lens that focuses the trailing edge of the pulse. As a result, the beam becomes distorted, evolving to a hornlike pattern [4.27].

The equation of self-focusing (4.75) allows a waveguide solution [4.28], which corresponds to the regime where the nonlinear lens exactly compensates for the diffraction of the laser beam. This solution is, however, unstable with respect to infinitely small fluctuations, which either give rise to a diffraction divergence or lead to a beam collapse. Such nonlinear waveguides can be stabilized, as shown by *Fibich* and *Gaeta* [4.29], by reflections of light from guiding boundaries in optical waveguides. To illustrate this regime of nonlinear beam dynamics, we consider a cylindrical gas-filled hollow waveguide and define nondimensional cylindrical coordinates r and z as $r = R/R_0$ (R is the dimensional radial coordinate and R_0 is the inner radius of the hollow fiber) and $z = Z/L_{df}$ (Z is the dimensional longitudinal coordinate). The radial profiles $Q_\beta(r)$ of light intensity distribution in the waveguide solutions $\psi \propto \exp(i\beta z)Q_\beta(r)$ to the NLSE governing self-focusing (i.e., waveguides induced through the Kerr nonlinearity along the z-axis on a bounded domain with a circular symmetry) are described [28, 29] by solutions to the ordinary differential equation $\Delta_\perp Q_\beta - \beta Q_\beta + Q_\beta^3 = 0$ [$\Delta_\perp = \partial^2/\partial r^2 + (1/r)\partial/\partial r$], subject to the boundary conditions $dQ_\beta(0)/dr = 0$, $Q_\beta(1) = 0$. Although this model neglects the fields outside the fiber core (e.g., radiation modes), it provides useful physical insights into the spatial self-action in hollow PCFs. This differential equation has an infinite number of solutions $Q_\beta^{(n)}$, $n = 0, 1, 2, \ldots$. The Hamiltonians for all the guided modes $Q_\beta^{(n)}$ are positive, preventing the blowup of the profiles $Q_\beta^{(n)}$ in the presence of small fluctuations, thus stabilizing the nonlinear waveguides in a hollow fiber. The ground-state solution $Q_\beta^{(0)}$ is

a monotonically decreasing function of r, tending to a zeroth-order Bessel function in the case of low field amplitudes $Q_\beta^{(0)} \propto \varepsilon J_0(2.4r)$, where ε is a small parameter controlled by the field intensity and the nonlinearity of the gas filling the fiber.

Although the modes $Q_\beta^{(n)}$ are stable with respect to small perturbations, these solutions are centers, rather than attractors, in a conservative system [4.30]. However, mode solutions corresponding to Kerr-nonlinearity-induced waveguides may become attractors in systems with dissipation, e.g., in hollow waveguides

Fig. 4.6a–d Four-wave mixing: (**a**) general-type FWM, (**b**) third-harmonic generation, (**c**) coherent anti-Stokes Raman scattering, and (**d**) degenerate four-wave mixing

with losses. The circularly symmetric field distribution is then formed at the output of the hollow wave-guide regardless of the initial beam profile [30]. As demonstrated by *Moll* et al. [4.31], collapsing light beams tend to form universal, Townesian profiles [4.28] while undergoing self-focusing on an infinite domain in bulk materials. Unlike Townesian beam profiles, which are known to be unstable in free space, the ground-state waveguide modes observed in hollow photonic-crystal fibers [4.32] remain stable with respect to small fluctuations, in agreement with the theory of self-focusing on bounded domains [4.29, 30], resulting in no blowup until the critical power of beam collapse is reached.

4.4.5 Four–Wave Mixing

In general-type four-wave mixing (Fig. 4.6a), three laser fields with frequencies ω_1, ω_2, and ω_3 generate the fourth field with a frequency $\omega_{FWM} = \omega_1 \pm \omega_2 \pm \omega_3$. In the case when all three laser fields have the same frequency (for example, when all the three pump photons are taken from the same laser field), $\omega_{FWM} = 3\omega$ (Fig. 4.6b), and we deal with third-harmonic gener-ation (THG), which is considered in greater detail for short-pulse interactions in Sect. 4.4.9. If the fre-quency difference $\omega_1 - \omega_2$ of two of the laser fields is tuned to a resonance with a Raman-active mode of the nonlinear medium (Fig. 4.6c), the FWM process $\omega_{FWM} = \omega_1 - \omega_2 + \omega_3 = \omega_{CARS}$ is refereed to as coher-ent anti-Stokes Raman scattering (CARS). An FWM process involving four fields of the same frequency (Fig. 4.6d) with $\omega_{DFWM} = \omega = \omega - \omega + \omega$ corresponds to degenerate four-wave mixing (DFWM). The FWM field in this nonlinear-optical process is the phase-conjugate of one of the laser fields, giving rise to another name of this type of FWM – optical phase conjugation.

For the general-type FWM $\omega_{FWM} = \omega_1 + \omega_2 + \omega_3$, we represent the pump fields as

$$\boldsymbol{E}_j = \boldsymbol{A}_j \exp\left[i\left(\boldsymbol{k}_j \mathbf{r} - \omega_j t\right)\right] + \text{c.c.} , \qquad (4.81)$$

where $j = 1, 2, 3$ and $\boldsymbol{k}_j = \boldsymbol{k'}_j + i\alpha_j$ are the complex wave vectors of the pump fields.

The FWM signal is written as

$$\boldsymbol{E}_{FWM} = \boldsymbol{A}_{FWM} \exp\left[i\left(\boldsymbol{k}_{FWM} \mathbf{r} - \omega_{FWM} t\right)\right] + \text{c.c.} \qquad (4.82)$$

where $\boldsymbol{k}_{FWM} = \boldsymbol{k'}_{FWM} + i\alpha_{FWM}$ is the complex wave vector of the FWM fields.

The third-order nonlinear polarization responsible for the considered FWM process is

$$\boldsymbol{P}^{(3)}_{FWM} = \chi^{(3)}\left(\omega_{FWM}; \omega_1, \omega_2, \omega_3\right)$$

$$\vdots \boldsymbol{E}\left(\omega_1\right) \boldsymbol{E}\left(\omega_2\right) \boldsymbol{E}\left(\omega_3\right) . \qquad (4.83)$$

With no depletion of the pump fields, the SVEA equa-tions give the following expression for the envelope of the i-th Cartesian component of the FWM field [4.9]:

$$[A_{FWM}(z)]_i = -\frac{2\pi\omega^2_{FWM}}{k_{FWM}c^2} \chi^{(3)}\left(\omega_{FWM}; \omega_1, \omega_2, \omega_3\right)$$

$$\times A_{1j} A_{2k} A_{3l} \exp\left(\frac{i\Delta k z}{2}\right)$$

$$\times \exp\left(-\alpha_{FWM} z\right) \frac{\sin\left(\frac{\Delta k z}{2}\right)}{\frac{\Delta k z}{2}} z , \qquad (4.84)$$

where

$$\Delta k = k'_1 + k'_2 + k'_3 - k'_{FWM}$$
$$+ i\left(\alpha_1 + \alpha_2 + \alpha_3 - \alpha_{FWM}\right) \qquad (4.85)$$

is the z-component of the wave-vector mismatch.

Phase matching, as can be seen from (4.84), is the key requirement for high efficiency of frequency conversion in FWM. The fields involved in FWM can be phase matched by choosing appropriate angles between the wave vectors of the laser fields and the wave vector of the nonlinear signal or using the waveguide regime with the phase mismatch related to the material dispersion compensated by the waveguide dispersion component.

4.4.6 Optical Phase Conjugation

Optical phase conjugation is generally understood as the generation of an optical field with a time-reversed wave front, or with a conjugate phase. This effect can be used to correct aberrations in certain types of optical problems and systems [4.33]. Suppose that a light beam with an initially plane wave front propagates through an aberrat-ing medium, such as, for example a turbulent atmosphere or a material with inhomogeneities of the refractive index. The wave front of the light beam transmitted through such a medium is distorted. We now use an op-tical phase-conjugate process to generate the field with a wave front time-reversed with respect to the wave front of the beam transmitted through the aberrating system. As the phase-conjugate beam now propagates through the aberrating medium in the backward direction, its wave front becomes restored.

A phase-conjugate field can be produced through the degenerate four-wave mixing of light fields

$$E_j (r, t) = A_j (r, t) \exp \left[i \left(k_j r - \omega t \right) \right] + \text{c.c.} , \tag{4.86}$$

where $j = 1, 2, 3, 4$.

The phase-conjugate geometry of DFWM is shown in Fig. 6d. In this scheme, two strong counterpropagating pump fields E_1 and E_2 with the same frequency ω and wave vectors k_1 and $k_2 = -k_1$ illuminate a medium with a cubic nonlinearity $\chi_{\text{DFWM}}^{(3)} = \chi^{(3)}(\omega; \omega, -\omega, \omega)$. The DFWM interaction of these two pump fields with a weak signal of the same frequency ω and an arbitrary wave vector k_3 gives rise to a field with a frequency ω that propagates in the opposite direction to the signal beam and that is phase-conjugate of the signal field. The phase-conjugate field generated through DFWM can be instructively thought of as a result of scattering of the forward pump field off the grating induced by the backward pump and the signal field or as a result of scattering of the backward pump from the grating induced by the forward pump and the signal field.

The nonlinear polarization responsible for phase conjugation in DFWM is

$$P_{\text{DFWM}}^{(3)} = 6\chi_{\text{DFWM}}^{(3)} \vdots E_1 E_2 E_3^* . \tag{4.87}$$

If the depletion of the pump fields is negligible, the nonlinear propagation equation (4.24) for the considered DFWM process is reduced to the following two equations for the amplitude of the signal field and its phase-conjugate [4.1]

$$\frac{dA_3}{dz} = i\kappa_3 A_3 + i\kappa_4 A_4^*, \tag{4.88}$$

$$\frac{dA_4}{dz} = -i\kappa_3 A_4 - i\kappa_4 A_3^*, \tag{4.89}$$

where

$$\kappa_3 = \frac{12\pi\omega}{cn} \chi_{\text{DFWM}}^{(3)} \left(|A_1|^2 + |A_2|^2 \right) , \tag{4.90}$$

$$\kappa_4 = \frac{12\pi\omega}{cn} \chi_{\text{DFWM}}^{(3)} A_1 A_2 . \tag{4.91}$$

By introducing

$$A_3 = B_3 \exp (i\kappa_3 z) , \tag{4.92}$$

$$A_4 = B_4 \exp (-i\kappa_3 z) , \tag{4.93}$$

we reduce the set of equations (4.88) and (4.89) to

$$\frac{dB_3}{dz} = i\kappa_4 B_4^* , \tag{4.94}$$

$$\frac{dB_4}{dz} = -i\kappa_4 B_3^* . \tag{4.95}$$

The solution can now be written as

$$B_3^* (z) = -\frac{i |\kappa_4|}{\kappa_4} \frac{\sin (|\kappa_4| z)}{\cos (|\kappa_4| L)} B_4 (L)$$
$$+ \frac{\cos [|\kappa_4| (z - L)]}{\cos (|\kappa_4| L)} B_3^* (0) , \tag{4.96}$$

$$B_4 (z) = \frac{\cos (|\kappa_4| z)}{\cos (|\kappa_4| L)} B_4 (L)$$
$$- \frac{i\kappa_4}{|\kappa_4|} \frac{\sin [|\kappa_4| (z - L)]}{\cos (|\kappa_4| L)} B_3^* (0) , \tag{4.97}$$

where $B_3(0)$ and $B_4(L)$ are the boundary conditions for the signal and DFWM fields. With $B_4(L) = 0$, (4.97) gives

$$B_4 (0) = \frac{i\kappa_4}{|\kappa_4|} \tan (|\kappa_4| L) B_3^* (0) . \tag{4.98}$$

This expression visualizes the structure of the phase-conjugate field generated through DFWM. The intensity reflection coefficient of the DFWM medium serving as a phase-conjugate mirror is given by

$$R_{\text{DFWM}} = \tan^2 (|\kappa_4| L) . \tag{4.99}$$

As can be seen from (4.99), the reflectivity of the DFWM-based phase-conjugate mirror can exceed 100%. This becomes possible due to the energy supplied by the strong pump fields.

4.4.7 Optical Bistability and Switching

In optical bistability or multistability, an optical system has two or more than two stable states, most often represented by the intensity at the output of the system as a function of the input intensity. With the level of the output intensity determined by a certain operation on a light beam, a bi- or multistable system makes a decision in which state it will operate, acting as a switch for optical communications or optical data processing.

As an example of an optical bistable system, we consider a Fabry–Perot cavity with a Kerr-nonlinear medium inside. We assume that the cavity mirrors are identical and have an amplitude reflectance r and transmittance t. Let A_1, A_2 and A_3 be the amplitudes of the incident, reflected, and transmitted fields, respectively. The amplitudes of forward and backward waves inside the cavity will be denoted as B_1 and B_2, respectively. The amplitudes of the fields inside and outside the cavity are related by the expressions [4.1]

$$B_2 = rB_1 \exp (2ikL - \alpha L) , \tag{4.100}$$

$$B_1 = tA_1 + rB_2 , \tag{4.101}$$

where k is the wave number and α is the intensity absorption coefficient.

Solving (4.100) and (4.101), we arrive at the relation

$$B_1 = \frac{tA_1}{1 - r^2 \exp(2ikL - \alpha L)} , \qquad (4.102)$$

which is known as the Airy equation. When k or α is a strongly nonlinear function of the light intensity, (4.102) leads to a bistable behavior of the system in the transmitted field.

Let us assume that the absorption is negligible and rewrite (4.102) as

$$B_1 = \frac{tA_1}{1 - R \exp(i\delta)} , \qquad (4.103)$$

where $R = \rho^2 \exp(-i\varphi)$ is the intensity reflectance of the cavity mirrors and the phase shift δ, corresponding to a full round trip around the cavity, is given by

$$\delta = \delta_0 + \delta_{nl} , \qquad (4.104)$$

where

$$\delta_0 = \varphi = 2n_0 \frac{\omega}{c} L \qquad (4.105)$$

is the linear phase shift and

$$\delta_{nl} = 2n_2 I \frac{\omega}{c} L \qquad (4.106)$$

is the nonlinear phase shift, with $I = [cn/(2\pi)](|B_1|^2 + |B_2|^2) \approx [cn/(\pi)]|B_1|^2$

The ratio of the field intensity inside the cavity $I_2 = [cn/(2\pi)]|B_1|^2$, to the intensity of the incident field $I_1 = [cn/(2\pi)]|A_1|^2$ is now given by

$$\frac{I_2}{I_1} = F(I_2) , \qquad (4.107)$$

where

$$F(I_2) = \frac{1}{T + \frac{4R}{T} \sin^2\left(\frac{\delta}{2}\right)} , \qquad (4.108)$$

where T is the intensity transmittance of the cavity mirrors, and

$$\delta = \delta_0 + \frac{4n_2 \omega L}{c} I_2 . \qquad (4.109)$$

In Fig. 4.7, we present the function $F(I_2)$ and the ratio I_2/I_1, i. e., the left- and right-hand sides of (4.107), plotted as functions of the intensity I_2 for different input field intensities I_1. The points where the straight lines representing the left-hand side of (4.107) cross the plot of the Airy-type function $F(I_2)$ define the operation points

Fig. 4.7 The function $F(I_2)$ and the ratio I_2/I_1, appearing on the right- and left-hand sides of (4.107), plotted as functions of the intensity I_2 normalized to $I_0 = \lambda/(n_2 L)$ for different input field intensities I_1: (1) $I_1 = I'$, (2) $I_1 = I''$, and (3) $I_1 = I'''$, $I''' > I'' > I'$. The *circles* in the Airy-function curve show the range of input intensities where the operation of the Fabry–Perot cavity is unstable

of the nonlinear Fabry–Perot cavity. The circles in the Airy-function curve show the range of input intensities where the operation is unstable. As the input intensity I_1 is increased, the system displays a bistable behavior and hysteresis. More hysteresis loops and a multistable behavior are observed, as can be seen from Fig. 4.7, with a further increase in I_1.

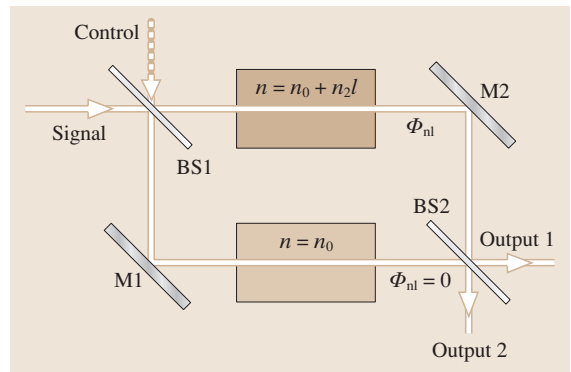

Fig. 4.8 Mach–Zehnder interferometer with a nonlinear medium in one of its arms, functioning as an all-optical switching device: BS1, BS2, beam splitters; M1, M2, mirrors

Optical switching can now be implemented [4.1] by including a nonlinear medium into one of the arms of a Mach–Zehnder interferometer Fig. 4.8. The intensities at the output ports 1 and 2 are determined by the interference of light fields transmitted through the arms of the interferometer. If there is only one input beam applied to the system with symmetric beam splitters BS1 and BS2, output intensities display an oscillating behavior as functions of the nonlinear phase shift Φ_{nl} acquired by the light field in one of the arms of the interferometer. When $\Phi_{nl} = 0$, the intensity at output port 1 is at its maximum, while the intensity at output port 2 is at its minimum. An opposite relation between the output intensities is achieved with $\Phi_{nl} = \pi$. The requirement $\Phi_{nl} = \pi$ is typical of a broad class of all-optical switching devices.

4.4.8 Stimulated Raman Scattering

Vibrations or rotations of molecules, electronic motions in atoms or collective excitations of matter can interact with light, shifting its frequency through an inelastic scattering process by the frequency Ω of Raman-active motions (as shown in Fig. 4.6c). This phenomenon was discovered by *Raman* and *Krishnan* [4.34] and almost simultaneously by *Mandelstam* and *Landsberg* [4.35] in 1928. In an intense laser field, pump laser photons and frequency-shifted photons act coherently to resonantly drive molecular motions, leading to the amplification of the Raman-shifted signal. This effect is called stimulated Raman scattering (SRS). In the SRS regime, Raman-active modes of a material function as optical modulators, forcing the driving laser field to oscillate at new frequencies. An intense laser field under these conditions not only gives rise to photons at new frequencies through interaction with Raman-active modes, but also amplifies the light consisting of those photons.

In the continuous-wave regime, the interaction between the pump field and the frequency-shifted (Stokes) signal is governed by the following set of coupled equations for the intensities of the pump I_p and Stokes I_s fields [4.23]:

$$\frac{dI_s}{dz} = g_R I_p I_s - \alpha_s I_s \ , \tag{4.110}$$

$$\frac{dI_p}{dz} = -\frac{\omega_p}{\omega_s} g_R I_p I_s - \alpha_p I_p \ . \tag{4.111}$$

Here, α_p and α_s are the losses at the frequencies of the pump and Stokes fields, ω_p and ω_s are the frequencies of the pump and Stokes fields, and g_R is the Raman gain, which is related to the imaginary part of the relevant third-order susceptibility [4.9],

$$g_R \propto \mathrm{Im}\left[\chi^{(3)} \left(\omega_s; \omega_p, -\omega_p, \omega_s \right) \right] \ . \tag{4.112}$$

Neglecting the action of the Stokes field on the pump, i. e., omitting the first term on the right-hand side of (4.111), we arrive at the following solution for the intensity of the Stokes field at the output of a Raman-active medium with a length L:

$$I_s (L) = I_s (0) \exp \left(g_R I_0 L_{eff} - \alpha_s L \right) \ , \tag{4.113}$$

where I_0 is the incident pump intensity at $z = 0$ and

$$L_{eff} = \frac{1}{\alpha_p} \left[1 - \exp \left(-\alpha_p L \right) \right] \ . \tag{4.114}$$

Thus, pump absorption restricts the nonlinear interaction length to L_{eff}.

In the absence of the Stokes field at the input of a Raman-active medium, $I_s(0) = 0$, the Stokes field builds up from spontaneous Raman scattering inside the medium. The power of the Stokes signal at the output of a medium with a length L is then given by

$$P_s (L) = \bar{P}_0 \exp \left[g_R (\omega_s) I_0 L_{eff} - \alpha_s L \right] \ , \tag{4.115}$$

where

$$\bar{P}_0 = \hbar \omega_s B_{eff}$$
$$B_{eff} = (2\pi)^{1/2} \left[|g_2(\omega_s)| I_0 L_{eff} \right]^{-1/2} \ ,$$

and

$$g_2(\omega_s) = (\partial^2 g_R / \partial \omega^2)|_{\omega = \omega_s} \ .$$

With an assumption of a Lorentzian Raman gain band, the critical pump power corresponding to the threshold of SRS effect is given by an approximate formula

$$P_{cr} \approx \frac{16 S_{eff}}{g_R L_{eff}} \ , \tag{4.116}$$

where S_{eff} is the effective mode area of the pump field.

In Sect. 4.6.3, we will consider in greater detail the influence of SRS on the propagation of ultrashort laser pulses in a nonlinear medium. It will be shown, in particular, that the Raman effect in fibers gives rise to a continuous frequency downshift of solitons propagating in optical fibers.

4.4.9 Third-Harmonic Generation by Ultrashort Laser Pulses

Third-harmonic generation (THG) is one of the basic nonlinear-optical processes, which has been intensely studied and employed for numerous applications since the early days of nonlinear optics [4.7–9]. The seminal work by *Miles* and *Harris* [4.17] has demonstrated a tremendous potential of direct THG related to the cubic optical nonlinearity $\chi^{(3)}$ of gases for efficient frequency conversion of laser radiation and for the diagnostics of the gas phase. Solid-state strategies of frequency conversion, on the other hand, mainly rely on the quadratic nonlinearity $\chi^{(2)}$ of non-centrosymmetric crystals, with frequency tripling conventionally implemented through cascaded second-order nonlinear-optical processes, phase matched by crystal anisotropy [4.13, 14] or periodic poling of nonlinear materials [4.16].

Photonic-crystal fibers (PCFs) [4.36, 37] – optical fibers of a new type where the solid continuous cladding of standard fibers is replaced by a microstructure with an array of air holes running along the fiber parallel to its core Fig. 4.9 – have opened a new phase in nonlinear optics [4.38, 39]. Controlled dispersion of guided modes [4.40] and large interaction lengths provided by these fibers for light fields strongly confined in a small fiber core [4.41] result in a radical enhancement of nonlinear-optical frequency conversion and spectral transformation of laser radiation through self- and cross-phase modulation (SPM and XPM) [4.38], supercontinuum generation [4.42–44], four-wave mixing (FWM) [4.45], third-harmonic generation [4.42–52], modulation instabilities [4.53], and soliton frequency shifting [4.54]. Third-order nonlinear-optical processes enhanced in PCFs now offer a useful alternative to frequency-conversion schemes using $\chi^{(2)}$ nonlinear crystals.

Highly efficient THG has recently been observed in fused silica [4.46–50] and multicomponent glass PCFs [4.51], as well as in tapered fibers [4.52]. These
Fig. 4.9a–d SEM images of photonic-crystal fibers: **(a)** periodic- and **(b)** double-cladding fused-silica PCFs, **(c)** high-index-step birefringent PCF, and **(d)** hollow-core PCF

experiments not only demonstrated the significance of THG for efficient, guided-wave frequency tripling of femtosecond laser pulses, but also revealed several new interesting nonlinear-optical phenomena. The third-harmonic signal has been shown to display asymmetric spectral broadening [4.51, 52] or even a substantial frequency shift. We will demonstrate here that such a behavior is a universal intrinsic feature of multi-mode guided-wave THG. Based on the arguments of the slowly varying envelope approximation (SVEA), we will show that the sign and the absolute value of the third-harmonic frequency shift, observed in many PCF experiments, is controlled by the phase- and group-index mismatch for the interacting pair of pump and third-harmonic modes. The possibility to tune the frequency of the main spectral peak in the spectrum of the third harmonic by varying the group-velocity mismatch is a unique property of THG-type processes, which is not typical of standard parametric FWM processes, where the first-order dispersion terms cancel out of the balance of the field momenta. New regimes of THG will be identified with no signal produced at the central frequency of the third harmonic $3\omega_0$ and with the pump energy efficiently converted to spectrally isolated narrowband frequency components, which can be tuned within a spectral range of several tens of terahertz from the $3\omega_0$ frequency.

We start with qualitative arguments illustrating phase matching for third-harmonic generation generalized to include the phase and group-velocity mismatch of the pump and third-harmonic fields, as well as the Kerr effect, broadening the pump spectrum through SPM. We represent the wave numbers (or the propagation constants of guided modes in a waveguide regime) k_p and k_h at the frequencies of the pump field and the third harmonic as

$$k_p(\omega) \approx k(\omega_0) + v_p^{-1}\Omega/3 + \kappa_{SPM}P , \qquad (4.117)$$

$$k_h(3\omega) \approx k(3\omega_0) + v_h^{-1}\Omega + 2\kappa_{XPM}P , \qquad (4.118)$$

where ω_0 is the central frequency of the pump field; $v_{p,h} = (\partial k/\partial\omega)^{-1}_{\omega_0, 3\omega_0}$ are the group velocities of the pump and its third harmonic; $\Omega = 3\omega - 3\omega_0$; $\kappa_{SPM} = \omega_0 n_2/cS_{eff}$ and $\kappa_{XPM} = 3\omega_0\bar{n}_2/cS_{eff}$ are the SPM and XPM nonlinear coefficients (S_{eff} is the effective beam, or mode, area and n_2 and $\bar{n}_2$ are the nonlinear refractive indices at ω_0 and $3\omega_0$, respectively); and P is the power of the pump field. In writing (4.117) and (4.118), we neglect group-velocity dispersion and higher-order dispersion effects, as well as the SPM of the third-harmonic field. With $n_2 \approx \bar{n}_2$, the phase mismatch

is then given by

$$\Delta k = k_h - 3k_p \approx \Delta k_0 + \xi\Omega + 3\kappa_{SPM}P , \qquad (4.119)$$

where $\Delta k_0 = k(3\omega_0) - 3k(\omega_0)$ is the phase mismatch of the pump and third-harmonic wave numbers at the central frequencies of these fields and $\xi = v_h^{-1} - v_p^{-1}$ is the group-velocity mismatch.

As can be seen from (4.119), the group delay of the pump and third-harmonic pulses is an important factor in THG momentum conservation. In this respect, the balance of momenta for THG radically differs from standard phase-matching conditions for parametric FWM processes [4.23], where the first-order dispersion order terms cancel out, reducing the FWM momentum balance to group-velocity dispersion (GVD)-related issues.

The phase-matching condition (4.119) suggests the possibility of substantially frequency shifting the maximum in the spectrum of the third harmonic. However, the amplitude of an Ω-shifted spectral component in the spectrum of the third harmonic and, hence, the efficiency of Ω-shifted peak generation is determined by the spectrum of the pump field. To specify this dependence, we proceed with an SVEA analysis of THG in the field of SPM-broadened pump field by writing SVEA coupled equations for the envelopes of the pump and third-harmonic fields, $A(t, z)$ and $B(t, z)$:

$$\left(\frac{\partial}{\partial t} + \frac{1}{v_p}\frac{\partial}{\partial z}\right)A = i\gamma_1 A |A|^2 , \qquad (4.120)$$

$$\left(\frac{\partial}{\partial t} + \frac{1}{v_h}\frac{\partial}{\partial z}\right)B = i\beta(A)^3 \exp(-i\Delta k_0 z)$$
$$+ 2i\gamma_2 B |A|^2 , \qquad (4.121)$$

where v_p and v_h are the group velocities of the pump and third-harmonic pulses, respectively, and γ_1, γ_2 and β are the nonlinear coefficients responsible for SPM, XPM, and THG, respectively; and $\Delta k = k_h - 3k_p$ is the phase mismatch (or the difference of propagation constants in the guided-wave regime) in the absence of the nonlinear phase shifts of the pump and third-harmonic fields.

Solution of (4.120) and (4.121) yields [4.24, 55]

$$A(t_p, z) = A_0(t_p)\exp\left[i\varphi_{SPM}(t_p, z)\right] , \qquad (4.122)$$

$$B(t_h, z) = i\sigma \int_0^z dz' A_0^3(t_h + \xi z')$$
$$\times \exp\left[-i\Delta\beta_0 z' + 3i\varphi_{SPM}(t_h + \xi z', z')\right.$$
$$\left. + i\varphi_{XPM}(t_h, z', z')\right] , \qquad (4.123)$$

where $t_l = (t - z/v_l)$ with $l = p, h$ for the pump and the field, respectively; $A_0(t)$ is the initial-condition envelope

of the pump pulse;

$$\varphi_{\text{SPM}}\left(t_{\text{p}}, z\right) = \gamma_1 \left|A_0\left(t_{\text{p}}\right)\right|^2 z \tag{4.124}$$

is the SPM-induced phase shift of the pump field; and

$$\varphi_{\text{XPM}}\left(t_{\text{h}}, z', z\right) = 2\gamma_2 \int\limits_{z'}^{z} \left|A_0\left(t_{\text{h}} + \xi z'\right)\right|^2 \, \mathrm{d}z' \tag{4.125}$$

is the XPM-induced phase shift of the third-harmonic field.

In the regime where the nonlinear phase shifts, given by (4.124) and (4.125), are small, the Fourier transform of (4.123) yields the following expression for the spectrum of the third-harmonic intensity:

$$I\left(\Omega, z\right) \propto \beta^2 \frac{\sin^2\left[\left(\Delta k_0 + \Omega\xi\right)\frac{z}{2}\right]}{\left(\Delta k_0 + \Omega\xi\right)^2}$$
$$\times \left| \int\limits_{-\infty}^{\infty} \int\limits_{-\infty}^{\infty} A\left(\Omega - \Omega'\right) A\left(\Omega' - \Omega''\right) \right.$$
$$\left. \times A\left(\Omega''\right) \, \mathrm{d}\Omega' \mathrm{d}\Omega'' \right|^2, \tag{4.126}$$

where $A(\Omega)$ is the spectrum of the input pump field. Analysis of the regime of small nonlinear phase shifts is thus very instructive as it allows phase-matching effects to be decoupled from the influence of the spectrum of the pump field. While the phase matching is represented by the argument in the exponential in the first factor on the right-hand side of (4.126), the significance of the pump spectrum is clear from the convolution integral appearing in this expression. Depending on the signs of the phase and group-velocity mismatch, Δk_0 and ξ, the peak in the spectrum of the third harmonic can be either red- or blue-shifted with respect to the frequency $3\omega_0$. The spectral width of this peak, as can be seen from (4.126), is given by $\delta \approx 2\pi(|\xi|z)^{-1}$, decreasing as z^{-1} with the growth in the propagation coordinate z (see inset in Fig. 4.10).

With low pump powers, the generalized phase-matching condition (4.119), as can be seen also from the exponential factor in (4.126), defines the central frequency $3\omega_0 + \Omega_{\text{max}}$, $\Omega_{\text{max}} = -\Delta k_0/\xi$, of the peak in the spectrum of the third harmonic. The amplitude of this peak, as shown by (4.126), is determined by the amplitudes of the pump field components with frequencies $\omega_1 = \omega_0 + \Omega_{\text{max}} - \Omega'$, $\omega_2 = \omega_0 + \Omega' - \Omega''$ and $\omega_3 = \omega_0 + \Omega''$, which can add up to transfer the energy to the $3\omega_0 + \Omega_{\text{max}}$ component in the spectrum of the

Fig. 4.10 Spectra of the third harmonic generated in the regime of weak self-phase modulation of the pump field with $\Delta k_0\tau/\xi = -2$ (*curve 1*), -3 (2) and 0 (3). The *inset* illustrates narrowing of the main peak in the spectrum of the third harmonic with $\Delta k_0\tau/\xi = -1$ and $\xi L/\tau = 2$ (1), 4 (2), and 10 (3)

third harmonic through the $\omega_1 + \omega_2 + \omega_3 = 3\omega_0 + \Omega_{\text{max}}$ process. The spectrum of the pump field should therefore be broad enough to provide a high amplitude of this peak. In the regime when the SPM-induced broadening of the pump spectrum is small, the tunability range of the third harmonic (i.e., the range of frequency offsets Ω) is mainly limited by the bandwidth of the input pump field. This regime of THG is illustrated in Fig. 4.10. As the ratio $\Delta k_0\tau/\xi$ changes from -2 (curve 1) to -3 (curve 2), the peak in the spectrum of the third harmonic is bound to shift from $\Omega_{\text{max}} = 2/\tau$ to $3/\tau$. A similar spectral shift limited by a field-unperturbed pump spectrum has been earlier predicted by *Akhmanov* et al. for second-harmonic generation [4.56]. For large $|\Delta k_0/\xi|$, however, the pump power density at the wings of the spectrum is too low to produce a noticeable peak with $\Omega_{\text{max}} = -\Delta k_0/\xi$ in the spectrum of the third harmonic (cf. curves 2 and 3 in Fig. 4.10).

In the general case of non-negligible nonlinear phase shifts, phase-matching effects cannot be decoupled from the influence of the pump spectrum, and we resort to approximate integration methods to identify the main features of the THG process. For a pump pulse with a Gaussian envelope, $A_0(t_p) = \tilde{A} \exp[-t_{\text{p}}^2/(2\tau^2)]$, where $\tilde{A}$ and τ are the amplitude and the initial duration

of the pump pulse, the spectrum of the third harmonic, in view of (4.123), is given by

$$B(\Omega, z) = i\beta\tilde{A}^3 \int_{-\infty}^{\infty} dt_h \int_0^z dz'$$

$$\times \exp\left[-\frac{3(t_h + \xi z')^2}{2\tau^2} - i\Delta k_0 z' + 3i\gamma_1 \left|\tilde{A}\right|^2 \right]$$

$$\times \exp\left(-\frac{(t_h + \xi z')^2}{\tau^2} \right) z' \right]$$

$$\times \exp\left[2i\gamma_2 \left|\tilde{A}\right|^2 \int_{z'}^z dz'' \right]$$

$$\times \exp\left(-\frac{(t_h + \zeta z'')^2}{\tau^2} \right) + i\Omega t_h \right] \tag{4.127}$$

Changing the order of integration in (4.127), we apply the saddle-point method to estimate the integral in dt_h:

$$B(\Omega, z) \propto i\beta\tilde{A}^3 \tau \int_0^z dz'$$

$$\times \exp\left\{ -i\left(\Delta k_0 + \Omega\xi - 3\gamma_1|\tilde{A}|^2 \right) z' \right.$$

$$\left. + 2i\gamma_2|\tilde{A}|^2 \frac{\tau}{\xi} \Phi\left[(z - z')\frac{\xi}{\tau} \right] \right\}, \tag{4.128}$$

where $\Phi(x) = \int_0^x \exp(-x^2)\,dx$.

With $\zeta z/\tau \gg 1$ and $\Phi[(z - z')\zeta]$ constant, the phase matching is controlled by the factor

$$F(\Omega, z) = \frac{\sin^2\left[\left(\Delta k + \Omega\xi + 3\gamma_1 \left|\tilde{A}\right|^2 \right) \frac{z}{2} \right]}{\left(\Delta k + \Omega\xi + 3\gamma_1 \left|\tilde{A}\right|^2 \right)^2}.$$

$$\tag{4.129}$$

Thus, the saddle-point estimate of the SVEA integral for the third-harmonic field recovers the generalized phase-matching condition in the form of (4.119). The frequency offset Ω_{max} providing the maximum efficiency of THG is now determined by the dispersion of the material, its nonlinear properties, and the intensity of the pump field.

Spectral broadening of the pump field due to SPM radically expands the tunability range of the third harmonic (Fig. 4.11). With $\gamma I_0 L = 1$ (L is the interaction length and I_0 is the pump-field peak intensity), the spectrum of the pump field is broad enough to produce a high-amplitude peak at $\Omega_{\text{max}} = -6/\tau$. The peak be-

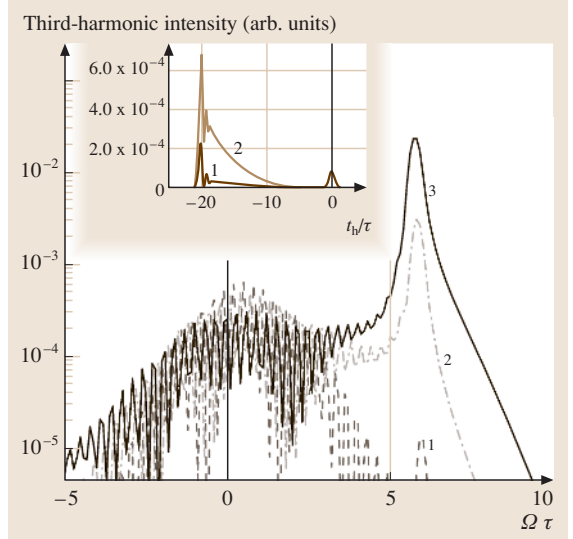

Fig. 4.11 Spectra of the third harmonic generated with no SPM of the pump (*curve 1*) and with an SPM-broadened pump (*curves 2, 3*) with $\gamma I_0 L = 1$ (1) and 2 (2); $\Delta k_0 \tau/\xi = -6$, $\xi L = 20$. The insets show the temporal structure of the third harmonic for $\gamma I_0 L = 1$ (1) and 2 (2) with $\xi L/\tau = 20$

comes narrower as the length of the nonlinear medium increases (cf. curves 2 and 3 in Fig. 4.11), suggesting a convenient way for an efficient generation of short-wavelength radiation with a well-controlled spectrum for spectroscopic and metrological applications. In the time domain, the third harmonic tends to break up into two pulses, as shown in the inset to Fig. 4.11 for $\gamma I_0 L = 1$ (curve 1) and 2 (curve 2) with $\xi L\tau = 20$. The first peak at $t_h\tau = -20$ represents a third-harmonic pulse that propagates with the pump pulse and that is phase-matched to the pump field in the sense of (4.119). The second pulse propagates with the group velocity of the third harmonic and is group-delayed in our case with respect to the pump field. Due to the phase matching, the ratio of the amplitudes of the first and second peaks increases with the growth in $\gamma I_0 L$ (cf. curves 1 and 2 in the inset to Fig. 4.11).

Examples of frequency-shifted THG can be found in the recent literature on nonlinear optics of PCFs and tapered fibers [4.48–52]. Interesting collinear and Cherenkov-type intermode phase-matching options [4.50, 51] have been highlighted. The nature of the frequency shift has been identified in [4.57, 58]. Generation of an asymmetrically broadened and spectrally shifted third harmonic is the most frequently encountered situation, observed in nonlinear-optical ex-
Fig. 4.12 The phase mismatch $\Delta k_0(1)$, group-velocity mismatch ξ (2), and the effective phase mismatch $\Delta k_0 + \xi\Omega$ (3) for third-harmonic generation in an air-clad fused-silica fiber with a core radius of 0.9 μm. The pump wavelength is 1.25 μm. The vertical dashed line shows the wavelength λ = 383 nm, where $\Delta k_0 + \xi\Omega = 0$. The insets show a typical experimental spectrum of blue visible emission (1) and the spectrum of the Cr:forsterite laser pump field (2) at the output of a photonic-crystal fiber with a length of 10 cm (after [4.57])

periments with PCFs [4.49–51] and tapered fibers [4.52]. The two most striking recent experimental findings include the observation of a 260 nm spectral component generated by Ti:sapphire laser pulses in high-delta PCFs [4.49] and the generation of a spectrally isolated frequency component at 380 nm by femtosecond pulses of 1.25 μm Cr:forsterite laser radiation [4.59]. In the former case, the central wavelength of the ultraviolet (UV) component remained stable [4.49] as the central pump wavelength was tuned from 770 to 830 nm [which seems to agree well with the phase-matching condition of (4.119)]. In the latter case, generation of the blue-shifted third harmonic allowed a highly efficient frequency conversion of pump radiation over the frequency interval exceeding 540 THz [4.59]. The spectral peak of visible blue emission was shifted from the frequency $3\omega_0$ in these experiments by 34 nm (a typical

spectrum is presented in the inset to Fig. 4.12), with no signal produced at $3\omega_0$.

To identify the main features of the dramatic frequency shift in the spectrum shown in the inset to Fig. 4.12, we consider the dispersion of guided modes in an air-clad fused-silica thread as a generic example of PCF dispersion. In Fig. 4.12, we plot the phase and group-velocity mismatch, Δk_0 and ξ, as well as the effective phase mismatch $\Delta k_{\text{eff}} = \Delta k_0 + \xi\Omega$ for intermodal THG in an air-clad fused silica fiber with a core radius of 0.9 μm. We assume that the pump field is coupled into the fundamental mode of the fiber, while the third harmonic is generated in one of high-order HE_{13}-type modes. The effective phase mismatch Δk_{eff} passes through zero at the wavelength of 383 nm, corresponding to a frequency shift of about 63 THz relative to $3\omega_0$, which agrees well with the typical spectrum of blue emission from a PCF [4.59] presented in inset 1 to Fig. 4.12. The main features and dominant tendencies of the third-harmonic spectrum are adequately described by (4.119) and (4.127). Comparison of the pump (inset 2 to Fig. 4.12) and third-harmonic spectra presented in Fig. 4.11 also suggests that a blue shifting of the main peak in the spectrum of the third harmonic by more than 60 THz becomes possible due to a strong broadening of the pump field, which is, of course, not only due to SPM in realistic conditions of PCF experiments.

We have shown that third-harmonic generation in the field of spectrally broadened short pump pulses can display interesting and practically significant new features. A short-pulse pump field broadened due to self-phase modulation can generate its third harmonic within a broad spectral range. However, the phase-matching condition generalized to include the phase and group-velocity mismatch of the pump and third-harmonic fields, as well as the Kerr-nonlinearity-induced spectral broadening of the pump field, tends to select a narrow spectral region of efficient THG. The possibility to tune the frequency of the main spectral peak in the spectrum of the third harmonic by varying the group-velocity mismatch is a unique property of THG-type processes, which is not typical of standard parametric FWM processes, where the first-order dispersion terms cancel out of the balance of the field momenta. For pump fields with large nonlinear frequency deviations, this spectral region may lie several tens of terahertz away from the central frequency of the third harmonic $3\omega_0$. This non-3ω THG process, leading to no signal at $3\omega_0$, is shown to result in interesting and practically significant spectral-transformation phenomena in photonic-crystal fibers.

4.5 Ultrashort Light Pulses in a Resonant Two-Level Medium: Self-Induced Transparency and the Pulse Area Theorem

4.5.1 Interaction of Light with Two-Level Media

The phenomenological approach based on nonlinear-optical susceptibilities does not include nonstationary phenomena related to a dynamic modification of the nonlinear medium by the laser field. Interaction of a resonant laser field with a two-level system is a physically interesting and methodologically important regime where the equations governing the evolution of the laser field in a nonlinear medium can be solved self-consistently with the equations of motion for the quantum system interacting with the field. Such a self-consistent analysis reveals the existence of a remarkable regime of nonlinear-optical interactions. A resonance laser pulse whose amplitude and pulse width are carefully matched to the two-level system can propagate in a two-level medium with no absorption-induced attenuation of the pulse amplitude, a phenomenon known as self-induced transparency.

The interaction of laser radiation with a two-level system is a classic problem of laser physics [4.60]. It has been extensively studied with the use of various approximate analytical approaches and numerical procedures over four decades, revealing important aspects of the interaction of laser radiation with a two-level system and, generally, laser–matter interactions. The standard approach based on the slowly varying envelope approximation (SVEA) and rotating-wave approximation gives Maxwell–Bloch equations in the case of a two-level atom [4.60, 61]. These equations provide an adequate description of laser radiation propagating in resonant media within a broad range of parameters and give the key to understanding such fundamental resonant optical phenomena as the formation of 2π solitons and self-induced transparency [4.60–63].

As shown in the classic works by *McCall* and *Hahn* [4.62, 63], light pulses with pulse areas multiple of π can propagate in a two-level medium with no changes in their shape, while pulses with other pulse areas tend to change their areas during the propagation in a two-level medium evolving to pulses with areas multiple of p. Much analytical and numerical work has been done over the past decade to extend this SVEA result to ultrashort pulses. *Eberly* [4.64] has rederived the area theorem for the case of short light pulses, modifying this theorem to include pulse chirping and homogeneous damping. *Ziolkowski* et al. [4.65]

applied the finite-difference time-domain (FDTD) technique [4.66] to solve the semiclassical Maxwell–Bloch equations numerically. This approach revealed several important features of short-pulse propagation in a two-level medium and allowed a more detailed analysis of self-induced transparency effects. *Hughes* [4.67, 68] has employed the FDTD approach to demonstrate the possibility of generating sub-femtosecond transients in a two-level medium.

Tarasishin et al. [4.69] have applied FDTD technique to integrate jointly the Maxwell and Schrödinger equations for an ultrashort light pulse propagating in a two-level medium. Below in this section, we explain the FDTD-based algorithm [4.69] solving the Maxwell and Schrödinger equations to model the interaction of ultrashort laser pulses with an ensemble of two-level atoms. FDTD simulations presented below reveal interesting regimes of short-pulse propagation and amplification in two-level media, including the evolution of the pulse to a 2π soliton, amplification of a single-cycle pulse in a medium with a spatially modulated distribution of dipole moments of resonant transitions, and amplification of chirped light pulses.

4.5.2 The Maxwell and Schrödinger Equations for a Two-Level Medium

We shall start with the extension of the standard FDTD procedure to the case of short pulses propagating in a two-level medium, when the Maxwell equation for the fields and the Schrödinger equation for the wave functions should be solved without any assumptions that are usually employed in the SVEA approach. In the one-dimensional case, the FDTD algorithm involves step-by-step integration of two Maxwell curl equations

$$\frac{\partial D_z(x,t)}{\partial t} = \frac{\partial H_y(x,t)}{\partial x} \,, \tag{4.130}$$

$$\frac{\partial H_y(x,t)}{\partial t} = \frac{\partial E_z(x,t)}{\partial x} \,. \tag{4.131}$$

To perform this integration, we have to define the relation between the components of the electromagnetic induction and the electromagnetic field. This can be done through the equation for the polarization of the medium. In our case of a two-level medium, this involves the solution of the Schrödinger equation for the wave functions of the energy levels.

We will consider an ensemble of noninteracting two-level atoms or molecules whose wave functions can be represented as superpositions of two basis states 1 and 2:

$$\psi(t) = a(x, t)\psi_1 + b(x, t)\psi_2, \qquad (4.132)$$

where ψ_1 and ψ_2 are the eigenfunctions of an unperturbed system corresponding to the states with energies E_1 and E_2 (we assume for definiteness that $E_1 > E_2$), respectively, and $a(x, t)$ and $b(x, t)$ are complex coefficients. Then, the Schrödinger equation for the wave function yields the following set of differential equations:

$$i\hbar \frac{da(x, t)}{dt} = E_1 a(x, t) - \mu E_z(x, t) b(x, t), \quad (4.133)$$

$$i\hbar \frac{db(x, t)}{dt} = E_2 b(x, t) - \mu E_z(x, t) a(x, t), \quad (4.134)$$

where μ is the dipole moment of transition between the levels 1 and 2. Following *Feynman* et al. [4.68], we introduce real combinations of the complex quantities $a(x, t)$ and $b(x, t)$:

$$r_1(x, t) = a(x, t)b^*(x, t) + a^*(x, t)b(x, t), \quad (4.135)$$

$$r_2(x, t) = i[a(x, t)b^*(x, t) - a^*(x, t)b(x, t)], \quad (4.136)$$

$$r_3(x, t) = a(x, t)a^*(x, t) - b(x, t)b^*(x, t), \quad (4.137)$$

$$r_4(x, t) = a(x, t)a^*(x, t) + b(x, t)b^*(x, t). \quad (4.138)$$

The physical content of the parameters defined by (4.135–4.138) is well known from classic textbooks on coherent optics [4.60, 61]. It can be easily verified using the set (4.133) and (4.134) that $r_4(x, t)$ is independent of time and can be interpreted as the probability to find the system in either state 1 or state 2. The quantities $r_1(x, t)$ and $r_3(x, t)$ play an especially important role. Depending on the sign of $r_3(x, t)$, resonant electromagnetic radiation can be either amplified or absorbed by a two-level system. The quantity $r_1(x, t)$ controls the polarization of the medium in the case of a linearly polarized light field:

$$P_z(x, t) = 4\pi\mu r_1(x, t)N, \qquad (4.139)$$

where N is the volume density of two-level atoms or molecules. Thus, the quantity $r_1(x, t)$ defines the sought relation between the components of the electromagnetic induction and the electromagnetic field.

Using (4.133) and (4.134), we arrive at the following set of equations for the quantities defined by (4.135–4.137):

$$\frac{dr_1(x, t)}{dt} = -\omega_0 r_2(x, t), \qquad (4.140)$$

$$\frac{dr_2(x, t)}{dt} = \omega_0 r_1(x, t) + 2(\mu/\hbar) E_z(x, t)r_3(x, t), \qquad (4.141)$$

$$\frac{dr_3(x, t)}{dt} = -2(\mu/\hbar) E_z(x, t)r_2(x, t), \qquad (4.142)$$

where $\omega_0 = (E_1 - E_2)/\hbar$. Differentiating (4.141), using (4.140) for $dr_1(x, t)/dt$, and taking into consideration that $r_1(x, t) = P_z(x, t)/(\mu N) = [D_z(x, t) - E_z(x, t)]/(4\pi\mu N)$, we find that

$$\frac{d^2 D_z(x, t)}{dt^2} - \frac{d^2 E_z(x, t)}{dt^2} + \omega_0^2 [D_z(x, t) - E_z(x, t)]$$
$$+ 2\frac{4\pi\mu^2\omega_0 N}{\hbar} E_z(x, t)r_3(x, t) = 0, \qquad (4.143)$$

$$\frac{dr_3(x, t)}{dt} = \frac{2}{4\pi\hbar\omega_0 N} E_z(x, t)$$
$$\times \left(\frac{dD_z(x, t)}{dt} - \frac{dE_z(x, t)}{dt} \right). \quad (4.144)$$

The FDTD approach involves difference approximation [4.66] of time and spatial derivatives involved in (4.130) and (4.131):

$$D_{z,i}^{n+1} = D_{z,i}^n + \frac{\Delta t}{\Delta x}(H_{y,i+1/2}^{n+1/2} - H_{y,i-1/2}^{n+1/2}), \quad (4.145)$$

$$H_{y,i+1/2}^{n+3/2} = H_{y,i+1/2}^{n+1/2} + \frac{\Delta t}{\Delta x}(E_{z,i+1}^{n+1} - E_{z,i}^{n+1}), \quad (4.146)$$

where i and n indicate the values of discrete spatial and temporal variables, respectively, $x = i\Delta x$, $t = n\Delta t$, Δx and Δt are the steps of discretization in spatial and temporal variables. This approach yields the following set of difference equations:

$$E_{z,i}^{n+1} = D_{z,i}^{n+1} + D_{z,i}^{n-1} - E_{z,i}^{n-1}$$
$$+ \frac{\left(4E_{z,i}^n - 4D_{z,i}^n + 4\Delta t^2 \frac{4\pi\mu^2\omega_0 N}{\hbar} E_{z,i}^{n-1} r_{3,i}^{n-1} \right)}{2 + \Delta t^2 \omega_0^2}, \qquad (4.147)$$

$$r_{3,i}^{n+1} = r_{3,i}^{n-1} + 0.5\frac{2}{4\pi\hbar\omega_0 N} \left(E_{z,i}^{n+1} + E_{z,i}^n \right)$$
$$\times \left(D_{z,i}^{n+1} - D_{z,i}^{n-1} - E_{z,i}^{n+1} + E_{z,i}^{n-1} \right). \qquad (4.148)$$

Thus, we arrive at the following closed algorithm of numerical solution:

1. substitute $D_{z,i}^{n+1}$ determined from (4.145) for the current value of the discrete-time variable into the set

of (4.147) and (4.148) and determine the values of $r_{3,i}^{n+1}$ and $E_{z,i}^{n+1}$,

2. substitute the quantities thus determined into (4.146) and determine the values of the magnetic field $H_{y,i}^{n+3/2}$,

3. substitute these values of the magnetic field into (4.145) and repeat the procedure for the next value of the discrete-time variable.

4.5.3 Pulse Area Theorem

To test the FDTD-based procedure of simulations described in Sect. 4.5.2, we model the propagation of light pulses

$$E(x, t) = A(x, t) e^{i\phi + ikz - i\omega t} + \text{c.c.}, \tag{4.149}$$

where $A(x, t)$ is the pulse envelope, in a two-level medium and compare the results of these simulations with the predictions of the McCall–Hahn area theorem [4.62, 63]. This plan can be accomplished by keeping track of the pulse area

$$\theta(x) = \int_{-\infty}^{\infty} \Omega(x, \tau) d\tau, \tag{4.150}$$

where $\Omega(x, t) = \frac{2\mu}{\hbar} A(x, t)$ is the real Rabi frequency.

The SVEA equation for the pulse envelope $A(x, t)$ can be represented as

$$\frac{\partial A(x, t)}{\partial x} + \frac{n}{c} \frac{\partial A(x, t)}{\partial t} = i \frac{2\pi\omega}{nc} P(x, t), \tag{4.151}$$

where n is the refractive index of the medium, $P(x, t)$ is the slowly varying amplitude of the polarization induced in the medium. As shown by *McCall* and *Hahn* [4.62, 63], on exact resonance, $P(x, t) = i\mu N \sin[\theta(x, t)]$, with $\theta(x, t) = \int_{-\infty}^{t} \Omega(x, \tau) d\tau$. Hence, (4.151) yields

$$\frac{\partial A(x, t)}{\partial x} + \frac{n}{c} \frac{\partial A(x, t)}{\partial t} = -\frac{2\pi\omega\mu N}{nc} \sin[\theta(x, t)]. \tag{4.152}$$

The celebrated solution to (4.152) is a pulse with a hyperbolic-secant shape, which propagates in a resonant two-level medium with no changes in its envelope:

$$A(x, t) = \frac{\hbar}{\mu\tau} \text{sech}\left(\frac{t - x/V}{\tau}\right), \tag{4.153}$$

where V is the pulse velocity in the medium,

$$V = \left(\frac{4\pi\mu^2 \omega N \tau^2}{\hbar nc} + \frac{n}{c}\right)^{-1}. \tag{4.154}$$

In the regime of weak absorption (when the pulse area only slightly deviates from its stable values), the evolution of the pulse area is governed by the equation

$$\frac{\partial\theta(x)}{\partial x} = -\frac{2\pi\omega\mu N}{ncE_0} \theta(x) \sin\theta(x), \tag{4.155}$$

where E_0 is the initial pulse amplitude. With $\theta \approx 2\pi$, we arrive at

$$\frac{\partial\theta(x)}{\partial x} = -\frac{\alpha}{2} \sin\theta(x), \tag{4.156}$$

where $\alpha = \frac{8\pi^2\omega\mu N}{ncE_0}$.

According to (4.156), pulses whose areas $\theta(x_0)$ are multiples of π propagate in a two-level medium with no changes in their envelopes (the soliton propagation regime). However, solitons with pulse areas equal to π, 3π, 5π, ... are unstable. Thus, a pulse with an arbitrary initial area changes its waveform propagating in a two-level medium until its pulse area becomes multiple of 2π. The characteristic spatial scale of this process is estimated as α^{-1}.

Numerical simulations [4.69] have been performed for hyperbolic-secant pulses:

$$E(x_0, t) = E_0 \frac{2 \cos[\omega(t - t_0)]}{\exp[-(t - t_0)/T] + \exp[(t - t_0)/T]}. \tag{4.157}$$

The parameters of the medium and the pulse were chosen as follows: $\Omega = 2\mu E_0/2\hbar = 0.0565\omega$, $4\pi\mu Nr_3(0) = -0.12E_0$, and $\omega = \omega_0$ (exact resonance).

In accordance with the area theorem, a pulse with a duration $T = 5.631\, 2\pi/\omega$ should propagate in the two-level medium with these specified parameters values without any changes in its envelope. FDTD simulations [4.69] reveal no changes in the waveform and the amplitude of such a pulse within a distance of 100 λ with an accuracy better than 0.1%.

Now, we examine how an arbitrary light pulse evolves to a 2π pulse in a two-level medium. FDTD simulations were performed for the propagation of a pulse (4.157) with a duration $T = 7.0392\pi/\omega$ in a two-level medium with these specified parameters values. While the amplitude of such a pulse increases by 15% as it propagates through the medium, the duration of the pulse decreases by a factor of about two. The pulse areas FDTD-simulated for these values of the propagation coordinate are equal to 2.5π, 2.33π, 2.24π, and 2.1π, while the pulse areas for the same values of x calculated from (4.156) are equal to 2.5π, 2.35π, 2.22π,

and 2.09π, respectively. Thus, the results of FDTD simulations agree very well with the predictions of the area theorem, indicating the adequacy of the numerical approach.

4.5.4 Amplification of Ultrashort Light Pulses in a Two–Level Medium

Since the numerical algorithm based on the FDTD technique is intended to simulate the evolution of very short pulses, it enables one to explore many important aspects of short-pulse amplification in a two-level medium, providing a deeper understanding of the problems arising in the amplification of short pulses and the ways that can be employed to resolve these problems.

Propagation of π pulses seems to provide optimal conditions for amplification in a two-level system, since such pulses transfer atoms (or molecules) in an initially inverted medium to the lower state. However, the Rabi frequency increases as a light pulse propagates through the medium and its amplitude increases due to the amplification. Because of this change in the Rabi frequency, the pulse now cannot transfer inverted atoms or molecules to the lower state, but leaves some excitation in a medium, which reduces the gain and leads to pulse lengthening due to the amplification of the pulse trailing edge in a medium with residual population inversion. Thus, some precautions have to be taken to keep the area of the pulse constant in the process of pulse amplification in the medium. Below, we use the FDTD technique to explore two possible ways to solve this problem: (i) modulation of the spatial distribution of the dipole moments of resonant transitions in a two-level system and (ii) amplification of a frequency-detuned chirped pulse.

Modulation of the Spatial Distribution of the Dipole Moment

First, let us explain why we expect that the modulation of the spatial distribution of the dipole moment may improve the efficiency of amplification of an ultrashort light pulse in a two-level medium. To do this, we multiply (4.152) by $A(x,t)$ and integrate the resulting expression in time. Then, introducing the pulse energy, $\Phi(x) = \int_{-\infty}^{\infty} A^2(x,t)\,\mathrm{d}t$, and taking into consideration that the pulse energy remains constant if $\theta(x_0) = 0, 2\pi, \ldots$, we arrive at the following equation relating the pulse energy and area:

$$\frac{\partial \Phi(x)}{\partial x} = \frac{2\pi\omega N\hbar}{nc} \left[\cos\theta(x) - 1\right] . \tag{4.158}$$

Thus, if the pulse area is kept equal to π, as the pulse propagates through an inverted two-level medium, then the energy of such a pulse would grow linearly as a function of the distance:

$$\Phi(x) = (1 + \beta x)\,\Phi(0) , \tag{4.159}$$

where $\beta = \frac{4\pi\omega N\hbar}{\Phi(0)nc}$ and $\Phi(0)$ is the initial energy of the pulse.

By looking at (4.150) and (4.159) and taking into consideration that $\Phi(0) = 2\tau E_0^2 = 2E_0\hbar/\mu(0)$ for a hyperbolic-secant pulse (4.157), we find that the pulse area can be kept equal to π by modulating the spatial distribution of the dipole moment in accordance with

$$\mu(x) = \frac{\mu_0}{\sqrt{1 + \beta x}} . \tag{4.160}$$

Such a modulation of the spatial distribution of dipole moments can be achieved, for example, by preliminarily orienting molecules in the medium.

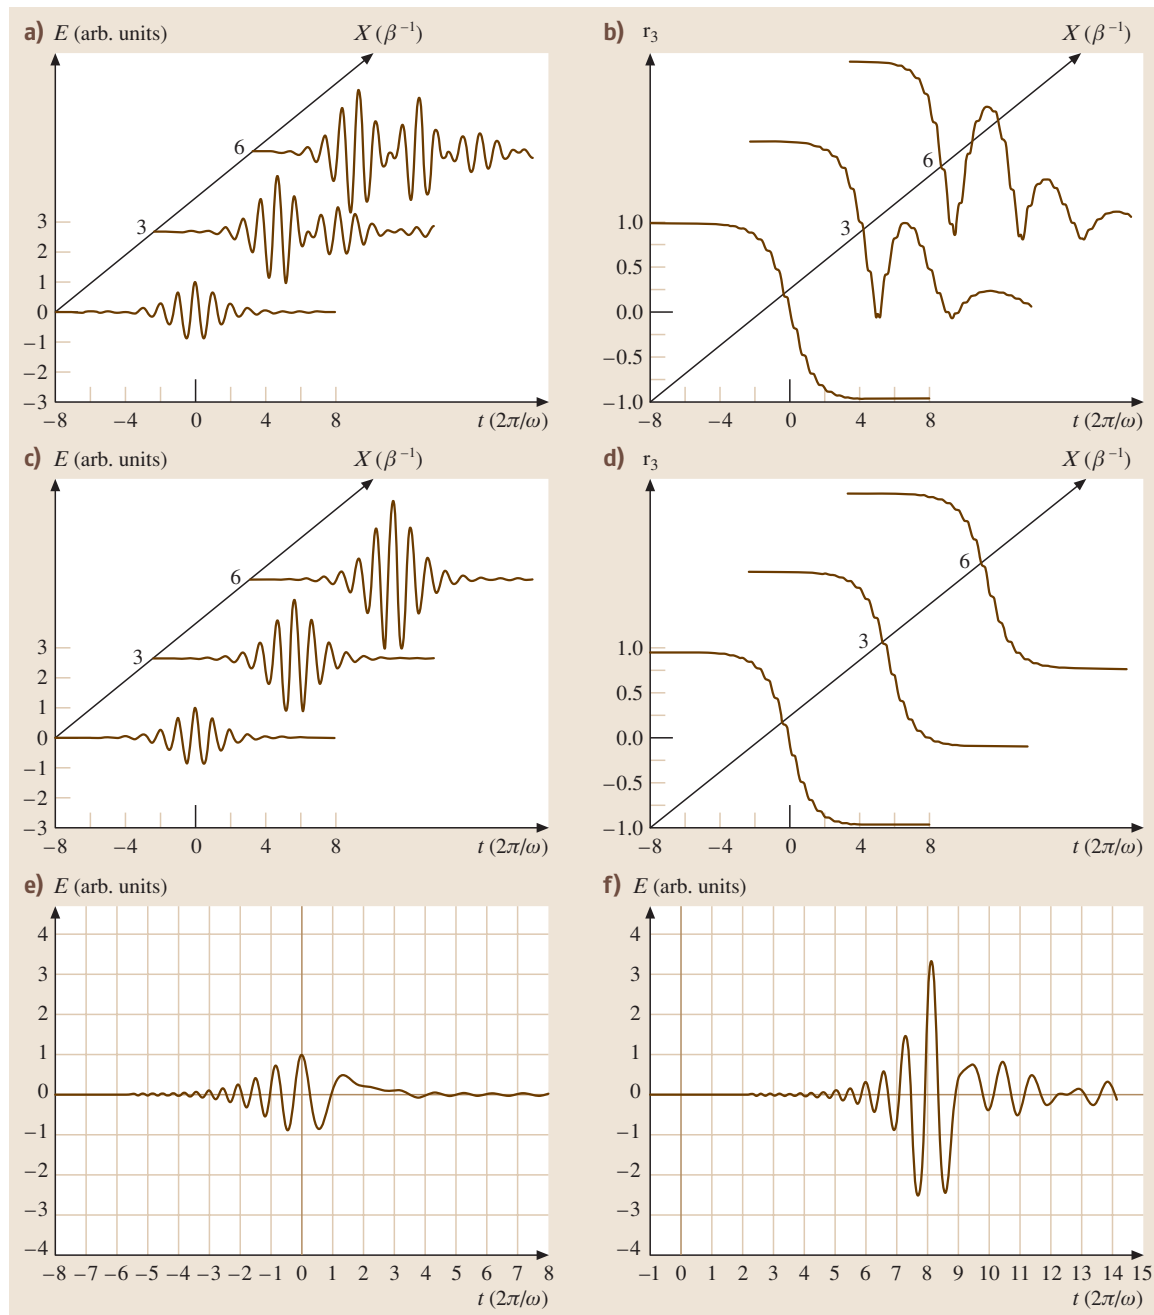
In accordance with the area theorem, the evolution of the amplitude of a π pulse propagating in an inverted two-level medium with a spatial profile of the dipole moment described by (4.160) is governed by

$$E(x) = E_0\sqrt{1 + \beta x} . \tag{4.161}$$

This growth of the pulse amplitude is exactly compensated by the decrease in the dipole moment of transitions in the two-level medium. The net effect is that the pulse area remains constant and equal to π.

Figures 4.13a–d present the results of FDTD simulations for the amplification of a light pulse with a duration $T = 2\pi/\omega$ corresponding to a single optical cycle in an inverted two-level medium with a uniform distribution of the dipole moment (Figs. 4.13a,b) and in an inverted two-level medium where the spatial distribution of dipole moments of resonant transitions is modulated in accordance with (4.160) (Figs. 4.13c,d). Simulations were performed for the case when $\Omega = 2\mu_0 E_0/2\hbar = 0.159\omega$, $4\pi\mu Nr_3(0) = 0.12E_0$, and $\omega = \omega_0$. The time in these plots is measured from the moment when the center of the pulse passes through the entrance boundary of the medium.

Figures 4.13a,b display the evolution of a π pulse in an inverted uniform two-level medium and the population difference in this medium at the distances 0, $3\beta^{-1}$ and $6\beta^{-1}$. These plots show that a two-level medium with a uniform distribution of the dipole moment of transitions cannot ensure an efficient amplification of a transform-limited resonant π pulse. Figures 4.13c,d present the results of FDTD simulation for a π pulse

propagating through a medium with a spatial evolution of the dipole moment described by (4.160). These simulations illustrate the possibility of efficient amplification of a single-cycle pulses in such a medium. Note that the pulse amplitude in Figs. 4.13c and 4.13d increases linearly with the propagation coordinate x (the deviation from the linear dependence does not exceed 10^{-4}). This result agrees very well with the predictions of the area theorem and can also be considered as another test of the reliability of the developed algorithm.


Frequency–Detuned Chirped Pulses

The second idea of keeping the area of the amplified pulse unchanged is to use chirped pulses whose frequency is detuned from the exact resonance. Such a pulse experiences compression as it propagates in the considered two-level medium. With an appropriate choice of pulse parameters, this decrease in pulse duration may serve to preserve the area of the light pulse undergoing amplification.

The Rabi frequency in this case is written

$$\Omega = \frac{1}{2}\sqrt{\Delta^2 + \left(\frac{2\mu_0 E_0}{\hbar}\right)^2} , \qquad (4.162)$$

where $\Delta = \omega - \omega_0$ is the detuning of the central frequency of the pulse from the resonance.

Figures 4.13e,f present the results of FDTD simulations for a single-cycle pulse with a quadratic initial chirp

$$E(0,t) = E_0 \frac{2\cos\left(\omega t + kt^2/T^2\right)}{\exp\left(-t/T\right) + \exp\left(-t/T\right)} , \qquad (4.163)$$

with $k = 1.4$, propagating in a uniform two-level medium with the same parameters as in Figs. 4.13a,b. The distance covered by the pulse in the medium is $6\beta^{-1}$, and the frequency detuning is $\Delta = \omega - \omega_0 = -0.02\omega_0$. As can be seen from Figs. 4.13e,f, although higher-order dispersion effects noticeably distort the waveform of the pulse, the peak intensity of an initially chirped pulse at the output of an amplifying uniform medium is nearly twice as high as the output energy of a transform-limited pulse. Furthermore, comparison of Figs. 4.13a,b,e,f shows that, chirping a light pulse, one can avoid undesirable pulse-lengthening effects.

Fig. 4.13 (a)–(d) The evolution of (a), (c) the pulse waveform and (b), (d) the population difference for a single-cycle light pulse propagating in an inverted two-level medium with (a), (b) a uniform distribution of the dipole moment and (c), (d) a spatial distribution of dipole moments of resonant transitions modulated in accordance with (4.160) simulated with the use of the FDTD technique [4.69] for $\Omega = 2\mu_0 E_0/2\hbar = 0.159\omega$, $4\pi\mu N r_3(0) = 0.12 E_0$, and $\omega = \omega_0$. The time in these plots is measured from the moment when the center of the pulse passes through the input boundary of the medium. (e), (f) Amplification of a single-cycle chirped laser pulse (4.163) in a two-level medium: (e) the input pulse and (f) the output pulse simulated with the use of the FDTD technique for $\Omega = 2\mu_0 E_0/2\hbar = 0.159\omega$, $4\pi\mu N r_3(0) = 0.12 \times 10^0$, and $\omega = \omega_0$ ◀

4.5.5 Few–Cycle Light Pulses in a Two–Level Medium

The results of FDTD simulations, as shown by *Tarasishin* et al. [4.70], typically agree very well with the predictions of *McCall* and *Hahn* theory [4.62, 63] for light pulses propagating in a two-level medium until the pulse duration T becomes less than the duration T_0 of a single optical cycle. In agreement with the general predictions of McCall and Hahn, a 2.9π pulse with $T = T_0$, $2\mu E_0 \pi T/\hbar = 2.9\pi$, $\mu N/E_0 = 0.00116$, for example, is transformed until its area becomes equal to 2π. The peak amplitude of the pulse increases by a factor of 1.31 under these conditions, while its duration decreases to $0.55T_0$.

Noticeable deviations from the McCall–Hahn regime were observed for pulses with durations shorter than the duration of a single field cycle. In particular, half-cycle 2π pulses become asymmetric as they propagate through a two-level medium (Fig. 4.14a), and the characteristic length corresponding to the phase shift (4.9) equal to π estimated on the basis of FDTD simulations for such pulses was equal to 9.4λ, which appreciably differs from the SVEA estimate for the characteristic length corresponding to the π phase shift, $L = (\hbar nc)/(4\omega^2\mu^2 T^2 N) = (E_0^2 nc)/(4\omega^2 N\hbar)$. Quarter-cycle 2π pulses display noticeable distortions and lengthening in the process of propagation through a two-level medium (Fig. 4.14b).

Deviations observed in the behavior of very short 2π pulses from the McCall–Hahn scenario are due to the fact that, although, formally, such pulses have an area of 2π, the cycle of interaction between light and a two-level system remains incomplete in this case, as the pulses do not even contain a full cycle of the field (Figs. 4.14a,b). As a result, such pulses leave some excitation in a two-level medium (Fig. 4.14d) instead of switching excited-state population back to the ground state, as in the case of longer 2π pulses (Fig. 4.14c).

The amplitude of the leading edge of the pulse becomes higher than the amplitude of its trailing edge, and the pulse waveform becomes noticeably asymmetric (Fig. 4.14a). The group velocity of such very short pulses increases due to this incompleteness of the light-two-level-system interaction cycle, leading to a discrepancy between the SVEA estimate and the FDTD result for the characteristic length corresponding to the π phase shift. The residual population in the medium and the asymmetry of the pulse waveform increase with pulse shortening.

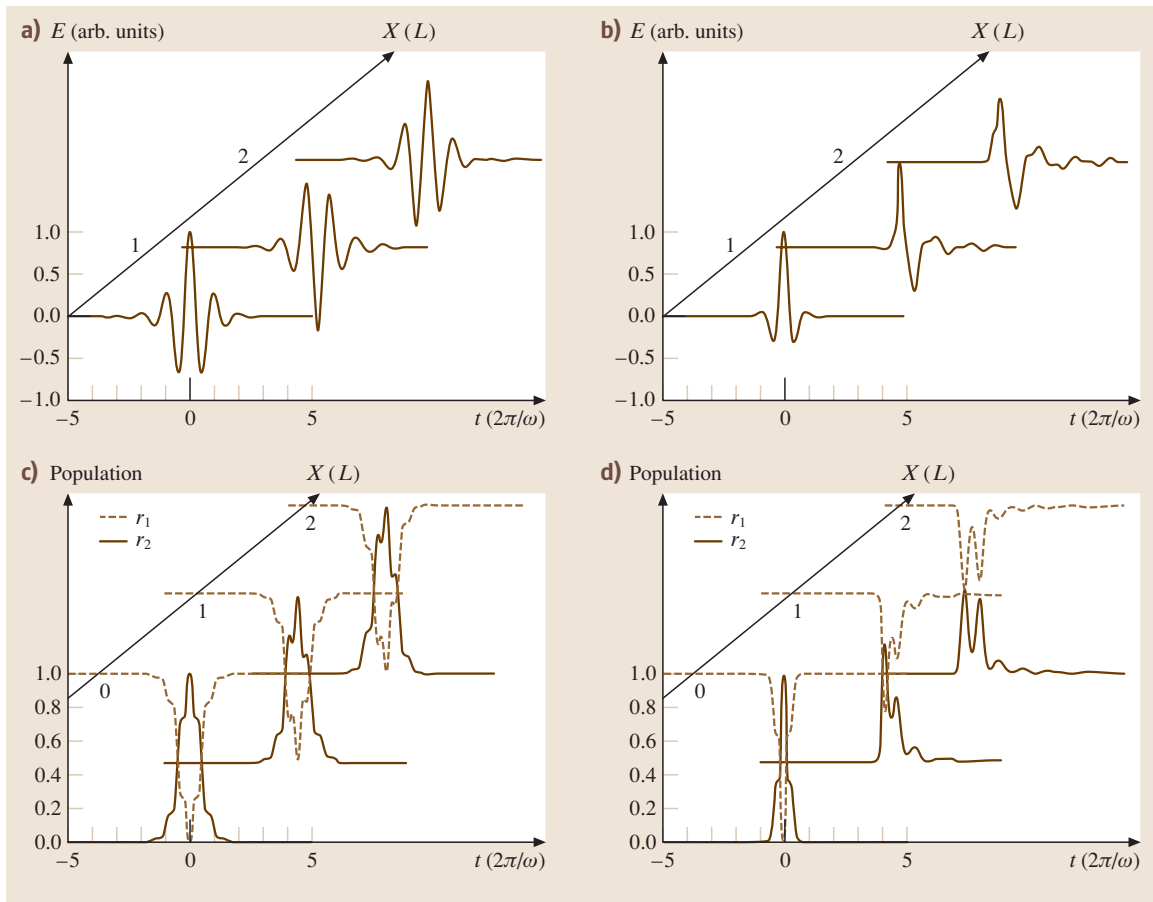
The results of FDTD simulations presented in this section thus show that the general predictions of McCall and Hahn for the evolution of the amplitude and the


Fig. 4.14 **(a)** Evolution of a half-cycle 2π pulse in a two-level medium: $T = 0.5T_0$, $2\mu E_0 \pi T/\hbar = \pi$, and $\mu N/E_0 = 0.0016$, **(b)** Evolution of a quarter-cycle 2π pulse in a two-level medium: $T = 0.25T_0$, $2\mu E_0 \pi T/\hbar = 2\pi$, and $\mu N/E_0 = 0.0032$. **(c)**, **(d)** Evolution of the excited- and ground-state populations in a two-level medium under the action of **(c)** a half-cycle 2π pulse and **(d)** a quarter-cycle 2π pulse: (*dashed line*) ground-state population r_1 and (*solid line*) excited-state population r_2. Simulations were performed with the use of the FDTD technique [4.70]

phase of short pulses in a two-level medium generally agree reasonably well with the results of numerical simulations until the pulse duration becomes less than the duration of a single optical cycle. Numerical analysis reveals several interesting physical features in the formation of 2π solitons produced as a result of splitting of single-cycle pulses propagating in a two-level medium. In particular, the resulting pulses may have different amplitudes, durations, and group velocities, allowing the formation of sub-femtosecond pulses and slowing down of the light in two-level media. Noticeable deviations from the McCall–Hahn regime can be observed

for pulses with durations shorter than the duration of a single field cycle. Half-cycle 2π pulses become asymmetric as they propagate through a two-level medium, while quarter-cycle 2π pulse display considerable distortions and lengthening in the process of propagation through a two-level medium. Deviations observed in the behavior of very short 2π pulses from the McCall–Hahn scenario are due to the fact that the cycle of interaction between light and a two-level system remains incomplete in this case, and light pulses leave some excitation in a two-level medium instead of switching excited-state population back to the ground state.

4.6 Let There be White Light: Supercontinuum Generation

Supercontinuum (SC) generation – a physical phenomenon leading to a dramatic spectral broadening of laser pulses propagating through a nonlinear medium – was first demonstrated in the early 1970s [4.71, 72] (see [4.73] for an overview of early experiments on supercontinuum generation). Presently, more than three decades after its discovery, supercontinuum generation is still one of the most exciting topics in laser physics and nonlinear optics [4.44], the area where high-field

Fig. 4.15a–c Spectral transformations of ultrashort pulses in photonic-crystal fibers: **(a)** supercontinuum generation, **(b)** third-harmonic generation, and **(c)** frequency shifting

science meets the physics of low-energy unamplified ultrashort pulses in the most amazing way. The advent of photonic-crystal fibers [4.36, 37], capable of generating supercontinuum emission with unamplified, nano- and even sub-nanojoule femtosecond pulses, has resulted in revolutionary changes in frequency metrology [4.74–77] opened new horizons in ultrafast science [4.78, 79] and allowed the creation of novel wavelength-tunable and broadband fiber-optic sources for spectroscopic [4.80] and biomedical [4.81] applications. The rainbow of colors produced by a laser beam Fig. 4.15 has become an optical instrument and a practical tool.

As a physical phenomenon, supercontinuum generation involves the whole catalog of classical nonlinear-optical effects, such as self- and cross-phase modulation, four-wave mixing, stimulated Raman scattering, solitonic phenomena and many others, which add up to produce emission with an extremely broad spectra, sometimes spanning over a couple of octaves. Below, we discuss the basic physical processes contributing to supercontinuum generation in greater detail, with special emphasis made on self-phase modulation, four-wave mixing, and modulation instabilities (Sect. 4.6.1), cross-phase modulation (Sect. 4.6.2), as well as the solitonic phenomena and stimulated Raman scattering (Sect. 4.6.3).
4.6.1 Self-Phase Modulation, Four-Wave Mixing, and Modulation Instabilities in Supercontinuum-Generating Photonic-Crystal Fibers

Propagation of laser pulses in PCFs is always accompanied by SPM-induced spectral broadening. The basic features of SPM are discussed in Sect. 4.4.1. For very short laser pulses and broadband field waveforms, SPM can be thought of as a four-wave mixing $\omega_{p1} + \omega_{p2} = \omega_3 + \omega_4$ with frequency components ω_{p1} and ω_{p2} from the spectrum of the laser field serving as pump photons generating new frequency components ω_3 and ω_4. In the case of a frequency-degenerate pump, $\omega_{p1} = \omega_{p2} = \omega_p$, the new frequency components generated through FWM appear as Stokes and anti-Stokes sidebands at frequencies ω_s and ω_a in the spectrum of the output field. Such FWM processes become especially efficient, as emphasized in Sect. 4.4.4, when phase matching is achieved for the fields involved in the nonlinear-optical interaction. Under certain condi-

tions, the pump fields modify the effective refractive indices of the guided modes involved in the FWM process, inducing the phase matching for the FWM and leading to a rapid growth of spectral sidebands representing the Stokes and anti-Stokes fields. This regime of four-wave mixing, referred to as modulation instability (MI), plays an especially important role in nonlinear-optical spectral transformations of ultrashort pulses in PCFs.

In the simplest, scalar regime of modulation instability, two photons of the pump field with the frequency ω_p generate Stokes and anti-Stokes sidebands with frequencies $\omega_s = \omega_p - \Omega$ and $\omega_a = \omega_p + \Omega$. To illustrate this regime of MI, we represent the propagation constants of the Stokes and anti-Stokes sidebands as Taylor-series expansions around ω_p,

$$\beta\left(\omega_p + \Omega\right) \approx \beta_0\left(\omega_p\right) + \frac{1}{u_p}\Omega$$
$$+ \frac{1}{2}\beta_2\left(\omega_p\right)\Omega^2 + 2\gamma P , \qquad (4.164)$$

$$\beta\left(\omega_p - \Omega\right) \approx \beta_0\left(\omega_p\right) - \frac{1}{u_p}\Omega$$
$$+ \frac{1}{2}\beta_2\left(\omega_p\right)\Omega^2 + 2\gamma P , \qquad (4.165)$$

where P is the peak power of the pump field, $\beta_0(\omega_p)$ is the Kerr-effect-free propagation constant of the pump field mode (i.e., the propagation constant of the pump field corresponding to the regime with $P = 0$), $u_p = (\partial\beta/\partial\omega|_{\omega=\omega_p})^{-1}$ is the group velocity of the pump pulse, $\beta_2(\omega_p) = \partial^2\beta/\partial\omega^2|_\omega = \omega_p$, $\gamma = (n_2\omega_p)/(cS_{\text{eff}})$ is the nonlinear coefficient, and $S_{\text{eff}} = [\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}|F(x, y)|^2\,dx\,dy]^2/\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}|F(x, y)|^4\,dx\,dy$ is the effective area of a guided mode with the transverse field profile $F(x, y)$.

With the propagation constant of the pump field written as

$$\beta\left(\omega_p\right) = \beta_0\left(\omega_p\right) + \gamma P , \qquad (4.166)$$

the mismatch of the propagation constants of the fields involved in the FWM process is given by

$$\Delta\beta_{\text{FWM}} = \beta\left(\omega_p + \Omega\right) + \beta\left(\omega_p + \Omega\right) - 2\beta\left(\omega_p\right)$$
$$\approx \beta_2\left(\omega_p\right)\Omega^2 + 2\gamma P . \qquad (4.167)$$

The phase matching can thus be achieved for this type of FWM at

$$\Omega = \pm\left(\frac{2\gamma P}{|\beta_2\left(\omega_p\right)|}\right)^{1/2} \qquad (4.168)$$

only when the central frequency of the pump field lies in the range of anomalous group-velocity dispersion, where $\beta_2(\omega_p) < 0$.

Figure 4.16 illustrates typical features of the scalar MI in PCFs observed by *Fedotov* et al. [4.82]. In those experiments, unamplified 50 fs pulses of 790–810 nm Ti:sapphire laser radiation with a repetition rate of 10 MHz and an energy of 0.1–1.4 nJ were coupled into micro-waveguide channels off the central core of the PCF (the inset in Fig. 4.16). The zero group-velocity dispersion (GVD) wavelength for the micro-waveguide channel used to observe MI is estimated as $\lambda_0 \approx 720$ nm, providing an anomalous GVD for the pump field. With a special choice of the pump pulse power, it is then possible to use the SPM phase shift to induce phase matching for efficient four-wave mixing (Fig. 4.16). This process can be understood as SPM-induced modulation instability, resulting in an exponential growth of spectral sidebands phase-matched with the pump field. In the output spectrum presented in Fig. 4.16, the 795 nm pump field generates sidebands centered at 700 and 920 nm. To understand this result, we use the standard result of MI theory (4.168) for the frequency shift corresponding to the maximum MI gain. With $\gamma \approx 50\,\text{W}^{-1}\text{km}^{-1}$, $D \approx 30\,\text{ps/(nm} \cdot \text{km)}$, pulse energy $E \approx 0.5$ nJ, initial pulse duration $\tau \approx 50$ fs, we find $\Omega_{\max}/2\pi \approx 50$ THz, which agrees well with the frequency shifts of the sidebands observed in the output spectra presented

Fig. 4.16 Sideband generation through modulation instability in the spectrum of an ultrashort pulse transmitted through a photonic-crystal fiber (shown in the *inset*). The input energy of laser pulses is 0.5 nJ. A scanning electron microscopy (SEM) image of the photonic-crystal fiber is shown in the *inset*

in Fig. 4.16. SPM-induced broadening sufficient to seed the considered MI-type FWM process is achieved within a fiber length $z \approx (2L_d L_{nl})^{1/2}$, where $L_d = \tau^2/|\beta_2|$ and $L_{nl} = (\gamma P)^{-1}$ are the dispersion and nonlinear lengths, respectively. For the above-specified parameters of laser pulses and a PCF, we have $L_d \approx 25$ cm and $L_{nl} \approx 0.2$ cm. SPM-induced broadening can thus provide seeding for sideband generation at Ω_{max} with PCF lengths exceeding 3.2 cm. This condition was satisfied in our experiments, where the PCF length was equal to 8 cm. Our experimental results thus demonstrate efficient regimes of SPM-induced MI in microchannel waveguides of PCFs, which offer much promise for parametric frequency conversion and photon-pair generation.

4.6.2 Cross-Phase-Modulation-Induced Instabilities

Self-induced MI in PCFs has been shown [4.53, 82] to provide a convenient means for broadband parametric amplification, permitting the creation of compact and convenient all-fiber optical parametric oscillators. Cross-phase-modulation-induced MI, on the other hand, does not require anomalous dispersion [4.23], suggesting convenient and practical control knobs for the frequency conversion of ultrashort pulses in PCFs, allowing the frequency shifts and amplitudes of sidebands in output spectra of the probe field to be tuned by varying the amplitude of the pump field.
Fig. 4.17 The group velocity (the *solid curve* and the *right-hand axis*) and the group-velocity dispersion (the *dashed curve* and the *left-hand axis*) calculated as functions of the radiation wavelength λ for the fundamental mode of the PCF with a cross-sectional structure shown in the inset

Experiments [4.83] were performed with high-index-step fused-silica PCFs having a cross-sectional geometry shown in the inset to Fig. 4.17 with a core diameter of 4.3 μm. Figure 4.17 displays the group velocity and GVD calculated for this PCF using the polynomial expansion technique [4.84]. The standard theory of XPM-induced MI, as presented by *Agrawal* [4.85], was used to analyze the main features of this phenomenon for fundamental-wavelength and second-harmonic femtosecond pulses of a Cr:forsterite laser co-propagating in a PCF with the above-specified structure. This theory predicts that stationary solutions to slowly varying envelope approximation equations for the pump and probe fields including dispersion up to the second order become unstable with respect to a small harmonic perturbation with the wave vector K and the frequency Ω if K has a nonzero imaginary part. The domains of this instability can be found by analyzing the dispersion relation

$$\left[(K - \Omega\delta g/2)^2 - h_1\right]\left[(K + \Omega\delta g/2)^2 - h_2\right] = C^2 , \tag{4.169}$$

where

$$h_j = \beta_{2j}^2 \Omega^2 \left(\Omega^2 + 4\gamma_j P_j g/\beta_{2j}\right)/4 , \tag{4.170}$$

$$C = 2\Omega^2 \sqrt{\beta_{21}\beta_{22}\gamma_1\gamma_2 P_1 P_2} , \tag{4.171}$$

$\gamma_j = n_2\omega_j/(cS_j)$ are the nonlinear coefficients, $\delta = (v_{g2})^{-1} - (v_{g1})^{-1}$, $\beta_{2j} = (d^2\beta_j/d\omega^2)_{\omega=\omega_j}$, P_j, ω_j, v_{gj} and β_j are the peak powers, the central frequencies, the group velocities, and the propagation constants of the pump ($j = 1$) and probe ($j = 2$) fields, n_2 is the nonlinear refractive index, and S_j are the effective mode areas for the pump and probe fields. The gain of instabilities with a wave number K is given by $G(\Omega) = 2\,\mathrm{Im}(K)$.

Analysis of the dispersion properties of the PCFs employed in our experiments (Fig. 4.17) yields $\beta_{21} \approx -500\,\mathrm{fs}^2/\mathrm{cm}$, $\beta_{22} \approx 400\,\mathrm{fs}^2/\mathrm{cm}$, and $\delta = 150\,\mathrm{fs/cm}$. The dimensionless frequency shift of the probe field, $f = \Omega/\Omega_c$ [where $\Omega_c = (4\gamma_2 P_2/|\beta_{22}|)^{1/2}$] changes from approximately 3.3 up to 3.8 as the $\gamma_1 P_1/\gamma_2 P_2$ ratio is varied from 0.3 to 2.5. As highlighted by *Agrawal* [4.85], such a weak dependence of the frequency shift of the probe field on the pump power is typical of XPM-induced MI in the regime of pump–probe group-velocity mismatch. With $\gamma_2 P_2 \approx 1.5\,\mathrm{cm}^{-1}$, the frequency shift $f \approx 3.8$ gives sidebands shifted by $\Omega/2\pi \approx 74\,\mathrm{THz}$ with respect to the central frequency ω_2 of the second harmonic (which corresponds to approximately 90 nm on the wavelength scale). As will

be shown below, this prediction agrees well with our experimental results.

The laser system used in experiments [4.83] consisted of a Cr^{4+}:forsterite master oscillator, a stretcher, an optical isolator, a regenerative amplifier, and a compressor. The master oscillator, pumped with a fiber ytterbium laser, generated 30–60 fs light pulses of radiation with a wavelength of 1.23–1.25 μm at a repetition rate of 120 MHz. These pulses were then transmitted through a stretcher and an isolator, to be amplified in a Nd:YLF-laser-pumped amplifier and recompressed to the 170 fs pulse duration with the maximum laser pulse energy up to 40 μJ at 1 kHz. A 1 mm-thick β barium borate (BBO) crystal was used to generate the second harmonic of amplified Cr:forsterite laser radiation. Fundamental-wavelength, 1235 nm radiation of a femtosecond Cr:forsterite laser and its second harmonic were used as pump and probe fields, respectively. As can be seen from Fig. 4.16, the pump wavelength falls within the area of anomalous dispersion for the fundamental mode of the PCF, while the second-harmonic probe lies in the range of normal dispersion. The faster pump pulse Fig. 4.17 was delayed in our experiments with respect to the slower probe pulse at the input of the PCF by a variable delay time of τ.

Figure 4.18 presents the results of experimental measurements performed with 170 fs pump pulses (the fundamental radiation of the Cr:forsterite laser) with an energy ranging from 0.2 up to 20 nJ and 3 nJ, 180 fs probe pulses (the second-harmonic output of the Cr:forsterite laser) transmitted through a 5 cm PCF with the cross-sectional structure shown in the inset to Fig. 4.17. For delay times τ around zero, the slower probe pulse sees only the trailing edge of the faster moving pump pulse. In such a situation, XPM predominantly induces a blue shift of the probe field. For $\tau \approx \delta L \approx$ 750 fs, where $L = 5$ cm is the PCF length, the leading edge of the pump pulse catches up with the probe field closer to the output end of the fiber, which results in a predominant red shift of the probe. To symmetrize the interaction between the pump and probe fields with respect to the XPM-induced frequency shift, we choose the delay time $\tau = \delta L/2 \approx 375$ fs. In the regime of low peak pump powers (less than 3 kW), the output spectrum of the probe field displays only slight broadening due to self-phase modulation (Fig. 4.18a). Pump pulses with higher peak powers lead to radical changes in the output spectra of the probe field, splitting the central spectral component of the probe field and giving rise to intense symmetric sidebands around the central frequency ω_2 (Figs. 4.18b–d).

The general tendencies in the behavior of the output spectrum of the probe field as a function of the pump power agree well with the prediction of the standard theory of XPM-induced MI. In view of the splitting and slight blue-shifting of the central spectral component of the probe field (Figs. 4.18b–d), we define the effective central wavelength of the pump-broadened probe spectrum as 605 nm. As the pump power changes from 5 kW up to 42 kW in our experiments, the shift of the short-wavelength sideband in the output spectrum of the second harmonic increases from 80 nm up to approximately 90 nm. The theory predicts the wavelength shifts of 76 nm and 90 nm, respectively, indicating the predominant role of XPM-induced MI in the observed spectral transformations of the probe field. The ampli-

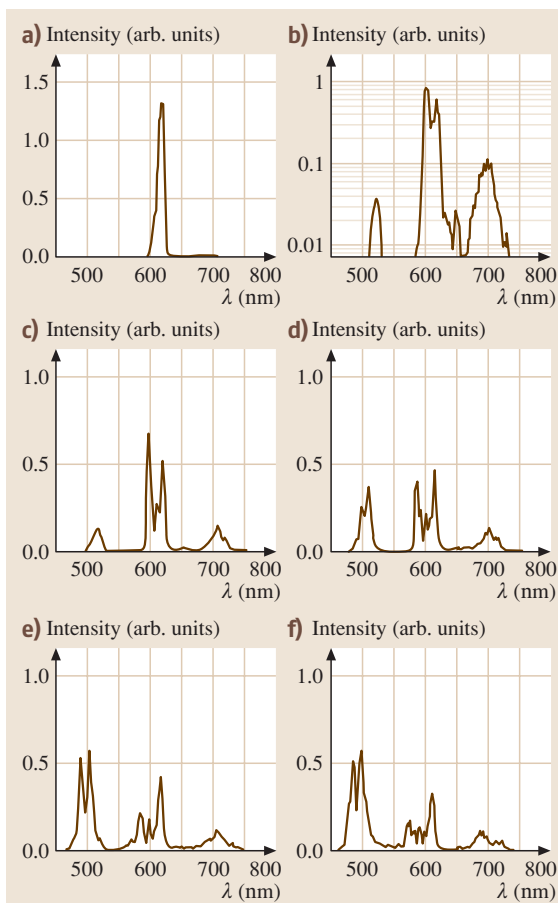

Fig. 4.18a–f Output spectra of the second-harmonic field transmitted through a 5 cm PCF. The power of the pump pulses is **(a)** 3, **(b)** 7, **(c)** 30, **(d)** 42, **(e)** 70, and **(f)** 100 kW. The power of the probe pulse is 8 kW

tudes of sidebands generated by pump pulses with a peak power of about 40 kW, as can be seen from Fig. 4.18d, become comparable or may even exceed the amplitude of the spectral components at the central part of the probe spectrum. The maximum frequency shift of the probe-field sidebands achieved in our experiments with 45 kW pump pulses is estimated as 80 THz, which is substantially larger than typical frequency shifts resulting from XPM-induced MI in conventional fibers [4.23]. With pump powers higher than 50 kW, both the central spectral components of the probe field and its sidebands featured a considerable broadening (Figs. 4.18e,f) and tended to merge together, apparently due to the cross-phase modulation induced by the pump field.

XPM-induced instabilities thus open an efficient channel of parametric FWM frequency conversion in photonic-crystal fibers. Fundamental-wavelength femtosecond pulses of a Cr:forsterite laser were used in our experiments as a pump field to generate intense sidebands around the central frequency of co-propagating second-harmonic pulses of the same laser through XPM-induced MI in a PCF. This effect leads to efficient pump-field-controlled sideband generation in output spectra of the second-harmonic probe field.

4.6.3 Solitonic Phenomena in Media with Retarded Optical Nonlinearity

Optical solitons propagating in media with noninstantaneous nonlinear response experience reshaping and continuous frequency down-shifting due to the Raman effect phenomenon, called soliton self-frequency shift (SSFS) [4.86, 87]. Photonic-crystal fibers substantially enhance this nonlinear-optical process due to strong field confinement in a small-size fiber core and the possibility to tailor dispersion of guided modes by varying the fiber structure. *Liu* et al. [4.54] have shown that 200 fs input pulses of 1.3 μm laser radiation can generate sub-100 fs soliton pulses with a central wavelength tunable down to 1.65 μm through the SSFS in a tapered PCF. Photonic-crystal fibers with the wavelength of zero group-velocity dispersion (GVD) shifted to shorter wavelengths have been used for the soliton frequency downshifting of 800–1050 nm laser pulses [4.88, 89]. *Abedin* and *Kubota* [4.90] have employed a PCF to demonstrate a 120 nm SSFS for 10 GHz-repetition-rate picosecond pulses. In recent experiments [4.91, 92], PCFs with a special dispersion profile have been shown to provide an efficient spectral transformation of chirped sub-6 fs Ti:sapphire laser pulses through SSFS, leading to the generation of a well-resolved solitonic spectral component cen-

tered at 1.06 μm. Red-shifted soliton signals formed by sub-6 fs laser pulses in PCFs have been demonstrated to allow to a synchronized seeding of a picosecond Nd:YAG pump laser, permitting a considerable simplification of a few-cycle optical parametric chirped-pulse amplification (OPCPA) scheme [4.79].

With many of the key tendencies in the evolution of ultrashort pulses in PCFs analyzed in the extensive literature, we focus here on the possibility of using the SSFS phenomenon for widely tunable frequency shifting of few-cycle laser pulses. Our theoretical analysis is based on the numerical solution of the generalized nonlinear Schrödinger equation [4.93]

$$
\frac{\partial A}{\partial z} = i \sum_{k=2}^{6} \frac{(i)^k}{k!} \beta^{(k)} \frac{\partial^k A}{\partial \tau^k} + i\gamma \left(1 + \frac{i}{\omega_0} \frac{\partial}{\partial \tau} \right)
$$
$$
\times \left[A(z, \tau) \int_{-\infty}^{\infty} R(\eta) |A(z, \tau - \eta)|^2 \, d\eta \right],
$$
(4.172)

where A is the field amplitude, $\beta^{(k)} = \partial^k \beta / \partial \omega^k$ are the coefficients in the Taylor-series expansion of the propagation constant β, ω_0 is the carrier frequency, τ is the retarded time, $\gamma = (n_2 \omega_0)/(c S_{\text{eff}})$ is the nonlinear coefficient, n_2 is the nonlinear refractive index of the PCF material,

$$
S_{\text{eff}} = \frac{\left[\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} |F(x, y)|^2 \, dx \, dy \right]^2}{\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} |F(x, y)|^4 \, dx \, dy}
$$
(4.173)

is the effective mode area [$F(x, y)$ is the transverse field profile in the PCF mode], and $R(t)$ is the retarded nonlinear response function. For fused silica, we take $n_2 \approx 3.2 \times 10^{-16} \, \text{cm}^2/\text{W}$, and the $R(t)$ function is represented in a standard form [4.93, 94]:

$$
R(t) = (1 - f_R)\delta(t)
$$
$$
+ f_R \Theta(t) \frac{\tau_1^2 + \tau_2^2}{\tau_1 \tau_2^2} e^{-\frac{t}{\tau_2}} \sin\left(\frac{t}{\tau_1} \right),
$$
(4.174)

where $f_R = 0.18$ is the fractional contribution of the Raman response; $\delta(t)$ and $\Theta(t)$ are the delta and the Heaviside step functions, respectively; and $\tau_1 = 12.5 \, \text{fs}$ and $\tau_2 = 32 \, \text{fs}$ are the characteristic times of the Raman response of fused silica.

We now apply (4.172) and (4.174) to compute the evolution of ultrashort pulses in two types of PCFs (Figs.

4.19, 4.20). PCFs of the first type consist of a fused silica core with a diameter of 1.6 μm, surrounded with two cycles of air holes (inset in Fig. 4.20a). To find the parameters $\beta^{(k)}$ for these fibers, we numerically solved the Maxwell equations for the transverse components of the electric field in the cross section of a PCF using a modification of the method of polynomial expansion in localized functions [4.84]. Polynomial approximation of the frequency dependence of the propagation constant β for the fundamental mode of the PCF computed with the use of this numerical procedure with an accuracy better than 0.1% within the range of wavelengths 580–1220 nm yields the following $\beta^{(k)}$ coefficients for the central wavelength of 800 nm: $\beta^{(2)} \approx -0.0293\,\mathrm{ps}^2/\mathrm{m}$, $\beta^{(3)} \approx 9.316 \times 10^{-5}\,\mathrm{ps}^3/\mathrm{m}$, $\beta^{(4)} \approx -9.666 \times 10^{-8}\,\mathrm{ps}^4/\mathrm{m}$, $\beta^{(5)} \approx 1.63 \times 10^{-10}\,\mathrm{ps}^5/\mathrm{m}$, $\beta^{(6)} \approx -3.07 \times 10^{-13}\,\mathrm{ps}^6/\mathrm{m}$. For the fundamental mode of such PCFs, the GVD, defined as $D = -2\pi c\lambda^{-2}\beta^{(2)}$, vanishes at $\lambda_z \approx 690$ nm. Fibers of the second type are commercial NL-PM-750 PCFs (from Crystal Fibre). The core diameter for these PCFs was equal to 1.8 μm. The parameters $\beta^{(k)}$ for these PCFs were defined as polynomial expansion coefficients for the dispersion profile of the fundamental mode of these fibers provided by the manufacturer. The group-velocity dispersion for PCFs of this type vanishes at $\lambda_z \approx 750$ nm.

In the case studied here, the laser field at the input of a PCF has the form of a few-cycle pulse (the upper panel in Fig. 4.19a) with a broad spectrum (the upper panel in Fig. 4.19b) and a complicated chirp [4.79, 92]. For both types of PCFs, the short-wavelength part of the spectrum lies in the range of normal dispersion, while the wavelengths above λ_z experience anomalous dispersion. A typical scenario of spectral and temporal evolution of a few-cycle laser pulse in PCFs of the considered types is illustrated by Figs. 4.19a,b. The initial stage of nonlinear-optical transformation of a few-cycle pulse involves self-phase modulation, which can be viewed as four-wave mixing of different frequency components belonging to the broad spectrum of radiation propagating through the fiber. Frequency components lying near the zero-GVD wavelength of the PCF then serve, as shown in the classical texts on nonlinear fiber optics [4.23], as a pump for phase-matched FWM. Such phase-matched FWM processes, which involve both frequency-degenerate and frequency-nondegenerate pump photons, deplete the spectrum of radiation around the zero-GVD wavelength and transfer the radiation energy to the region of anomalous dispersion (spectral components around 920 nm for $z = 2$ cm in Fig. 4.19b). A part of this frequency-downconverted radiation then couples into a soliton, which undergoes continuous frequency downshifting due to the Raman effect (Fig. 4.19b), known as soliton self-frequency shift [4.23,85,86]. In the time domain, the red-shifted solitonic part of the radiation field becomes

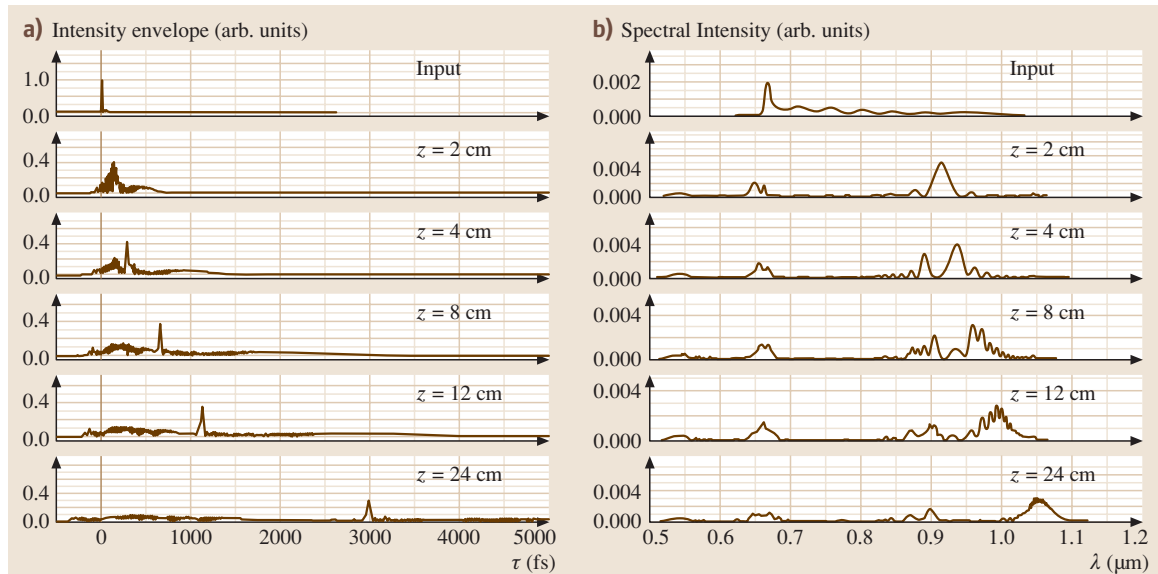

Fig. 4.19 Temporal (**a**) and spectral (**b**) evolution of a laser pulse with an initial energy of 0.25 nJ and an input temporal envelope and chirp shown in Fig. 4.1b propagating through the second-type PCF (shown in the inset)

delayed with respect to the rest of this field (Fig. 4.19a) because of the anomalous GVD of the fiber. As a result of these processes, the red-shifted soliton becomes increasingly isolated from the rest of the light field in both the time and frequency domains, which reduces, in particular, the interference between the solitonic and nonsolitonic part of radiation, seen in Fig. 4.19b.

High-order fiber dispersion induces soliton instabilities, leading to Cherenkov-type emission of dispersive waves [4.21, 22] phase-matched with the soliton, as discussed in the extensive literature (see, e.g., [4.95, 96]).

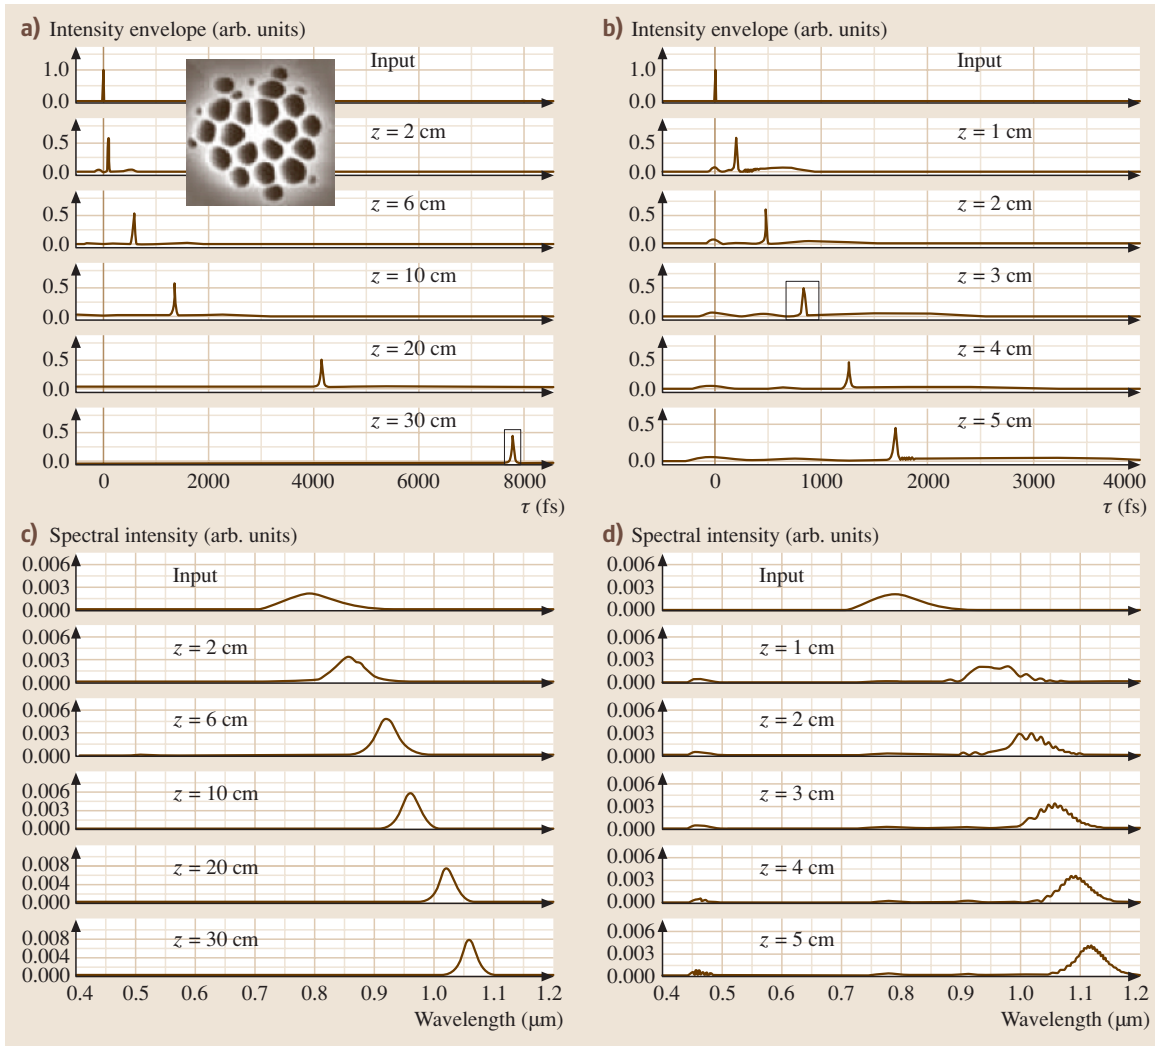
This resonant dispersive-wave emission gives rise to a spectral band centered around 540 nm in Fig. 4.19b. As a result of the above-described nonlinear-optical transformations, the spectrum of the radiation field for a PCF with a characteristic length of 20 cm typically features four isolated bands, representing the remainder of the FWM-converted pump field (the bands centered at 670 and 900 nm in Fig. 4.19b), the red-shifted solitonic part (reaching 1.06 μm for $z = 24$ cm in Fig. 4.19b), and the blue-shifted band related to the Cherenkov emission of dispersive waves in the visible. In the time domain, as


Fig. 4.20 Temporal (**a**), (**b**) and spectral (**c**), (**d**) evolution of laser pulses with an initial energy of (**a**), (**c**) 0.15 nJ and (**b**), (**d**) 0.5 nJ and an initial pulse width of 6 fs in the first-type PCF (shown in the *inset*). The input pulses are assumed to be transform limited

can be seen from Fig. 4.19a, only the solitonic part of the radiation field remains well localized in the form of a short light pulse, the remaining part of the field spreading out over a few picoseconds.

In Figs. 4.20a–d, we illustrate tunable frequency shifting of few-cycle laser pulses through SSFS in PCFs by presenting the results of simulations performed for an idealistic input pulse with an initial pulse width of 6 fs and a Gaussian pulse shape. For the first-type PCF (shown in the inset to Fig. 4.20a), almost the entire spectrum of the input pulse falls within the range of anomalous dispersion, and the pulse tends to form solitons, observed as well-resolved prominent spikes in the time domain (Figs. 4.20a,b). In the frequency domain, the Raman effect leads to a continuous frequency downshifting of the soliton (Figs. 4.20c,d). The rate of this frequency shift $d\nu/dz$, where ν is the carrier frequency and z is the propagation coordinate, rapidly grows with a decrease in the pulse duration τ_0. With a linear approximation of the Raman gain as a function of the frequency, the integration of the nonlinear Schrödinger equation, as shown by *Gordon* [4.97], yields $d\nu/dz \propto \tau_0^{-4}$. Although high-order dispersion and deviations of the Raman gain curve from the linear function generally make the relation between $d\nu/dz$ and τ in soliton dynamics much more complicated [4.98], the soliton pulse width remains one of the key parameters controlling the soliton frequency shift for a given Raman gain profile. In the case considered here, the short duration of 6 fs input pulses provides a high rate of soliton-frequency shifting at the initial stage of pulse propagation through the PCF. As the spectrum of the soliton is shifted toward the spectral range with larger values of GVD, the pulse width increases, which slows down the frequency shift.

It is instructive to illustrate the main tendencies in the spectral and temporal evolution of few-cycle laser pulses in PCFs using the results of analysis of ideal solitons, i.e., solitons governed by the nonlinear Schrödinger equation [(4.68) in Sect. 4.4.2]. The NLSE (4.68) is recovered from (4.172) by setting $\beta^{(k)} = 0$ for $k \geq 3$, taking $f_R = 0$, and keeping only the term representing the Kerr effect, i.e., the term proportional to $i\gamma A |A|^2$, in the nonlinear part of the equation. In normalized, soliton units, the energy carried by a soliton j is [4.98] $E_j = 4\xi_j$, where $\xi_j = W - j + 0.5$ is the soliton eigenvalue, controlled by the input pulse energy $2W^2$. The soliton pulse width is given by $\tau_j = \tau_0/2\xi_j$, where τ_0 is the input pulse width. The soliton pulse width can thus be reduced, leading to higher SSFS rates, by increasing the energy of the input pulse.

In the case of solitary waves evolving in fibers with high-order dispersion and retarded nonlinearity, the results of NLSE analysis for the soliton energy and the soliton pulse width are no longer valid. In particular, as the soliton spectrum is shifted toward larger values of GVD, the soliton pulse width is bound to increase, while the soliton amplitude decreases (Figs. 4.20a,b). These changes in the soliton pulse width and amplitude are dictated by the balance between the dispersion and the nonlinearity, necessary for the existence of the soliton. On the qualitative level, however, being applied to short sections of a fiber, these simple relations provide important clues for the physical understanding of the evolution of Raman-shifted solitons in a PCF. Indeed, as can be seen from the comparison of the results of simulations performed for input pulses with the same initial pulse width (6 fs), but different energies, the SSFS rate in the case of higher energy pulses can substantially exceed the frequency-shift rate of solitons produced by lower energy pulses. A pulse with an input energy of 0.15 nJ, as can be seen from Fig. 4.20c, is coupled into a soliton, which undergoes a permanent red-shift as it propagates through the fiber. At $z = 30$ cm, the spectrum of this soliton peaks at $1.06\,\mu$m. A similar input pulse that has an initial energy of 0.5 nJ forms a soliton that exhibits a much faster frequency downshift. The central wavelength of this soliton reaches $1.12\,\mu$m already at $z = 5$ cm.

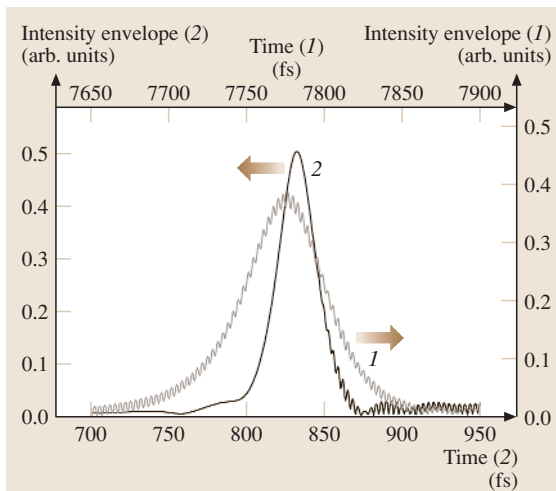

Fig. 4.21 Temporal envelopes of red-shifted solitons (close-up of the peaks labeled with boxes in Figs. 4.20a,b) generated by laser pulses with an initial pulse width of 6 fs and an initial energy of (1) 0.15 nJ and (2) 0.5 nJ in a PCF at $z = 30$ cm (1) and 3 cm (2)

To provide illustrative physical insights into the observed behavior of red-shifted solitons in PCFs as a function of the input pulse energy, we plot in Fig. 4.21 the snapshots of temporal envelopes of the solitonic part of the field corresponding to the input energies of 0.15 nJ (curve 1) and 0.5 nJ (curve 2). We take these snapshots of solitons, representing close-up views of intensity envelope sections labeled with boxes in Figs. 4.20a,b, for two different values of the propagation coordinate, $z = 30$ cm in the case of a 0.15 nJ input pulse and $z = 3$ cm for the 0.5 nJ input energy. With the spectra of red-shifted solitons centered around 1.06 μm in both cases (Figs. 4.20c,d), these values of the propagation coordinate allow a fair comparison of SSFS dynamics in terms of the dependence of the frequency shift rate on the soliton pulse width. As is seen from Fig. 4.21, the SSFS rate correlates well with the soliton pulse width. While the soliton produced by a pulse with an initial energy of 0.15 nJ has a pulse width of about 50 fs (curve 1 in Fig. 4.21), the pulse width of the soliton emerging from the 0.5 nJ laser pulse is about 20 fs. In qualitative agreement with predictions of *Gordon* [4.97] and *Lucek* and *Blow* [4.98], this shorter soliton in Figs. 4.20b,d displays a faster downshifting as compared with the longer soliton in Figs. 4.20a,c. In the following section, this dependence of the SSFS rate on the energy of the pulse launched into the fiber will be used for the experimental demonstration of widely tunable soliton frequency shift of 6 fs pulses produced by a Ti:sapphire oscillator.

At higher input powers, the spectral features originating from FWM, SSFS, dispersive-wave emission of solitons experience broadening due to SPM and XPM effects, merging together and giving rise to a broadband white-light emission (Figs. 4.15, 4.22). This supercon-
Fig. 4.22 The spectrum of supercontinuum emission produced by 820 nm pump pulses with an initial duration of 35 fs and an input power of 320 mW in a microstructure fiber with a length of 30 cm and the cross-section structure shown in the inset to Fig. 4.20a.

tinuum radiation generated in PCFs has been intensely employed through the past few years to measure and control the offset between the carrier and envelope phases of ultrashort laser pulses, as well as for the creation of novel broadband sources for nonlinear spectroscopy, biomedical applications, and photochemistry. Examples of applications of PCF light sources based on enhanced nonlinear-optical interactions of guided modes will be given in Sect. 4.9.

4.7 Nonlinear Raman Spectroscopy

Nonlinear Raman spectroscopy is one of the most powerful techniques of nonlinear spectroscopy, which has found numerous applications in condensed- and gas-phase analysis, plasma diagnostics, investigation of molecular relaxation processes, temperature and concentration measurements, condensed-phase studies, and femtochemistry. While many of modifications of nonlinear Raman spectroscopy have become a routine tool of modern optical experiments, giving rise to many successful engineering applications, some of nonlinear Raman experiments carried out in the last decade have shown that the potential of this technique for many topical and sometimes interdisciplinary problems of modern

physics, chemistry, and biology is far from being completely realized. Similar to frequency-tunable sources of coherent radiation, which revolutionized nonlinear optics in its early days, allowing many delicate spectroscopic experiments, including nonlinear spectroscopic studies, to be performed, the impressive progress of femtosecond lasers in the 1990s has resulted in the breakthrough of the nonlinear Raman spectroscopy to new unexplored areas, giving rise to several elegant new ideas and approaches, permitting more-complicated systems and problems to be attacked, and leading to the measurements of fundamental importance. This new phase of nonlinear Raman spectroscopy also promoted

the development of new spectroscopic concepts, including time-resolved schemes, broadband spectroscopy, polarization measurements, and CARS generalizations based on higher-order nonlinear processes. This conceptual and technical progress achieved in the last decade shows us some very important features of what nonlinear Raman spectroscopy is going to be in the nearest future, encouraging the application of new ideas, techniques, and methods in this area of spectroscopy.

This section provides a brief introduction to the main principles of nonlinear Raman spectroscopy, giving a general idea of how the measurements are performed and the spectroscopic data are extracted from the results of these measurements. Following this plan, we will first give a brief introduction to the basic concepts of nonlinear Raman spectroscopy. Then, we will consider various modifications of coherent Raman four-wave mixing (FWM) spectroscopy, including the standard CARS scheme, stimulated Raman scattering, Raman-induced Kerr effect, degenerate four-wave mixing (DFWM), and coherent hyper-Raman scattering. We will also briefly describe polarization techniques for nonlinear Raman spectrometry and coherent ellipsometry, allowing selective investigation of multicomponent molecular and atomic systems and permitting the sensitivity of nonlinear Raman spectrometry to be radically improved. Finally, in the context of the growing interest in the applications of short-pulse spectroscopy for the investigation of ultrafast processes, we will provide an introduction to time-resolved nonlinear Raman spectroscopy.

4.7.1 The Basic Principles

Nonlinear Raman spectroscopy is based on nonlinear-optical interactions in Raman-active media. The nonlinear character of light interaction with a medium implies that molecular, atomic, or ionic vibrations in a medium are no longer independent of the light field. Instead, pump light waves with frequencies ω_1 and ω_2 modulate Raman-active vibrations in a medium at the frequency $\Omega \approx \omega_1 - \omega_2$, which can be then probed with another light beam, generally having a frequency ω_3 (Fig. 4.6c). This wave-mixing process involving the inelastic scattering of the probe wave by molecular vibrations gives rise to coherent Stokes- and anti-Stokes-frequency-shifted signals, whose amplitude I, polarization (the ellipticity χ and the tilt angle ψ of the principal axis of the polarization ellipse), and phase φ carry the spectroscopic information concerning the medium under study. This is the general idea of nonlinear Raman spectrometry, illustrated by Fig. 4.6c.

In practical terms, to undertake a simple three-color CARS experiment, one generally needs three laser sources generating radiation with the frequencies meeting the requirements specified above. In the most popular scheme of two-color CARS, where the anti-Stokes signal is generated through the frequency-mixing scheme $\omega_a = 2\omega_1 - \omega_2$, the number of lasers required is reduced to two. The light beams have to be brought into coincidence in space to excite Raman-active transitions in a medium and to generate the anti-Stokes signal. Introducing some delay time between pumping and probing pulses, one can also perform time-resolved CARS measurements to keep track of the temporal dynamics of excitation in the system under investigation.

While spontaneous Raman scattering often suffers from the low quantum yield, which eventually results in the loss of sensitivity, coherent Raman scattering allows much more intense signals to be generated, thus allowing very high sensitivities to be achieved. Coherent Raman scattering also offers several other very important advantages that stem from the coherent character of the signal, which is thus well collimated and generated in a precisely known direction.

Generally, the analysis of the amplitude, phase, and polarization of the signal resulting from a nonlinear wave-mixing process in a Raman-resonant medium involves the calculation of the nonlinear response of the medium in terms of the relevant nonlinear susceptibilities and the solution of Maxwell equations for the field of the signal. Below, we restrict our brief introduction to the theory of nonlinear Raman processes to the description of the basic notions and terminology, which will be employed later to explain the main concepts of various nonlinear Raman methods, including frequency- and time-domain CARS, coherent ellipsometry, and the Raman-induced Kerr effect (RIKE).

Excitation of Raman Modes

Within the framework of a simple, but physically instructive, semiclassical model of a nonlinear medium consisting of noninteracting molecules with a Raman-active vibration with frequency Ω, the interaction of light with molecules (atoms or ions) can be described in terms of the electronic polarizability of molecules α depending on the generalized normal coordinate Q (e.g., defined as the distance between the nuclei in a molecule) [4.99]:

$$\alpha(Q) = \alpha_0 + \left(\frac{\partial \alpha}{\partial Q}\right)_0 Q + \dots, \tag{4.175}$$

where α_0 is the equilibrium polarizability of a molecule, $(\partial\alpha/\partial Q)_0$ is the derivative of the electronic polarizability in the normal coordinate taken for the equilibrium position of nuclei, and we restrict our consideration to terms in this expansion linear in Q. The term $(\partial\alpha/\partial Q)_0 Q$ in (4.175) is responsible for the modulation of light by molecular vibrations, as it gives rise to new frequency components in the induced polarization of the system, whose frequency shift is determined by the frequency of molecular vibrations. This can be seen from the expression for the polarization of a medium:

$$P = Np \,, \tag{4.176}$$

where N is the number density of Raman-active molecules,

$$p = \alpha(Q)E = \alpha_0 E + \left(\frac{\partial\alpha}{\partial Q}\right)_0 QE + \ldots \tag{4.177}$$

is the dipole moment of a molecule and E is the electric field strength. The energy of a molecule in a light field is written as

$$H = -pE = -\alpha(Q)E^2 \,. \tag{4.178}$$

Thus, the light-induced force driving molecular vibrations is given by

$$F = -\frac{\partial H}{\partial Q} = \frac{\partial\alpha}{\partial Q}E^2 \,. \tag{4.179}$$

As can be seen from (4.179) the force acting on a molecule in a light field may result in a resonant excitation of Raman-active vibrations with a frequency Ω if the field involves frequency components ω_1 and ω_2 with $\omega_1 - \omega_2 \approx \Omega$.

Wave Mixing in Raman-Active Media

The propagation of light waves in a nonlinear medium is governed by the wave equation

$$\Delta\boldsymbol{E} - \frac{n^2}{c^2}\frac{\partial^2\boldsymbol{E}}{\partial t^2} = \frac{4\pi}{c^2}\frac{\partial^2\boldsymbol{P}_{nl}}{\partial t^2}, \tag{4.180}$$

where $\boldsymbol{E}$ is the field in the light wave, n is the refractive index, c is the speed of light, and $\boldsymbol{P}_{nl}$ is the nonlinear polarization of the medium.

Consider for example the CARS process, as an example of a nonlinear Raman process, assuming that it involves plane and monochromatic waves,

$$\begin{aligned}
\boldsymbol{E}(\boldsymbol{r}, t) &= \boldsymbol{E}_1 \exp(-i\omega_1 t + i\boldsymbol{k}_1\boldsymbol{r}) \\
&\quad + \boldsymbol{E}_2 \exp(-i\omega_2 t + i\boldsymbol{k}_2\boldsymbol{r}) \\
&\quad + \boldsymbol{E} \exp(-i\omega t + i\boldsymbol{k}\boldsymbol{r}) \\
&\quad + \boldsymbol{E}_a \exp(-i\omega_a t + i\boldsymbol{k}_a\boldsymbol{r}) + \text{c.c.} \,,
\end{aligned} \tag{4.181}$$

where ω_1 and ω_2 are the frequencies of pump waves, ω is the frequency of the probe wave, $\omega_a = \omega + \omega_1 - \omega_2$, the field envelopes $\boldsymbol{E}$, $\boldsymbol{E}_1$, $\boldsymbol{E}_2$, and $\boldsymbol{E}_a$ are slowly varying functions of coordinates $\boldsymbol{r}$ and time t, $\boldsymbol{k}$, $\boldsymbol{k}_1$, $\boldsymbol{k}_2$, and $\boldsymbol{k}_a$ are the wave vectors of light waves with frequencies ω, ω_1, ω_2, and ω_a, respectively, and c.c. stands for a complex conjugate. Then, representing the nonlinear polarization in the medium as a superposition of plane waves, we can write the equation for the amplitude of the anti-Stokes wave as

$$\frac{n_a}{c}\frac{\partial\boldsymbol{E}_a}{\partial t} + \frac{\partial\boldsymbol{E}_a}{\partial z} = i\frac{2\pi\omega_a}{cn_a}\boldsymbol{P}_{nl}(\omega_a)\exp(i k_a z) \,, \tag{4.182}$$

where $\boldsymbol{P}_{nl}(\omega_a)$, n_a, and k_a are the amplitude of the nonlinear polarization, the refractive index, and the z-component of the wave vector at the frequency ω_a. The pump wave amplitudes will be assumed to be constant. Now, the nonlinear polarization of a medium has to be found with the use of some model of the nonlinear medium.

Raman-Resonant Nonlinear Polarization and Nonlinear Susceptibilities

Within the framework of our model of a nonlinear medium, the third-order nonlinear polarization of the medium at the anti-Stokes frequency ω_a is given by [4.99]

$$P^{(3)}(\omega_a) = \frac{N}{4MD(\Omega, \omega_1 - \omega_2)}\left(\frac{\partial\alpha}{\partial Q}\right)_0^2 EE_1 E_2^* \,, \tag{4.183}$$

where

$$\begin{aligned}
D(\Omega, \omega_1 - \omega_2) &= \Omega^2 - (\omega_1 - \omega_2)^2 \\
&\quad - 2i\Gamma(\omega_1 - \omega_2) \,,
\end{aligned} \tag{4.184}$$

derivatives are taken in the equilibrium position, Γ is the phenomenologically introduced damping constant, M is the reduced mass of a molecule, N is the number density of molecules, an asterisk indicates a complex conjugate, Q is the amplitude of the Raman-active molecular vibration, which can be expressed in terms of the density matrix ρ of an ensemble of molecules,

$$Q = \mathrm{Sp}(\rho q) = \rho_{ab}q_{ba} \,, \tag{4.185}$$

where Sp is the trace operator and q is the operator of the vibrational coordinate.

Introducing the third-order nonlinear-optical susceptibility of the medium,

$$\chi^{(3)R} = \frac{N}{24MD(\Omega, \omega_1 - \omega_2)}\left(\frac{\partial\alpha}{\partial Q}\right)_0^2, \tag{4.186}$$

and solving (4.182), we arrive at the following expression for the intensity of the CARS signal I_a:

$$
I_a \propto \left| \chi^{(3)} (\omega_a; \omega, \omega_1, -\omega_2) \right|^2
$$
$$
\times II_1 I_2 l^2 \left(\frac{\sin\left(\frac{\Delta k l}{2}\right)}{\frac{\Delta k l}{2}} \right)^2 , \tag{4.187}
$$

where I, I_1, I_2 are the intensities of the pump and probe beams, l is the length of the nonlinear medium, and $\Delta k = |\Delta \boldsymbol{k}| = |\boldsymbol{k}_a - \boldsymbol{k} - \boldsymbol{k}_1 + \boldsymbol{k}_2|$ is the wave-vector mismatch. As can be seen from (4.187), the anti-Stokes wave is generated especially efficiently in the direction of phase matching, where $\Delta k = 0$.

The cubic nonlinear-optical susceptibility of a medium $\chi^{(3)}_{ijkl}$ is a fourth-rank tensor. The knowledge of the form of this tensor is important, in particular, for understanding the polarization properties of the signal of nonlinear Raman scattering. The form of the $\chi^{(3)}_{ijkl}$ tensor is determined by the symmetry properties of a medium. For an isotropic medium, only 21 of 81 tensor components of $\chi^{(3)}_{ijkl}$ are nonvanishing. Only three of these components are independent of each other, as the relations

$$
\chi^{(3)}_{1111} = \chi^{(3)}_{2222} = \chi^{(3)}_{3333} , \tag{4.188}
$$

$$
\chi^{(3)}_{1122} = \chi^{(3)}_{1133} = \chi^{(3)}_{2211} = \chi^{(3)}_{2233} = \chi^{(3)}_{3311} = \chi^{(3)}_{3322} , \tag{4.189}
$$

$$
\chi^{(3)}_{1212} = \chi^{(3)}_{2121} = \chi^{(3)}_{1313} = \chi^{(3)}_{3131} = \chi^{(3)}_{2323} = \chi^{(3)}_{3232} , \tag{4.190}
$$

$$
\chi^{(3)}_{1221} = \chi^{(3)}_{2112} = \chi^{(3)}_{1331} = \chi^{(3)}_{3113} = \chi^{(3)}_{2332} = \chi^{(3)}_{3223} , \tag{4.191}
$$

$$
\chi^{(3)}_{1111} = \chi^{(3)}_{1122} = \chi^{(3)}_{1212} = \chi^{(3)}_{1221} \tag{4.192}
$$

hold true for an isotropic medium [4.9, 99]. The form of the $\chi^{(3)}_{ijkl}$ tensor for all the crystallographic classes can be found in many textbooks on nonlinear optics [4.9, 10].

Phase Matching of Focused Beams
Generally, in the case of focused beams, phase-matching effects in nonlinear Raman scattering are taken into account through the phase-matching integral. In particular, for Gaussian beams, the expression for the overall power of the two-color CARS signal occurring in accordance with the scheme $\omega_a = 2\omega_1 - \omega_2$ is written

as [4.11, 100, 101]

$$
P_a = \left(\frac{3\pi^2 \omega_a}{c^2 n_a} \right)^2 \left| \chi^{(3)} \right|^2
$$
$$
\times P_1^2 P_2 \frac{32}{\pi^3} \left(\frac{b}{w_0^3} \right)^2 \int_0^\infty 2\pi r \, |J|^2 \, dr . \tag{4.193}
$$

Here, P_1 and P_2 are the powers of the pump beams with frequencies ω_1 and ω_2, respectively, w_0 is the waist size of the focused pump beams, b is the confocal parameter,

$$
J = \int_{-C_1}^{C_2} \frac{\exp\left(-\frac{r^2}{bH} \right)}{(1 + i\xi') (k'' - ik'\xi') \, H} \, d\xi' , \tag{4.194}
$$

where $-C_1$ and C_2 are the coordinates of the boundaries of the nonlinear medium,

$$
H = \frac{1 + \xi'^2}{k'' - ik'\xi} - i\frac{\xi' - \zeta}{k'} , \tag{4.195}
$$

$k'' = 2k_1 + k_2$, $k' = 2k_1 - k_2$, $\zeta = 2(z - f)/b$ is the normalized coordinate along the z-axis (f is the coordinate of the beam waist along the z-axis).

Equations (4.193–4.195) show that the information on the nonlinear cubic susceptibility in the CARS signal may be distorted by phase-matching effects. This problem has been analyzed both theoretically and experimentally for different modifications of nonlinear Raman spectroscopy [4.102]. The influence of absorption at the wavelength of pump and probe waves and at the frequency of the FWM signal can be taken into account by including the imaginary parts of the relevant wave vectors. The integral in (4.194) can be calculated in an analytical form for several particular cases, giving a clear physical understanding of the role of phase-matching and absorption effects in coherent FWM spectroscopy and imaging [4.103].

4.7.2 Methods of Nonlinear Raman Spectroscopy

In this section, we will briefly consider standard and widely used schemes for nonlinear Raman spectroscopy (Fig. 4.2), including coherent Raman scattering, stimulated Raman scattering, and the Raman-induced Kerr effect and provide a brief introduction into the vast area of DFWM.

Stimulated Raman Scattering
The idea of using stimulated Raman scattering (SRS) as a spectroscopic technique is based on the measurement

of the frequency dependence of the SRS small-signal gain, which is proportional to the imaginary part of the nonlinear cubic susceptibility of a Raman-active medium [4.9, 99]. The power of the pump wave in such measurements has to be chosen in such a way as to avoid uncontrollable instabilities and to obtain noticeable SRS gain. The SRS-based approach was successfully employed, in particular, for high-resolution spectroscopy of Raman transitions [4.104].

Limitations of SRS as a spectroscopic technique are due to instabilities arising for light intensities exceeding the threshold SRS intensity. These instabilities build up under conditions when several nonlinear processes, including self-focusing and self-phase modulation, compete with each other, often rendering the SRS method impractical for spectroscopic applications.

Coherent Anti–Stokes Raman Scattering

Instead of measuring the gain of one of two waves, as is done in SRS, Maker and Terhune [4.105] have demonstrated a spectroscopic technique based on measuring the frequency dependence of the intensity of a new wave generated at the anti-Stokes frequency $\omega_a = 2\omega_1 - \omega_2$ in the presence of two light waves with frequencies ω_1 and ω_2 chosen in such a way as to meet the condition of a Raman resonance with a Raman-active transition in a medium: $\omega_1 - \omega_2 \approx \Omega$ (Fig. 4.6c). This approach, called coherent anti-Stokes Raman scattering, has become one of the most widespread nonlinear Raman methods, allowing many urgent spectroscopic problems to be successfully solved and stimulating numerous engineering applications of nonlinear laser spectroscopy (so-called three-color CARS with $\omega_a = \omega_1 - \omega_2 + \omega_3$ is shown in Fig. 4.6c). Similar to the SRS process described in the previous section, CARS involves the stimulated scattering of light in a Raman-active medium. However, in contrast to the standard SRS scheme, where a Stokes wave is generated or amplified, the CARS process gives rise to the appearance of a new frequency component, suggesting a spectroscopic approach that is free of instabilities typically arising in SRS due to the competition of different nonlinear processes.

Due to its high spatial, temporal, and spectral resolution, the possibilities of studying highly luminous objects, and a rich variety of polarization methods, the CARS technique has gained a wide acceptance for temperature and concentration measurements in excited gases, combustion, and flames [4.99, 106–108], gas-phase analysis [4.99, 109, 110], high-resolution molecular spectroscopy [4.111, 112]. Short-pulse CARS gives an access to ultrafast processes and wave-packet

dynamics in molecular systems [4.113]. The nonlinear nature and the spectral selectivity of CARS make this method an ideal tool for nonlinear spectroscopy [4.114, 115]. The most recent advances in nonlinear Raman techniques include coherence-controlled CARS [4.116], enhancing the potential of CARS microscopy [4.117], and CARS in photonic-crystal fibers [4.118, 119].

The widely employed geometry of nonlinear Raman measurements implies the use of collinear focused laser beams. While focusing allows the intensity sufficient to ensure a reliable detection of the nonlinear Raman signal to be achieved, the collinear geometry of wave mixing increases the length of nonlinear interaction. However, such an approach is reasonable as long as the spatial resolution along the propagation coordinate is not important. The scheme of nonlinear Raman spectroscopy becomes resolvable along the propagation coordinate as soon as collinear beams are replaced by a noncollinear one (Fig. 4.6c). In CARS, this technique is called the boxcars geometry [4.120]. The interaction area is confined in this case to the region where the beams intersect each other, allowing a high spatial resolution to be achieved.

In the broad-beam CARS geometry Fig. 4.23, focused laser beams are replaced with broad or sheetlike beams. This approach allows the nonlinear Raman signal to image the whole areas of a nonlinear medium

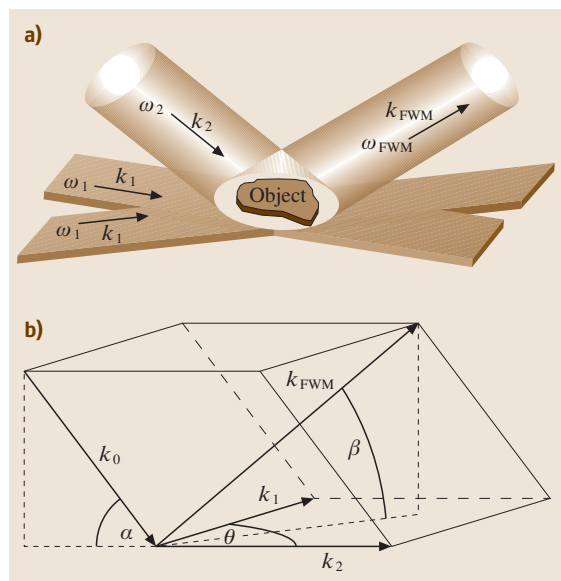

Fig. 4.23a,b Broad-beam folded coherent-anti-Stokes Raman scattering: (**a**) beam arrangements and (**b**) wave-vector diagram

on a charge-coupled device (CCD) camera. The idea of broad-beam CARS imaging, which was discussed by *Regnier* and *Taran* [4.121] in 1973, has later proved to be efficient for the solution of many problems of gas-phase and plasma diagnostics [4.102, 122, 123]. Significant progress in extracting the data concerning parameters of a gas medium was achieved, allowing CARS signals from molecules of different types to be simultaneously detected, with the development of a dual broadband CARS scheme [4.124, 125] and angularly resolved CARS [4.126].

Figure 4.23 illustrates the application of the broad-beam folded CARS geometry for the investigation of excited and ionized gases [4.122, 123]. In this scheme, a pair of cylindrically focused coplanar broad light beams with frequencies ω_1 and ω_2 and wave vectors $\mathbf{k}_1$ and $\mathbf{k}_2$, forming a small angle θ, irradiate a thin plasma layer in a plane parallel to the plane of the target (Fig. 4.23a). A cylindrically focused or a collimated nonfocused laser beam with frequency ω_3 and wave vector $\mathbf{k}_3$, which makes an angle α with the plane of the $\mathbf{k}_1$ and $\mathbf{k}_2$ vectors (Fig. 4.23b), irradiates the laser-produced spark from above. The FWM signal is generated in the direction $\mathbf{k}_{\text{FWM}}$ determined by phase-matching conditions, forming an angle β with the plane of the target (Figs. 4.23a,b). Imaging the one-dimensional FWM signal onto a CCD array, we were able to map the spatial distribution of resonant particles in the plasma line by line. The use of a collimated unfocused beam ω_3 enables slice-by-slice plasma imaging [4.102].

Raman-Induced Kerr Effect

The Raman-induced Kerr effect (RIKE) [4.9] is understood as an optical birefringence induced in an initially isotropic medium due to an anisotropic Raman-resonant third-order polarization of a medium. In this scheme, a nonlinear medium is irradiated with a pair of light beams with frequencies ω_1 and ω_2 whose difference is tuned, in accordance with the general idea of probing Raman-active vibrations, to a resonance with Raman-active transitions in a medium. Then, the polarization of a probe wave at the frequency ω_1 becomes perturbed due to the anisotropic nonlinear polarization induced in the Raman-active medium, which can be detected with the use of a polarization analyzer and a detector. The RIKE technique provides us with a convenient method for measuring the frequency dependence of the cubic susceptibility $\chi_{ijkl}^{(3)}$ around a Raman resonance. The transmission coefficient T of a polarization analyzer aligned in such a way as to block the probe beam in the absence of the pump beam is given

by [4.99]

$$T_1(\omega_1 - \omega_2) \propto \sin^2 2\gamma \left| \chi_{1122}^{(3)}(\omega_1; \omega_2, \omega_1, -\omega_2) \right.$$
$$\left. + \chi_{1221}^{(3)}(\omega_1; \omega_2, \omega_1, -\omega_2) \right|^2 I_2^2$$

(4.196)

in the case of a linearly polarized pump (I_2 is the intensity of the pump beam and γ is the angle between the polarization vectors of the pump and probe waves) and

$$T_c(\omega_1 - \omega_2) \propto \left| \chi_{1122}^{(3)R}(\omega_1; \omega_2, \omega_1, -\omega_2) \right.$$
$$\left. - \chi_{1221}^{(3)R}(\omega_1; \omega_2, \omega_1, -\omega_2) \right|^2 I_2^2$$

(4.197)

in the case of a circularly polarized pump. As can be seen from (4.197), the coherent background is completely suppressed in the case of a circularly polarized pump.

Importantly, RIKE is one of the four-wave mixing processes where the phase-matching condition is satisfied automatically regardless of the arrangement of the wave vectors of pump and probe waves, since the phase-matching condition $\mathbf{k}_1 = \mathbf{k}_2 + \mathbf{k}_1 - \mathbf{k}_2$ becomes an identity in this case.

Degenerate Four-Wave Mixing

Although, rigorously speaking, degenerate four-wave mixing does not employ Raman transitions and the models used to describe DFWM may sometimes differ from the standard ways of CARS description [4.9, 10], it is reasonable to briefly introduce DFWM as a nonlinear technique here, as it very frequently offers a useful alternative to CARS, allowing valuable data on a medium to be obtained in a convenient and physically clear way. DFWM is closely related to CARS as both processes are associated with the third-order nonlinearity of a medium. The main difference between these methods is that CARS implies the use of a two-photon Raman-type resonance (Fig. 4.6c), while DFWM is a frequency-degenerate process (Fig. 4.6d), involving either four one-photon resonances or a pair of two-photon resonances. With modern lasers capable of generating very short pulses, having large spectral widths, the DFWM signal can be detected simultaneously with CSRS and CARS in the same experimental geometry with the same molecular system by simply tuning the detection wavelength [4.127]. The combination of these nonlinear-optical approaches allows a more elaborate study of molecular relaxation and photochemistry processes, providing a much deeper insight

into the ultrafast molecular and wave-packet dynamics [4.127, 128].

The main advantages of DFWM as a spectroscopic technique are associated with the technical simplicity of this approach, which requires only one laser source and allows phase-matching conditions to be automatically satisfied regardless of the dispersion of the medium under study. Broadband DFWM [4.129] makes it possible to measure the temperature of excited gases, including atomic gases [4.130], with a single laser pulse. Folded broad-beam DFWM schemes are employed in several convenient and elegant methods for two-dimensional imaging of spatial distributions of gas parameters [4.131, 132].

4.7.3 Polarization Nonlinear Raman Techniques

Methods of polarization-sensitive four-photon spectroscopy provide an efficient tool for the solution of many problems arising in the investigation of Raman resonances. In particular, the polarization technique is a standard method to suppress the coherent background in CARS measurements [4.99, 106], which makes it possible to considerably improve the sensitivity of spectroscopic measurements [4.99] and improves the contrast in CARS microscopy [4.115]. Polarization techniques in FWM spectroscopy can separately measure the real and imaginary parts of the relevant third-order nonlinear-optical susceptibility [4.133, 134], resolve closely spaced lines in FWM spectra of molecules [4.99, 135] and atoms [4.102], and improve the contrast of cubic-susceptibility dispersion curves near Raman resonances [4.136, 137]. Polarization methods in nonlinear Raman spectroscopy [4.138–140] help to analyze the interference of vibrational Raman resonances with one- and two-photon electronic resonances in CARS spectra [4.141], and can be used to determine invariants of atomic and molecular Raman and hyper-Raman scattering tensors [4.102] and to perform conformational analysis for complex organic molecules [4.141]. A comprehensive review of polarization techniques employed for molecular spectroscopy was provided by *Akhmanov* and *Koroteev* [4.99].

Polarization Properties of the Coherent FWM Signal

When analyzing polarization properties of the FWM signal, one has to take into account the interference of resonant components of FWM related to various (molecular or atomic) transitions in the medium and the
Fig. 4.24a,b Polarization technique of nonlinear Raman spectrometry: **(a)** coherent ellipsometry and **(b)** polarization suppression of the nonresonant background in CARS spectroscopy

nonresonant coherent background. In particular, it is the interference of the resonant FWM component with the nonresonant coherent background that ensures the possibility to record complete spectral information concerning the resonance under study, including the data on the phase of resonant FWM.

The polarization ellipse of a Raman-resonant FWM signal is characterized by its ellipticity χ (which is defined as $\chi = \pm \mathrm{atan}(b/a)$, where atan stands for the arctangent function, b and a are the small and principal semiaxes of the polarization ellipse, respectively) and the tilt angle ψ of its principal axis (Fig. 4.24a). These parameters are related to the Cartesian components of the third-order polarization of a medium P_x and P_y by the following expressions [4.99]:

$$\tan(2\psi) = \tan(2\beta)\cos(\delta) , \tag{4.198}$$

$$\sin(2\chi) = \sin(2\beta)\sin(\delta) , \tag{4.199}$$

where β and δ are defined as

$$\tan(\beta) = \left| \frac{P_y}{P_x} \right| , \qquad (4.200)$$

$$\delta = \arg(P_y) - \arg(P_x) . \qquad (4.201)$$

The frequency dependencies of the FWM polarization ellipse parameters, as can be seen from (4.198) and (4.199), provide information concerning the phase of the resonant FWM component, allowing a broad class of phase measurements to be performed by means of nonlinear Raman spectroscopy.

Suppressing the Nonresonant Background

Polarization suppression of the nonresonant background in CARS is one of the most useful, practical, and widely employed polarization techniques in nonlinear Raman spectroscopy. Physically, the possibility of suppressing the nonresonant background in coherent Raman spectroscopy is due to the fact that the resonant and nonresonant components of the nonlinear polarization induced in a Raman-active medium are generally polarized in different ways. Let us illustrate this technique for the CARS process $\omega_a = 2\omega_1 - \omega_2$, where ω_a is the frequency of the anti-Stokes signal and ω_1 and ω_2 are the frequencies of pump waves, in the case of an isotropic medium. The third-order polarization responsible for the generation of the signal with the frequency ω_a is then written as

$$\boldsymbol{P}^{(3)} = [\boldsymbol{P}_r + \boldsymbol{P}_{nr}] E_1^2 E_2^* , \qquad (4.202)$$

where E_1 and E_2 are the amplitudes of the light fields, $\boldsymbol{P}_r$ and $\boldsymbol{P}_{nr}$ are the resonant and nonresonant components of the third-order polarization induced in the Raman-active medium.

In the case of an isotropic medium, relations (4.188–4.192) are satisfied for both resonant and nonresonant components of the nonlinear-optical susceptibility. However, only the nonresonant part of the cubic susceptibility satisfies the Kleinman relations [4.9, 99],

$$\chi_{1111}^{(3)nr} = 3\chi_{1122}^{(3)nr} = 3\chi_{1221}^{(3)nr} = 3\chi_{1212}^{(3)nr} , \qquad (4.203)$$

while the resonant part of the cubic susceptibility is usually characterized by a considerable dispersion near a Raman resonance, which implies that the resonant cubic susceptibility tensor components are not invariant with respect to the permutation of their frequency arguments. Taking into account relations (4.203) for the nonresonant part of the cubic susceptibility, we arrive at the following expression for the nonresonant and

resonant components of the third-order polarization of a Raman-active medium:

$$\boldsymbol{P}_{nr} = \chi_{1111}^{(3)nr} \left[2\boldsymbol{e}_1 \left(\boldsymbol{e}_1 \boldsymbol{e}_2^* \right) + \boldsymbol{e}_2^* \left(\boldsymbol{e}_1 \boldsymbol{e}_1 \right) \right] , \qquad (4.204)$$

$$\boldsymbol{P}_r = 3\chi_{1111}^{(3)r} \left[(1 - \bar{\rho}) \boldsymbol{e}_1 \left(\boldsymbol{e}_1 \boldsymbol{e}_2^* \right) + \bar{\rho} \boldsymbol{e}_2^* \left(\boldsymbol{e}_1 \boldsymbol{e}_1 \right) \right] , \qquad (4.205)$$

where $\bar{\rho} = \chi_{1221}^{(3)r} / \chi_{1111}^{(3)r}$ and $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ are the unit polarization vectors of the light fields with frequencies ω_1 and ω_2, respectively (Fig. 4.24b).

Suppose that the pump fields with frequencies ω_1 and ω_2 are linearly polarized and their polarization vectors $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ are oriented at an angle μ with respect to each other, as shown in Fig. 4.24b. The vectors $\boldsymbol{P}_{nr}$ and $\boldsymbol{P}_r$, in accordance with (4.204) and (4.205), generally have different orientations in space making a nonzero angle θ with each other. Therefore, by orienting the polarization analyzer in such a way as to suppress the nonresonant component of the CARS signal (by setting the angle ε measured from the direction perpendicular to the vector $\boldsymbol{P}_{nr}$ equal to zero, see Fig. 4.24b), one can analyze background-free CARS spectra.

In many situations, nonlinear Raman study of Raman-active media would be simply impossible without this technique. This is the case, for example, when the CARS signal from a resonant gas under investigation is too weak to be reliably detected against the nonresonant CARS signal from the windows of a gas cell. Another example is the CARS spectroscopy on low concentrations of complex biological molecules, when the coherent background due to solvent molecules may be so strong that it leaves no way to detect the CARS signal from the molecules being studied without polarization suppression of the nonresonant nonlinear Raman signal. Even small deviations of the orientation of the polarization analyzer from the background-suppression position may be crucial, leading to dramatic changes in the signal-to-noise ratio. Another important conclusion that can be made from (4.204) and (4.205) is that, measuring the ratio of the CARS signals for different polarization arrangements is a convenient way of determining the properties of the nonlinear susceptibility tensor and, thus, characterizing the symmetry properties of molecular transitions under investigation.

Coherent Ellipsometry

Coherent ellipsometry, i.e., the measurement of the parameters of the polarization ellipse corresponding to the FWM signal, is one of widely used modifications of polarization-sensitive four-photon spectroscopy. Below,

we consider the main physical principles and discuss the main ideas of coherent ellipsometry.

The possibility of reconstructing the real and imaginary parts of the nonlinear-optical susceptibility of a medium as functions of frequency and time is due to the interference of the resonant FWM component with the nonresonant coherent background, which ensures the recording of the phase information for the resonance being studied. For a broad class of problems, the nonlinear polarization of a medium responsible for coherent FWM processes can be represented as a sum of the nonresonant and resonant components described by a real vector $\boldsymbol{P}_{\mathrm{nr}}$ and a complex vector $\boldsymbol{P}_{\mathrm{r}}$, respectively. Choosing the x-axis along the vector $\boldsymbol{P}_{\mathrm{nr}}$ (Fig. 4.24b), we can write the Cartesian components of the total polarization of a medium cubic in the external field as

$$P_x = P_{\mathrm{nr}} + P_{\mathrm{r}} e^{\mathrm{i}\varphi} \cos(\theta), \qquad (4.206)$$

$$P_y = P_{\mathrm{r}} e^{\mathrm{i}\varphi} \sin(\theta), \qquad (4.207)$$

where φ is the phase of the resonant component of the nonlinear polarization and θ is the angle between the resonant and nonresonant components.

Knowing the parameters of the polarization ellipse from ellipsometric measurements, we can reconstruct, with the use of (4.198), (4.199), (4.206), (4.207), the real and imaginary parts of the resonant nonlinear polarization as functions of frequency and time from the experimental data of coherent ellipsometry.

In the important particular case when the resonant component of the FWM signal can be considered as a small correction to the nonresonant component, the general procedure of separating the real and imaginary parts of the nonlinear polarization of a medium becomes especially simple. One can easily verify that the relations [4.99]

$$\psi = \beta \cos(\varphi) \propto \mathrm{Re}(P) \qquad (4.208)$$
$$\chi = \beta \sin(\varphi) \propto \mathrm{Im}(P) \qquad (4.209)$$

are satisfied in this case, showing that the spectral or temporal dependencies of the parameters ψ and χ of the FWM polarization ellipse respectively reproduce the spectral or temporal dependencies of the real and imaginary parts of the resonant component of the nonlinear polarization of a medium.

Thus, the data obtained by means of coherent ellipsometry enable one to extract complete information concerning the resonant component of the nonlinear polarization of a medium, including information on its phase [4.134]. Note that no assumptions regarding the

shape of the line observed in a nonlinear Raman spectrum was made in our consideration, which means that this approach can be applied to a broad class of spectral lines. This procedure can be also extended to the time domain, allowing not only the spectra but also the time dependencies of the real and imaginary parts of the nonlinear polarization of a medium to be reconstructed. Finally, close molecular and atomic lines unresolvable in amplitude nonlinear Raman spectra can be also resolved in certain cases with the use of the phase information stored in coherent nonlinear spectra.

4.7.4 Time–Resolved Coherent Anti–Stokes Raman Scattering

The method of time-resolved FWM spectroscopy implies that information on the parameters of atomic or molecular systems is extracted from an impulse response of a coherently excited system rather than from the frequency dispersion of nonlinear susceptibilities, as is done in frequency-domain FWM spectroscopy. The original idea of time-resolved CARS is that a light pulse with a duration shorter than the characteristic transverse relaxation time T_2 induces coherent molecular vibrations with amplitude $Q(t)$, and the decay kinetics of these vibrations is analyzed with the use of another, probe light pulse, which is delayed in time with respect to the pump pulses. The complete set of equations governing the processes related to time-domain CARS includes the SVEA wave equation (4.182) and the equations for the amplitude of coherent molecular vibrations $Q(t)$, defined in accordance with (4.185), and the normalized population difference between the levels involved in the Raman resonance, $n = \rho_{\mathrm{aa}} - \rho_{\mathrm{aa}}$:

$$\frac{\partial^2 Q}{\partial t^2} + \frac{2}{T_2} \frac{\partial Q}{\partial t} + \Omega^2 Q = \frac{1}{2M} \frac{\partial \alpha}{\partial Q} n E^2, \qquad (4.210)$$

$$\frac{\partial n}{\partial t} + \frac{n-1}{T_1} = \frac{1}{2\hbar\Omega} \frac{\partial \alpha}{\partial Q} E^2 \frac{\partial Q}{\partial t}, \qquad (4.211)$$

where T_1 is the population relaxation time.

In many cases, (4.182), (4.210), and (4.211) can be simplified with the use of the slowly varying envelope approximation. In this approximation, the energy of the CARS signal as a function of the delay time τ of the probe pulse in the scheme of time-resolved CARS with short light pulses and $\Delta k = 0$ is given by [4.99]

$$W_{\mathrm{a}}(\tau) \propto \int_{-\infty}^{\infty} |Q(t)A(t-\tau)|^2 \, \mathrm{d}t. \qquad (4.212)$$

Since the intensity of the CARS signal in such a scheme is determined by (4.212), the use of sufficiently short probe pulses makes it possible to measure the kinetics of $Q(t)$. Experiments by *Alfano* and *Shapiro* [4.142] and *von der Linde* et al. [4.143] have demonstrated the possibility of using the time-domain CARS technique to directly measure the T_2 time for Raman-active modes in crystals and organic liquids.

Formulas (4.185–4.187) and (4.212) show the relation between the information that can be obtained by frequency- and time-domain CARS spectroscopy. In fact, this information is essentially the same, and frequency- and time-domain CARS methods can successfully complement each other in studies of complex inhomogeneously broadened spectral bands. For example, in frequency-domain CARS spectroscopy, the phase information on molecular resonances can be extracted through polarization measurements and coherent ellipsometry (see the discussion above), and the level of coherent nonresonant background can be suppressed by means of the relevant polarization technique [see (4.204), (4.205) and Fig. 4.24b]. In time-domain CARS, on the other hand, the nonresonant background appears only at zero delay time between the pump and probe pulses, having no influence on the transient signal, while the impulse-response measurements may directly provide the information not only on the amplitude, but also on the phase of a molecular or atomic resonance. The development of femtosecond laser systems resulted in the impressive technical and conceptual progress of time-domain FWM spectroscopy, allowing photochemistry processes and molecular dynamics to be monitored in real time (see [4.109, 110, 113] for a review).

4.8 Waveguide Coherent Anti–Stokes Raman Scattering

4.8.1 Enhancement of Waveguide CARS in Hollow Photonic–Crystal Fibers

The general idea of waveguide CARS [4.144–149] is to improve the efficiency of four-wave mixing by increasing the interaction length and increasing the intensity of pump waves with given pump powers by reducing the transverse size of the wave-guiding layer in planar waveguides or the core diameter in optical fibers. CARS spectroscopy of the gas phase leaves no alternative to hollow waveguides and fibers. Since the refractive index of the core in such waveguides is lower than the refractive index of the cladding, the modes guided in the hollow core are always characterized by nonzero losses. The magnitude of these losses scales [4.150, 151] as λ^2/a^3 preventing fibers with small inner diameters to be used in nonlinear-optical experiments, which limits the waveguide CARS enhancement factors attainable with such fibers. In hollow-core photonic-crystal fibers [4.36, 152, 153], which guide light due to photonic band gaps, optical losses can often be kept low even in the case of small core diameters. Hollow PCFs with an inner diameter of $\approx 15\,\mu m$ demonstrated by *Benabid* et al. [4.154] have the magnitude of optical losses on the order of $1-3\,dB/m$. We will show below that this property of hollow-core microstructure fibers makes them very attractive for waveguide CARS spectroscopy.

We start with the expression [4.11] for the power of the three-color CARS signal generated at the frequency $\omega_s = \omega_0 + \omega_1 - \omega_2$ by pump fields with frequencies ω_0, ω_1 and ω_2:

$$P_{CARS} = 1.755 \times 10^{-5} \frac{\omega_s^4 k_0 k_1 k_2}{c^4 k_s^2 k'} D^2$$
$$\times \left| \chi_{eff}^{(3)} \right|^2 P_0 P_1 P_2 F_2, \qquad (4.213)$$

where k_0, k_1, k_2, k_s are the wave numbers of light fields with frequencies ω_0, ω_1, ω_2, ω_s, respectively; P_0, P_1, P_2 are the powers of the fields with frequencies ω_0, ω_1, ω_2, respectively; $\chi_{eff}^{(3)}$ is the effective combination of cubic nonlinear-optical susceptibility tensor components corresponding to the chosen set of polarization vectors of pump and signal fields; D is the frequency degeneracy factor of the four-wave mixing process defined after *Maker* and *Terhune* [4.105];

$$F_2 = \frac{2k'}{\pi b} \int_0^\infty 2\pi R \, dR$$
$$\times \left| \int_{-\zeta}^{\xi} d\xi' \frac{\exp\left(\frac{ib\Delta k\xi'}{2}\right)}{(1 + i\xi')(k'' - ik'\xi')\,H} \exp\left(-\frac{R^2}{bH}\right) \right|^2$$
$$(4.214)$$

is the phase-matching integral, $\Delta k = k_s - (k_0 + k_1 - k_2)$, $k' = k_0 + k_1 - k_2$, $k'' = k_0 + k_1 + k_2$, $\xi = 2(z - f)/b$, $\zeta = 2f/b$, $b = n_j\omega_j w_0^2/c$ is the confocal parameter, w_0 is the

beam waist diameter,

$$H = \frac{(1+\xi')^2}{(k'' - \mathrm{i}k'\xi')} - \mathrm{i}\frac{\xi' - \xi}{k'}. \qquad (4.215)$$

In the limiting case of tight focusing, when the confocal parameter b is much less than the length of the nonlinear medium l, $b \ll l$, no increase in the CARS power can be achieved by reducing the pump-beam waist radius because of the simultaneous decrease in the interaction length. Mathematically, this well-known result is a consequence of the tight-focusing limit existing for the phase-matching integral (4.214). For small phase mismatches, $\Delta k l \ll \pi$, the phase-matching integral can be written in this limiting case as

$$F_2 = \frac{4\pi^2}{\left(1 + \frac{k''}{k'}\right)^2}. \qquad (4.216)$$

In the opposite limiting case of loosely focused pump beams, $b \gg l$, weak absorption and negligible phase mismatches, the phase-matching integral is reduced to

$$F_2 = \frac{k'}{k''}\frac{4l^2}{b^2}. \qquad (4.217)$$

Since the latter regime is exactly the case of waveguide CARS, we can use (4.216) and (4.217) to estimate the enhancement of waveguide CARS with respect to the regime of tight focusing. Phase mismatches in waveguide CARS should be understood as difference of propagation constants of waveguide modes involved in the wave-mixing process, and the mode-overlapping integral should generally be included to allow for the contribution of waveguide effects, in particular, the influence of higher-order waveguide modes.

Assuming that the beam waist radius of focused pump beams is matched to the inner radius of a hollow fiber, a, we find from (4.216) and (4.217) that the waveguide CARS enhancement factor scales as $\lambda^2 l^2/a^4$. The length l can be made very large in the case of fibers, but the fundamental limitation of waveguide CARS in hollow fibers comes from optical losses, whose magnitude scales as λ^2/a^3. The influence of optical losses and phase-mismatch effects on the CARS process in the loose-focusing regime can be included through the factor

$$M \propto \exp\left[-(\Delta\alpha + \alpha_4)\,l\right]$$
$$\times \left(\frac{\sinh^2\left(\frac{\Delta\alpha l}{2}\right) + \sin^2\left(\frac{\Delta k l}{2}\right)}{\left(\frac{\Delta\alpha l}{2}\right)^2 + \left(\frac{\Delta k l}{2}\right)^2}\right) l^2, \qquad (4.218)$$

where $\Delta\alpha = (\alpha_1 + \alpha_2 + \alpha_3 - \alpha_4)/2$, α_1, α_2, α_3, α_4 are the magnitudes of optical losses at frequencies ω_0, ω_1, ω_2, ω_s, respectively.

It is straightforward to see from (4.218) that the amplitude of the CARS signal in a lossy waveguide reaches its maximum at some optimal length $l_{\mathrm{opt}}^{\mathrm{CARS}}$, which is given by

$$l_{\mathrm{opt}}^{\mathrm{CARS}} = \frac{1}{\Delta\alpha} \ln\left(\frac{\alpha_1 + \alpha_2 + \alpha_3}{\alpha_4}\right). \qquad (4.219)$$

With $\alpha_1 \approx \alpha_2 \approx \alpha_3 \approx \alpha_4 = \alpha$, (4.219) yields

$$l_{\mathrm{opt}}^{\mathrm{CARS}} = \frac{\ln 3}{\alpha}. \qquad (4.220)$$

Then, setting $\Delta k = 0$ for phase matching and $w_0 = 0.73a$ for the best matching of input beams with the fiber mode radius, assuming that the refractive index of the gas filling the fiber core is approximately equal to unity, and taking into consideration that $M = (3^{1/2} - 3^{-1/2})^2/(3\ln 3)^2 \approx 0.123$ for $\Delta k = 0$ and $l = l_{\mathrm{opt}}^{\mathrm{CARS}} = \ln 3/\alpha$, we arrive at the following expression for the waveguide CARS enhancement factor:

$$\mu = 1.3 \times 10^{-3} \frac{(k' + k'')^2}{k'k''}\frac{\lambda^2}{\alpha^2 a^4}. \qquad (4.221)$$

We can now see from (4.221), that the waveguide CARS enhancement factor scales as $\lambda^2/\alpha^2 a^4$ and is limited by fiber losses. We will show in the next section that, due to the physically different mechanism behind light guiding, hollow microstructure fibers allow CARS enhancement factors to be substantially increased with respect to standard, solid-cladding hollow fibers. We will examine also the CARS enhancement factors as functions of the core radius for the fibers of both types and investigate the influence of the phase mismatch.

We start with the case of standard, solid-cladding hollow fibers. The magnitude of optical losses for EH_{mn} modes in such fibers is given by [4.150]

$$\alpha = \left(\frac{u_{mn}}{2\pi}\right)^2 \frac{\lambda^2}{a^3}\frac{n^2 + 1}{\sqrt{n^2 - 1}}, \qquad (4.222)$$

where u_{mn} is the eigenvalue of the characteristic equation for the relevant hollow-fiber mode (the mode parameter), n is the refractive index of the fiber cladding, and the refractive index of the gas filling the fiber core is set equal to unity.

Plugging optical losses into the CARS enhancement factor by substituting (4.222) into (4.221) with $u_n = 2.4$ for the limiting eigenvalue of the EH_{11} mode of a hollow fiber, we derive the following expression for the factor of CARS enhancement in a solid-cladding hollow fiber

relative to the tight-focusing regime in the case of exact phase matching:

$$\rho = 6.1 \times 10^{-2} \frac{(k' + k'')^2}{k' k''} \left(\frac{a}{\lambda}\right)^2 \frac{n^2 - 1}{(n^2 + 1)^2}. \quad (4.223)$$

Optical losses, which grow with decreasing inner radius a, limit the CARS enhancement, with the factor ρ rapidly lowering with decreasing a for small values of the fiber inner radius. The situation radically changes in the case of a microstructure fiber. The magnitude of optical losses for such fibers, as mentioned above, may be on the order of $1-3\,\text{dB/m}$ in the case of fibers with a hollow core diameter of about $15\,\mu\text{m}$ [4.154]. In the case of small inner radii, microstructure fibers provide much higher CARS enhancement factors than solid-core hollow fibers. The CARS enhancement factor in hollow microstructure fibers with the magnitude of optical losses equal to 0.1 and $0.01\,\text{cm}^{-1}$ starts to exceed the CARS enhancement factor in a solid-cladding hollow fiber for core radii less than 20 and $45\,\mu\text{m}$, respectively. For hollow fibers with small core radii, the factor μ may be several orders of magnitude higher than the enhancement factor ρ.

An additional source of radiation losses in hollow fibers is related to radiation energy transfer to higher-order waveguide modes. The efficiency of this nonlinear-optical mode cross-talk process depends on radiation intensity and the mismatch Δk_c of propagation constants of waveguide modes involved in energy exchange. Starting with the standard expression for the propagation constants of EH_{mn} modes in a hollow fiber, we arrive at the following formula for the coherence length $l_c = \pi(2|\Delta k_c|)^{-1}$ of the mode cross-talk process:

$$l_c = \frac{2\pi^2}{\lambda} \frac{a^2}{|u_2^2 - u_1^2|}, \quad (4.224)$$

where u_2 and u_1 are the parameters of cross-talking fiber modes. The coherence length l_c, as can be seen from (4.224), becomes very small for guided modes of high orders, making the efficiencies of energy transfer from the fundamental to very high order modes negligible. For the cross-talk between the lowest order EH_{11} and EH_{12} modes, with $u_1 \approx 2.4$ and $u_2 \approx 5.5$, the coherence length can be estimated as $l_c \approx 0.8a^2/\lambda$. The coherence length of such a cross-talk process is typically much smaller than the optimal length for the wave-mixing process (4.220). However, for high-intensity pump beams, the efficiency of this cross-talk

process increases [4.155], and the energy lost from the fundamental mode due to the excitation of higher-order modes may become comparable with radiation energy leakage with the characteristic length governed by (4.222).

Importantly, the scaling law of the waveguide CARS enhancement factor as a function of the magnitude of optical losses, fiber inner radius, and radiation wavelength differs from a similar scaling law of the waveguide SRS enhancement factor [4.23], $\eta = \lambda/\alpha a^2$. Physically, this difference stems from differences in scattering mechanisms involved in SRS and CARS, with SRS and CARS signals building up in different fashions as functions of the interaction length and pump field amplitudes. The difference in waveguide enhancement factors for SRS and CARS suggests different strategies for optimizing fibers designed to enhance these processes.

Phase mismatch, resulting from the difference in propagation constants of guided modes involved in the CARS process, is another important factor limiting the efficiency of CARS in a hollow fiber. In the case of nonzero phase mismatch Δk, the optimal length for the CARS process can be found from a transcendental equation that immediately follows from (4.218):

$$\Delta\alpha \sinh\left(\Delta\alpha l_{\text{opt}}^{\text{CARS}}\right) + \Delta k \sin\left(\Delta k l_{\text{opt}}^{\text{CARS}}\right)$$
$$+ (\Delta\alpha + \alpha_4)$$
$$\times \left[\cos\left(\Delta k l_{\text{opt}}^{\text{CARS}}\right) - \cosh\left(\Delta\alpha l_{\text{opt}}^{\text{CARS}}\right)\right] = 0 \,.$$
$$(4.225)$$

Phase mismatch reduces the maximum waveguide CARS enhancement attainable with a hollow microstructure fiber, with the power of the CARS signal becoming an oscillating function of the fiber length. The characteristic period of these oscillations is determined by the coherence length. Oscillations become less pronounced and then completely flatten out as optical losses build up. No oscillations is observed when the attenuation length becomes less than the coherence length. An important option offered by hollow microstructure fibers is the possibility to compensate for the phase mismatch related to the gas dispersion with an appropriate choice of waveguide parameters due to the waveguide dispersion component, scaling as a^{-2} in the case of a hollow fiber.

We have shown in this section that hollow microstructure fibers offer a unique opportunity of implementing nonlinear-optical interactions of waveguide modes with transverse sizes of several microns in a gas medium, opening the ways to improve the

efficiency of nonlinear-optical processes, including four-wave mixing and coherent anti-Stokes Raman scattering, and suggesting the principle for the creation of highly sensitive gas-phase sensors based on nonlinear spectroscopic techniques. Hollow-core microstructure fibers have been demonstrated to allow the waveguide CARS efficiency to be substantially increased as compared to standard, solid-cladding hollow fibers. The theorem predicting an l^2/a^4 enhancement for a waveguide CARS process in a hollow fiber with an inner radius a and length l has been extended to include new solutions offered by microstructure fibers. The maximum CARS enhancement in a hollow microstructure fiber was shown to scale as $\lambda^2/\alpha^2 a^4$ with radiation wavelength λ, radiation losses α, and the inner fiber radius, allowing CARS efficiency to be substantially improved in such a fiber. This $\lambda^2/\alpha^2 a^4$ CARS enhancement factor differs from the $\lambda/\alpha a^2$ ratio, characterizing waveguide SRS enhancement in a hollow microstructure fiber, which is related to the difference in the physical nature of SRS and CARS signals and suggests different strategies for optimizing fibers designed to enhance CARS and SRS processes.

4.8.2 Four–Wave Mixing and CARS in Hollow–Core Photonic–Crystal Fibers

Hollow-core photonic-crystal fibers (PCFs) [4.36, 152, 153] offer new interesting options for high-field physics and nonlinear optics. Waveguide losses can be radically reduced in such fibers relative to standard, solid-cladding hollow fibers due to the high reflectivity of a periodically structured fiber cladding within photonic band gaps (PBGs) [4.152, 153, 156], allowing transmission of high-intensity laser pulses through a hollow fiber core in isolated guided modes with typical transverse sizes of $10–20\,\mu m$. Due to this unique property, hollow PCFs can substantially enhance nonlinear-optical processes [4.157], including stimulated Raman scattering [4.154, 158, 159], four-wave mixing (FWM) [4.160], coherent anti-Stokes Raman scattering (CARS) [4.118], and self-phase modulation [4.161]. Air-guided modes in hollow PCFs can support high-power optical solitons [4.162, 163], allow transportation of high-energy laser pulses for technological [4.68, 164] and biomedical [4.165] applications.

In this section, we discuss phase-matched FWM of millijoule nanosecond pulses in hollow PCFs with a period of the photonic-crystal cladding of about $5\,\mu m$ and a core diameter of approximately $50\,\mu m$. We will show that Raman-resonant FWM in large-core hollow

PCFs enhances the potential of waveguide CARS in hollow fibers, providing a convenient sensing tool for condensed-phase species adsorbed on the inner fiber walls and trace-gas detection.

Large-core-area hollow PCFs employed in experiments [4.119, 166] were fabricated using a standard procedure, which involves stacking glass capillaries into a periodic array and drawing this preform at a fiber-drawing tower. Several capillaries have been omitted from the central part of the stack, to produce a hollow core of the fiber. While in standard hollow PCFs, the number of omitted capillaries is seven, PCFs used in our experiments had a hollow core in the form of a regular hexagon with each side corresponding to five cane diameters. The inset in Fig. 4.25 shows an image of a hollow PCF with a period of the cladding of approximately $5\,mm$ and a core diameter of about $50\,\mu m$. The baking of capillaries forming the photonic-crystal structure, as shown in the image, allows a hollow waveguide with a nearly ideal $50\,\mu m$-diameter hexagonal core to be fabricated. It is still to be explored whether this technique can be scaled up to the fabrication of hollow PCFs with even larger core diameters. Transmission spectra
Fig. 4.25 Transmission spectrum of the hollow-core PCF. The *inset* shows the cross-section view of the PCF with a period of the cladding structure of about $5\,\mu m$

of hollow PCFs employed in our experiments display well-pronounced passbands (Fig. 4.25), indicating the PBG guidance of radiation in air modes of the fiber.

The laser system used in experiments [4.119, 166] consisted of a Q-switched Nd:YAG master oscillator, Nd:YAG amplifiers, frequency-doubling crystals, a dye laser, as well as a set of totally reflecting and dichroic mirrors and lenses adapted for the purposes of CARS experiments. The Q-switched Nd:YAG master oscillator generated 15 ns pulses of 1.064 μm radiation, which were then amplified up to about 30 mJ by Nd:YAG amplifiers. A potassium dihydrogen phosphate (KDP) crystal was used for the frequency doubling of the fundamental radiation. This second-harmonic radiation served as a pump for the dye laser, generating frequency-tunable radiation within the wavelengths ranges 540–560 and 630–670 nm, depending on the type of dye used as the active medium for this laser. All the three outputs of the laser system, viz., the fundamental radiation, the second harmonic, and frequency-tunable dye-laser radiation, were employed as pump fields in FWM, as described below. The frequency dependencies of the anti-Stokes signals produced through different FWM processes were measured point by point by scanning the frequency of dye-laser radiation. The energies of these pump fields were varied in our experiments from 0.5 up to 10 mJ at the fundamental wavelength, from 0.5 to 8 mJ in the second harmonic, and from 0.05 to 0.7 mJ for dye-laser radiation. To couple the laser fields into the fundamental mode of the PCF, we focused laser beams into spots with a diameter of 35 μm at the input end of the fiber. The PCF could withstand the energy of fundamental radiation up to 10 mJ, corresponding to a laser fluence of approximately 630 J/cm^2, without an irreversible degradation of fiber performance because of optical breakdown. Laser-induced breakdown on PCF walls was judged by a dramatic irreversible reduction in fiber transmission and intense sideward scattering of laser radiation, visible through the fiber cladding. While the achieved level of input energies was sufficient to produce reliably detectable FWM signals in our experiments, a further increase in the laser radiation energy coupled into the PCF is possible through a more careful optimization of the coupling geometry.

FWM processes with the CARS-type frequency-mixing scheme $\omega_a = 2\omega_1 - \omega_2$ (ω_1 and ω_2 are the frequencies of the pump fields and ω_a is the frequency of the anti-Stokes signal produced through FWM) were studied in our experiments for two different sets of pump and signal frequencies. In the first FWM process, used

in our experiments to test phase matching and assess the influence of waveguide losses, two waves with the wavelength $\lambda_1 = 2\pi c/\omega_1$ ranging from 630 to 665 nm, provided by the dye laser, are mixed with the fixed-frequency field of the fundamental radiation at $\lambda_2 = 1064$ nm, to generate an anti-Stokes signal within the range of wavelengths λ_a from 445 to 485 nm. The second FWM process, designed to demonstrate the potential of CARS spectroscopy with hollow PCFs, is a standard Nd:YAG-laser CARS arrangement with $\lambda_1 = 532$ nm and λ_2 ranging from 645 to 670 nm.

To assess the influence of phase matching and radiation losses on the intensity of the FWM signal generated in a hollow PCF, we use (4.213), (4.218), and (4.225) to write the power of the anti-Stokes signal as $P_a \propto |\chi_{eff}^{(3)}|^2 P_1 P_2^2 M$, where P_1 and P_2 are the powers of the fields with frequencies ω_1 and ω_2, respectively; $\chi_{eff}^{(3)}$ is the effective combination of cubic nonlinear-optical susceptibility tensor components; and the factor M includes optical losses and phase-mismatch effects: $M(\Delta\alpha l, \alpha_a l, \delta\beta l) = \exp[(\Delta\alpha + \alpha_a)l][\sinh^2(\Delta\alpha l/2) + \sin^2(\delta\beta l/2)][(\Delta\alpha l/2)^2 + (\delta\beta l/\delta\beta l/2)^2]^{-1}l^2$, where $\Delta\alpha = (2\alpha_1 + \alpha_2 - \alpha_a)/2$, α_1, α_2, and α_a are the magnitudes of optical losses at frequencies ω_1, ω_2, and ω_a, respectively, and $\delta\beta$ is the mismatch of the propagation constants of waveguide modes involved in the FWM process. In order to provide an order of magnitude estimate on typical coherence lengths $l_c = \pi/(2|\delta\beta|)$ for FWM processes in hollow PCFs and to choose PCF lengths L meeting the phase-matching requirement $L \leq l_c$ for our experiments, we substitute the dispersion of a standard hollow fiber with a solid cladding for the dispersion of PCF modes in these calculations. As shown by earlier work on PBG waveguides [4.167], such an approximation can provide a reasonable accuracy for mode dispersion within the central part of PBGs, but fails closer to the passband edges. For the waveguide FWM process involving the fundamental modes of the pump fields with $\lambda_1 = 532$ nm and $\lambda_2 = 660$ nm, generating the fundamental mode of the anti-Stokes field in a hollow fiber with a core radius of 25 μm, the coherence length is estimated as $l_c \approx 10$ cm. Based on this estimate, we choose a fiber length of 8 cm for our FWM experiments. With such a choice of the PCF length, effects related to the phase mismatch can be neglected as compared with the influence of radiation losses.

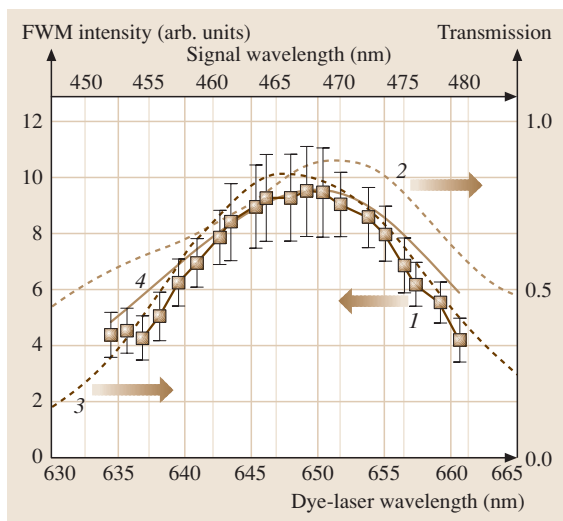
Phase matching for waveguide CARS in the PCF was experimentally tested by scanning the laser frequency difference $\omega_1 - \omega_2$ off all the Raman resonances (with λ_1 ranging from 630 to 665 nm and $\lambda_2 = 1064$ nm)


Fig. 4.26 Intensity of the $\omega_a = 2\omega_1 - \omega_2$ four-wave mixing signal from the hollow PCF with the length of 8 cm versus the wavelength of dye-laser radiation with λ_1 ranging from 630 to 665 nm and $\lambda_2 = 1064$ nm: (1) the measured spectrum of the FWM signal, (2) fiber transmission for dye-laser radiation, (3) fiber transmission for the FWM signal, and (4) the spectral profile of the factor M

and using the above expression for $M(\Delta\alpha l, \alpha_a\, l, \delta\beta l)$ with $\delta\beta L \approx 0$ to fit the frequency dependence of the FWM signal. Dots with error bars (line 1) in Fig. 4.26 present the intensity of the anti-Stokes signal from hollow PCFs measured as a function of the frequency of the dye laser. Dashed lines 2 and 3 in this figure display the transmission of the PCF for dye-laser radiation and the anti-Stokes signal, respectively. Solid line 4 presents the calculated spectral profile of the factor $M(\Delta\alpha L, \alpha_a\ L, 0)$. Experimental frequency dependencies of the FWM signals, as can be seen from the comparison of lines 1 and 4 in Fig. 4.26, are fully controlled by the spectral contours of PCF passbands (lines 2 and 3), indicating that phase-mismatch effects are much less significant for the chosen PCF lengths than variations in radiation losses.

The second series of experiments was intended to demonstrate the potential of waveguide CARS in a hollow PCF for the sensing of Raman-active species. For this purpose, the frequency difference of the second-harmonic and dye-laser pump fields was scanned through the Raman resonance, $\omega_1 - \omega_2 = 2\pi c\Omega$, with O$-$H stretching vibrations of water molecules, adsorbed on the inner PCF walls. The frequencies Ω of O$-$H

stretching vibrations of water molecules typically fall within a broad frequency band of 3200–3700 cm^{-1}. The frequency dependence of the FWM signal from the PCF substantially deviates from the spectral profile of the factor $M(\Delta\alpha L, \alpha_a\ L, 0)$ (cf. lines 1 and 4 in Fig. 4.27), clearly indicating the contribution of Raman-active species to the FWM signal. To discriminate between the CARS signal related to water molecules adsorbed on the PCF walls against the OH contamination of the PCF cladding, we measured the spectrum of the CARS signal from a PCF heated above a burner. Heating by 30 K during 30 min reduced the amplitude of the Raman resonance in the spectrum of the CARS signal by a factor of about seven. The high level of the CARS signal was then recovered within several days. This spectrum of the CARS signal from the dry PCF was subtracted from the CARS spectrum recorded at the output of the hollow PCF under normal conditions. The difference spectrum was normalized to the spectral profile of the factor $M(\Delta\alpha L, \alpha_a\ L, 0)$. The result of this normalization is shown by line 5 in Fig. 4.27.

Fig. 4.27 Intensity of the $\omega_a = 2\omega_1 - \omega_2$ four-wave mixing signal from the hollow PCF with the length of 8 cm versus the wavelength of dye-laser radiation with $\lambda_1 = 532$ nm and λ_2 ranging from 645 to 670 nm: (1) the measured spectrum of the FWM signal, (2) fiber transmission for dye-laser radiation, (3) fiber transmission for the FWM signal, (4) spectral profile of the factor M and (5) the spectrum of the FWM signal corrected for the factor M upon the subtraction of the spectrum of the CARS signal from the heated hollow PCF

Notably, the contrast of the experimental wavelength dependence of the FWM intensity (squares with error bars) in Fig. 4.26 is higher than the contrast of a similar dependence for the CARS signal in Fig. 4.27. This variation in the ratio of the maximum amplitude of the nonlinear signal correlates well with the behavior of transmission for dye-laser radiation and the nonlinear signal, shown by curves 2 and 3 in both figures. With the dye-laser radiation wavelength set around 650 nm, both the pump and nonlinear signal wavelengths λ_1 and λ_a in Fig. 4.26 are close to the respective maxima of PCF transmission. The CARS signal, on the other hand, is detected away from the maximum transmission for the dye-laser radiation and the nonlinear signal (Fig. 4.27). It is therefore important to normalize the measured CARS spectrum to the wavelength dependence of the M factor, taking into account wavelength-dependent losses introduced by the PCF. This normalization procedure considerably improves the contrast of the CARS spectrum, as shown by curve 5 in Fig. 4.27.

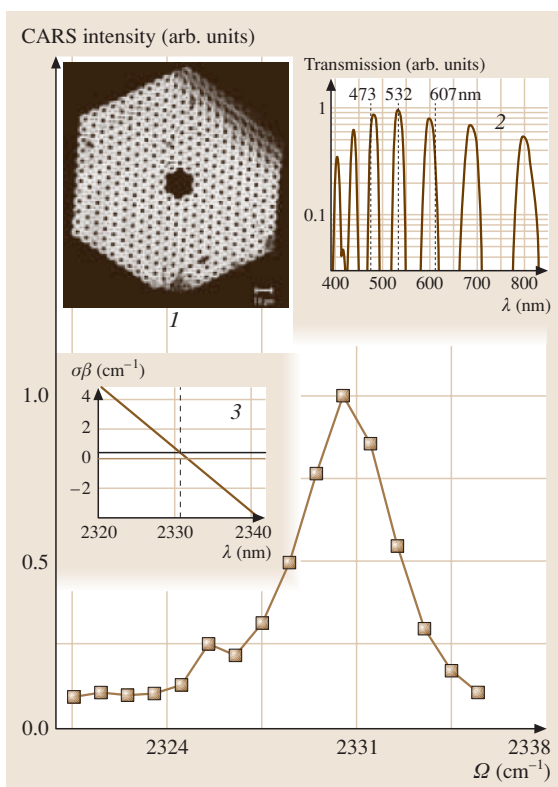
Experiments presented above demonstrate the potential of waveguide CARS in PCFs to detect trace concentrations of Raman-active species, suggesting PCF CARS as a convenient diagnostic technique. However, CARS signals detected in these experiments do not allow the origin of Raman-active species in the fiber to be reliably identified, as it is not always possible to discriminate between the contributions to the CARS signal provided by the hollow core and PCF walls. As an example of a more easily quantifiable Raman medium, permitting the CARS signal from the PCF core to be separated from the signal from PCF walls, we chose gas-phase molecular nitrogen from atmospheric-pressure air filling the hollow core of a PCF. A two-color Raman-resonant pump field used in these experiments consisted of 15 ns second-harmonic pulses of Nd:YAG laser radiation with a wavelength of 532 nm (ω_1) and dye-laser radiation (ω_2) with a wavelength of 607 nm. The dye-laser frequency was chosen in such a way as to satisfy the condition of Raman resonance $\omega_1 - \omega_2 = \Omega$ with a Q-branch Raman-active transition of N_2 at the central frequency $\Omega = 2331$ cm^{-1}. Coherently excited Q-branch vibrations of N_2 then scatter off the second-harmonic probe field, giving rise to a CARS signal at the frequency $\omega_{CARS} = 2\omega_1 - \omega_2$ (corresponding to a wavelength of 473 nm). The hollow PCF (shown in inset 1 to Fig. 4.28) was designed to simultaneously provide high transmission for the air-guided modes of the second harmonic, dye-laser radiation, and the CARS signal. With an appropriate fiber structure, as can be


Fig. 4.28 CARS spectrum of Q-branch Raman-active vibrations of N_2 molecules in the atmospheric-pressure air filling the hollow core of the PCF. The *insets* show: (1) an image of the PCF cross section; (2) the transmission spectrum of the hollow PCF designed to simultaneously support air-guided modes of the pump, probe, and CARS signal fields (their wavelengths are shown by *vertical lines*) in the hollow core of the fiber; and (4.3) the mismatch of the propagation constants $\delta\beta = 2\beta_1 - \beta_2 - \beta_a$ calculated for the $\omega_a = 2\omega_1 - \omega_a 2$ CARS process in fundamental air-guided modes of the hollow PCF with β_1, β_2, and β_a being the propagation constants of the Nd:YAG-laser second-harmonic (ω_1) and dye-laser (ω_2) pump fields and the CARS signal (ω_a) in the hollow PCF

seen from inset 2 to Fig. 4.28, PCF transmission peaks can be centered around the carrier wavelengths of the input light fields and the CARS signal (shown by vertical lines in inset 2 to Fig. 4.28). Phase matching for CARS with the chosen set of wavelengths has been confirmed [4.168] (inset 3 in Fig. 4.28) by a numerical analysis of PCF dispersion based on a modification of the field-expansion technique developed by *Poladian* et al. [4.169].

The resonant CARS signal related to Q-branch vibrations of N_2 in these experiments can be reliably separated from the nonresonant part of the CARS signal originating from the PCF walls. The spectra of the CARS signal at the output of the PCF Fig. 4.28 are identical to the N_2 Q-branch CARS spectrum of the atmospheric air [4.99] measured in the tight-focusing regime. In view of this finding, the CARS signal can be completely attributed to the coherent Raman scattering in the gas filling the fiber core with no noticeable contribution from the nonlinearity of PCF walls.

Results presented here show that large-core-area hollow PCFs bridge the gap between standard, solid-cladding hollow fibers and hollow PCFs in terms of effective guided-mode areas, allowing energy fluence scaling of phase-matched waveguide four-wave mixing of laser pulses. We used hollow PCFs with a core diameter of about $50\,\mu m$ to demonstrate phase-matched FWM for millijoule nanosecond laser pulses. Intense CARS signal has been observed from stretching vibrations of water molecules inside the hollow fiber core, suggesting CARS in hollow PCFs as a convenient sensing technique for pollution monitoring and trace gas detection. Hollow PCFs have been shown to offer much promise as fiber-optic probes for biomedical Raman applications, suggesting the way to substantially reduce the background related to Raman scattering in the core of standard biomedical fiber probes [4.170].

4.9 Nonlinear Spectroscopy with Photonic–Crystal–Fiber Sources

4.9.1 Wavelength-Tunable Sources and Progress in Nonlinear Spectroscopy

The progress in wavelength-tunable light sources through the past decades has been giving a powerful momentum to the development of nonlinear laser spectroscopy. Nonlinear Raman spectroscopy, in particular, has benefited tremendously more than 30 years ago from the application of tunable laser sources, as optical parametric oscillators [4.171] and dye lasers [4.172] were demonstrated to greatly simplify measurements based on coherent anti-Stokes Raman scattering (CARS), making this technique much more informative, efficient, and convenient. Broadband laser sources later contributed to the technical and conceptual progress in nonlinear Raman spectroscopy [4.99, 106–110], allowing single-shot CARS measurements. In the era of femtosecond lasers, several parallel trends have been observed in the development of laser sources for nonlinear Raman spectroscopy [4.113]. One of these tendencies was to adapt broadband femtosecond pulses for spectroscopic purposes [4.113, 173, 174] and to use different spatial phase-matching geometries to simultaneously generate coherent Stokes and anti-Stokes, as well as degenerate four-wave mixing signals [4.113, 127, 128]. The rapid progress in nonlinear materials, on the other hand, resulted in the renaissance of optical parametric oscillators and amplifiers (OPOs and OPAs) for nonlinear spectroscopy [4.175]. Chirped pulses were used [4.176, 177] to probe broad spectral regions and large ranges of delay times, suggesting efficient single-shot nonlinear spectroscopic approaches [4.178–180].

In this section, we focus on the potential of photonic-crystal fibers [4.36, 37] as novel efficient sources for nonlinear spectroscopy. PCFs are unique waveguide structures allowing dispersion [4.40] and spatial field [4.181] profiles to be engineered by modifying the design of the fiber structure. Nonlinear-optical PCF components and novel PCF-based light sources have been intensely used through the past few years in frequency metrology [4.74, 77], biomedical optics [4.81], ultrafast photonics [4.78, 79], and photochemistry [4.182].

Coherent nonlinear spectroscopy and microscopy open up a vast area for applications of PCF light sources and frequency shifters. Efficient frequency conversion and supercontinuum generation in PCFs have been shown to enhance the capabilities of chirped-pulse CARS [4.183] and coherent inverse Raman spectroscopy [4.184]. Cross-correlation frequency-resolved optically gated CARS (XFROG CARS) has recently been demonstrated [4.80] using specially designed PCF frequency converters for ultrashort laser pulses. Novel light sources based on frequency shifting in PCFs provide a useful tool for the measurement of second-order optical nonlinearities in organic materials [4.185] and offer interesting new options in CARS microscopy [4.186]. Efficient spectral broadening of ultrashort pulses in PCFs with carefully engineered dispersion profiles [4.42–44] makes these fibers ideal light sources for pump–supercontinuum probe time- and frequency-resolved nonlinear-optical measurements [4.187].

Below in this section, we demonstrate applications of PCF light sources for chirped-pulse CARS

and nonlinear absorption spectroscopy. We will show that PCFs can provide efficient nonlinear-optical transformations of femtosecond Cr:forsterite laser pulses, delivering linearly chirped frequency-shifted broadband light pulses with central wavelengths ranging from 400 to 900 nm. These pulses were cross-correlated in our experiments with the femtosecond second-harmonic output of the Cr:forsterite laser in toluene solution, used as a test object, in boxcars geometry to measure CARS spectra of toluene molecules (XFROG CARS). The blue-shifted chirped-pulse output of a photonic-crystal fiber with a spectrum stretching from 530 to 680 nm is shown to be ideally suited for the nonlinear absorption spectroscopy of one- and two-exciton bands of thiacarbocyanine J aggregates in a polymer film excited by femtosecond second-harmonic pulses of the Cr:forsterite laser.

4.9.2 Photonic–Crystal Fiber Frequency Shifters

Spectroscopic measurements were performed with multicomponent-glass PCFs [4.51, 188], fabricated with the use of the standard PCF technology [4.36, 37]. In PCFs used in our experiments (Fig. 4.29a), the solid fiber core is surrounded by a single ring of thin-wall capillaries whose outer diameters are equal to the diameter of the PCF core. The outer part of the microstructure cladding consists of 11 rings of capillaries with outer diameters approximately three times larger than the diameter of the PCF core and a high air-filling fraction. Dispersion and nonlinearity of the PCFs were managed by scaling the geometric sizes of the PCF structure. Technologically, this was realized by using the same preform to fabricate PCFs with the same type of the structure, but with different magnifying factors. This procedure allowed to scale the sizes of PCF structure without changing its geometry.

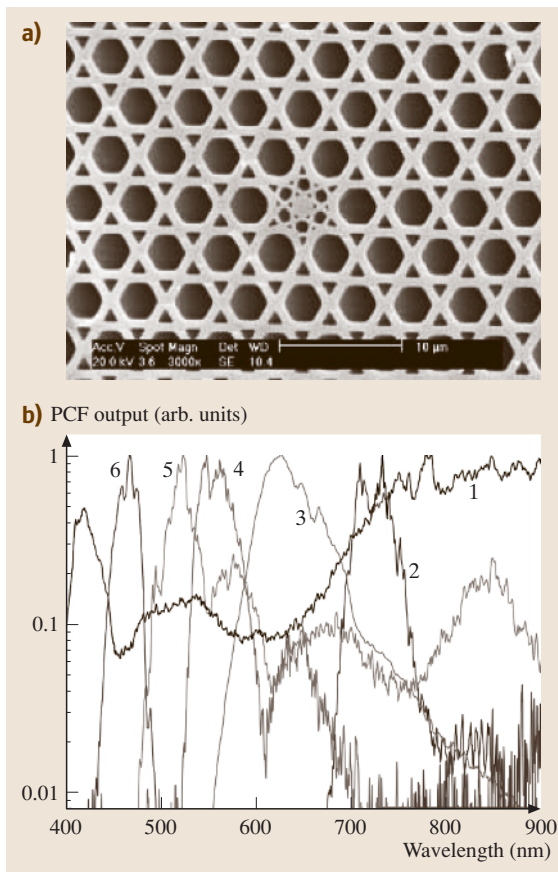
The laser system used in experiments consisted of a Cr^{4+}:forsterite master oscillator, a stretcher, an optical isolator, a regenerative amplifier, and a compressor [4.189]. The master oscillator, pumped with a fiber ytterbium laser, generated 30–60 fs light pulses of radiation with a wavelength of 1.23–1.25 μm at a repetition rate of 120 MHz. These pulses were then transmitted through a stretcher and an isolator, to be amplified in a Nd:YLF-laser-pumped amplifier and recompressed to the 200 fs pulse duration with the maximum laser pulse energy up to 20 μJ at 1 kHz. The energy of laser pulses used in experiments presented in this paper ranged from 0.5 up to 200 nJ.


Fig. 4.29 **(a)** An SEM image of soft-glass photonic-crystal fibers. **(b)** Intensity spectra of the dispersion-managed blue-shifted output of soft-glass PCFs. The wavelength offset δ is 50 nm (1), 110 nm (2), 150 nm (3), 190 nm (4), 220 nm (5), and 300 nm (6)

For the PCFs used in experiments, the central wavelength of Cr:forsterite laser pulses falls within the range of anomalous dispersion. Such pulses can therefore form solitons in the fiber. High-order dispersion induces wave-matching resonances between solitons and dispersive waves [4.21, 22], giving rise to intense blue-shifted emission, observed as prominent features in the PCF output spectra (Fig. 4.29b). The central wavelength of this blue-shifted emission correlates well with the wavelength where dispersive waves guided in the fundamental mode of the PCF are phase-matched with the soliton produced by Cr:forsterite laser pulses. The phase matching between the soliton produced by the input laser pulse and the dispersive wave, which defines the frequency of the dominant peaks in output

spectra of PCFs, is controlled by the dispersion of the fiber. The central frequency of the blue-shifted signal in the output of PCFs can thus be tuned by modifying the dispersion profile of the fiber. The GVD profiles of waveguide modes were modified in our experiments by scaling the geometric sizes of the fiber without changing the type of the structure shown in Fig. 4.29a. The core diameter of PCFs fabricated for these experiments was varied from 0.9 to 3.8 µm. Figure 4.29b shows the spectra of the blue-shifted output of the fiber, tuned by changing the offset $\delta = \lambda_0 - \lambda_z$ between the central wavelength of the input laser field, λ_0, and the zero-GVD wavelength λ_z. With the PCF length remaining unchanged (10 cm), larger blue shifts are achieved by increasing the offset δ (cf. curves 1–6 in Fig. 4.29b). The power of the input laser field needs to be increased for larger δ in these experiments to keep the amplitude of the blue-shifted signal constant. In these experiments, dispersion-managed soft-glass PCFs are shown to serve as frequency shifters of femtosecond Cr:forsterite laser pulses, providing an anti-Stokes output tunable across the range of wavelengths from 400 to 900 nm.

Experiments presented in this section show that the structural dispersion and nonlinearity management of multicomponent-glass photonic-crystal fibers allows a wavelength-tunable frequency shifting and white-light spectral transformation of femtosecond Cr:forsterite laser pulses. We have explored the ways toward optimizing non-silica PCFs for frequency shifting and white-light spectral superbroadening of femtosecond Cr:forsterite laser pulses and identified important advantages of multicomponent-glass PCFs over silica microstructure fibers for the spectral transformation of laser pulses in the 1.2−1.3 µm spectral range. By coupling 200 fs pulses of 1.24 µm Cr:forsterite laser radiation into different types of multicomponent-glass PCFs, where the zero-GVD wavelength is tuned by scaling the sizes of the fiber structure, we have demonstrated spectrally tailored supercontinuum generation and frequency upshifting providing a blue-shifted output tunable across the range of wavelengths from 400 to 900 nm.

4.9.3 Coherent Anti-Stokes Raman Scattering Spectroscopy with PCF Sources

In this section, we show that PCF frequency shifters can serve as convenient sources of chirped wavelength-tunable pulses for CARS spectroscopy. In CARS
Fig. 4.30 Diagram of femtosecond CARS spectroscopy with the use of ultrashort pulses frequency-upconverted and chirped in a photonic-crystal fiber. The *inset* shows the cross-sectional view of the central part of the photonic-crystal fiber

experiments, sub-microjoule Cr:forsterite-laser pulses with an initial duration of about 90 fs are launched into the central core of the PCF (Fig. 4.30), resulting in the efficient generation of a blue-shifted signal (Fig. 4.31), with a central wavelength dictated by phase matching for dispersive-wave emission and controlled by fiber dispersion. The wavelength of the blue-shifted signal can be finely tuned by changing the intensity of the pump pulse (Fig. 4.31) due to the nonlinear change in the refractive index of the fiber core and the spectral broadening of the pump pulse.

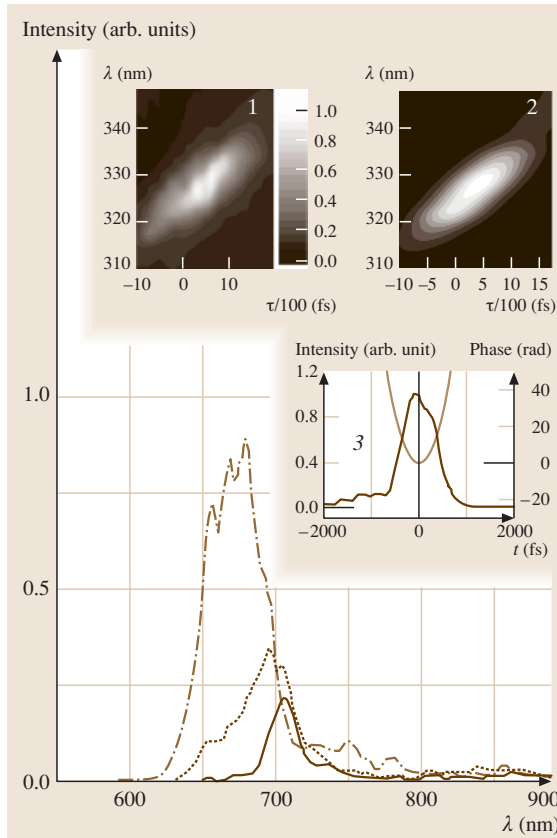
Cross-correlation frequency-resolved optical gating (XFROG) [4.190, 191] was used to characterize the blue-shifted output of the PCF. An XFROG signal was generated by mixing the blue-shifted signal from the fiber E_a with the 620 nm 90 fs second-harmonic output of the Cr:forsterite laser E_{SH} in a BBO crystal. A two-dimensional XFROG spectrogram, $S(\omega, \tau) \propto |\int_{-\infty}^{\infty} E_a(t) E_{SH}(t - \tau) \exp(-i\omega t) \, dt|^2$, was then plotted by measuring the XFROG signal as a function of the delay time τ between the second-harmonic pulses and the blue-shifted output of the PCF and spectrally dispersing the XFROG signal. The XFROG spectrogram shown in inset 1 to Fig. 4.31 visualizes


Fig. 4.31 The spectrum of the blue-shifted output of a photonic-crystal fiber pumped by 1.24 μm 90 fs Cr:forsterite-laser pulses with an input energy of (*solid line*) 170 nJ, (*dashed line*) 220 nJ, and (*dash–dotted line*) 270 nJ. The insets show: (1) the intensity of the sum-frequency signal generated in a BBO crystal by the second-harmonic pulse from the Cr:forsterite laser and the blue-shifted PCF output as a function of the wavelength and the delay time τ between the second-harmonic and anti-Stokes pulses, (2) theoretical fit of the XFROG trace, and (3) the pulse envelope and the phase of the anti-Stokes pulse providing the best fit

Fig. 4.32 (a) A diagram of femtosecond CARS spectroscopy with chirped pulses is shown on the *left*. The first pulse (frequency ω_1) is transform limited. The second pulse (frequency ω_2) is linearly chirped. The linear chirp of the second pulse maps the delay time between the pulses on the frequency, allowing the frequency difference $\omega_1 - \omega_2$ to be scanned through Raman resonances Ω by tuning the delay time τ. **(b)** The intensity of the CARS signal generated in a noncoplanar boxcars geometry from toluene solution as a function of the wavelength and the delay time τ between the second-harmonic and the blue-shifted PCF output pulses used as a biharmonic pump. **(c)** A model of the Raman spectrum, including a doublet of Lorentzian lines and a frequency-independent nonresonant background used in the theoretical fit. **(d)** Theoretical fit of the XFROG CARS spectrogram

the temporal envelope, the spectrum, and the chirp of the blue-shifted PCF output. A reasonable fit of the experimental XFROG trace was achieved (inset 2 in Fig. 4.31) with a blue-shifted pulse having a duration of about 1 ps and a linear positive chirp corresponding to the phase $\varphi(t) = \alpha t^2$ with $\alpha = 110\,\text{ps}^{-2}$. The spectrum and the phase φ of the blue-shifted pulse reconstructed with this procedure are shown in inset 3 in Fig. 4.31.

The linear chirp defines a simple linear mapping between the instantaneous frequency of the blue-shifted PCF output and the delay time τ, allowing spectral measurements to be performed by varying the delay time between the pump pulses. Experiments were performed with 90 fs second-harmonic pulses of the Cr:forsterite laser (at the frequency ω_1) and the linearly chirped pulses from the PCF (the frequency ω_2) as a biharmonic pump for the CARS spectroscopy of toluene solution. The frequency difference $\omega_1 - \omega_2$ was scanned

through the frequencies of Raman-active modes of toluene molecules by tuning the delay time between the pump pulses (Fig. 4.32a). The second-harmonic pulse also served as a probe in our CARS scheme, generating the CARS signal at the frequency $\omega_{CARS} = 2\omega_1 - \omega_2$ through the scattering from Raman-active vibrations coherently excited by the pump fields. The light beams with frequencies ω_1 and ω_2 were focused into a cell with toluene solution at a small angle with respect to each other (Fig. 4.30). The CARS signal generated in the area of beam interaction in this non-coplanar boxcars geometry had a form of a sharply directed light beam with a low, phase-matching-controlled angular divergence spatially separated (Fig. 4.30) from the pump beams. Figure 4.32b presents the map of CARS spectra from the toluene solution measured for different delay times τ between the biharmonic pump pulses. This procedure of measurements, in fact, implements the XFROG technique [4.190, 191]. However, while FROG-based techniques [4.192] are usually employed to characterize ultrashort pulses, our goal here is to probe Raman-active modes of toluene molecules, used as a test object, by means of CARS spectroscopy.

In the case of a positively chirped pulse from the PCF (insets 2 and 3 in Fig. 4.31), small delay times τ correspond to the excitation of low-frequency Raman-active modes ($\tau \approx -200$ fs in Fig. 4.32b). In particular, the 1004 cm^{-1} Raman mode of toluene is well resolved in the presented XFROG CARS spectrogram. This mode is excited with the second harmonic of Cr:forsterite-laser radiation and the spectral slice around the wavelength of $\lambda_2 \approx 661$ nm picked with an appropriate τ (Fig. 4.32a) from the positively chirped blue-shifted PCF output, giving rise to a CARS signal with the wavelength $\lambda_{CARS} \approx 584$ nm. Raman modes with higher frequencies are probed at larger delay times ($\tau \approx 100$–200 fs in Fig. 4.32b).

As a simple model of the Raman spectrum of toluene molecules in the studied spectral range, we employ a doublet of Lorentzian lines interfering with the coherent nonresonant background (Fig. 4.32c). The frequencies of the peaks in these spectra are used as fitting parameters. The ratio of the peak value of the resonant part of the CARS susceptibility, $\bar{\chi}^{(3)}$, to the nonresonant susceptibility, $\chi^{(3)nr}$, was estimated by measuring the intensities of the CARS signal on and off the Raman resonances, yielding $|\chi^{(3)nr}|/|\bar{\chi}^{(3)}| \approx 0.05$. The best fit (Fig. 4.32d) is achieved with the Raman peaks centered at 1004 and 1102 cm^{-1}, which agrees well with earlier CARS studies of toluene [4.99].

Although the slope of the XFROG CARS trace and positions of Raman peaks can be adequately described with the use of this simple model, some of the spectroscopic features of the experimental XFROG CARS trace deviate from the theoretical fit. These deviations may originate from variations in the coherent background as a function of the frequency. For a quantitative spectroscopic analysis, these inhomogeneities in the frequency dependence of the coherent background should be carefully measured and included in the fit. On the other hand, the nonresonant contribution to CARS spectral profiles can be efficiently suppressed [4.99, 106] by using three input pulses in the CARS arrangement instead of two and by introducing the delay time between the third pulse (probe) and the two-color pump, tuned to a Raman resonance under study.

4.9.4 Pump–Probe Nonlinear Absorption Spectroscopy using Chirped Frequency–Shifted Light Pulses from a Photonic–Crystal Fiber

Time-resolved nonlinear-optical spectroscopy of molecular dynamics and fast excitation transfer processes typically involves specifically designed sequences of pump and probe pulses with a variable delay time and a smoothly tunable frequency of the probe field. In a laboratory experiment, such pulse sequences can be generated by femtosecond optical parametric amplifiers (OPAs). Femtosecond OPAs, however, inevitably increase the cost of laser experiments and make the laser system more complicated, unwieldy, and difficult to align. An interesting alternative strategy of pump–probe spectroscopy employs a pump field in the form of a broadband radiation (supercontinuum) with a precisely characterized chirp. A time–frequency map, defined by the chirp of such a supercontinuum pulse, allows time- and frequency-resolved measurements to be performed by tuning the delay time between the transform-limited pump pulse and chirped supercontinuum pulse [4.176, 193]. The supercontinuum probe pulse for pump–probe experiments is most often generated by focusing amplified femtosecond pulses into a silica or sapphire plate. The chirp of the probe pulse in such an arrangement is dictated by the regime of nonlinear-optical spectral transformation and dispersion of the nonlinear material, leaving little space for the phase tailoring of the probe field.

In this section, we demonstrate the potential of PCFs as compact and cost-efficient fiber-optic sources

of probe pulses with a tunable frequency and tailored phase for a time-resolved nonlinear spectroscopy of molecular aggregates. We will show that PCFs can provide efficient nonlinear-optical transformations of femtosecond Cr:forsterite laser pulses, delivering linearly chirped frequency-shifted broadband light pulses, optimized for pump–probe nonlinear absorption spectroscopy of molecular aggregates. The blue-shifted output of a photonic-crystal fiber with a spectrum stretching from 530 to 680 nm will be used to probe one- and two-exciton bands of thiacarbocyanine J aggregates in a polymer film excited by femtosecond second-harmonic pulses of the Cr:forsterite laser.

Molecular aggregates are interesting and practically significant objects encountered in many physical, chemical and biological systems [4.194]. Interactions between the molecules forming aggregates give rise to collective electronic states, which can be delocalized over large chains of molecules, modifying the optical response of the system [4.195]. Specific types of molecular aggregation, known as J and H aggregation, give rise to a pronounced spectral shift and dramatic narrowing of absorption bands, indicating the cooperative nature of the optical response of molecular aggregates [4.196]. In natural systems, molecular aggregates are involved in the processes and functions of vital importance as they play the key role in light harvesting and primary charge separation in photosynthesis [4.197]. On optical resonances, the nonlinear susceptibility of molecular aggregates displays a collective enhancement [4.195], scaling as N^2 with the number of particles N forming an aggregate. Dramatic enhancement of optical nonlinearity and the available pathways for ultrafast relaxation of excited states [4.194] suggest a variety of interesting applications of molecular aggregates, such as terahertz demultiplexing of optical signals [4.198], spectral sensitization in optical data storage and photography [4.199], energy transfer from light-harvesting antennas and complexes in artificial photosynthesis [4.197], mode locking in laser cavities, and creation of novel devices for ultrafast photonics.

Collective electronic eigenstates in aggregates of strongly coupled molecules are grouped into excitonic bands [4.194–196]. In the ground state of this band structure, all N molecules of the aggregate reside in the ground state. In the lowest excited band, the molecules coupled into an aggregate share one excitation. The eigenstates of this first excited band (one-excitons, or Frenkel excitons) are represented by linear combinations of basis states corresponding to one excited and $N-1$ ground-state molecules. Eigenstates that can be reached from the ground state via two optical transitions, making the molecules of an aggregate share two excitations, form a two-exciton band. The third-order susceptibility $\chi^{(3)}$, responsible for four-wave mixing (FWM) processes, can involve only one- and two-excitons. Although three-exciton states can be reached

mative techniques for the characterization of one- and two-exciton states of aggregates, providing the data on the strength of dipole–dipole interaction between molecules in aggregates, as well as on the disorder and typical relaxation and exciton annihilation times in aggregates [4.194].

Experiments [4.200] were performed with thin-film samples of J aggregates of thiacarbocyanine dye. Film samples of J aggregates were prepared by spin-coating the solution of thiacarbocyanine dye on a thin substrate. The concentration of thiacarbocyanine dye was 5×10^{-3} mol/l. The spinning speeds ranged from 1000 up to 3000 revolutions per minute. A mixture of acetonitrile, dichloroethane, and chloroform with a volume ratio of 2:2:1 was used as a solvent. The thickness of the dye layer applied to a substrate was estimated as 30 nm, and the total thickness of the sample was about 1 μm.

Absorption spectra of J-aggregate films (curve 1 in Fig. 4.33a) display two pronounced peaks. The broader peak centered at 595 nm corresponds to thiacarbocyanine monomers, while the narrower peak at 660 nm represents the excitonic absorption of J aggregates. To provide a rough estimate of the delocalization length N_d of excitons in aggregates, we apply the formula [4.201] $N_d^W \approx (3\pi^2|J|3\pi^2|J|W)^{1/2} - 1$, which expresses N_d through the half-width at half-maximum W of the aggregate peak in the absorption spectrum and the energy J of dipole–dipole interaction between nearest-neighbor molecules in the aggregate ($J < 0$ for J aggregates). With the J parameter estimated as $J \approx 900\,\text{cm}^{-1}$ from the aggregation-induced red shift of the absorption peak in Fig. 4.33a, we find $N_d \approx 6$. Experimental results presented below in this paper show that, with such a delocalization length of excitons in molecular aggregates, spectra of nonlinear absorption display well-pronounced nonoverlapping features indicating [4.194–196] bleaching through transitions between the ground and one-exciton states and induced absorption via transitions between one- and two-exciton states of molecular aggregates.

The laser system used in experiments [4.200] was based on the Cr^{4+}:forsterite laser source with regenerative amplification, as described in Sect. 4.9.2. A 1 mm-thick BBO crystal was used to generate the second harmonic of amplified Cr:forsterite laser radi-

by three transitions, they do not contribute to the third-order polarization as they do not have a transition dipole that would couple them to the ground state. Time-resolved nonlinear spectroscopic methods based on $\chi^{(3)}$ processes, such as spectroscopy of nonlinear absorption, degenerate four-wave mixing, and third-harmonic generation, have proven to be convenient and infor-

ation. The spectrum of the second-harmonic output of the Cr:forsterite laser was centered at 618 nm (curve 2 in Fig. 4.33a). Second-harmonic pulses with a pulse width of about 120 fs and the energy ranging from 10 to 80 nJ were used as a pump field in our experiments on the nonlinear spectroscopy of molecular aggregates.

Frequency-tunable upconversion of fundamental-wavelength Cr:forsterite-laser pulses was performed through the nonlinear-optical spectral transformation of these pulses in soft-glass PCFs with the cross-section structure shown in Fig. 4.29a. The properties of such fibers and the methods of frequency conversion of Cr:forsterite laser pulses in these PCFs have been discussed in Sect. 4.9.2 Intensity spectrum of the frequency-shifted output of the PCF best suited as a probe field for time-resolved nonlinear-absorption spectroscopy of J aggregates is presented by curve 3 in Fig. 4.33a. At the level of 20% of its maximum, the intensity spectrum of the blue-shifted PCF output stretches from 530 to 680 nm. Dispersion of the PCF frequency shifter used in our experiments provided a linear chirp of the output pulse Sect. 4.9.3 with the pulse chirp rate controlled by the fiber length.

The spectrum of 120 fs second-harmonic pulses of the Cr:forsterite laser partially overlaps the absorption spectrum of molecular aggregates (Fig. 4.33a). These pulses were used in our experiments to excite the aggregates through the transitions from the ground state to the one-exciton band (Fig. 4.33b). The spectra of absorption modified by the pump field were measured by chirped blue-shifted pulses delivered by the PCF (Fig. 4.33b). Figures 4.34a–c present the results of experimental measurements upon the subtraction of absorption spectra measured in the absence of the pump pulse and normalization to the spectrum of the probe field. Nonlinear absorption spectra shown in Figs. 4.34a–c display well-pronounced minima at 665 nm and blue-shifted peaks at 640 nm. Such features are typical of nonlinear absorption spectra of J aggregates measured by the pump–probe technique (see [4.194] for a review).

The negative feature is indicative of bleaching through pump-induced transitions between the ground state and the one-exciton band, while the blue-shifted peak originates from induced absorption due to transitions between one- and two-exciton bands of molecular aggregates (Fig. 4.34a–c).

For highly ordered aggregates, the spectrum of nonlinear absorption is dominated by transitions between the ground state and lowest one- and two-exciton states [4.195, 196]. The exciton delocalization length can be then estimated from the spectral shift Δ of the induced-absorption peak relative to the bleaching minimum using the following formula [4.202]: $N_d^\Delta \approx (3\pi^2 |J|/\Delta)^{1/2} - 1$. With the spectral shift estimated as $\Delta \approx 470\,\text{cm}^{-1}$, we find that $N_d^\Delta \approx 6$, in perfect agreement with the value of N_d^W obtained from aggregate absorption spectra.

The amplitudes of both positive and negative features in nonlinear absorption spectra decay on a sub-picosecond time scale with increasing delay time between the pump and probe pulses (Fig. 4.34a–c), indicating a sub-picosecond relaxation rate of the one-exciton state of molecular aggregates in our experiments. This finding suggests, in agreement with earlier studies of ultrafast excitation energy transfer processes in molecular aggregates, that the relaxation dynamics of aggregates in our experimental conditions is mainly controlled by the quenching of excited states of aggregates through exciton–exciton annihilation [4.194].

We have thus shown that photonic-crystal fibers with a specially designed dispersion offer the ways to create efficient sources of ultrashort pulses for coherent nonlinear spectroscopy. These fibers provide a high efficiency of frequency upconversion of femtosecond laser pulses, permitting the generation of sub-picosecond linearly chirped anti-Stokes pulses ideally suited for femtosecond coherent anti-Stokes Raman scattering spectroscopy. Experimental studies demonstrate that PCFs can deliver linearly chirped frequency-shifted broadband light pulses, optimized for pump–probe nonlinear absorption spectroscopy.

4.10 Surface Nonlinear Optics, Spectroscopy, and Imaging

In this section, we will dwell upon the potential of nonlinear-optical methods for the investigation of surfaces and interfaces. The ability of second-order nonlinear-optical processes, such as SHG and SFG (Sect. 4.3), to probe surfaces and interfaces is most

clearly seen in the case of a centrosymmetric material. In this situation, the electric-dipole SHG and SFG response from the bulk of the material vanishes. At a surface or an interface, the bulk symmetry is broken, and electric-dipole second-order nonlinear-optical

effects are allowed. Such surface-specific SHG and SFG processes enable a highly sensitive nondestructive local optical diagnostics of surfaces and interfaces (Fig. 4.35a–b). Illuminating and physically insightful discussion of this technique can be found in the classical texts on nonlinear optics [4.9, 203].

The $\chi^{(2)}$ signal from a surface or an interface is, however, not entirely background-free, as the second-order

Fig. 4.35 Nonlinear optics, spectroscopy, and imaging of surfaces and buried structures. **(a)** Nonlinear-optical probing of surfaces and interfaces using second-harmonic generation. **(b)** Surface vibrational spectroscopy using sum-frequency generation. Diagram of Raman-active transitions selectively addressed through CARS is shown on the *left*

nonlinear optical processes are not strictly forbidden even in a centrosymmetric medium. Beyond the electric-dipole approximation, the second-order nonlinear signal, as can be seen from (4.6–4.8) and (4.14), can be generated through the electric-quadrupole and magnetic-dipole effects. It is generally very difficult, often impossible, to completely distinguish between the surface and bulk contributions to the nonlinear signal. Luckily enough, the electric-quadrupole and magnetic-dipole components in the nonlinear-optical response are typically ka times less significant than the dipole-allowed part [4.9], with $k = 2\pi/\lambda$ and a being a typical size of an atom or a unit cell in a crystal. The ratio of the surface dipole-allowed susceptibility $\chi_s^{(2)}$ to the bulk susceptibility $\gamma_b^{(2)}$ can be then estimated as $|\chi_s^{(2)}|/|\gamma_b^{(2)}| \sim d/(ka)$, where d is the thickness of the surface layer. In reflection SHG (Fig. 4.35a), the bulk contribution is typically generated in a subsurface layer with a thickness of $d \sim \lambda/(2\pi)$. The ratio of the surface part of the total reflected SHG signal to the bulk contributions in this case is on the order of d^2/a^2, which can be easily made much larger than unity. This ratio can be substantially enhanced on frequency resonances or with an appropriate choice of polarization arrangement.

A combination of the high spatial and temporal resolution with a spectral selectivity makes $\chi^{(2)}$ techniques a powerful tool for time-resolved species-selective studies of surfaces and buried interfaces (see, e.g., [4.204] for a comprehensive review of recent results), detection and size and shape analysis of adsorbed species, nanoparticles, and clusters on surfaces [4.205, 206], as well as imaging and microscopy of biological species [4.207]. The sensitivity and selectivity of the $\chi^{(2)}$ technique are enhanced when the frequency of one of the laser fields (ω_1 in the inset to Fig. 4.35b) is tuned to a resonance with a frequency of one of the vibrations typical of species on a surface or an interface (Fig. 4.35b). This method of surface analysis is referred to as sum-frequency surface vibrational spectroscopy. The capabilities of this technique have been impressively

demonstrated for vapor–liquid and liquid–solid interfaces [4.205].

In sum-frequency surface vibrational spectroscopy [4.207] an infrared laser pulse $\boldsymbol{E}_1$ with a frequency ω_1 overlaps on the surface of a sample with the second laser pulse $\boldsymbol{E}_2$, which typically has a frequency ω_2 in the visible, to induce a second-order polarization at the sum frequency $\omega_{SF} = \omega_1 + \omega_2$:

$$\boldsymbol{P}^{(2)}_{SF}(\omega_{SF}) = \widehat{\chi}^{(2)}(\omega_{SF}; \omega_1, \omega_2) : \boldsymbol{E}_1 \boldsymbol{E}_2 . \quad (4.226)$$

The intensity of the optical signal at the sum frequency is given by

$$I_{SF} \propto \left| \chi^{(2)}_{eff} \right|^2 I_1 I_2 . \quad (4.227)$$

Here, I_1 and I_2 are the intensities of the laser beams and

$$\chi^{(2)}_{eff} = \left(\widehat{L}_{SF} \cdot \boldsymbol{e}_{SF} \right) \cdot \widehat{\chi}^{(2)}_s : \left(\widehat{L}_2 \cdot \boldsymbol{e}_2 \right) \left(\widehat{L}_1 \cdot \boldsymbol{e}_1 \right) , \quad (4.228)$$

where $\widehat{L}_1$, $\widehat{L}_2$ and $\widehat{L}_3$ are the Fresnel factors at the frequencies ω_1, ω_2, and ω_{SF}, respectively, $\boldsymbol{e}_1$, $\boldsymbol{e}_2$, and $\boldsymbol{e}_{SF}$ are the unit polarization vectors of the laser and sum-frequency fields, and the surface quadratic susceptibility $\widehat{\chi}^{(2)}_s$ is written as

$$\widehat{\chi}^{(2)}_s = \widehat{\chi}^{(2)nr} + \sum_q \frac{\widehat{a}_q}{\omega_1 - \omega_q + i\Gamma_q}, \quad (4.229)$$

with $\widehat{\chi}^{(2)nr}$ being the nonresonant quadratic susceptibility and $\widehat{a}_q$, ω_q, and Γ_q being the strength, the frequency, and the damping constant for the q-th vibrational mode, respectively.

When the infrared field is scanned over the frequency of the q-th vibrational mode, the SFG signal is resonantly enhance, and its spectrum gives the spectrum of the vibrational mode. Tunable dye lasers [4.204], optical parametric oscillators and amplifiers [4.205], or PCF frequency shifters [4.185, 208] are employed as sources of frequency tunable radiation, allowing selective probing of vibrational (as well as electronic and excitonic) transitions in molecules and molecular aggregates.

Through the past few years, nonlinear-optical methods of surface spectroscopy have been extensively involved in the rapid growth of nonlinear microscopic techniques based on $\chi^{(2)}$ and $\chi^{(3)}$ processes. In particular, SHG and THG processes have proven to be convenient techniques for high-resolution three-dimensional microscopy of biological objects [4.207, 209], as well as laser-produced plasmas and micro-explosions [4.210]. In early experimental demonstrations of SHG microscopy, grain structures and defects on the surface of thin films were visualized using SHG in transmission [4.211] and surface monolayers were imaged by reflection-geometry SHG microscopy [4.212]. In recent years, progress in laser technologies and the advent of new-generation imaging and scanning systems made it possible to extend nonlinear microscopy techniques to three-dimensional structures, buried objects, and biological tissues [4.207, 209]. In this modification of nonlinear microscopy, the nonlinear signal is generated in the focal region of the laser beam in the bulk of a sample, originating from optical micro-inhomogeneities, which break the point-group symmetry of the medium or change phase-matching conditions. In two transverse dimensions, the high spatial resolution of nonlinear microscopy techniques is controlled by the nonlinear nature of the process, tightly confining the area where the signal is generated to the focal region. Resolution in the direction of probing is achieved either due to symmetry breaking, similar to nonlinear-optical surface-imaging techniques, or through phase-matching modification.

In CARS microscopy [4.207, 209, 213, 214], the nonlinear signal is resonantly enhanced when a frequency difference between two laser fields is tuned to a Raman-active mode of molecules under study, as described in Sect. 4.4.8 (see also Fig. 4.35c). This makes microscopy also species-selective as Raman resonances serve as fingerprints of a certain type of molecules or molecular aggregates. Forward CARS and backward CARS (also called epi-CARS) geometries have been developed (Fig. 4.35c). In the forward-CARS microscopy, the mismatch $|\Delta\boldsymbol{k}|$ of the wave vectors involved in wave mixing (Sect. 4.7) is typically much smaller than $2\pi/\lambda_{CARS}$, where λ_{CARS} is the wavelength of the CARS signal. For epi-CARS, $|\Delta\boldsymbol{k}|$ is larger than $2\pi/\lambda_{CARS}$. The intensity of the epi-CARS signal can thus be comparable with the forward-CARS signal intensity only for a thin sample with a sample thickness d meeting the inequality $|\Delta\boldsymbol{k}|d < \pi$. CARS microscopy has been one of the most successful recent developments in the field of nonlinear-optical microscopy. In addition to the high spatial resolution, this technique has a number of other important advantages over, for example, microscopy based on spontaneous Raman scattering. In particular, in CARS microscopy, laser beams with moderate intensities can be used, which reduces the risk of damaging biological tissues. The anti-Stokes signal in CARS microscopy is spectrally separated from the laser beams and from fluorescence, as the anti-Stokes wavelength is shorter than the wavelengths of the laser beams. In transparent materials, CARS microscopy can be used to image tiny buried objects inside the sample in three

dimensions. Due to the coherent nature of CARS, the capabilities of CARS microscopy can be enhanced by

means of coherence control, as recently demonstrated by *Dudovich* et al. [4.117].

4.11 High–Order Harmonic Generation

4.11.1 Historical Background

The invention of the laser in 1960 opened many new fields of research. One of them is *nonlinear optics* triggered by *Franken* [4.215] with the first demonstration of frequency doubling in a crystal (1961) and pioneered by Bloombergen and coworkers. Third-harmonic generation in gases was observed for the first time by *New* and *Ward* in 1967 [4.216], fifth and higher-order harmonic generation a few years later by *Reintjes* and others [4.217]. The main objectives of this research were to increase the conversion efficiency, to cover a large (continuous) spectral range with, for example, frequency mixing processes and to reach very short wavelengths. The most natural route for the latter goal was to use fundamental fields with the shortest possible wavelength, to produce short-wavelength radiation through a low-order nonlinear-optical process.

Another research area, which started in the late sixties, is the study of *atoms in strong laser fields*. The objective of this fundamental research was simply to understand the behavior of atoms and molecules exposed to intense electromagnetic fields. This field evolved in parallel with the development of pulsed lasers towards increasing peak powers, increasing repetition rates and decreasing pulse durations. The character of the laser–atom interaction also evolved from being essentially perturbative for laser intensities below 10^{13} W/cm^2 to strongly nonperturbative for higher intensities. For many years, this regime of nonlinear optics was studied only by looking at ionization processes. The number and charge of the produced ions, as well as the energy and angular emission of the electrons, were experimentally detected and compared with theoretical predictions.

At the end of the 1980s, it was realized that looking at the emitted photons would bring complementary information on the physical processes taking place. Indeed, efficient photon emission in the extreme ultraviolet (XUV) range, in the form of high-order harmonics of the fundamental laser field, was observed for the first time in 1987, in Saclay [4.218] (33rd harmonic of a Nd:YAG laser) and in Chicago [4.219] (17th harmonic of a KrF laser). The harmonic spectra were characterized by a decrease in efficiency for the first harmonics,

followed by a broad *plateau* of nearly constant conversion efficiency, ending up by an abrupt cutoff. The existence of such a plateau was clearly a nonperturbative signature of the laser-atom interaction. Most of the early work concentrated on the extension of the plateau, i.e. the generation of harmonics of higher frequency and shorter wavelength going progressively from ≈ 20 nm at the end of the 1980s to ≈ 7 nm by the middle of the 1990s [4.220–224]. It was soon realized that, in contrast to the ideas promoted in the nonlinear-optics community, the shortest wavelengths were obtained with long-wavelength lasers. Today, harmonic spectra produced with short and intense laser pulses extend to the water window (below the carbon K-edge at 4.4 nm) [4.225, 226].

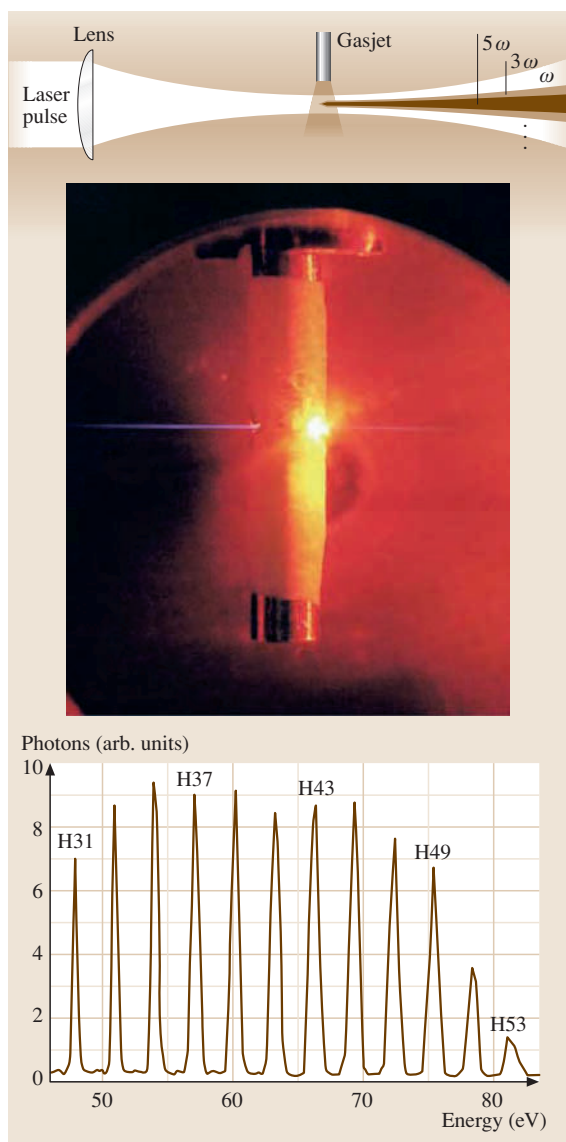
A breakthrough in the theoretical understanding of high-order harmonic generation processes was initiated by *Krause* and coworkers [4.227] who showed that the cutoff position in the harmonic spectrum follows the universal law $I_p + 3U_p$, where I_p is the ionization potential, whereas $U_p = e^2 E^2 / 4m\omega^2$, is the ponderomotive potential, i.e. the mean kinetic energy acquired by an electron oscillating in the laser field. Here e is the electron charge, m is its mass, and E and ω are the laser electric field and its frequency, respectively. An explanation of this universal fact in the framework of a simple semiclassical theory was found shortly afterwards [4.228, 229], and confirmed by quantum-mechanical calculations [4.230, 231].

Progress in experimental techniques and theoretical understanding stimulated numerous studies of harmonic generation. The influence of the laser polarization was investigated in great detail [4.232–239] (see also [4.240–242] for the theory). The nonlinear conversion process was optimized with respect to the laser parameters [4.243, 244], and to the generating medium [4.245–250]. Finally, the spatial [4.251–256] and temporal [4.257–263] properties of the radiation were characterized and optimized. The specifications of the harmonic emission (ultrashort pulse duration, high brightness, good coherence) make it a unique source of XUV radiation, used in a growing number of applications ranging from atomic [4.264, 265] and molecular [4.266–268] spectroscopy to solid-state [4.269–

271] and plasma [4.272–274] physics. Finally, it has recently been demonstrated that the low-order harmonics are intense enough to induce nonlinear optical processes in the XUV range [4.275–277].

Almost immediately after the first observation of the harmonic plateau, it was realized that, if the harmonics were emitted in phase, i.e. phase-locked, the temporal structure of the radiation emitted from the medium would consist of a "train" of attosecond pulses separated by half the laser period [4.278, 279]. There is a clear analogy here with mode-locked lasers, where ax-

ial modes oscillating in a laser cavity are locked in phase, leading to the production of trains of short pulses. Attosecond pulses have remained, however, a theoretical prediction until recently [4.280–282]. A first possible indication of harmonic radiation containing an attosecond sub-structure was in a high-order autocorrelation of the driving laser pulse [4.283]. This was followed by a beautiful experiment showing evidence for phase-locking between five consecutive harmonics generated in argon, thus indicating that trains of 250 as pulses were formed [4.284]. In a series of experiments performed in Vienna, single pulses of duration of a few hundred attoseconds were demonstrated by using ultrashort (5 fs) laser pulses and spectrally filtering a few harmonics in the cutoff spectral region [4.285, 286]. These experimental results are the beginning of a new field of research *attophysics*, where processes in atoms and molecules can be studied at an unprecedented time scale.

The purpose of this section is to present to the nonexpert reader a simple description of high-order-harmonic generation, and its application to attosecond metrology. In Sect. 4.11.2, we describe the most important aspects of high-order-harmonic generation processes. We begin with a short description of the experimental set up needed to obtain high-order harmonics. Then we discuss the microscopic and macroscopic physics underlying the generation of high-order harmonics. We focus on the physics of importance for the generation of attosecond pulse trains and single attosecond pulses. We refer the reader to several review articles for a more complete overview of this research topic [4.245, 287, 288]. In Sect. 4.12, the emerging field of attosecond science is reviewed. The different measurement techniques are described and the first application of attosecond pulses is presented.


4.11.2 High–Order–Harmonic Generation in Gases

Experimental Method
Generating high-order harmonics is experimentally simple. A typical set up is shown in Fig. 4.36. A laser pulse

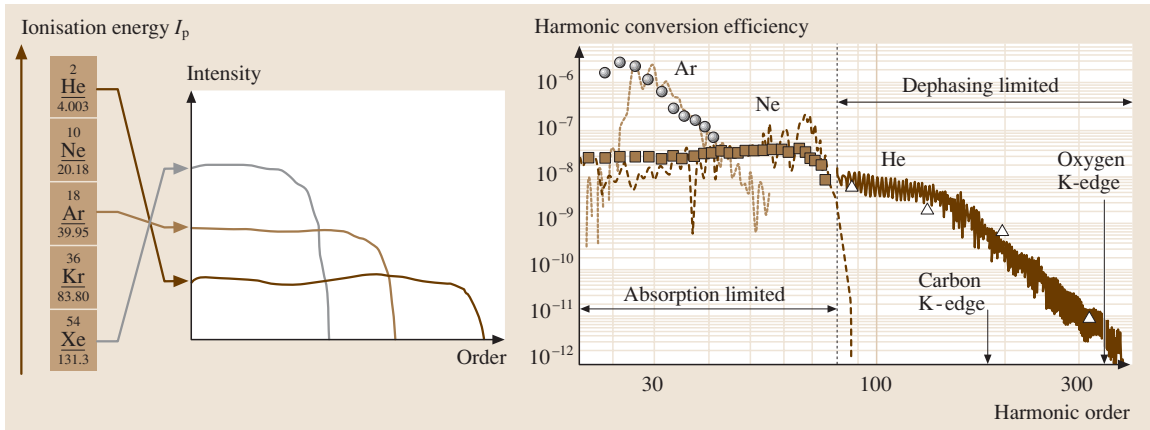
Fig. 4.36 Schematic representation of a typical experimental setup for high-order-harmonic generation. An intense short pulse laser is focused into a vacuum chamber containing a gas medium. Harmonics are emitted along the laser propagation axis. A photograph of a gas target is shown *below*. A typical spectrum obtained in neon is shown at the *bottom*. It shows a plateau ending with a sharp cutoff


Fig. 4.37 Illustration of the influence of the gas species on the generation efficiency (*left*). The result presented at the *right* has been obtained with 5 fs 800 nm laser pulses (after [4.302])

is focused into a vacuum chamber containing a rather small gas target with an atomic pressure of at least a few mbar. The harmonics (only of odd order, owing to inversion symmetry) are emitted along the laser propagation axis. Many types of lasers have been used, excimers, Nd:YAG, Nd:glass, Ti:sapphire, dye lasers, etc. [4.218, 219, 222, 223, 289, 290]. In addition, the second harmonic of these lasers [4.291–293] as well as the radiation from sum- or difference-frequency mixing processes [4.294, 295] for example to get into the mid-infrared range [4.296], have also been employed. Typical energies are between a fraction to a few tens of mJ, typical pulse durations are from a few femtoseconds to a few tens of picoseconds. In the last five years, the favorite tool has become the Ti:sapphire laser, providing very short pulse lengths, high laser intensities at high repetition rates. The shortest laser pulses used today to study atoms in strong laser fields are about 5 fs (two cycles) long [4.285]. The advantage of using short pulses is that atoms get exposed to higher laser intensity before they ionize, leading to higher-order harmonics. The different parameters of the laser pulses, such as the polarization, the focusing characteristics, the spatial and temporal profiles are often varied and optimized in the experiments. Recent studies do not simply vary a given parameter, but attempt to shape a laser pulse (by varying, for example, its phase [4.244], its degree of ellipticity [4.297–299], or its spatial properties [4.300, 301]) to tailor the harmonics for different applications.

The gas medium is provided by a gas jet, hollow fiber [4.246–248] or a (small) gas cell [4.249, 250, 303]. Figure 4.36 shows a photograph of such a gas target containing argon atoms irradiated by an intense

laser pulse. Rare gases are the favored species, for obvious technical reasons. In addition, some work has been done with alkali atoms [4.296], ions [4.220, 304], molecules [4.305–308] and clusters [4.309–311]. Photons are separated in energy and detected by an XUV spectrometer, including a grating, sometimes a refocusing mirror, and a detector (electron multiplier, microchannel plates, etc.). A typical experimental spectrum is shown in Fig. 4.36. This result has been obtained in a gas of neon using a 100 fs 800 nm Ti:sapphire laser [4.312]. It shows odd harmonic peaks up to the 53rd order, with a rapid decrease beyond the 49th harmonic, characteristic of the cutoff region. The spectral range of the harmonic emission as well as the conversion efficiency depends strongly on the gas medium. As schematically illustrated in Fig. 4.37 (left), the efficiency is highest in the heavy atoms Ar, Xe, Kr, but the highest photon energies are obtained in He and Ne [4.222, 245, 302]. Figure 4.37 (right) presents
Fig. 4.38 Illustration of the two aspects of high-order-harmonic generation. (*Top*) harmonic emission from a single atom. (*Bottom*) phase matching in the nonlinear medium

a comparison between the generation efficiency for three rare gases Ar, Ne, He, when ultrashort laser pulses (of duration 5 fs) are used for the excitation [4.245, 302].

As illustrated in Fig. 4.38, two conditions are necessary to observe efficient harmonic emission. First, each individual atom must generate light at these frequencies, requiring a highly nonlinear response to the radiation field. Second, the harmonic field results from the coherent superposition of all the emitting atoms in the medium. Harmonic generation will be efficient only if phase matching is achieved, requiring the generated field to be in phase with the nonlinear polarization creating it over the medium's length. We discuss these two aspects in more details in the following sections.

4.11.3 Microscopic Physics

Electrons in an atom in the presence of a time-dependent radiation field oscillate. This is described by a dipole moment $d(t) = \langle \Phi(t)|er|\Phi(t)\rangle$, where $|\Phi(t)\rangle$ is the time-dependent electronic wavefunction, the solution of the Schrödinger equation. When the radiation field is weak, there is mainly one oscillation frequency, that of the field. In a strong radiation field, the oscillatory motion becomes distorted and the dipole moment now includes a series of higher-order frequencies, odd harmonics of the fundamental one. The harmonic emission from a single atom can thus be calculated by taking the Fourier transform of the dipole moment. Theorists often use a single-active-electron approximation, assuming that the interaction with the field involves essentially one active electron, to describe the response of the atom to a strong laser field. A number of methods have been proposed to solve this problem and it is beyond the scope of this paper to review all of these approaches. The most realistic approach is probably the numerical solution of the time-dependent Schrödinger equation, pioneered by *Kulander* at the end of the 1980s [4.313]. Many important results, such as the determination of the cutoff law for high-order harmonics in 1992 [4.227] or proposals for single attosecond pulse generation using few-cycle laser pulses at the end of the 1990s [4.245,314,315] were obtained directly from numerical calculations. The semiclassical strong field approximation, originating from a seminal paper of *Keldysh* in 1964 [4.316], applied by *Lewenstein* in the 1990s to high-order-harmonic generation [4.230, 231] allows to explore a larger parameter space as well as to gain intuitive insight. This model and a related one approximating the atomic potential by a $\delta(r)$ potential [4.240] have been extensively used to interpret experimental results.
Fig. 4.39 Schematic picture of different regimes for harmonic generation. The multiphoton, perturbative regime is illustrated on the *top*, while the semiclassical model is presented on the *bottom*

Many insights in the physical understanding of the interaction between atoms and strong laser fields have been provided by a simple semiclassical model, proposed first by *Van der Linden*, *van der Heuvell*, and *Muller* in the context of above-threshold ionization and extended by *Corkum* and others [4.228, 229] to multiple ionization and high-order-harmonic generation. According to this model, illustrated in Fig. 4.39 (bottom), the electron tunnels through the Coulomb energy barrier modified by the presence of the relatively slowly varying linearly polarized electric field of the laser. It then undergoes (classical) oscillations in the field, during which the influence of the Coulomb force from the nucleus is practically negligible. If the electron comes back to the vicinity of the nucleus, it may be rescattered one or several times by the nucleus, thus acquiring a high kinetic energy, and in some cases, kicking out a second or third electron. It may also recombine back to the ground state, thus producing a photon with energy I_p, the ionization potential, plus the kinetic energy acquired during the oscillatory motion. We also show in Fig. 4.39 (top) for comparison the more traditional harmonic-generation process based on

multiphoton absorption in the (barely perturbed) atomic potential.

An intuitive understanding of some of the properties of harmonic generation can be gained by elementary classical calculations of the electron motion outside the binding potential. Assuming the electron to have zero velocity immediately after it has tunneled through the potential barrier at time $t = t_0$, and the laser field to be simply described by $E = E_0 \sin(\omega t)$, we obtain:

$$v = -v_0 \cos(\omega t) + v_0 \cos(\omega t_0) , \tag{4.230}$$

$$x = -\frac{v_0}{\omega} \sin(\omega t)$$
$$+ \frac{v_0}{\omega} \sin(\omega t_0) + (t - t_0)v_0 \cos(\omega t_0) , \tag{4.231}$$

where $v_0 = qE_0/m\omega$. Depending on the time at which the electron is released into the continuum (t_0), it will follow different trajectories, as illustrated in Fig. 4.40. Only those electrons released between $T/4$ and $T/2$

(where T is the laser period) are of interest for harmonic generation. When the laser field changes its sign, they come back towards the core (at $x = 0$) with a certain kinetic energy. This energy, which determines the emitted harmonic order, is proportional to the square of the slope of the trajectory as it crosses the time axis [open circles in Fig. 4.40 (top)]. Except for the trajectory starting at approximately $0.3T$, giving the highest kinetic energy (cutoff), there are two (main) trajectories leading the same kinetic energy. This is illustrated in Fig. 4.40 (bottom), showing the kinetic energy when the electron returns to the core (solid line), as well as the time spent in the continuum (dot-dashed line), as a function of release time. As shown in the figure, for each energy (dashed line), and hence

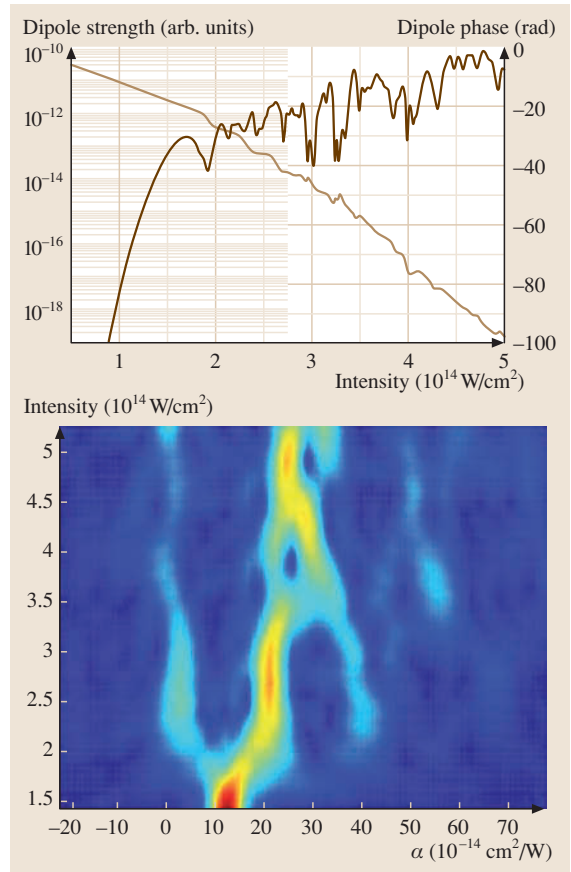
Fig. 4.40 (*Top*) Electron trajectories in the continuum corresponding to different release times. The laser electric field is represented in *dotted line*. (*Bottom*) kinetic energy (*solid line*) and time in the continuum (*dot-dashed line*)as a function of the release time


Fig. 4.41 (*Top*) Single atom response within the strong-field approximation. Intensity (*dark line*) and phase (*light line*) of the 35-th harmonic in neon as a function of the laser intensity. (*Bottom*) Quantum path analysis of the same harmonic

for each harmonic order, there are mainly two trajectories, a short and a long one, contributing to the harmonic emission. The periodicity (for a pulse several cycles long) of the process implies that the light emission is not continuous but at discrete (odd-harmonic) frequencies.

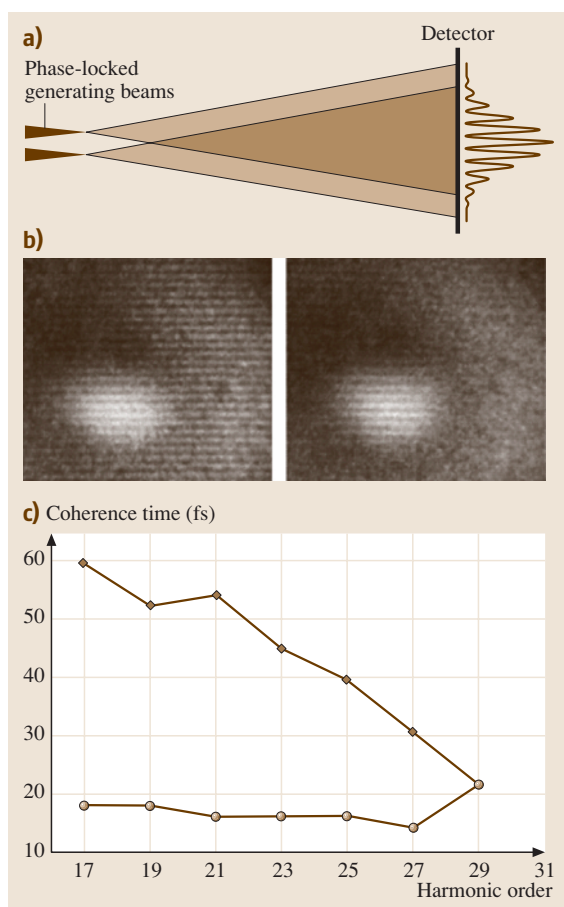
The influence of the complex electron dynamics inherent to the harmonic-generation process is clearly visible on the intensity dependence of the harmonic components of the quantum-mechanical dipole moment. Figure 4.41 shows for example the 35-th harmonic


Fig. 4.42a−c Spatially-resolved temporal coherence measurements of high-order harmonics. The principle of the measurement is shown in **(a)**. Two images obtained on the 13-th harmonic in xenon obtained for two different time delays (0 and 25 fs) between the two pulses are shown in **(b)**. A summary of the measured coherence times in the two spatial regions for high harmonics in xenon is presented in **(c)**

generated in neon, calculated within the strong field approximation. The intensity and phase are represented respectively in solid and dashed line as a function of the laser intensity. The sharp intensity and phase variation at low intensity corresponds to the cutoff region. In the plateau, oscillations are clearly visible in the variation of both the intensity and the phase. They originate from interference effects between the contributions from the multiple trajectories. This fascinating conclusion stimulated the development of analysis techniques to extract the contributing electron trajectories (or rather the relevant quantum paths) from quantum-mechanical approaches [4.317, 318]. The result of such an analysis for the 35-th harmonic in neon is shown at the bottom in Fig. 4.41. The contributions to the dipole phase varying linearly with the intensity $\phi_{dip}(I) = \alpha_j I$, corresponding to a quantum path (j), are identified as vertical lines in Fig. 4.41. In this case, the dominant trajectory is the "second" one, with a coefficient $\alpha_2 = 24 \times 10^{-14}$ cm^2 W. At low intensity, in the cutoff region, there is only one quantum path.

The microscopic physics (the quantum orbits) behind high-order-harmonic generation was shown in a series of experiments investigating the temporal coherence of the harmonics [4.319–321]. We present in Fig. 4.42 the principle as well as some results obtained in xenon [4.320]. Two phase-locked spatially separated harmonic sources are created by splitting the laser into two replicas in a Michelson interferometer and by slightly misaligning one of the arms. A variable time delay can be introduced between the two pulses. The generated harmonics are separated by a grating and interfere in the far field. The variation of the contrast of the fringes as a function of time delay gives the coherence time. Figure 4.42b shows images obtained for the 13-th harmonic in xenon. (For experimental reasons, the images are not symmetrical.) These images present two spatial regions with different coherence times. The central region exhibits a long coherence time, whereas the outer region a much shorter one. Figure 4.42c summarizes measurements on the harmonics generated in xenon.

These results can be interpreted in a simple way by recalling that the harmonic field is a sum of the contributions from each quantum path j

$$E_q(\boldsymbol{r}, t) = \sum_j A_j(\boldsymbol{r}, t) \, \mathrm{e}^{-[iq\omega t + \alpha_j I(\boldsymbol{r}, t)]} \qquad (4.232)$$

where A_j is an envelope function, representing the strength of each path. The temporal variation of the laser intensity $I(t)$ will produce a chirp in the emitted field,

and consequently a spectral broadening (or a reduced coherence time). The radial variation of the laser intensity $I(r)$ will affect the curvature of the phase front of the harmonics, and therefore their divergence. The contribution from the quantum paths with a long excursion time in the continuum (Fig. 4.40), resulting in a large α_j, will have a short coherence time and a pronounced curvature in the far field, whereas that from the quantum paths with a short excursion time will have a longer coherence time and be more collimated [4.322]. Similar evidence for the existence of (at least) two quantum paths has been obtained by analyzing the harmonic spectra in combination with measuring the harmonic pulse duration [4.321]. Contributions of different quantum paths can be selected macroscopically, either by spatial or spectral filtering.

4.11.4 Macroscopic Physics

We now turn to the second aspect of harmonic generation, namely the response of the whole medium. To achieve phase matching, i.e. to ensure efficient conversion, the wave vector difference (traditionally called the phase mismatch) between the harmonic wave and the polarization must be minimized, so that the phase difference varies as little as possible over the medium's length. For an incident Gaussian beam, this phase difference on the propagation axis (z) is given by

$$\delta\phi_q = \phi_q - \phi_q^{\text{pol}}$$
$$\approx k_q z - q k_1 z + q \arctan(2z/b) - \phi_{\text{dip}} . \quad (4.233)$$

In this equation, the first two terms characterize the difference in dispersion at the fundamental and q-th harmonic frequencies, mainly due to the effect of the free electrons in the medium. The third one is a geometrical term originating from the Gouy phase shift of a Gaussian beam with confocal parameter b across the focus. The fourth term is the dipole phase described above. According to the previous discussion, it is more physically correct to consider separately the contributions from the different quantum paths, before making a (coherent) sum. The phase difference to minimize depends on the trajectory and is given by

$$\delta\phi_{q,j} = \phi_q - \phi_q^{\text{pol}}$$
$$\approx k_q z - q k_1 z + q \arctan(2z/b) - \alpha_j I(r,z,t) . \quad (4.234)$$

Figure 4.43 illustrates the variation of $\delta\phi_q$ along the propagation axis (z). Most contributions are monotonic. Focusing as well as the free electron dispersion (not shown in Fig. 4.43) lead to a contribution to $\delta\phi_q$ increasing with z, while the (normal) dispersion leads to
Fig. 4.43 (*Top*) phase difference between the harmonic wave and the polarization for the 35-th harmonic generated in neon on the propagation axis. In *dashed line*, we show the term coming from the geometrical phase shift of a Gaussian beam and in *dotted line*, the term coming from the dipole phase. The laser intensity is 6×10^{14} W/cm^2. The confocal parameter is chosen to be $b = 1$ cm. (*Bottom*) corresponding phase matching map (after [4.317])

a term decreasing with z, usually quite small. In contrast, the contribution of the dipole phase, here due mainly to the second trajectory, with a transition to the cutoff for $|z| \geq 7.5$ mm, first increases, then decreases with z. In the particular case shown in Fig. 4.43, phase matching on the propagation axis is best realized for $z \geq 7$ mm, requiring the medium to be located after the focus. In general, the situation can be rather complicated. Methods have been developed to visualize where (in the nonlinear medium) and when (during the laser pulse) phase matching was best realized [4.317], using in particular three-dimensional maps representing the local coherence length, defined as

$$L_q = \pi \left(\frac{\partial \delta\phi_q}{\partial z} \right)^{-1} . \quad (4.235)$$

An example of such a map for the situation corresponding to Fig. 4.43 (top) is shown at the bottom of the same

figure. The white areas indicate where phase-matching is best realized. The two parts of the figure correspond to the transition between cutoff and plateau.

The brief analysis presented above can easily be generalized to include propagation in waveguides [4.246–248], which modifies somewhat the phase-matching conditions, since the geometrical and dipole phase effects are much reduced (owing to a constant intensity in the waveguide). Absorption in the nonlinear medium starts to play a role for high conversion efficiencies and long medium lengths and/or high pressures. The optimization of phase matching of high-order-harmonic generation has stimulated a great deal of efforts during the last five years. The so-called *absorption limit*, where the limitation on the conversion efficiency is due to absorption, and not to the coherence length, has been reached in different wavelength ranges [4.249,250,302]. Recently, the use of extremely long focusing geometries (which minimize both the effect of the dipole phase and that of the Gouy phase shift) has led to conversion efficiencies as high as a few times 10^{-5} and energies in the μ J range [4.303,323]. Phase matching of high-order-harmonic generation is by no means a solved issue, since it is a complicated three-dimensional problem, involving a number of parameters (laser focusing, pressure, medium length and geometry, laser intensity). In addition, the problem is quite different for the low-order harmonics with energy around a few tens of eV, where most of the work has been done, and for the high-order harmonics at 100 eV or more. An interesting idea, similar to quasi-phase-matching has recently been investigated [4.324]. A modulated waveguide, used for the generation of high-order harmonics, induces a periodic variation of the degree of ionization leading to enhanced conversion efficiency, especially for the high harmonics.

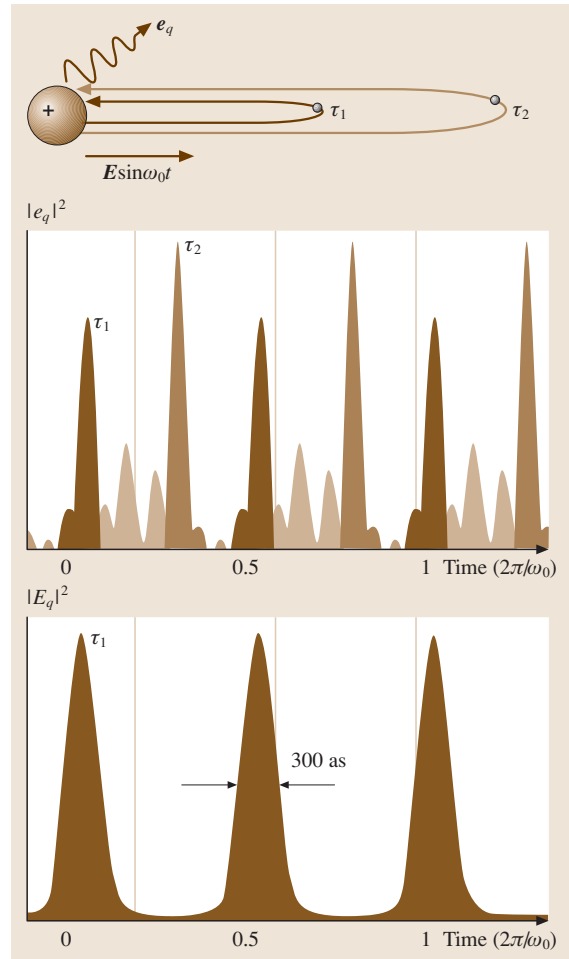
Finally, a conclusion of importance for the generation of attosecond pulse trains is that the different quantum paths contributing to harmonic generation discussed in the previous section are not phase matched in the same conditions (4.234). The axial variation of the laser intensity $I(z)$ leads to different phase matching conditions for the contributions from the different quantum paths. In other words, depending on the geometry, ionization, pressure conditions, phase matching will enhance one of the contributing trajectories to the detriment of the others. This conclusion is extremely important for the generation of attosecond pulse trains. As illustrated in Fig. 4.44 (top), the electron trajectories contributing to harmonic generation in the single-atom response lead to bursts of light at different times during


Fig. 4.44 Illustration of the temporal structure of a few harmonics in the single atom response (*top*, *middle*). In some conditions, phase matching selects only one burst of light per half cycle, leading to phase locking (*bottom*)

the laser half-cycle. Phase locking between consecutive harmonics is not realized. In some conditions, however, phase matching results in efficient generation of only one of these contributions [Fig. 4.44 (bottom)] [4.325, 326], leading to a train of attosecond pulses. Another possibility, that makes use of the different spatial properties of the contributing trajectories, is to select the shortest trajectory by spatially filtering the harmonic beam with an aperture. Finally, a spectral filter can be used to select only the harmonics in the cutoff region, where the electron dynamics is much simpler, with only one electron trajectory in a single-atom response.

4.12 Attosecond Pulses: Measurement and Application

4.12.1 Attosecond Pulse Trains and Single Attosecond Pulses

The first experimental indication of harmonic radiation containing a substructure was observed in a high-order autocorrelation of the driving laser pulse [4.283]. The experimental set up was similar to that described in Fig. 4.42 (top), except that the two harmonics sources were spatially overlapped and no spectral selection with a grating was done. The signal was studied as a function of time delay, and showed substructures.

More-recent experiments [4.284] showed conclusive evidence for a group of harmonics beating together to form a sequence of XUV bursts. In perfect phase-locking conditions, a combination of $N = 5$ harmonics generated by a 800 nm laser can form a train of pulses separated by half the laser period $T_0/2 = 1.35$ fs, with a duration as short as $T_0/2N$. In the experiment described in [4.284], the signal used to study the phase locking of the harmonics were the sidebands in the photoelectron spectra, which are due to the coherent superposition of two processes, combined absorption of a harmonic and infrared (IR) laser photon, and absorption of the next harmonic and emission of a laser photon [Fig. 4.45 (top)]. The sideband intensity depends on the phase difference between the two harmonics involved, as well as on the time delay between the XUV and IR pulses. Monitoring the intensity as a function of time delay for several sideband peaks allows one to study the variation of the phase difference between consecutive harmonics [Fig. 4.45 (bottom)]. The relative phases of the harmonics were found to be fairly constant, yielding a train of 250 as pulses spaced by half the oscillation period of the laser field [Fig. 4.45 (middle)].

The high repetition rate (twice the laser frequency) of this train of pulses may pose problems when it comes to spectroscopic applications, because the interpretation of pump–probe experiments tends to be ambiguous. Using such a train for either triggering or probing a dynamic process that does not completely come to a standstill within $T_0/2 (\approx 1.3$ fs for 800 nm driver laser light from a Ti:sapphire laser) gives rise to multiple pumping or probing, complicating the interpretation of measured data. This recognition led to the proposal that a single pulse could possibly be selected from the attosecond train by a driving laser pulse with a polarization state rapidly varying in time to confine pure linear polarization (which is a prerequisite for harmonic emission) to a single laser cycle at the pulse peak [4.280, 281, 327].

This *polarization gating* technique has been experimentally implemented using different methods to achieve the modulation of the degree of ellipticity of the fundamental laser pulse. A significant confinement of the harmonic emission (however not in the attosecond regime) has been shown using both spectral and temporal diagnostics [4.297, 298, 328, 329]. This technique could be a way to isolate single as pulses in the plateau energy region.

A more straightforward approach to confining high-harmonic emission to a single laser cycle became feasible with the availability of intense few-cycle (sub-10 fs) laser pulses. When driven with a laser pulse consisting of only a few oscillation cycles, the harmonic emission at the highest photon energies (near cutoff region) can be confined to one half of the oscillation period near the pulse peak. By selecting a well-defined photon energy band near the cutoff region, which requires the highest driving field intensity, it is expected to be possible to isolate one single sub-femtosecond burst, as illustrated in Fig. 4.46. This diagram also shows the sensitivity of isolated pulse generation to the absolute (or carrier-envelope) phase φ of the fundamental laser pulse

$$E_L(t) = E_a(t)\cos(\omega_L t + \varphi). \tag{4.236}$$

Only pulses with $\varphi \approx 0$ have the potential for producing a single burst. For such a fundamental pulse with a "cosine" waveform, the peak intensity of the laser pulse can be adjusted to give rise to a single burst within a preselected frequency band (beige band in Fig. 4.46). Recently, carrier-envelope-phase-controlled few-cycle pulses opened the door to the reproducible generation of single sub-femtosecond XUV pulses [4.330].

The feasibility of a single sub-femtosecond pulse produced by few-cycle-driven high-order harmonic generation was corroborated by numerical studies based on a computer code [4.331] solving Maxwell's wave equations in three dimensions and calculating the radiation of the strongly driven atomic dipoles using the quantum theory of *Lewenstein* et al. [4.231]. These numerical calculations predict the feasibility of isolated near-bandwidth-limited XUV pulse generation with durations down to the 100 as range.

4.12.2 Basic Concepts for XUV Pulse Measurement

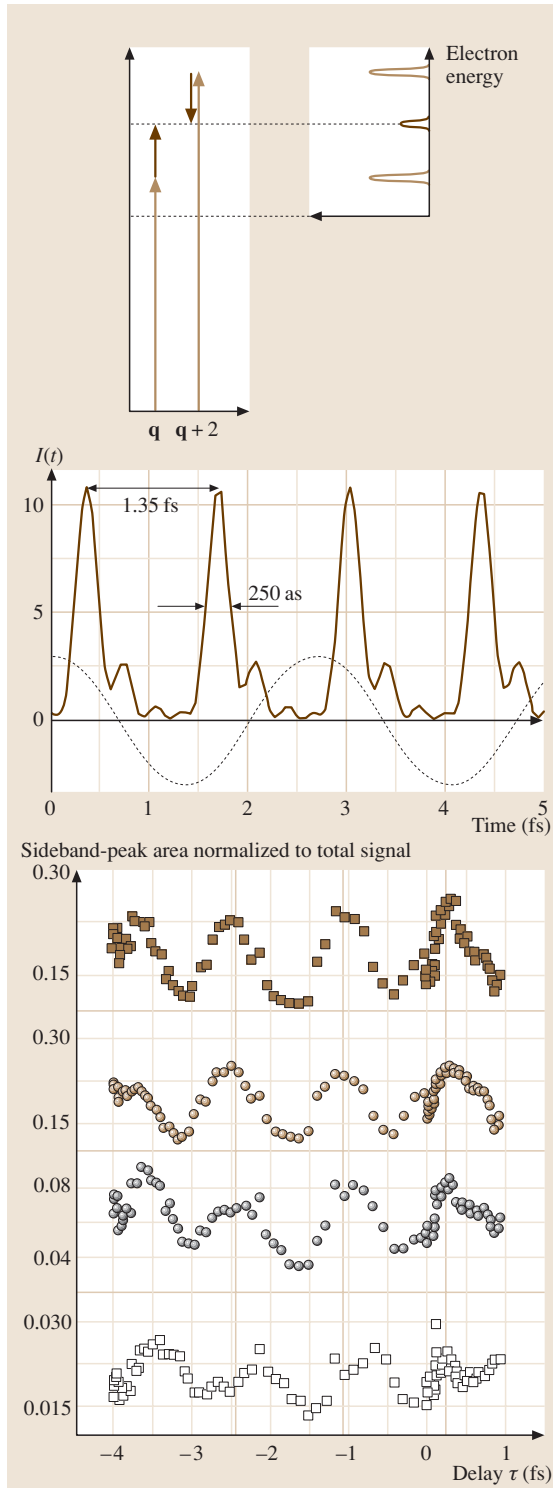
The most direct information about the duration of short flashes of electromagnetic radiation can be gained from time-domain measurements. To this end, the burst to


Fig. 4.45 Experimental evidence for phase-locking of high-order harmonics; principle of measurement (*top*), experimental results (*bottom*) and reconstructed temporal intensity profile (*middle*). Reprinted from [4.284] with permission from the authors

be characterized must be probed by a sampling pulse that is comparable to or shorter than the duration of the burst. In the optical regime this concept has been implemented by nonlinear autocorrelation techniques, where the burst to characterize is probed by itself. The extension of these techniques to the XUV spectral range is not trivial, because of the unfavorable scaling of the nonlinear polarizability with wavelength and because of the low power of the XUV pulse to be measured. Only a few results have been obtained so far for relatively low-order harmonics. The nonlinear process used for the autocorrelation is two-photon ionization of a gas target. Experiments have demonstrated two-photon ionization in Xe, Kr [4.277, 332] by low-order harmonics and recently two-photon ionization in He with a combination of harmonics from the 7-th to the 13-th [4.333]. In the first autocorrelation experiments [4.275, 334], harmonics generated by a 1 TW 30 fs laser beam were used to ionize He atoms. The number of He^+ ions was measured as a function of the delay between two identical ninth-harmonic pulses (14.1 eV) generated by two replicas of the fundamental pulse. A pulse width of 27 fs was obtained by assuming a $sech^2$ pulse shape (Fig. 4.47). In a more recent experiment a two-photon-absorption-based auto-correlation was implemented for a frequency-resolved optical gating (FROG) measurement [4.335]. Here the two replicas of the fifth harmonic of a 7 mJ Ti:sapphire laser pulse were focused into a Xe gas jet. From the recorded FROG trace the intensity profile and chirp of a high-harmonic pulse could be retrieved. In another recent experiment [4.336], an autocorrelation of a bunch of harmonics (from the 7-th to the 11-th) gives evidence for attosecond bunching.

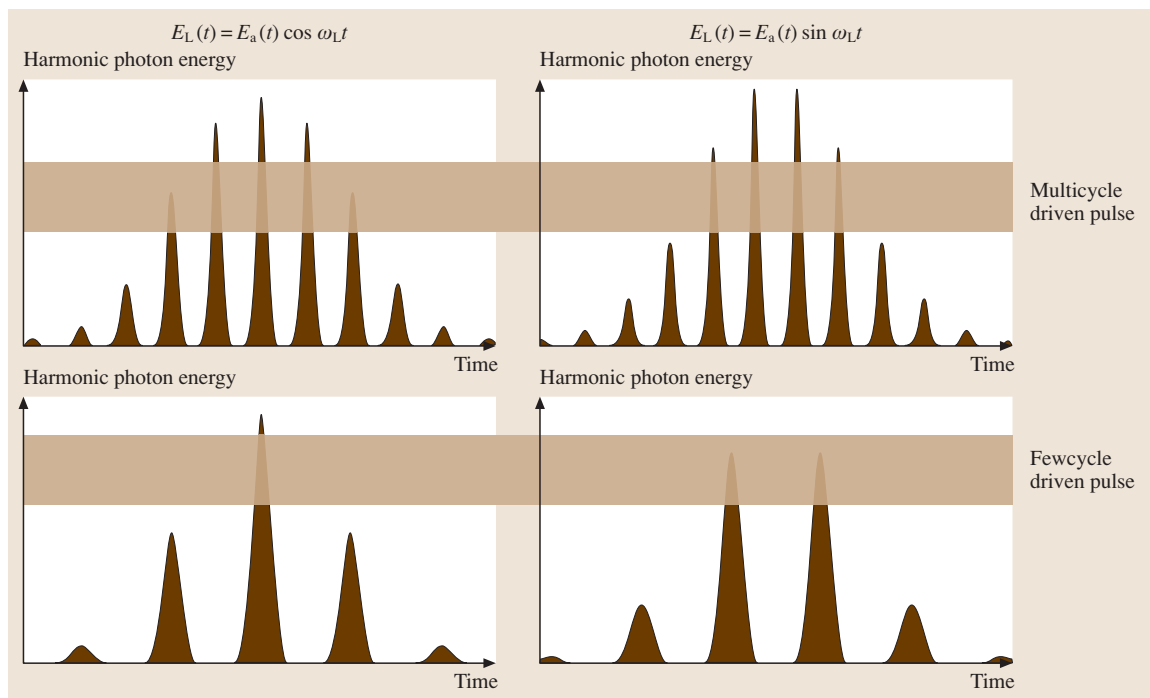
The extension of auto-correlation techniques to higher-order harmonics, with energies in the XUV/soft-X-ray region, remains, however, a formidable challenge. The atomic cross section of the absorption process σ scales with λ^6, implying a dramatic decrease of the two-photon transition probability with decreasing wavelength. As a consequence auto-correlation schemes require photon fluences orders of magnitude higher than those available from existing harmonic sources in the XUV regime. In order to circumvent the difficulties resulting from low two-photon transition cross sections


Fig. 4.46 Comparison of the temporal structure of harmonics of multi-cycle or few-cycle pulses for different values of the carrier-envelope phase. The peaks sketch the temporal structure (*horizontal axis*) of emitted XUV radiation as a function of XUV photon energy (*vertical axis*)

at short wavelengths, the XUV pulse can be correlated with the strong laser pulse previously used for its generation. The cross-correlation can be implemented by XUV photoionization in the presence of the laser pulse. XUV pulses have been cross-correlated with the femtosecond

Fig. 4.47 Auto-correlation trace of the ninth harmonic by two-photon ionization of He (after [4.334])
infrared (IR) laser pulses in a number of experiments over the past decade [4.257–260,262,337,338]. All these experiments had in common that the temporal intensity envelope of the laser pulse served as a sampling function for measuring the XUV pulse shape and duration, which limits the temporal resolution to several femtoseconds or more.

Here we review a novel implementation of XUV/IR cross-correlation technique that correlates the XUV pulse *envelope* with the oscillating laser *field* rather than its envelope, providing a sub-$T_0/4$ probe (T_0 is the laser cycle) for measuring the XUV pulse duration. The method exploits the dependence of the final kinetic energy of the XUV-pulse-generated photoelectron on the phase (and strength) of the laser field at the instant of photoionization. The width and position of the resultant photoelectron spectra are measured as a function of the relative delay between XUV and laser pulse and yield a convolution of the oscillating laser light field with the XUV pulse envelope. Careful deconvolution allows one

to determine the duration of the XUV pulse and its timing jitter with respect to the light field with as resolution [4.261, 285]. The concept has been termed attosecond streak camera because it is the streaking of the electron's kinetic energy by the rapidly varying laser field that yields direct time-domain information of the time structure of emitted electron wave packet, which mimics that of the XUV pulse [4.339–341].

4.12.3 The Optical–Field–Driven XUV Streak Camera Technique

XUV photoionization in the presence of a strong laser field can be accounted for by a simple quasi-classical model, similar to that presented above, treating the interaction as a two-step process [4.261]. According to this model, the photoelectron is first ejected by a short XUV pulse with a distribution of initial momenta known from conventional photoionization studies [4.342]. Subsequently, it is accelerated (or decelerated) by the light field. For XUV pulse durations τ_x very short compared to $T_0/2$, the model predicts that, depending on the oscillation phase of the light field at the instant of "birth" of the electron, a momentum component is added to the initial momentum of the electron.

The concept of laser-field-assisted XUV photoionization can be implemented in various detection geometries. The two most important ones are shown in
Fig. 4.48 Two-color (XUV/IR) photoionization in different geometries: the strong electric field of the infrared laser pulse can be polarized along the direction of detection of the photoelectrons or orthogonally to it, giving rise to substantial differences in the photoelectron's motion after its liberation. The polarization of the XUV pulse has little influence on the electron motion

Fig. 4.48. The photoelectrons are detected within a cone aligned parallel and orthogonally to the electric field vector of the linearly polarized laser field (henceforth referred to as the parallel and orthogonal detection geometry, respectively). Here we focus on the orthogonal geometry because the first sub-femtosecond pulse measurement used this configuration [4.285]. In the next section we shall demonstrate that the parallel geometry can also be employed for efficient as diagnostics.

Figure 4.49 depicts the final momentum distribution of the photoelectron for different instants of release in the strong laser field. In general, a laser-induced momentum component is added to the initial momentum vector of the photoelectron, resulting in a shift of the photoelectron angular distribution along the laser polarization in momentum space. The momentum transferred from the IR light field is largest if the electric field of the light wave is zero, i. e. its slope is maximum, at the instant of birth of the photoelectron. The width of the XUV photoelectron energy spectrum ΔW, which is equal to the bandwidth of the XUV pulse spectrum in the absence of the light field, increases with increasing momentum shift, within a finite detection cone aligned orthogonally to the laser polarization.

Scanning the instant of birth of the photoelectron through the light field oscillations by changing the relative delay t_d between the light pulse and XUV pulse results in a modulation of the center of gravity as well as the width $\Delta W(t_d)$ of the XUV photoelectron spectrum with a period equal to one half of the light oscillation period T_0. In the first time-resolved sub-femtosecond XUV pulse measurement [4.285] the modulation of the field-induced spectral broadening $\Delta W(t_d)$ was recorded. The detection of such a modulation relies on an XUV pulse short compared to half the laser period, i. e. $\tau_x \ll T_0/2$, implying also a fast (attosecond) ionization of the bound electrons by the XUV photons, and a timing firmly fixed (with as precision) of the XUV pulse with respect to the laser field. A finite XUV pulse duration or a finite timing jitter of the XUV pulse (relative to the phase of the light field) of any origin results in a reduced contrast of the predicted variation of $\Delta W(t_d)$ versus time delay (illustrated in Fig. 4.49). An XUV pulse duration or a timing jitter exceeding $T_0/2$ (≈ 1.25 fs in the case of near-infrared laser light from the Ti:sapphire laser) would smear out the modulation completely. Hence, the modulation depth of $\Delta W(t_d)$ provides a sub-femtosecond probe for setting a reliable upper limit on the XUV pulse duration and timing jitter.

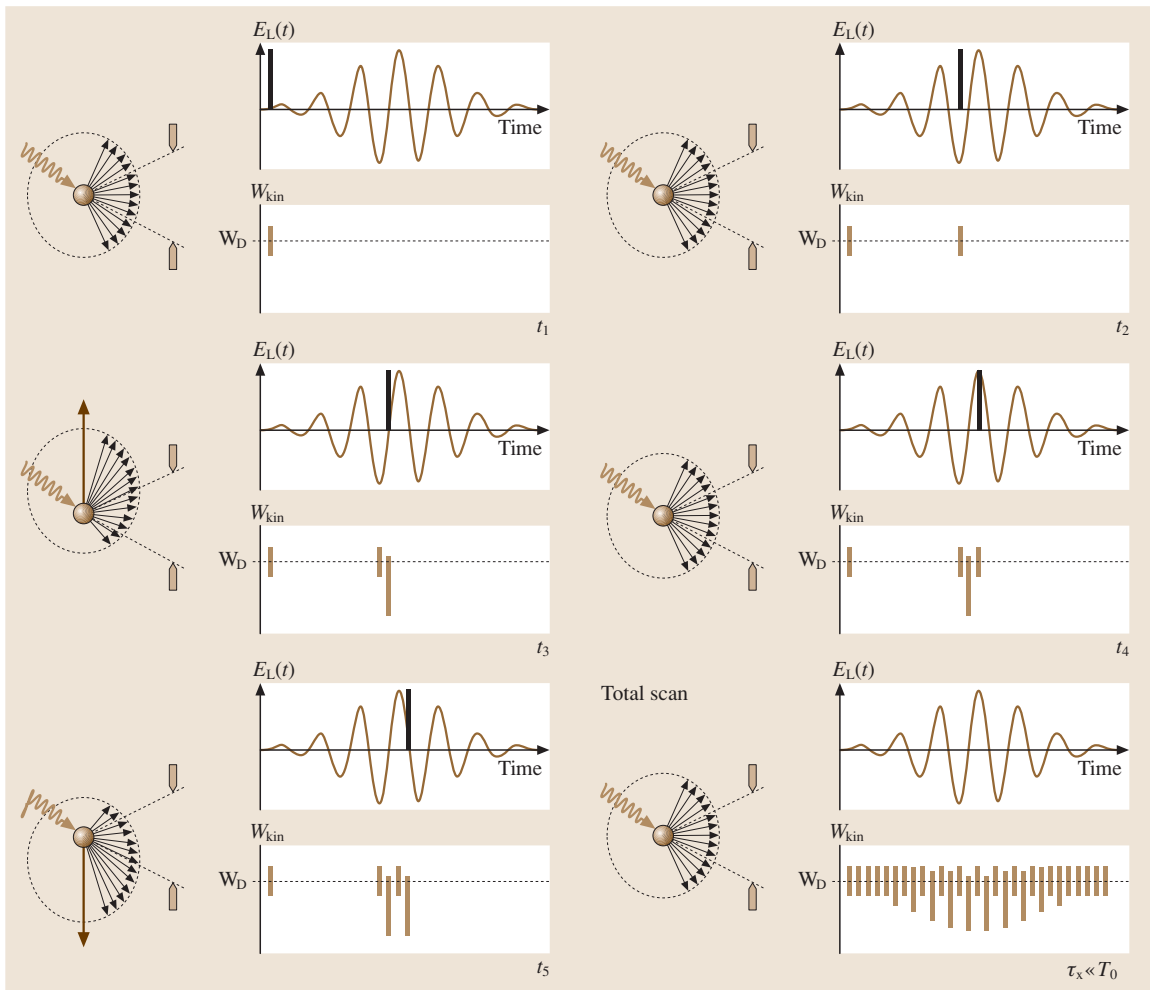
Figure 4.50 displays the experimental set up for the generation of sub-femtosecond XUV pulses by har-


Fig. 4.49 Principle of measuring XUV-intensity/IR-light-field cross-correlation with attosecond resolution. The photoelectrons created initially with isotropic momentum distribution by the absorption of XUV photons pick up momentum from the strong laser light field. The light-induced momentum change Δp_x deforms the final photoelectron momentum distribution at instants t_1, t_2, $t_3 = t_2 + T_0/4$, $t_4 = t_2 + T_0/2$, and $t_5 = t_2 + 3T_0/4$ as shown, where $E_L(t_3) = E_L(t_5) = 0$. Photoelectrons detected within a cone aligned orthogonally to the direction of the light field vector (x-direction) display a kinetic energy spread at t_3 and t_5 whilst remaining unaffected by the light field at t_1, t_2 and t_4. The full scan shows schematically the expected modulation of the spectra if $\tau_x < T_0/2$

monic generation and their time-resolved measurement by the attosecond streak-camera technique described in the previous section. A 200 nm-thick zirconium foil with an aperture of 2 mm is placed 150 cm downstream from the XUV pulse source. The aperture is matched to the beam diameter of the harmonic beam, which has a low divergence of ≈ 0.7 mrad. This filter is placed in the beam to block the laser and low-order harmonics across the XUV beam, transmitting only photons

with an energy of higher than 70 eV. It is mounted on a nitrocellulose membrane of 5 μm thickness to cover a 2 mm-diameter hole in the membrane. This device is virtually dispersion-free and produces an annular laser beam confining the XUV beam in its center. The energy in the laser beam is adjusted by a motorized iris and measured by a photodiode. Both the laser and the collinearly propagating XUV beam are focused with a two-component focusing mirror directing the XUV
Fig. 4.50 Experimental set up for the attosecond pulse measurement. The focused 7 fs laser beam interacts with neon atoms to produce high-harmonic radiation. The laser and the highly collimated XUV beam co-propagate collinearly through a 2 m beam line towards the measurement. In the beaml ine the laser and harmonic beams pass through a 200 nm-thick 3 mm-diameter zirconium foil placed on a 5 μm-thick nitrocellulose pellicle to cover a hole of 2 mm diameter. The energy transported by the resulting annular beam can be adjusted with a motorized iris between a fraction of a microjoule and a few tens of microjoules. The Mo/Si multilayer consists of an annular part having an outer diameter of 10 mm with a concentric hole of 3 mm diameter hosting a miniature mirror of slightly smaller diameter. Both parts originate from the same substrate, ensuring identical radii of curvature ($R = 70$ mm). The miniature central mirror is mounted on a wide-range nanometer-precision piezo-driven stage, allowing alignment and translation with respect to the external part
and IR beam with an adjustable time delay into a common focus of the two focusing mirrors, where a nozzle supplying the target atoms is placed. The focusing mirror is coated with a Mo/Si multilayer stack designed to reflect photons with 90 eV energy within a 5 eV bandwidth. This bandwidth is large enough to support XUV pulses as short as 0.4 fs.

The contour plot in Fig. 4.51 depicts the variation of the energy distribution of photoelectrons knocked out

Fig. 4.51 Energy distributions of the Kr-4p photoelectrons (binding energy ≈ 15 eV) as a function of the delay t_d between the ionizing sub-femtosecond 90 eV XUV pulse and the *dressing* few-cycle laser wave over some tens of femtoseconds

from the 4p shell of krypton by 90 eV XUV pulses (y-axis) as a function of delay t_d (x-axis). The XUV pulses were filtered out from the high-harmonic emission spectrum of Ne atoms driven by few-cycle (7 fs, 750 nm) laser pulses by the Mo/Si mirror within a 5 eV bandwidth at 90 eV near the cutoff of the emission spectrum. The XUV pulse were delayed by 150 as steps with respect to the few-cycle laser pulse to record the laser-affected XUV photoelectron spectra versus delay. The data clearly bring to light a quasi-periodic evolution of the photoelectron energy spectrum with a period of $\approx T_0/2$. From the depth of this modulation an XUV pulse duration of $\tau_{XUV} = 650 \, \text{as} \pm 150 \, \text{as}$ was evaluated [4.285].

Figure 4.52 shows two representative spectra sliced out from the contour plot in Fig. 4.51 at delays of $t_d = -450$ as and $t_d = 0$, as indicated by the arrows. The marked difference between the two spectra recorded at delays just 450 as apart provides a clear evidence for the photoelectron emission time (and hence the XUV pulse) being temporally confined to a fraction of a femtosecond.

In the analysis presented in the previous subsections, the laser field was used to probe the XUV pulse duration. With its duration known, the sub-femtosecond XUV pulse can take over the role of the probe as it is scanned across the laser pulse (in time) and measure the frequency of light for the first time in a time-resolved experiment. A possible sweep of instantaneous frequency ν_{inst} (or wavelength λ_{inst}) of the few-cycle laser pulse
Fig. 4.52 Kr-4p photoelectron spectra extracted from the contour plot in Fig. 4.51 at delays indicated by the *arrows*. The *dots* represent spectra normalized to the same number of electron counts in the time-of-flight electron spectrometer. The *lines* show asymmetric Gaussian fits to the data
Fig. 4.53 Calculated (*line*) and measured blue shift of the fundamental pulse, probed by the XUV pulse. The steep rising edge indicates the presence of single XUV pulses without significant satellites

can be evaluated from the modulation in $\Delta W(t_d)$ by fitting a sinusoidal half-oscillation of adjustable period to $\Delta W(t_d)$ at different values of t_d. The sampling interval was scanned through the range of $-8 \, \text{fs} \leq t_d \leq 8 \, \text{fs}$. The dots in Fig. 4.53 show the carrier-frequency sweep evaluated in this manner, revealing a dynamic blue shift from a carrier wavelength of ≈ 750 to $\approx 550 \, \text{nm}$.

This strong dynamic frequency shift carried by the few-cycle laser pulse has been found to originate from the interaction of the pulse with the ionizing gas source of the XUV pulses. In fact, the line in Fig. 4.53 is obtained from propagating a bandwidth-limited 7 fs laser pulse through the volume of neon gas emitting the high harmonics in a numerical experiment [4.331]. The measured $\approx 30\%$ dynamic frequency blue shift at the center of the pulse is larger than predicted by the simulations but reflects qualitatively the predicted behavior. The qualitative agreement suggests that the observed blue shift can be attributed to ionization-induced self-phase modulation in the high-harmonic-generation process. This direct probing of the field oscillations of a light wave can be regarded as the first application of sub-femtosecond XUV pulses.

The observed sub-femtosecond rise time of the ionization-induced dynamic blue shift provides conclusive evidence for the isolated nature of the sub-femtosecond XUV burst. Any satellite of substantial energy spaced by some $T_0/2 \approx 1.30 \, \text{fs}$ from the main burst would broaden this rise time to more than 1 fs. The agreement of the measured XUV pulse duration and that obtained from simulations [4.285] within the experimental error suggests that the timing jitter of

the XUV pulse with respect to the phase of the IR light wave must be small compared to 1 fs, indicating that the sub-femtosecond XUV pulse is locked to the carrier wave of its generating few-cycle light pulse with as precision. The attosecond timing stability of the sub-femtosecond XUV pulse to a few-cycle IR light wave makes these pulses a unique tool for investigating the dynamic behavior of matter on an attosecond time scale. The light-field-controlled photoemission experiment already demonstrates this capability. In the measured energy distribution $\Delta W(t_d)$ it is implicit, that in the investigated spectral range near 90 eV bound–free electronic transitions from the 4p state in krypton respond to XUV excitation within less than 500 as, constituting

Fig. 4.54 Energy shift of XUV photoelectrons ejected nearly parallel to the polarization direction of a strong laser field near the instant of zero transition of the laser field by a sub-$T_0/2$-duration XUV pulse

the first time-resolved measurement on an atomic time scale.

Another implementation of the attosecond streak-camera technique is shown in Fig. 4.54 [4.286]. Here the photoelectrons are detected in the parallel geometry as sketched in the top of Fig. 4.48. If the photoelectron is ejected near the zero crossing of the laser electric field, its energy spectrum may get up- or downshifted by many electronvolts. This is in strong contrast with the orthogonal geometry used before, where the primary effect of the laser field is a broadening rather than a shift of the photoelectron energy spectrum.

The predicted spectral shift relies not only on a precise timing of the XUV pulse to the zero transition of the laser field. This shift without substantial broadening happens only if the generated XUV burst (and therefore the generated photoelectron wave packet) is very short compared to the laser field half-oscillation period $T_0/2$. If the XUV pulse and therefore the electron wave packet approaches or exceeds $T_0/2$, different portions of the wave packet experience different momentum transfer, resulting in a large spread of energies. A recent experiment using XUV pulses of 8 eV bandwidth verified this prediction and allowed to set an upper limit of 500 as and 200 as on the duration of the XUV pulse and its timing jitter with respect to its generating laser wave, respectively [4.286].

4.12.4 Applications of Sub-femtosecond XUV Pulses: Time-Resolved Spectroscopy of Atomic Processes

Finally, we show, how pump–probe spectroscopy of atomic excitation and relaxation processes – such as e.g. optical-field ionization and inner-shell relaxation processes – can be traced directly in the time domain by drawing on low-energy isolated X-ray pulses in combination with synchronized strong few-cycle laser pulses, i. e. on tools that are available now.

Pump–probe techniques offer the most direct experimental approach to tracing microscopic dynamics. The extension of time-resolved spectroscopy to ultrafast electronic processes taking place deep inside atoms has so far been frustrated by the simultaneous requirements of short wavelengths (i. e. high photon energy) and sub-femtosecond pulse duration. There is the additional difficulty that a straightforward interpretation of spectroscopic data requires isolated (single) pulses. With these pulses now available from few-cycle-driven high-order harmonic generation, extension of time-resolved spectroscopy into the attosecond domain can now be
Fig. 4.55 Tracing inner-shell relaxation processes by XUV–pump/XUV–probe spectroscopy. The kinetic energy of photoelectrons detached by the probe pulse from the atom following excitation by an XUV pump pulse is analyzed as a function of the delay between the pump and the probe pulse

tackled. Figure 4.55 shows the principle of an XUV-pump/XUV-probe experiment. In this – conceptually most straightforward – implementation of as spectroscopy, the sub-femtosecond XUV pulses are used for both triggering and probing bound–bound or bound–free transitions in atoms or molecules.

However, the sub-femtosecond XUV pulses currently available do not have sufficient flux for XUV–pump/XUV–probe spectroscopy yet. This is because in this kind of experiments the physical quantity measured as a function of delay between pump and probe pulse relies on a two-XUV-photon transition, the probability of which scales with $\sigma I_{pump} I_{probe}$, where σ is the atomic cross section of the absorption process and I_{pump} and I_{probe} are the intensities of the pump and probe XUV bursts, respectively. Both I_{pump} and I_{probe} are many orders of magnitude less than what can be achieved in the optical regime. Moreover σ is also reduced by many orders of magnitude because it scales with λ^6.

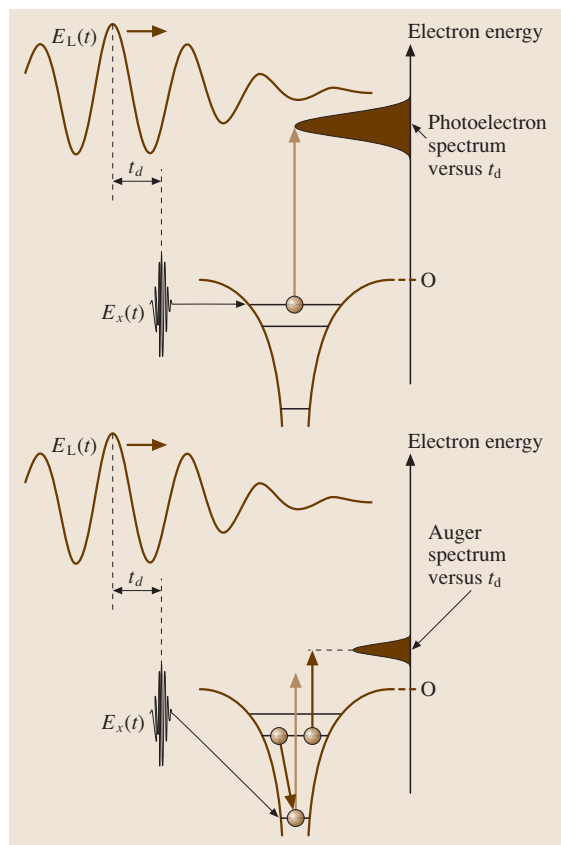
Extension of the concept of laser-field-assisted XUV photoelectron emission to sampling the emission of secondary (Auger) electrons offers an alternative solution to time-resolving inner-shell atomic processes with as accuracy. The underlying principle is illustrated in Fig. 4.56. The sub-femtosecond XUV pulse excites a core electron and produces thereby a short-lived inner-shell vacancy. This is rapidly filled by an electron from a higher energy level (outer shell). The energy lost by the electron undergoing this transition is carried away either by an energetic (XUV/X-ray) photon or by a secondary (Auger) electron. The emission


Fig. 4.56 Schematic representation of the Auger process and its temporal evolution displaying the decay of an inner-shell vacancy

time of this Auger electron corresponds exactly to the lifetime of the inner-shell vacancy. Hence, sampling the Auger electron emission in the same way as the primary photoelectron emission with the oscillating laser field enables researchers to gain direct time-domain access to inner-shell atomic processes with as resolution. The first proof-of-principle time-resolved inner-shell spectroscopic experiment was recently demonstrated [4.343]. Although the decay time measured in this experiment can also be inferred from energy-domain measurements, it served as a benchmark process for testing the feasibility of the methods described above for attosecond time-resolved spectroscopy.

The frontiers of both time-resolved spectroscopy and the control of microscopic dynamics are about to be radically extended due to the new technical capability that allows scientists to synthesize intense pulses containing a few cycles evolving in a precisely determined way

[4.330]. With this tool it should be possible to precisely control the motion of energetic electron wave packets around atoms on attosecond timescales just as the motion of nuclear wave packets in molecules can be controlled within a few femtoseconds. The single sub-femtosecond electron bunches and (XUV/X-ray) photon bursts that arise from the recently gained ability to control electron wave packets will enable the scientific community to excite and probe atomic dynamics on atomics time scales.

4.12.5 Some Recent Developments

Attosecond science is rapidly evolving [4.344] and the last three years have seen important progress both in the performances of femtosecond and attosecond light pulses based on high-order harmonic generation in gases and in their applications in different scientific areas.

Harmonic sources now reach pulse energies in the microjoule range [4.345] and their spectra extend to energies of several keV (though with a lower throughput) [4.346]. Applications are flourishing, going from the determination of vibration frequencies in molecules [4.347] to microscopy [4.348, 349] and even recently to seeding of X-ray laser plasmas [4.350] and possibly, in the future, free-electron lasers.

Attosecond pulses have been studied in more details with different techniques [4.351, 352] and the method to isolate a single pulse refined [4.353, 354]. Their time-frequency characteristics have been mapped out [4.355–357] and ways to control both the individual pulses [4.358] and the train structure [4.359] have been developed. The shortest isolated pulse produced to date is 130 as, using the polarization gating technique for the temporal confinement [4.360, 361]. Applications now include characterization of electromagnetic fields [4.362], tomography of molecular orbitals [4.363], molecular dynamics studies of simple molecules [4.364, 365], dynamical studies and interferometric measurements of electron wavepackets [4.366, 367], and time-resolved inner-shell spectroscopy in atoms and solids [4.368].

5. Optical Materials and Their Properties

This chapter provides an extended overview on today's optical materials, which are commonly used for optical components and systems. In Sect. 5.1 the underlying physical background on light–matter interaction is presented, where the phenomena of refraction (linear and non-linear), reflection, absorption, emission and scattering are introduced. Sections 5.2 through 5.8 focus on the detailed properties of the most common types of optical materials, such as glass, glass ceramics, crystals, and plastics. In addition, special materials displaying "unusual nonlinear" or "quasi–nonreversible" optical behavior such as photorefractive or photorecording solids are described in Sect. 5.9. The reader could use this chapter as either a comprehensive introduction to the field of optical materials or as a reference text for the most relevant material information.

Part A | 5

5.1 Interaction of Light with Optical Materials

In this section the general physics of the interaction of light with matter is briefly presented. A detailed insight into theoretical electrodynamics cannot be given here. The interested reader might refer to standard textbooks on electrodynamics e.g. [5.1, 2].

5.1.1 Dielectric Function

The starting point for an analysis of any interaction between electromagnetic waves with matter is Maxwell's equations. The static interaction for the dielectric displacement and the magnetic induction is described by

$$\boldsymbol{\nabla} \cdot \boldsymbol{D} = \rho \,,$$
$$\boldsymbol{\nabla} \cdot \boldsymbol{B} = 0 \,, \tag{5.1}$$

whereas the dynamic interaction of the electric and magnetic fields is given by

$$\boldsymbol{\nabla} \times \boldsymbol{E} = -\dot{\boldsymbol{B}} \,,$$
$$\boldsymbol{\nabla} \times \boldsymbol{H} = \boldsymbol{j} + \dot{\boldsymbol{D}} \,. \tag{5.2}$$

$\boldsymbol{E}$ and $\boldsymbol{B}$ are the electric and magnetic fields; $\boldsymbol{D}$ and $\boldsymbol{H}$ are the electric displacement and the auxiliary magnetic fields; ρ and $\boldsymbol{j}$ are the charge and the current density.

Material equations are needed to close Maxwell's equations:

$$\boldsymbol{D} = \varepsilon_0 \boldsymbol{E} + \boldsymbol{P} \,,$$
$$\boldsymbol{B} = \mu_0 \boldsymbol{H} + \boldsymbol{M} \,, \tag{5.3}$$

where $\boldsymbol{P}$ and $\boldsymbol{M}$ are the polarization and magnetization densities. The vacuum permittivity (in SI units) is $\varepsilon_0 = 8.854 \times 10^{-12}$ A s/V m and the vacuum permeability is $\mu_0 = 4\pi \times 10^{-7}$ V s/A m.

The complete optical properties for any spatial combination of matter are included in the solution of (5.1), (5.2), which are closed by using the material equations (5.3) and by using appropriate boundary conditions. For only a few special cases such a solution can be written down directly. In the following we give a few examples.

Wave Equation in Vacuum

If we want to solve (5.1), (5.2) in infinite vacuum we have the following boundary conditions and material equations:

$$\boldsymbol{P}(\boldsymbol{r}) = 0 \,, \quad \boldsymbol{M}(\boldsymbol{r}) = 0 \,, \quad \rho(\boldsymbol{r}) = 0 \,, \quad \boldsymbol{j}(\boldsymbol{r}) = 0 \,, \tag{5.4}$$

where $\boldsymbol{r} = (x, y, z)$ are the three spatial coordinates. With these simplest possible boundary conditions the material equations (5.3) read

$$\boldsymbol{D} = \varepsilon_0 \boldsymbol{E} \,,$$
$$\boldsymbol{B} = \mu_0 \boldsymbol{H} \,. \tag{5.5}$$

After applying a few vector operations, one gets the wave equation for the electromagnetic field $\boldsymbol{E}$ in vacuum:

$$\boldsymbol{\Delta} \boldsymbol{E} - \mu_0 \varepsilon_0 \ddot{\boldsymbol{E}} = 0 \,. \tag{5.6}$$

An identical wave equation can be derived for the magnetic field $\boldsymbol{B}$. (5.6) immediately defines the speed of light c (in vacuum).

$$c = \sqrt{\frac{1}{\mu_0 \varepsilon_0}} \,. \tag{5.7}$$

Equation (5.6) is generally solved by all fields which fulfill $\boldsymbol{E}(\boldsymbol{r}, t) = \boldsymbol{E}_0 \cdot f(\boldsymbol{kr} \pm \omega t)$ involving any arbitrary scalar function f. The most common systems of function f are plane waves:

$$\boldsymbol{E}_\mathrm{s}(\boldsymbol{r}, t) = \boldsymbol{E}_0 \operatorname{Re} \left(\mathrm{e}^{-\mathrm{i}(\boldsymbol{kr} - \omega t)} \right) \,. \tag{5.8}$$

These plane waves, with a time and spatial dependent phase $\theta = \boldsymbol{kr}$, are described by a wave vector $\boldsymbol{k}$, an angular frequency ω, and a corresponding wavelength $\lambda = 2\pi/k = 2\pi c/\omega$, where $k = |\boldsymbol{k}|$ is the absolute value of the wave vector. Describing an arbitrary field $\boldsymbol{E}$ in terms of plane waves is identical to decomposing this electrical field into its Fourier components.

Wave Propagation in an Ideal Transparent Medium

We can describe an ideal material by simply replacing the speed of light in vacuum by that of the medium.

$$c \rightarrow \frac{c}{n} \,, \tag{5.9}$$

where n is the (in this case only real) refractive index of the material. Wave propagation in a dispersing or weakly absorbing medium is considered at the end of the present section. In fact, most parts of an optical design can be done by treating optical glasses as such ideal transparent materials (see Sect. 5.1.2). Even though such an ideal material cannot exist in reality, optical glasses come very close to it (for electromagnetic radiation in the visible range). For such an ideal material the wave equation (5.6) reads:

$$\boldsymbol{\Delta} \boldsymbol{E} - \frac{n^2}{c^2} \ddot{\boldsymbol{E}} = 0 \,. \tag{5.10}$$

It is solved again by plane transverse waves. Where the speed of light is now reduced to the speed of light in the transparent medium $c_{\mathrm{med}} = c/n$ and the wavelength of the lightwave is reduced to $\lambda_{\mathrm{med}} = \lambda/n$.

Refraction and Reflection

We now derive the laws of refraction and reflection for the ideal transparent medium just described. They are obtained by solving Maxwell's equations at the (infinite) boundary between two materials of different refractive indices n_1 and n_2 (see Fig. 5.1). As boundary conditions one obtains that the normal component of the electric displacement (and magnetic induction) and the tangential component of the electric (and magnetic) field have to be continuous at the interface:

$$D_1^{\mathrm{n}} = D_2^{\mathrm{n}}, \qquad E_1^{\mathrm{t}} = E_2^{\mathrm{t}}. \tag{5.11}$$

Further, a phase shift of an incoming wave occurs upon reflection

$$\theta_{\mathrm{r}} = \pi - \theta_{\mathrm{i}}, \tag{5.12}$$

where $\theta_{\mathrm{r,i}}$ are the phases of the reflected and incident wave, respectively. If we solve Maxwell's equations for an incoming plane wave (applying the boundary conditions stated above), Snell's law of refraction is obtained

$$n_1 \sin \alpha_1 = n_2 \sin \alpha_2 \tag{5.13}$$

together with that of reflection

$$\alpha_{\mathrm{r}} = \alpha_1. \tag{5.14}$$
Fig. 5.1 The polarization directions of the E and B fields for reflection and refraction at an interface between two optical materials of different refractive indices are shown. A circle indicates that the vector is perpendicular to the plane shown

Now, the electric field E is decomposed into its components which are defined relative to the plane outlined by the three beams of incoming, transmitted and reflected light. This decomposition is shown in Fig. 5.1. The coefficients for reflection and transmission are defined as:

$$r_{\parallel} = \frac{E_{0r}^{\parallel}}{E_{0i}^{\parallel}}; \qquad t_{\parallel} = \frac{E_{0t}^{\parallel}}{E_{0i}^{\parallel}},$$
$$r_{\perp} = \frac{E_{0r}^{\perp}}{E_{0i}^{\perp}}; \qquad t_{\perp} = \frac{E_{0t}^{\perp}}{E_{0i}^{\perp}}. \tag{5.15}$$

The Fresnel formula for these coefficients can be derived as

$$r_{\perp} = \frac{n_1 \cos(\alpha_1) - n_2 \cos \alpha_2}{n_1 \cos(\alpha_1) + n_2 \cos(\alpha_2)} = -\frac{\sin(\alpha_1 - \alpha_2)}{\sin(\alpha_1 + \alpha_2)},$$
$$r_{\parallel} = \frac{n_2 \cos(\alpha_1) - n_1 \cos \alpha_2}{n_1 \cos(\alpha_2) + n_2 \cos(\alpha_1)} = -\frac{\tan(\alpha_1 - \alpha_2)}{\tan(\alpha_1 + \alpha_2)},$$
$$t_{\perp} = \frac{2 n_1 \cos(\alpha_1)}{n_1 \cos(\alpha_1) + n_2 \cos(\alpha_2)}$$
$$= -\frac{2 \sin(\alpha_2) \cos(\alpha_1)}{\sin(\alpha_1 + \alpha_2)},$$
$$t_{\parallel} = \frac{2 n_1 \cos(\alpha_1)}{n_1 \cos(\alpha_2) + n_2 \cos(\alpha_1)}$$
$$= -\frac{2 \sin(\alpha_2) \cos(\alpha_1)}{\sin(\alpha_1 + \alpha_2) \cos(\alpha_1 - \alpha_2)}. \tag{5.16}$$

Here the usual convention has been used that the coefficients of reflectivity obtain an additional minus sign in order to indicate backtraveling of light. The quantities that are measured in an experiment are intensities. The relationship between the intensities defines the reflectivity and transmissivity of a material

$$R_{\perp} := |r_{\perp}|^2; \qquad R_{\parallel} := |r_{\parallel}|^2,$$
$$T_{\perp} := |t_{\perp}|^2; \qquad T_{\parallel} := |t_{\parallel}|^2. \tag{5.17}$$

The angular-dependent coefficients of reflection from (5.16) are displayed in Fig. 5.2. In Fig. 5.2a the case of light propagating from an optically thin medium with refractive index n_1 to an optically thicker medium with refractive index $n_2 > n_1$ is plotted. At the so called Brewster angle α_{B} the reflected light is completely polarized; α_{B} is given by the condition $\alpha_1 + \alpha_2 = \pi/2$. Therefore, the Brewster angle α_{B} results as a solution of

$$\alpha_1 = \frac{\pi}{2} - \arccos\left(\frac{n_2}{n_1} \cos \alpha_1\right) \tag{5.18}$$

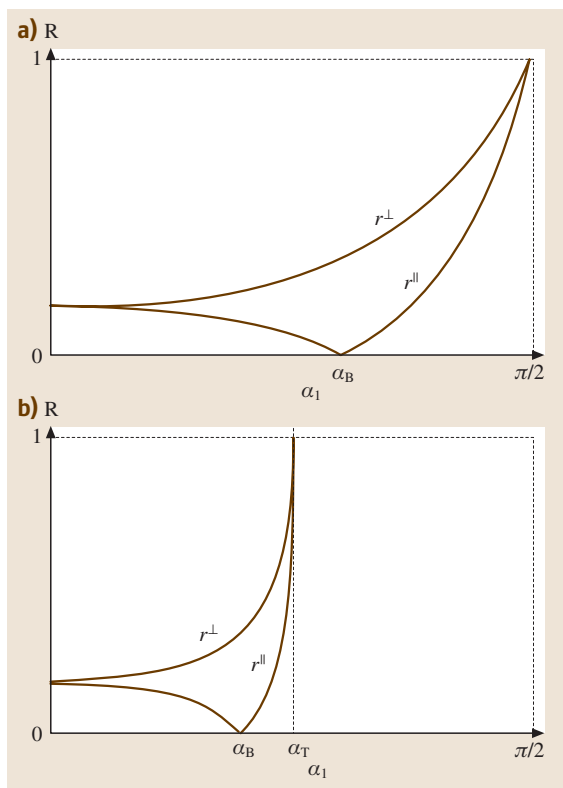
which gives $\alpha_{\mathrm{B}} = \arctan \frac{n_2}{n_1}$. In Fig. 5.2b the case of light propagating from an optically thick to an opti-


Fig. 5.2a,b The reflection coefficients are plotted as a function of incident scattering angle for light propagating from a medium of (**a**) smaller refractive index into a medium of larger index and (**b**) larger refractive index into a medium of smaller index. Here, total reflection occurs at an angle α_T and α_B is the Brewster angle

cally thin medium is plotted. Here an additional special angle occurs – the angle of total reflection, α_T. All light approaching the surface at an angle larger than α_T is totally reflected. At $\alpha_1 = \alpha_T$ the angle for refraction in the medium with refractive index n_2 is $\alpha_2 = \pi/2$. For α_T it follows that:

$$\alpha_T = \arcsin\left(\frac{n_2}{n_1}\right) . \tag{5.19}$$

Evaluating (5.16) for the special case of incident light as $\lim_{\alpha \to 0}$ allows one to calculate the reflectivity for normal incidence

$$R_{norm} = \left|\frac{n_1 - n_2}{n_1 + n_2}\right|^2 . \tag{5.20}$$

For practical applications it is important to note that the Fresnel equations remain valid in the case of weakly

absorbing media discussed at the end of the present section. Here, only the refractive indices have to be replaced by the complex quantities of (5.36). It is further helpful to define a transmittivity and reflectivity for unpolarized light

$$R^{unpol} = \frac{E_{0r}^{\|2} + E_{0r}^{\perp 2}}{E_{0i}^{\|2} + E_{0i}^{\perp 2}} ; \quad T^{unpol} = \frac{E_{0t}^{\|2} + E_{0t}^{\perp 2}}{E_{0i}^{\|2} + E_{0i}^{\perp 2}} . \tag{5.21}$$

Inserting the expressions for the reflection coefficients we obtain e.g. the total reflectivity as a function of the incident and refracted angular

$$R_{all}^{unpol} = \frac{E_{0i}^{\|2} \frac{\tan^2(\alpha_1 - \alpha_2)}{\tan^2(\alpha_1 + \alpha_2)} + E_{0i}^{\perp 2} \frac{\sin^2(\alpha_1 - \alpha_2)}{\sin^2(\alpha_1 + \alpha_2)}}{E_{0i}^{\|2} + E_{0i}^{\perp 2}}$$

With the definitions from (5.21) the following sum rule must be fulfilled:

$$R^{unpol} + \frac{n_2}{n_1} \frac{\cos \alpha_2}{\cos \alpha_1} T^{unpol} = 1 . \tag{5.22}$$

The rule provides an easy check for transmitted and reflected total intensities, especially for normal incidence.

Wave Propagation in an Isotropic, Homogeneous Medium

We now consider wave propagation in an ideal optical material. This is a nonmagnetic, homogeneous, isotropic, perfectly insulating medium, which is further a perfectly linear optical material. Considering time dependence including retardation in the materials (5.2) leads to:

$$D(r, t) = \varepsilon_0 E(r, t) + P(r, t) . \tag{5.23}$$

The polarizability is related to the electric field via the susceptibility χ. In the case of a homogeneous isotropic material χ is a scalar function. In Sect. 5.1.4 we will consider the case of optically anisotropic media, where χ becomes a second-rank tensor.

$$P(r, t) = \int dr' \int_{-\infty}^{t} dt' \chi(r - r', t - t') E(r, t') . \tag{5.24}$$

Fourier transformation in time and space deconvolutes the integral and leads to:

$$P(k, \omega) = \chi(k, \omega) E(k, \omega) , \tag{5.25}$$

where $\chi(k, \omega)$ is, in general, a complex analytic function of the angular frequency ω. The complex function $\chi(k, \omega)$ unifies the two concepts of a low-frequency

polarizability χ' and a low-frequency conductivity σ of mobile charges to a single complex quantity

$$\lim_{\omega \to 0} \chi(\omega) = \chi'(\omega) + 4\pi i \frac{\sigma(\omega)}{\omega} . \tag{5.26}$$

At larger frequencies the separation of the two concepts breaks down, since above the frequencies of optical phonon modes in the IR the bound charges are unable to follow the electric field, whereas below the phonon modes the charges can follow this motion (Sect. 5.1.3). The usual form in which the susceptibility enters the equations for optical purposes is via the dielectric function

$$\varepsilon(\boldsymbol{k}, \omega) = 1 + \chi(\boldsymbol{k}, \omega) . \tag{5.27}$$

Inserting the dielectric function into the material equation (5.23) gives:

$$\boldsymbol{D}(\boldsymbol{k}, \omega) = \varepsilon_0 \varepsilon(\boldsymbol{k}, \omega) \boldsymbol{E}(\boldsymbol{k}, \omega) . \tag{5.28}$$

Here, we restrict ourselves to ideal optically isotropic materials by neglecting the nature of the dielectric function as a second-rank tensor. In Sect. 5.1.4 we will extend our considerations to optically anisotropic materials. With the same steps as in Eqs. (5.5–5.6) a wave equation can be derived which has the following form in Fourier space:

$$\left[k^2 - \varepsilon(\boldsymbol{k}, \omega) \frac{\omega^2}{c^2} \right] \boldsymbol{E}_0 = 0 , \tag{5.29}$$
Fig. 5.3 Dielectric function $\varepsilon(\omega)$ for the "model optical solid" with one generic absorption in the infrared ω_{IR} and a second one in the ultraviolet ω_{UV}. The dielectric function is plotted on a logarithmic energy scale. The *solid line* is the real part and the *dashed line* is the imaginary part of $\varepsilon(\omega)$

where the relations $\partial^2/\partial t^2 \boldsymbol{E}_s(\boldsymbol{r}, t) \to -\omega^2 \boldsymbol{E}_s(\boldsymbol{r}, t)$ and $\Delta \boldsymbol{E}_s(\boldsymbol{r}, t) \to -k^2 \boldsymbol{E}_s(\boldsymbol{r}, t)$ have been used. The expression in brackets in (5.29) defines the dispersion relation for an optically linear, homogeneous, isotropic material.

Poynting Vector and Energy Transport

The energy flux density of the electric field is obtained via the Poynting vector, given by

$$\boldsymbol{S} = \boldsymbol{E} \times \boldsymbol{H} . \tag{5.30}$$

It gives the rate at which electromagnetic energy crosses a unit area and has the unit W/m^2. It points in the direction of energy propagation. The time average of the absolute value of the Poynting vector $\langle |\boldsymbol{S}| \rangle$ is called the intensity I of the electromagnetic wave

$$I = \langle |\boldsymbol{S}| \rangle = \frac{1}{2} |\boldsymbol{E} \times \boldsymbol{H}| \tag{5.31}$$

and is the energy flux density of the electromagnetic radiation. In thespecial case of propagation of transverse plane waves [as given in (5.8)], it simplifies to

$$I = \frac{1}{2} \frac{n}{c\mu_0} |\boldsymbol{E}_0|^2 , \tag{5.32}$$

where in vacuum $n = 1$ is valid.

General Form of the Dielectric Function

For most optical materials the dielectric function has a form in which a transparent frequency (or wavelength) window is bounded at the high energy site by electron–hole excitations (dominating the UV edge) and at the low energy site by IR absorptions given by optical phonon modes (lattice vibrations). The general form of the dielectric function is given by the Kramers–Heisenberg equation [5.3]

$$\varepsilon(\boldsymbol{k}, \omega) = 1 + \sum_j \frac{\alpha_{k,j}}{\omega^2 - \omega_{k,j}^2 - i\omega\eta_{k,j}} . \tag{5.33}$$

Here $\alpha_{k,j}$ is the amplitude, $\omega_{k,j}$ the frequency and $\eta_{k,j}$ the damping of the particular excitation j. A schematic view of the dielectric function is plotted in Fig. 5.3. Here we use a model for a transparent homogeneous, isotropic solid (such as glass) with one generic absorption at low energies (ω_{IR} in the infrared, IR) and another one at large phonon energies (ω_{UV} in the ultraviolet spectral range, UV). In the following this model solid is used to discuss optical material properties.

Dispersion Relation

Solving (5.29) gives two frequency-dependent solutions for the wave vector $\boldsymbol{k}$ as a function of ω since the left-hand side of (5.29) is quadratic in $\boldsymbol{k}$. Far away from
Fig. 5.4 Dispersion relation $\omega(k)$ for the "model optical solid" on a double logarithmic scale. The *solid line* is the real part of k and the *dashed line* the imaginary part of k. For comparison the simply linear dispersion relation for light propagating in vacuum $\omega = ck$ is shown with a *long-dashed line*

Fig. 5.5 The group velocity $v_{gr}(k) = \partial\omega/\partial k$ (*solid line*) and the phase velocity $v_{ph}(k) = \omega/k$ (*dashed line*) are plotted on a logarithmic frequency scale. Far away from absorptions both velocities approach each other while the group velocity is always smaller than the phase velocity

absorptions the dielectric function is real and positive. Here only one solution exists, which describes the wave propagating with the speed of light in the medium. Close to an absorption two solutions exist which are even more complicated. This means that near a resonance the dispersion of the light cannot be considered independently from the dispersion of the excitations in the material. They both form a composite "new" entity propagating in the medium. This is called the polariton [5.4]. For our model solid with two generic absorptions (ω_{IR} and ω_{UV}), the dispersion is plotted in Fig. 5.4.

Wave Propagation, Phase and Group Velocity

When an electromagnetic wave propagates through a medium one can define two velocities. The phase velocity is the speed with which a certain phase propagates. It is, for example, the velocity of the wavefront maxima moving through the medium. The phase velocity is given as

$$v_{ph} = \frac{\omega}{k} \,. \tag{5.34}$$

In Fig. 5.5 the phase velocity of the model solid is plotted on a logarithmic frequency scale. Close to the absorption edges of the material it loses its meaning because attenuation due to the absorption processes will dominate most processes. Far away from absorptions it reaches a nearly constant value. The second velocity is the group

velocity

$$v_{gr}(k) = \frac{\partial\omega}{\partial k} \,. \tag{5.35}$$

This is the velocity at which a complete wave packet travels through the medium and is, hence, the speed with which information can travel through the system. It is plotted in Fig. 5.5 for the model solid. Reasonably far away from material absorptions the group and phase velocities approach each other. However, the group velocity is always smaller than the phase velocity.

Refractive Index

The refractive index n is the most widely used physical quantity in optical design. It is the square root of the dielectric function. The dynamic refractive index is generally a complex quantity

$$\tilde{n}(\omega) = n(\omega) + i\kappa(\omega) \tag{5.36}$$

and must fulfill the Kramers–Kronig relations [5.3]. The refractive index for our generic model solid is plotted as a function of logarithmic frequency in Fig. 5.6. In practical use, the wavelength dependence is often exploited

$$\tilde{n}(k, \lambda) = \sqrt{\varepsilon(k, 2\pi c/\lambda)} \,. \tag{5.37}$$

With a few basic steps, (5.33) can be rewritten as a function of wavelength alone. If one further restricts to wavelengths which are far away from absorptions $(\omega^2 - \omega_{k,j}^2) \ll \omega\eta_{k,j}$, the Sellmeier formula (see
Fig. 5.6 The complex refractive index $n(\omega) = n^*(\omega) + i\kappa(\omega)$ is plotted on a logarithmic frequency scale. The real part is plotted with a *solid line* and the imaginary part with a *dashed line*

Sect. 5.1.2), which is widely used for characterizing optical materials, is obtained

$$n(\lambda)^2 \approx 1 + \sum_j \frac{B_j \lambda^2}{\lambda^2 - \lambda_j^2} , \qquad (5.38)$$

where $\lambda_i = 2\pi c/\omega_i$ with $i \in \{(k, j)\}$ is used and $B_j = a_{k,j}\lambda_{k,j}/(2\pi c)^2$. Normally B_j and λ_j are just fitting constants to describe the dispersion of the refractive index over a certain wavelength range. They are, however, connected to the microscopic fundamental absorption behavior of the material. Sometimes also $n(\lambda)$ and not $n(\lambda)^2$ is approximated with a Sellmeier formula. Since as well $n(\lambda)$ as well as $n(\lambda)^2$ are complex differential (analytic) functions both formula give refractive indices and dispersions with the same accuracy. However care has to be taken, which quantity is expressed when using a Sellmeier formula.

Wave Propagation in Weakly Absorbing Medium

In this subsection the link between the attenuation of a wave and the imaginary part of the refractive index is given. A weakly absorbing medium is defined by the imaginary part of the refractive index (5.37) being much smaller than the real part

$$\kappa \ll n \qquad (5.39)$$

(the coefficient κ/n is also called the attenuation index). In this case light propagates as transverse waves through the medium. We consider two points in our medium: P$_1$ and P$_2$. Between these points the light travels the distance l. In the absence of absorption, the electric and
Fig. 5.7 Reflectivity R for normal incidence plotted on a logarithmic frequency scale

magnetic fields at point P$_2$ are given by

$$\boldsymbol{E}_2 = \boldsymbol{E}_1 \, e^{i\frac{\omega}{c}\tilde{n}l} , \qquad \boldsymbol{H}_2 = \boldsymbol{H}_1 \, e^{i\frac{\omega}{c}\tilde{n}l} . \qquad (5.40)$$

Using (5.31) we obtain for weak absorption the radiation intensity at point P$_1$. The radiation intensity at P$_2$ is:

$$
\begin{aligned}
I_2 &= \frac{1}{2}|\boldsymbol{E}_2 \times \boldsymbol{H}_2| , \\
&= \frac{1}{2}|\boldsymbol{E}_1 \times \boldsymbol{H}_1| e^{-2\frac{\omega}{c}\kappa l} , \\
&= I_1 e^{-2\frac{\omega}{c}\kappa l} = I_1 e^{-\alpha l} . \qquad (5.41)
\end{aligned}
$$

The absorption coefficient α is connected to the complex refractive index by

$$\alpha = 2\frac{\omega}{c}\kappa ; \qquad (5.42)$$

α can easily be measured and its importance for optical properties is discussed in Sect. 5.1.3.

It is also important to note that the Fresnel equations (5.16) remain valid in the case of a weakly absorbing medium if the complex refractive indices are used. As an example, we plot the reflectivity (at the interface air–model solid) near an absorption resulting from (5.20) for a complex refractive index $n_2 \to \tilde{n}_2$. In Fig. 5.7 the reflectivity is plotted on a logarithmic frequency scale. Note that the absorption seems to be shifted compared to the plots of the complex dielectric function or the complex refractive index. Measurement of the reflectivity is of importance for reflection spectroscopy.

5.1.2 Linear Refraction

As already introduced in Sect. 5.1.1, two phenomena occur when light impinges upon the surface of any optical material: reflection and refraction [5.5]. The reflected

light bounces off the glass surface, while the refracted light travels through the material. The amount of light that is reflected depends on the refractive index of the sample, which also affects the refractive behavior of the sample [5.6]. The refractive index of optical materials turns out to be one of the most important factors that must be considered when designing systems to transmit and modulate light [5.7]. The refractive index is a complex material property that depends on temperature and wavelength [5.8]. The wavelength dependence of the refractive index is the dispersion [5.5].

Law of Refraction

When a light ray impinges upon a glass surface, a portion is reflected and the rest is either transmitted or absorbed. The material modulates the light upon transmission. The light travels at a different velocity as it is transmitted through the glass as compared to through vacuum. As introduced in Sect. 5.1.1, the index of refraction (n), is defined as the ratio of the speed of light in vacuum (c) to that in the material (c_m) [5.11]:

$$n = \frac{c}{c_m} . \tag{5.43}$$

Most commonly, the reported refractive indices are relative to the speed of light in air, rather than in vacuum, no matter which technique is used to measure the refractive index [5.12]. The index of refraction for vacuum, by definition, must be exactly 1. The index of refraction of air is 1.00029 at standard temperature (25 °C) and pressure (1 atm) (STP). Therefore, the index of refraction of optical matter (n_{rel}) relative to air (n_{air}), rather than vacuum is [5.11]:

$$n_{rel} = \frac{n_m}{n_{air}} . \tag{5.44}$$

Table 5.1 Indices of common materials at standard temperature and pressure at 587.56 nm (helium d line) [5.9]

Material	n_d	Material	n_d
Vacuum	1	Crown glass	1.52
Air	1.00029	Sodium chloride	1.54
Water	1.33	Polystyrene	1.55
Acetone	1.36	Carbon disulfide	1.63
Ethanol	1.36	Flint glass	1.65
Sugar solution (30 wt %)	1.38	Sapphire	1.77
Fused silica	1.46	Heavy flint glass	1.89
Sugar solution (80 wt %)	1.49	Diamond	2.42
Fig. 5.8 Ray tracings of incident, reflected, and transmitted light from one medium to another representing the angles and indices necessary to apply Snell's law (after [5.10])

The STP indices of some common compounds, and classes of compounds, are shown in Table 5.1 [5.9].

As discussed in Sect. 5.1.1, when light hits a glass surface at an angle α_i, it is Fresnel-reflected back at an angle α_t. The angle of incidence is equal to the angle of reflection ($\alpha_i = \alpha_r$), as shown in Fig. 5.8 [5.10]. The percentage of light reflected for $\alpha_i = 0$ at each interface (R) relative to the incident intensity (Sect. 5.1.1) is dependent on the index of refraction of the two media the light is passing through, typically air (n_2) and glass (n_1) Fig. 5.8 and (5.20) [5.10]

$$R_{norm} = 100 \left(\frac{n_1 - n_2}{n_1 + n_2} \right)^2 . \tag{5.45}$$

Fresnel's formula (5.45) assumes smooth surfaces that produce only specular reflection. Diffuse reflection occurs when the surface is rough, so the incident light is reflected through a range of angles, thereby reducing the intensity of the reflected light at any given angle [5.10] (see Sect. 5.1.8). The specular reflection that is taken into consideration by Fresnel's relationship can be monitored and used to estimate the refractive index of samples in situ [5.13].

The angle of the light transmitted within the material (α_t), relative to the incident light transmitted through air, is dependent on the refractive indices of the air (n_{air}) and solid (n_m) and the incident light angle (α_i) [5.10]:

$$n_{air} \sin \alpha_i = n_m \sin \alpha_t . \tag{5.46}$$
Fig. 5.9 Dispersion present in BK-7 optical glass. Common index of refraction measurement wavelengths are indicated

This is the general form of Snell's law of refraction to predict transmitted angles in media [5.14].

Dispersion Relationships in Glass

The refractive index of a medium is dependent upon the wavelength of the light being transmitted (see Sect. 5.1.1). This wavelength dependence is dispersion, which means that different wavelengths of light will be modulated differently by the same piece of matter [5.10]. Each wavelength of light will be subject to a different index of refraction. One ramification of dispersion is that white light can be separated into its principal visible components through a glass prism, or a simple raindrop. It is the dispersion of white light through raindrops that causes rainbows. The dispersion of light through optical materials results in the light being refracted at various angles because of Snell's law (5.46). The various components of white light experience different indices of refraction, which leads to different angles of exiting light. The difference in refractive index with wavelength is illustrated in Fig. 5.9 for BK-7 optical glass, which is a high dispersion material.

In normal dispersion, the index increases for shorter wavelengths of light [5.15]. Normal dispersion is valid only far away from absorption bands (see Fig. 5.6). Water has a normal dispersion response in the visible, so the red light is refracted by a lower index, and thus a greater angle, which is why red is on top in a rainbow. Discussion of rainbow formation is presented elsewhere in depth [5.10].

Anomalous dispersion is an increase in refractive index with an increase in wavelength. Anomalous dispersion typically occurs at frequencies that represent a crossover between the polarization mechanisms (dipolar, ionic, electronic etc.) that are responsible for absorption of electromagnetic radiation. This is further discussed in [5.11].

Due to dispersion, the index of refraction must be reported with the wavelength of measurement. The most common wavelengths at which n is measured are reported in Table 5.2. These wavelengths most often correspond to common sharp emission lines. The index can be determined most accurately $(\pm 1 \times 10^{-6})$ by measuring the angle of minimum deviation of light in a prism [5.15]. However, a Pulfrich refractometer $(\pm 1 \times 10^{-5})$ is most commonly used in industry. Details of measurement techniques are given in [5.16].

The index at various wavelengths is commonly referred to by the designations in Table 5.2: i. e. n_d is the refractive index measured at the yellow helium d line of 582.5618 nm. The dispersion is often given as a difference in n at two wavelengths. For instance, the primary dispersion is given by $n_F - n_C$ (hydrogen lines) and $n_{F'} - n_{C'}$ (cadmium lines). The most commonly reported measure of dispersion is the Abbe number (ν), which is

Table 5.2 Wavelength of spectral lines used for measuring index of refraction, with the common designation and spectral line source [5.11]

Wavelength (nm)	Designation	Spectral line

365.0146	i	Hg UV line

commonly given for two sets of conditions

$$\nu_d = \frac{n_d - 1}{n_F - n_C} \, , \quad \nu_e = \frac{n_e - 1}{n_{F'} - n_{C'}} \, . \quad (5.47)$$

The Abbe number is a measure of the ratio of the refractive power to the dispersion. In most optical materials catalogs, a six-digit number is assigned to the solid that is dependent upon the index and the Abbe number: $1000(n_d - 1) + 10\nu_d$. Using this property, e.g. optical glasses are divided into two general categories: crowns and flints (see Sect. 5.2). Crown glasses typically have a low index of refraction and a high Abbe number ($n_d < 1.60$ and $\nu_d > 55$), whereas flint glasses have high indices and low Abbe numbers ($n_d > 1.60$ and $\nu_d > 50$) [5.15]. The terms crown and flint have historical significance in that flint glasses typically had lead oxide added to them to increase the refractive index (see Sect. 5.2) and crown glasses were typically blown and had curvature – a crown. Typically, to make an achromatic optical system crown and flint lenses are combined in series. The n_d and ν_d are plotted for various types of optical glasses in Fig. 5.87. The n_d and ν_d are listed with glass type and manufacture in Table 5.37.

Often it is desired to have a mathematical representation of the index as a function of wavelength. A considerable number of models exist for just this purpose. Perhaps the best known, and most widely used, is the Sellmeier form [5.15]

$$n^2(\lambda) - 1 = \frac{B_1\lambda^2}{\lambda^2 - C_1} + \frac{B_2\lambda^2}{\lambda^2 - C_2} + \frac{B_3\lambda^2}{\lambda^2 - C_3} \, . \quad (5.48)$$

Most major optical material manufacturers supply the Sellmeier coefficients for their glasses on the product data sheets. With the six Sellmeier coefficients it is possible to estimate the index of refraction at any wavelength, given that it is not near a strong absorption. Numerous other dispersion models have been developed and are presented elsewhere [5.10, 15].

The index of refraction is also dependent upon temperature, and similar formulas and tables of constants have been developed for the differential change in n with temperature [5.15]

$$\frac{dn_{abs}(\lambda, T)}{dT} = \frac{[n^2(\lambda, T_0) - 1]}{2n(\lambda, T_0)}$$
$$\times \left(D_0 + 2D_1\Delta T + 3D_2\Delta T^2 + \frac{E_0 + 2E_1\Delta T}{\lambda^2 - \lambda_{TK}^2} \right) , \quad (5.49)$$

where T_0 is 20 °C, T is the temperature in °C, ΔT is $T - T_0$, λ is the wavelength in microns, and λ_{TK} is the average effective resonance wavelength for the temperature coefficients in microns. The constants E_0, E_1, D_0, D_1, and D_2 are provided on the manufacture product data sheets for each composition. The index of refraction must be measured.

5.1.3 Absorption

Based on the discussion in Sect. 5.1.1 the most common processes causing absorption in optical materials will be discussed here.

Introduction to Absorption

Absorption in glass is characterized by a decrease in transmitted light intensity through the sample that is not accounted for by reflection losses at the surface or scattering by inclusions [5.14]. As already introduced in Sect. 5.1.1 absorption is not uniform across all wavelengths of interest (UV–VIS–IR; $\approx 200–2000$ nm) and can be characterized by absorption bands [5.17]. The absorption bands are due to both intrinsic and extrinsic effects [5.14, 18, 19].

The quantity used to discuss absorption as a function of wavelength in glass is the transmittance (T), which is the ratio of the transmitted light intensity (I) to the initial light intensity (I_0) after passing through a glass plate of thickness L [5.20]:

$$T = I/I_0 \, . \quad (5.50)$$

The transmittance is related to the more common percent transmittance (%T) through:

$$\%T = 100\,T \, . \quad (5.51)$$

Sometimes it is more practical or convenient to look at the optical spectra in terms of absorbance rather than the transmittance. Absorbance (A) is defined as the $\log_{10}$ of $(1/T)$ [5.20]

$$A = \log_{10}\frac{I_0}{I} = \log_{10}\frac{1}{T} = 2 - \log_{10}\%T \, , \quad (5.52)$$
$$\%T = 100/10^A \, . \quad (5.53)$$

Absorbance is often referred to as optical density (OD). When the absorbance changes linearly with concentration of the absorbing species (C), then Beer's law, which relates absorbance with concentration, path length (l) and extinction coefficient (ε), is applicable [5.20]

$$A = \varepsilon C l \, . \quad (5.54)$$

The typical units of ε are liters mole^{-1} cm^{-1} and are often omitted.

From Beer's law we see that the absorbance changes with path length. To account for this, the spectra (in A or $\%T$) must list the sample thickness. Absorbance can also be normalized to path length in terms of an absorption coefficient (α). The connection of an optical absorption to a microscopic property of an underlying absorption process is straightforward. A light beam propagating through a medium is exponentially damped if absorption is present. This follows directly from the fact that the attenuation inside the optical material is proportional to the present (wavelength-dependent) intensity $I(\lambda)$ [5.21]

$$dI(\lambda) = N\sigma^{\text{abs}}(\lambda)I(\lambda)\,dz\,. \tag{5.55}$$

Where dz is an infinitesimally small part of the propagation part (unit meter) and N is the density of absorbing centers (in units of m^{-3}). The quantity $\sigma^{\text{abs}}(\lambda)$ is the absorption cross section. Since both sides of (5.55) must have the same units, it follows that the absorption cross section is measured in m^2. It therefore has the meaning of an area and can be interpreted as the effective area perpendicular to the direction of an incoming beam that is seen by that beam and causes an absorption process. Figure 5.10 illustrates this. The solution of (5.55) for an optical plate of thickness L and initial intensity I_0 gives the intensity of the beam after traveling the distance L through the material [5.21]

$$I_{L,G}(\lambda) = I_{0,G}\,e^{-\alpha(\lambda)L} \tag{5.56}$$

with $I_{0,G}$ and $I_{L,G}$ being taken at both surfaces, but inside the solid. They are related to the measurable values I_0 and I_L outside the material by $I_{0,G} = (1-R)I_0$ and $I_L = (1-R)I_{L,G}$ with R being the Fresnel losses as described in Sect. 5.1.1. Equation (5.56) is known as

the law of Lambert–Beer, where the absorption coefficient $\alpha(\lambda)$ is defined as [5.21]

$$\alpha(\lambda) = N\sigma^{\text{abs}}(\lambda)\,. \tag{5.57}$$

In contrast to the absorbance A, the absorption coefficient takes into account the reduction in transmission at both surfaces due to Fresnel-type losses [5.15]

$$\alpha = \frac{-\ln\left[T/(1-R)^2\right]}{L}\,. \tag{5.58}$$

The absorption coefficient normalizes for path length, while the absorption cross section σ^{abs} normalizes for absorbing ion (AI) concentration [AI] (in ions/m^3) [5.15]

$$\sigma(\lambda) = \frac{\alpha(\lambda)}{[\text{AI}]}\,. \tag{5.59}$$

The absorption cross section allows for a more fundamental comparison of various concentrations of absorbing ions (as long as they obey Beer's law) within different matrices.

Summary of Absorption Mechanisms in Glass

Glasses, as typical candidates for the simple optical solid model described in Sect. 5.1.1, are transparent from the near UV to the near IR. The regions of transparency and semi-transparency in the visible and near IR are shown for a typical optical glass (BK-7) in Fig. 5.11. The intrinsic absorption is dominated by electronic transitions in the UV–VIS range, while in the IR it is dominated by molecular vibrations [5.20]. There are multiple extrinsic mechanisms, which occur with the inclusion of ionic

Fig. 5.10 Illustration of the Lambert–Beer law, displaying the bulk absorption inside the optical material and reflective Fresnel losses R at both surfaces
Fig. 5.11 Transmission through 10 mm thick BK-7 optical glass showing regions of transparency (visible), semi-transparency (near IR) and opacity (far IR)

complexes, insulators (crystals and phase separation), semiconductors, and conductors [5.19].

Intrinsic Absorption Mechanisms in Glass. The UV–VIS absorption is dominated by electronic transitions [5.22]. The electronic transitions that occur in the UV–VIS range involve a transition from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO). The difference in energy (ΔE) between the LUMO (E_{LUMO}) and HOMO (E_{HOMO}) energy levels corresponds to the energy of the corresponding absorption maxima, which can be related to the wavelength, and frequency of the absorption through Plank's constant and the speed of light [5.22]

$$\Delta E = E_{LUMO} - E_{HOMO} = h\nu = hc/\lambda \,. \quad (5.60)$$

The bonds present dominate the energy gap between the HOMO and LUMO, and thus the energy of the transition [5.22]. For example, the UV absorption is very similar between crystalline and fused silica, indicating that the short-range structure dominates the electronic transitions [5.22]. It is in the long-range structure of silica that fused and crystalline differ due to the random connections of the SiO_4 tetrahedra in fused silica.

The absorption band present in Fig. 5.12 represents the intrinsic UV absorption in silica. The increase in peak width is due to the distribution of tetrahedra in the fused silica. The lowest energy peak is associated with a Wannier exciton, but the next three peaks are associated with electronic transitions between the oxygen 2p electrons with the silicon 3d electrons [5.15].
Fig. 5.12 Intrinsic absorption of glassy and crystalline SiO_2 (after [5.15]). The values for fused silica have been lowered by 5% for improved visibility

The intrinsic absorption of glass in the IR is due to molecular vibrations, which begin at the multiphonon edge [5.23]. These vibrations can be understood using a harmonic oscillator model. For a diatomic molecule, the frequency of vibration, ν_{Ph}, is dependent upon the reduced mass (M) and the force constant (f) [5.15]:

$$\nu_{Ph} = \frac{1}{2\pi}\sqrt{\frac{f}{M}} \,, \quad (5.61)$$

where the reduced mass between two atoms is

$$\frac{1}{M} = \frac{1}{m_1} + \frac{1}{m_2} \,. \quad (5.62)$$

However, in glasses we are not dealing with a simple diatomic system, which makes it really an *anharmonic* oscillator giving rise to overtone vibrations at higher energies (shorter wavelengths). However, the harmonic oscillator model can be used to gain a qualitative understanding of vibrational frequencies in various glasses. The most common extrinsic absorption centers in the IR are OH, CO_2 and iron [5.15]. The multiphonon edge is shifted to longer wavelengths (smaller frequencies) by heavier ions (greater M) and weaker bonds (smaller f), which is why chalcogenide glasses transmit further into the IR than more traditional oxide glasses [5.23].

In the visible wavelength region, glasses normally display no intrinsic absorption.

Ionic Absorption in Glass. Absorption in glass due to ionic impurities involves transition-metal (TM) and rare-earth (RE) ions that act as the central atom (CA) in ligand complexes absorbing light in different wavelength bands [5.20,22,24,25]. The absorption due to TM and RE ions results from electronic transitions within the d or f orbitals of the TM or RE elements [5.22]. The energy of the absorption band is dependent upon the coordination environment of the CA (coordination number and geometry), the chemical identity of the CA (Cr, Co, Cu . . .) and the ligand (O versus F). The base composition of the glasses affects the nature of the ligand bonds available for the CA. This change affects the energy of the absorption bands and thus the resulting color of the glass [5.19]. This effect is taken advantage of when designing filter glass (see Sect. 5.3), and can be used to explain the differences in color of the same TM or RE in different glass matrices. The absorptions result from a splitting of the d orbitals for TM elements and the 4f orbitals for the RE elements in the presence of a ligand field. The ligand field theory that governs these splittings and interactions are covered in detail for TM elements in *Bersuker* [5.22] and in general in

Douglas et al. [5.24]. The absorption cross section for TM elements is approx. 100 times that of the absorption cross section for RE elements [5.15]. This results in distinct coloration at the ppm concentration level for TM elements.

Figure 5.13 shows the variation in absorption due to various TM elements in BK 7 glass at the 1 ppm dopant level [5.15]. The intensity of cobalt and nickel absorption is clearly shown.

These intraband transitions due to electronic transitions within the ionic species d or f orbitals are formally Laporte-forbidden transitions by selection rules, so the intensity is low [5.22, 24]. Charge-transfer transitions involve an electron transition between the CA and the coordinating ligand (interband). These interband transitions are formally allowed, and thus have approx. 100–1000 times greater intensity than the intraband electronic transitions [5.24].

Absorption by Semiconductor Particles. Semiconductor particles in glass are typically too small (1–10 nm) to scatter visible light, however they absorb light over a continuum of wavelengths corresponding to energies greater than the band gap (E_g) of the semiconductor particles [5.10]. The band gap of the semiconductor particles is controlled by the size of the particle and the chemical composition. Typically, semiconductor glasses are melted with Zn, Cd, S, Se and Te raw materials in the batch and upon casting the glasses cool colorless [5.15]. Secondary heat treatment (striking) results in the crystallization of various semiconductor crystal phases in the glass, or a mixture thereof: ZnS, ZnSe, ZnTe, CdS, CdSe, and CdTe. The size and distribution of the semiconductor particles can be controlled by the heat treatment and thus so can the optical properties of the resulting glasses. With the proper heat treatment, one glass can be "struck" into multiple glasses with absorptions leading to red, yellow and orange coloration [5.15]. When the band gap of the particles is large enough, the absorption edge is shifted into the UV and the glass appears colorless. The opposite can also occur when the band gap energy is so low that it absorbs all visible light, and the sample appears black [5.15].

Semiconductor-doped glasses are often used as low-pass filter glasses because of their sharp absorption cutoff. Semiconductor-doped glasses are covered in more detail in Sect. 5.3.

Absorption by Conducting Particles. The coloration of glasses due to small conducting particles in the glass is
Fig. 5.13 Absorption due to 1 ppm of transition metal elements in BK 7 glass in 100 mm thick samples (after [5.15])

a combination of both absorption and scattering effects. For small metallic particles, the scattering is governed specifically by Mie's theory but can also be treated in general with the Rayleigh scattering theory [5.10]. Mie scattering is covered in depth in Sect. 5.1.7 and Rayleigh scattering in Sect. 5.1.8.

Part A | 5.1

5.1.4 Optical Anisotropy

Maxwell's Equation in Dielectric Media

In the following section we will discuss the behavior of electromagnetic fields in media, especially in anisotropic materials. The basic interaction of light with matter consists of the interaction of the electric field with charges (electrons and ions) in a material (see Sects. 5.1–5.3). The propagation of light through matter is driven by the polarization of the material. Here we only consider linear effects in the material, i. e. the polarizability depends only linearly on the electric field strength. In a macroscopic formulation the material's response to the external field is given by the dielectric function (Sect. 5.1.1). From a microscopic point of view it is obvious that the polarization and thus the dielectric function

Fig. 5.14 The fourteen Bravais lattices [5.26]

depend on the atomic structure of the material. Looking at the various crystal structures [5.26] shown in Fig. 5.14 one can easily understand that along different crystal orientations the dielectric function has different values since the atomic distances have different values. Thus the dielectric function of a crystalline material will not just be a number, but will be represented by a matrix (a two-dimensional tensor). The well-known occurrence of birefringence in certain materials is a consequence of the orientation-dependent dielectric function.

We start again with the Maxwell equation [5.27] for the solution of a plane wave. This is appropriate since any solution can be described as the superposition of plane waves. Inserting a plane wave ansatz

$$E = E_0 \, e^{i(k \cdot r - \omega t)} = E_0 \, e^{i\omega\left(\frac{k}{\omega} l \cdot r - t\right)} = E_0 \, e^{i\omega\left(\frac{1}{v} l \cdot r - t\right)} \tag{5.63}$$

(with the phase velocity $v = \omega/k$ and $l = k/k$) into Maxwell's equations we find the following relations for the field components

$$D = -\frac{1}{\mu\mu_0\omega} k \times (k \times E_0) \, e^{i(k \cdot r - \omega t)} \,, \tag{5.64}$$

$$B = \frac{1}{\omega}(k \times E_0) \, e^{i(k \cdot r - \omega t)} \,, \tag{5.65}$$

and

$$H = \frac{1}{\mu\mu_0\omega}(k \times E_0) \, e^{i(k \cdot r - \omega t)} \quad (B = \mu\mu_0 H) \,. \tag{5.66}$$

The relation of the linear response of the material to the external electric field together with the Maxwell equation will give conditions for the existence of the above ansatz of a plane wave. Not taking into account dispersion, i. e. the frequency dependence of the dielectric function, the material's polarization is given by [5.28]

$$D_i = \varepsilon_{ij}\varepsilon_0 E_j \tag{5.67}$$

(where i and j are indices for the spatial components and the Einstein sum convention is used). Since the dielectric tensor is symmetric one can always find a coordinate system, where the tensor is diagonal, the system of principle axes [5.28, 29]. In the following we will always work in this reference system.

$$\begin{pmatrix} \varepsilon_1 & 0 & 0 \\ 0 & \varepsilon_2 & 0 \\ 0 & 0 & \varepsilon_3 \end{pmatrix} . \tag{5.68}$$

The relation between D and E now gives $D_i = \varepsilon_i \varepsilon_0 E_i$, (no sum over i). Inserting this into (5.64) and using the expansion of two cross products one finds

$$\varepsilon_i \varepsilon_0 \mu \mu_0 \omega^2 E_i = k^2 E_i - k_i (\mathbf{k} \cdot \mathbf{E}) . \tag{5.69}$$

This is the basic equation which determines the solution that can exist in the material. Introducing a unit vector in the direction of propagation $\mathbf{l}$ and defining a velocity v_i one gets:

$$\frac{\omega^2}{v_i} E_i = k^2 [E_i - l_i(\mathbf{l} \cdot \mathbf{E})] ,$$

$$\left(\mathbf{k} = k\mathbf{l} , \quad |\mathbf{l}| = 1 , \quad \frac{1}{v_i} = \sqrt{\varepsilon_i \varepsilon_0 \mu \mu_0} , \right.$$

$$\left. E_i = \frac{l_i(\mathbf{l} \cdot \mathbf{E})}{1 - v^2/v_i^2} , \quad v = \frac{\omega}{k} \right) . \tag{5.70}$$

Multiplying the last equation by l_i and summing over i results in a quadratic equation for v, the so called Fresnel equation of wave normals [5.28, 29]

$$\ell \cdot \mathbf{E} = \sum_i \frac{l_i^2}{1 - v^2/v_i^2} (\mathbf{l} \cdot \mathbf{E})$$

$$\Leftrightarrow 1 = \sum_i \frac{l_i^2}{1 - v^2/v_i^2} \quad \left(1 = \sum_i l_i^2 \right)$$

$$0 = \sum_i \frac{l_i^2}{1 - v^2/v_i^2} - l_i^2 = v^2 \sum_i \frac{l_i^2}{v^2 - v_i^2}$$

$$\Leftrightarrow \sum_i \frac{l_i^2}{v^2 - v_i^2} = 0 . \tag{5.71}$$

This is the equation usually discussed in crystal optics. Since it is a quadratic equation in the variable v, there are at most two solutions for the phase velocity. This is the origin of birefringence which we will discuss in detail in the section on uniaxial materials.

Classes of Optical Anisotropy Materials

From the representation of the dielectric tensor in the system of principle axes we see that there are at most three different values possible for the dielectric function. Before discussing in detail birefringence in matter, we discuss first the different classes of optical anisotropic materials resulting from the dielectric tensor [5.29].

Group I. Crystals in which all three values in the dielectric tensor in (5.68) are equal, $\varepsilon_1 = \varepsilon_2 = \varepsilon_3 = \varepsilon$, belongs to the so called cubic class. The material is said to be *optical isotropic*. The relation between D and E reduces to the well-known form $\mathbf{D} = \varepsilon \mathbf{E}$.

Group II. The next possible case is that in which two of the three axes are equivalent. The corresponding dielectric tensor has the property $\varepsilon_1 = \varepsilon_2 \neq \varepsilon_3$. Such a crystal is said to be *uniaxial*. This group of crystals belong to the trigonal, tetragonal and hexagonal system (Fig. 5.14).

Group III. The last group of crystals has three different values in the dielectric tensor $\varepsilon_1 \neq \varepsilon_2 \neq \varepsilon_3$. All three axes are different and the crystals belong to the orthorhombic, monoclinic and triclinic class (Fig. 5.14).

Uniaxial Materials: Ordinary and Extraordinary Rays

As discussed above a material is said to be uniaxial if two of the three values of the dielectric tensor are equal $\varepsilon_1 = \varepsilon_2 \neq \varepsilon_3$. As a result the velocities v_1 and v_2 are also equal ($v_1 = v_2$). The Fresnel equation of the wave normals (5.71) for this case have the following form

$$0 = (v^2 - v_1^2)(v^2 - v_3^2)(l_1^2 + l_2^2) + (v^2 - v_1^2)^2 l_3^2 \Leftrightarrow$$
$$0 = (v^2 - v_1^2) \left[(v^2 - v_3^2)(l_1^2 + l_2^2) + (v^2 - v_1^2) l_3^2 \right] . \tag{5.72}$$

This equation has two solutions for the phase velocity

$$1 : v = v_1$$
$$2 : (v^2 - v_3^2)(l_1^2 + l_2^2) + (v^2 - v_1^2) l_3^2 = 0$$
$$\Rightarrow v^2 = v_3^2(l_1^2 + l_2^2) + v_1^2 l_3^2 . \tag{5.73}$$

Expressing the unit vector $\mathbf{l}$ in spherical coordinates, $l_3^2 = \cos^2(\vartheta)$, $l_1^2 + l_2^2 = \sin^2(\vartheta)$, one gets

$$v^2 = v_3^2 \sin^2(\vartheta) + v_1^2 \cos^2(\vartheta) . \tag{5.74}$$

Usually one uses the notation $v_o = v_1$ (index o: ordinary) and $v_e = v_3$ (index e: extraordinary) (Fig. 5.16). Finally we arrive at the two solutions for the phase velocity of a plane wave propagating through the medium

$$1. \ v = v_o,$$
$$2. \ v = \sqrt{v_e^2 \sin^2(\vartheta) + v_o^2 \cos^2(\vartheta)} . \tag{5.75}$$

The z-axis is called the optical axis. For the refractive index one obtains

$$n = \frac{c}{v} \Rightarrow$$

$$n(\vartheta) = c \frac{1}{\sqrt{v_o^2 \cos^2(\vartheta) + v_e^2 \sin^2(\vartheta)}}$$
$$= \frac{n_o n_e}{\sqrt{n_o^2 + (n_e^2 - n_o^2) \cos^2(\vartheta)}} . \tag{5.76}$$
Fig. 5.15 Birefringence in calcite ($CaCO_3$), ordinary (o) and extraordinary ray (e) observed by perpendicular incidence to a surface that has an angle of approximately 45° to the optical axis [5.30]

The case $v_e > v_o$, corresponding to $n_o > n_e$, is called a positive crystal; the other case $v_e < v_o$ corresponding to $n_o < n_e$ is called a negative crystal.

Thus we have derived that in a uniaxial crystal there are always two solutions – the ordinary and extraordinary beam – with different phase velocities; one of them, the extraordinary beam, depends on the direction. To be able to understand the picture of these two rays traveling through for example a calcite crystal one must consider another quantity used in the theory of electro-magnetic radiation – namely the Poynting vector S, which describes the energy flux of electromagnetic radiation (Sect. 5.1.1). For a plane wave with propagation vector k it follows from the Maxwell equation that the field vectors E, H, S and D, H, k form a set of orthogonal vectors:

$$S = E \times H \rightarrow S \perp H \text{ and } E,$$
$$k \cdot D = 0 \rightarrow k \perp D,$$
$$k \cdot H = 0 \rightarrow k \perp H$$
$$D = -\frac{1}{\omega}(k \times H). \tag{5.77}$$

The angle α between the vectors k and S is the same as that between D and E (Fig. 5.17). In an isotropic medium the angle α is zero, since D is proportional to E. As a consequence, k and S point in the same direction. In an anisotropic medium this is generally no longer true. The light traveling through a uniaxial material and in particular the two rays shown in the calcite example are in fact the S vectors of the ordinary and extraordinary rays [5.30].

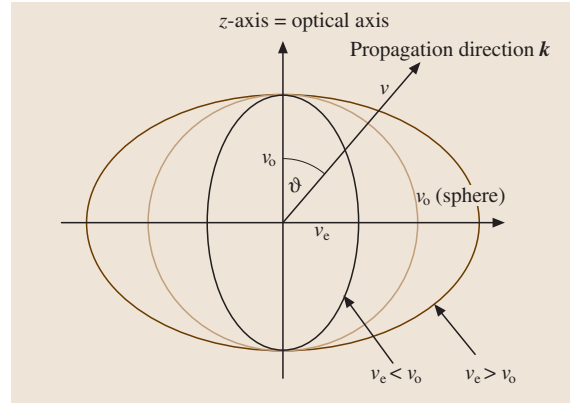
The angle between the ordinary and extraordinary ray is given by α, since the ordinary ray travels along k (remember, k and S point in the same direction). Thus the angle α gives the splitting between the ordinary


Fig. 5.16 Graphical representation of the solution to Fresnel's equation (Indikatrix)

and extraordinary ray in a uniaxial crystal. In the following derivation we want to obtain a rather simple expression for the angle α determined by the refractive indices n_e and n_o. Since we are only interested in the angle between two vectors we can consider unit vectors. Taking D as a unit vector, E is given for the material equation. In the framework of the principle axis

$$k = \begin{pmatrix} \sin(\vartheta)\cos(\varphi) \\ \sin(\vartheta)\sin(\varphi) \\ \cos(\vartheta) \end{pmatrix}, \quad D = \begin{pmatrix} \sin(\vartheta')\cos(\varphi') \\ \sin(\vartheta')\sin(\varphi') \\ \cos(\vartheta') \end{pmatrix}, \tag{5.78}$$

since $k \cdot D = 0$, it follows that

$$\cos(\vartheta)\cos(\vartheta') + \sin(\vartheta)\sin(\vartheta')\cos(\varphi - \varphi') = 0 \Leftrightarrow$$
$$\cot(\vartheta') = -\tan(\vartheta)\cos(\varphi - \varphi').$$

For the angle-independent solution v_o it follows that

$$\cos(\varphi - \varphi') = 0 \Rightarrow \varphi' = \varphi - \frac{\pi}{2}$$
$$\text{and } \cot(\vartheta') = 0 \Rightarrow \vartheta' = \frac{\pi}{2}. \tag{5.79}$$
Fig. 5.17 Angle α between k, S, D and E

For the second solution, which must be orthogonal to the first, it follows that: $\varphi' = \varphi$, $\vartheta' = \vartheta - \frac{\pi}{2}$.

Together with the relation between D and E one has

$$
D^{(1)} = \begin{pmatrix} -\cos(\vartheta)\cos(\varphi) \\ -\cos(\vartheta)\sin(\varphi) \\ \sin(\vartheta) \end{pmatrix}, \quad D^{(2)} = \begin{pmatrix} \sin(\varphi) \\ -\cos(\varphi) \\ 0 \end{pmatrix}
$$

$$
\text{and } E^{(1)} = \begin{pmatrix} -\cos(\vartheta)\cos(\varphi)\dfrac{1}{\varepsilon_1} \\ -\cos(\vartheta)\sin(\varphi)\dfrac{1}{\varepsilon_1} \\ \sin(\vartheta)\dfrac{1}{\varepsilon_3} \end{pmatrix}, \quad E^{(2)} = \dfrac{1}{\varepsilon_1}D^{(2)} .
$$

$$(5.80)$$

In the second case $D \propto E$ and, hence, $\alpha = 0$, which is obviously the ordinary ray. For the first solution, the extraordinary ray, we calculate the angle α from the scalar product $D \cdot E = |D|\,|E|\cos(\alpha)$, substituting D and E it follows that

$$
\frac{1}{\varepsilon_1}\cos^2(\vartheta)\cos^2(\varphi)
$$
$$
+\frac{1}{\varepsilon_1}\cos^2(\vartheta)\sin^2(\varphi) + \frac{1}{\varepsilon_3}\sin^2(\vartheta) =
$$
$$
1\left(\frac{1}{\varepsilon_1^2}\cos^2(\vartheta)\cos^2(\varphi) + \frac{1}{\varepsilon_1^2}\cos^2(\vartheta)\sin^2(\varphi)\right.
$$
$$
\left. +\frac{1}{\varepsilon_3^2}\sin^2(\vartheta)\right)^{1/2}\cos(\alpha) \Leftrightarrow
$$
$$
\frac{1}{\varepsilon_1}\cos^2(\vartheta) + \frac{1}{\varepsilon_3}\sin^2(\vartheta) =
$$
$$
\left(\frac{1}{\varepsilon_1^2}\cos^2(\vartheta) + \frac{1}{\varepsilon_3^2}\sin^2(\vartheta)\right)^{1/2}\cos(\alpha) \Leftrightarrow
$$
$$
\cos(\alpha) = \frac{\varepsilon_3\cos^2(\vartheta) + \varepsilon_1\sin^2(\vartheta)}{\left(\varepsilon_3^2\cos^2(\vartheta) + \varepsilon_1^2\sin^2(\vartheta)\right)^{1/2}} ,
$$
$$
\cos(\alpha) = \frac{n_{\mathrm{e}}^2\cos^2(\vartheta) + n_{\mathrm{o}}^2\sin^2(\vartheta)}{\left(n_{\mathrm{e}}^4\cos^2(\vartheta) + n_{\mathrm{o}}^4\sin^2(\vartheta)\right)^{1/2}} , \quad (5.81)
$$

with the relation $\varepsilon = n^2$ and the notation $n_3 = n_{\mathrm{e}}$, $n_1 = n_{\mathrm{o}}$. As an example let us consider the aforementioned calcite. The surface of the calcite that one gets by cleaving the crystal has an angle of approximately 45°. Light incident perpendicular to the surface thus gives $\cos^2(\vartheta) = \sin^2(\vartheta) = 0.5$. The refractive indices for the ordinary and extraordinary rays in calcite are: $n_{\mathrm{e}} = 1.4864$, $n_{\mathrm{o}} = 1.6584$. From these values one finds the angle between the ordinary and extraordinary

ray as (Fig. 5.15):

$$
\cos(\alpha) = \frac{1}{\sqrt{2}}\frac{n_{\mathrm{e}}^2 + n_{\mathrm{o}}^2}{\sqrt{n_{\mathrm{e}}^4 + n_{\mathrm{o}}^4}} \Rightarrow \alpha = 6.22° . \quad (5.82)
$$

5.1.5 Nonlinear Optical Behavior and Optical Poling

Since the first observation of nonlinear (NL) effects, many materials have been investigated concerning their nonlinear optical properties [5.31,32]. Nonlinear materials can be found among gases and vapors, polymers, liquid crystals, organic solvents, or crystals – in short, in nearly every material system.

A linear dielectric medium is characterized by a linear relation between the polarization density P and the electric field E, $P = \varepsilon_0\chi E$ (5.25), where ε_0 is the vacuum permittivity and χ is the electric susceptibility of the medium (see Sect. 5.1.1). A nonlinear dielectric medium, on the other hand, is characterized by a nonlinear relation between P and E, as illustrated in Fig. 5.18.

The nonlinearity may be of microscopic or macroscopic origin. The polarization density $P = Np$ is a product of the individual dipole moment p (which is induced by the applied electric field E) and the number density of dipole moments N. The nonlinear behavior may have its origin in either p or N.

The relation between p and E is linear when E is small, but becomes nonlinear as E acquires values comparable with interatomic electric fields (typically $10^5 - 10^8$ V/m). This may be explained in terms of the simple Lorentz model in which the dipole moment is $p = -ex$, where x is the displacement of a mass with charge $-e$ to an applied electric force $-eE$. If the restraining elastic force is proportional to the displacement (i.e., if Hooke's law is satisfied), the equilibrium displacement x is proportional to E. Hence, P is proportional to E, and the medium is linear. However, if the restraining force is a nonlinear function of the
Fig. 5.18a,b The P–E relation for (a) a linear dielectric medium, and (b) a nonlinear medium

displacement, the equilibrium displacement x and the polarization density P are nonlinear functions of E and, consequently, the medium is nonlinear.

Another possible origin of the nonlinear response of an optical material to light is the dependence of the number density N on the optical field. An example is a laser medium for which the number of atoms occupying the energy levels involved in the absorption and emission of light is dependent upon the light intensity itself (see Sect. 5.1.7).

Since externally applied optical fields are typically small in comparison with characteristic interatomic or crystalline fields, even when focused laser light is used the nonlinearity is usually weak. The relation between P and E is then approximately linear for small E, deviating only slightly from linearity as E increases (Fig. 5.18). Under these circumstances, it is possible to expand the function that relates P to E in a Taylor series about $E = 0$

$$P(E) = \varepsilon_0 \left(\chi^{(0)} E + \chi^{(2)} E^2 + \chi^{(3)} E^3 + \dots \right) , \quad (5.83)$$

where $\chi^{(0)}$ is the linear susceptibility and $\chi^{(n>0)}$ are the higher-order coefficients.

For the nonlinear refractive index n, we get

$$n(E) = n_0 + n_1 E + n_2 E^2 + \dots . \quad (5.84)$$

Equations (5.83) and (5.84) provide the basic description for a nonlinear optical medium. Anisotropy (Sect. 5.1.4), dispersion (Sect. 5.1.2), and inhomogeneities (Sect. 5.1.7) have been ignored both for simplicity and to enable us to focus here on the basic nonlinear effect.

In centrosymmetric media with inversion symmetry (like glass), in which the properties of the medium are not altered by the transformation $r \rightarrow -r$, the $P(E)$ function must have odd symmetry so that the reversal of E results in the reversal of P without any other change. The second-order nonlinear coefficient $\chi^{(2)}$ must then vanish, and the lowest nonlinear term is of third order. Typical values of the second-order nonlinear coefficient $\chi^{(2)}$ for dielectric crystals, semiconductors, and organic materials lie in the range $\chi^{(2)} = 10^{-24}$ to 10^{-21} m/V. Typical values of the third-order nonlinear coefficient $\chi^{(3)}$ for glasses, crystals, semiconductors, semiconductor-doped glasses, and organic materials are $\chi^{(3)} = 10^{-34}$ to 10^{-29} (m/V)^2.

Nonlinear Wave Equation

The propagation of light in a nonlinear medium is governed by the wave equation (5.29), which can be written in the form [5.34]:

$$\Delta E - \frac{n^2}{c_0^2} \frac{\partial^2 E}{\partial t^2} = -\mu_0 \frac{\partial^2 P_{\mathrm{NL}}}{\partial t^2} \quad (5.85)$$

where P_{NL} is the nonlinear part of the polarization density:

$$P_{\mathrm{NL}} = \varepsilon_0 \left(\chi^{(2)} E^2 + \chi^{(3)} E^3 + \dots \right) . \quad (5.86)$$

It is useful to regard (5.85) as a wave equation in which the term $-\mu_0 \partial^2 P_{\mathrm{NL}}/\partial t^2$ acts as a source radiating in a linear medium of refractive index n. Because P_{NL} is a nonlinear function of E, (5.85) is a nonlinear partial differential equation in E. This is the basic equation that underlies the theory of nonlinear optics. There are two approximate approaches to solve the nonlinear wave equation: the Born approximation and the coupled wave theory.

Optical Classification of Nonlinear Effects

Generally, the term "nonlinear optics" describes that part of the interaction between light and matter in which the optical material properties of the light beam passing through a nonlinear medium are changed by the beam itself or another electromagnetic field. Table 5.3 gives a short overview over the various nonlinear effects and their order of nonlinearity.

Here, we will focus our discussion on one of the most prominent effects: second-harmonic generation.

Second-Harmonic Generation (SHG)

In the case of the main second-order application [5.31] – second-harmonic (SH) generation – which e.g. can

Table 5.3 Nonlinear processes [5.33]

Nonlinear optical effect	Order
nth harmonic generation (e.g. SHG, rectification)	n
n-wave mixing	$n - 1$
nth photon absorption	n
Phase conjugation	3
Intensity-dependent refraction (e.g. Kerr effect, self phase modulation, self modulation)	2, 3
Optical parametric oscillation	2
Induced opacity	2
Induced reflectivity	2
Raman and Brillouin scattering	2

be used to convert IR laser light to Vis–UV light, the amount of second-harmonic light generated by the material depends on $\chi^{(2)}$.

When applying (5.85) to planar waves (5.8) the source term $-\mu_0 \partial^2 \boldsymbol{P}_{NL}/\partial t^2$ in (5.85) has a complex amplitude $4(\omega/c_0)^2 \chi^{(2)} E^2(\omega)$ which radiates an optical field component at frequency 2ω. Thus the SH optical field has a component at the second harmonic of the incident optical field. Fig. 5.19 illustrates the SHG effect.

Since the amplitude of the emitted second-harmonic light is proportional to $\omega^2 \chi^{(2)} I$, its intensity is proportional to $\omega^4 (\chi^{(2)})^2 I^2$, where I is the intensity of the incident wave. The intensity of the second-harmonic wave is therefore proportional to $(\chi^{(2)})^2$, to $1/\lambda^4$, and to I^2. Consequently, the efficiency of second-harmonic generation is proportional to $I = P/A$, where P is the incident power and A is the cross-sectional area.

It is therefore essential that the incident wave have the largest possible power and be focused to the smallest possible area to produce strong second-harmonic radiation. Pulsed lasers are convenient in this respect since they deliver large peak powers. To enhance the efficiency of second-harmonic generation, the interaction region should also be as long as possible. Since diffraction effects limit the distances within which light remains confined, waveguide structures that confine light for relatively long distances offer a clear advantage.

Third-Order Nonlinear Effects in Glass

For materials which have a center of inversion $\boldsymbol{P}(\boldsymbol{E})$ is an odd function. This means that even terms are all zero and no even harmonics can be observed. This is the case for isotropic media like glass. Third-order effects are orders of magnitude smaller than second-order ones. Besides polarization, the effective refractive index n_{eff} of the material depends on the intensity of the radiation (5.84). The nonlinear refractive index n_2 is usually determined by the polarizability of the ionic components of the material. In conventional glass systems, n_2 is determined by the amount of nonbridging oxygens and thus on the concentration of glass modifiers (see Sect. 5.2).

Material-Based Classification of Nonlinear Optical Effects

When considering nonlinear effects [5.34], one must distinguish between resonant (where the optical frequency is resonant with an electronic transition in the material), nonresonant, and intrinsic and extrinsic effects [5.35–38].
Fig. 5.19 A planar wave of frequency ω in a second-order nonlinear optical medium creates a polarization with component 2ω and a steady (dc) component (optical rectification)

Resonant Nonlinearities are found when the light wavelength is in the spectral range of a fundamental absorption due to electronic transitions or molecular vibrations. Resonant effects are usually rather large, but have slow relaxation times, depending on the relaxation time of the excited carriers. They show higher power dissipation and are accompanied by sample heating.

Nonresonant Nonlinearities are of purely electronic origin and arise from the distortion of the electron orbits (polarizability). The electronic effects range in a sub-ps time scale, with minimum heating of the device, but have only small nonlinearities and thus require high intensities [5.39].

Intrinsic effects are nonlinear effects where the material itself is responsible for the NL properties, for instance the Kerr effect. In crystallites as well as in glasses with intrinsic nonlinearity, three types of anion groups are believed to be mainly responsible for large nonlinearities [5.40]:

- distorted $\text{Met}-\text{O}_6$ octahedra: Tm^{3+}, Yb^{3+}, Sr^{2+};
- anion groups with a lone electron pair: e.g. Bi^{3+};
- anion groups with dislocated conjugated π-bond planar structure, like organic molecules or $[\text{BO}_3]^{3-}$-plane.

Extrinsic effects are properties of materials or dopants embedded in the material, such as rare-earth (RE) ions, microcrystallites, dyes or impurities, where the nonlinear effect is associated with the dopant, or are due to light-induced compositional changes, such as reversible or irreversible chemical reactions.

As a rule of thumb one can say that to get a NRI (nonresonant intrinsic) at least in the range of 10^{-11}, a linear refractive index $n_D > 2$ and Abbe number $\nu < 20$ are required. Most of the oxide glasses have refrac-

tive indices below 2 but some glasses which fulfill these requirements are the chalcogenide glasses, chalcohalides, heavy metal oxide (HMO)- and RE-doped oxide glasses [5.37, 38, 41–43].

Coherent Nonlinear effects are characterized by an instantaneous response of the material to the incident fields. This condition is fulfilled if the corresponding electronic excitation in the dielectric material is created only virtually – using the language of coupled wave theory, see p. 266 – or, within the quantum mechanical treatment, if we treat only interactions of coherent polaritons [5.31].

Incoherent Nonlinear effects involve modifications of the optical properties by really or incoherently excited species, e.g. electron–hole pairs, excitons, or phonons. These species have finite lifetimes τ which can be on the order of ns to ms. Due to this finite lifetime, their density does not instantaneously follow the incident light field, but depends on the generation and depopulation rate, which are characterized by an instantaneous response of the material to the incident field. Table 5.4 lists some effects in optical materials and typical values.

Creation of Artificial Second–Order Nonlinearity: Optical Poling

As mentioned before, the SHG process is related to the second-order susceptibility and thus allowed only in non-centrosymmetric materials. On the other hand, third-order nonlinear materials such as glass offer advantages such as easier and cheaper fabrication with high homogeneity. Thus, attempts have been made either to increase the field strength (electric poling) or create artificial symmetry (thermal or optical poling [5.37, 38, 44, 45]), or combine the two methods.

There exist two types of electric field poling: electrode poling (in which a DC field is applied to a pair of electrodes) and corona discharge poling (where the surface of a film is charged under a strong potential). Annealing in vacuum is effective in enhancing the SHG intensity, whereas addition of hydrogen at room temperature increases the lifetime of the optical nonlinearity. Further methods are poling by mechanical stress or with a chemical dilutant [5.33, 40, 42, 46–48].

Higher SHG intensities than those obtained with thermal or electric poling can usually be derived by optical poling. This is due to the fact that an artificial phase matching (quasi phase matching) can be achieved by creating a stable $\chi^{(2)}$-grating in the glass (see Sect. 5.6). Thus, with optical poling phase matching over a sample length of several cm can be achieved, whereas the active region for thermal or electric poling is only between $5-15\,\mu m$.

Optical poling is achieved by intensive irradiation by, e.g. 1064 nm light and irradiation by additional light of the SH wavelength during the poling procedure (seeding light). After this procedure intensive SHG (e.g. in Pb–silica, Ge–silica, metal- or SC-doped, or $ZnO-TeO_2$ glasses) has been observed. Fundamental and SH cause a semipermanent DC electric field in the glass (by photoinduced current or structural orientation) which cancels the inversion symmetry and allows the periodic phase matching of the SHG (see also Table 5.22).

Optical poling can be also used for organic materials, e.g. dyes, which have asymmetric structure and exhibit polarization. Dispersed in a glass matrix, they have random orientation and thus are isotropic. Even growth of crystals in the glass does not result in the desired second-order nonlinearity because of the usually centrosymmetric (antiparallel) arrangement of the polar molecules. By irradiation with two laser beams or by applying an electric field, the random orientation can be changed to an ordered configuration.

In detail, poling is a process which can be found especially in the fabrication of photonic devices. Most

Table 5.4 Third-order susceptibility, response time τ, and magnitude of n_2 for various sources of n_2 (NRI) [5.43] (SC = semiconductor, MQW = multi quantum well)

Mechanism	Typical materials	$\chi^{(3)}$ (esu)	Response time τ (s)	n_2 (esu)	Type

Fig. 5.21 Schematic plot of a three level laser system Via a pump level with a very short lifetime $\tau_1 \ll \tau_2$ the upper laser level (u) is populated. Depolulation can either occur via stimulated emission, where copies of photons are made or via sponateous emission where the probability is determined by the lifetime τ_2

of the optical poling experiments to date have been performed in fibers. But additional SHG in waveguide geometries is also possible. In the case of waveguides, the poling was performed near the glass transition point of a nonlinear core polymer in order to establish a permanent orientation of the nonlinear chromophor dipoles. In the case of e.g. glasses containing Na^+ and H^+ a charge field is established by wandering of these mobile ions in a strong electric field (thermo-electric poling).

5.1.6 Emission

For numerous applications for active optical materials the interrelation between specific absorption and emission processes [5.49] is of crucial importance. One example is a laser or an optical amplifier, where a specific absorption on a well-defined level in the optically active material is needed for pumping. This leads to the building of an inversion in a lower laying state. The inversion can either be emptied by spontaneous emission, which causes noise, or by stimulated emission which amplifies a laser (or signal) mode.

The microscopic processes between these absorption and emission levels can have different origins, for example several levels of 4f electron systems of a rare earth. These levels only interact weakly with lattice vibrations and therefore barely show thermal broadening (zero phonon lines). Examples for laser materials are Nd^{3+}-doped YAG (yttrium aluminate garnet) single crystals and Nd^{3+}-doped phosphate glasses. Examples of optical amplifier materials are

Er^{3+}-doped fused silica and Er^{3+}/Yb^{3+}-doped multicomponent glasses (see Fig. 5.23). Here the optical emission of Er^{3+} in the wavelength range of optical telecommunication is used. Further laser systems are e.g. ruby lasers (Cr^{3+} + doped Al_2O_3); semiconductor lasers, where the pumping is done electronically; gas lasers such as the helium–neon laser, where the energy levels of He are used for pumping and the inversion is built up in the energy levels of Ne; or dye lasers where broad π-electron systems of organic molecules are used to provide the necessary tunable energy levels. For more details on laser physics see also [5.49]. The absorption and the absorption cross sections can be directly measured and are described in Sect. 5.1.3. As we will see, the approach to treating spectral emission of an excited material is more sophisticated.

Emission Cross Section
Although absorption has a well-defined meaning with respect to attenuation of light and can be measured quantitatively via the absorption coefficient α it has a quantummechanical origin. Especially for making absorption (and emission) quantitative the quantummechanical concept of transition probabilities is needed. It is also usually expressed via oscillator strengths of certain transitions. The fact that light is absorbed at certain frequencies ω (or energies $\hbar\omega$) means that light is portioned in packages (photons) of energy given by

$$\hbar\omega = \frac{hc}{\lambda} \,, \tag{5.87}$$

Part A | 5.1

where h is Planck's quantum and $\hbar = h/2\pi$. The absorption cross section is connected to the transition probability R_{ij}, which is the probability for absorbing a photon to induce a transition in the medium from state i to state j. In general the transition probability depends on the detailed wavelength dependence of the transition and on the wavelength dependence of the incoming light. Therefore the transition probability is related to the cross section as follows:

$$R_{ij} = \int \sigma(\omega)\Phi(\omega)\,d\omega = \int \frac{-2\pi c}{\lambda^2}\sigma(\lambda)\Phi(\lambda)\,d\lambda \,,$$

(5.88)

where Φ is the photon flux measured in units of m^{-2}, which is related to the light intensity $I = \hbar\omega\Phi$.

Quantum Emissions

Furthermore, emission and emission cross sections have a quantum-mechanical nature. Historically the work of Einstein did not only bring its author a Nobel prize but also laid the foundation of laser physics. Einstein introduced the fundamental concepts of stimulated and spontaneous emission. The stimulated emission process makes copies of photons with identical energy and – more importantly – phase. This is the process behind laser activity and amplification. While stimulated emission is just the opposite process of absorption, spontaneous emission is caused by the finite lifetime of an excited state. It is responsible for noise in a laser or optical amplifier. The lifetime τ_2 of the upper, excited level with only one transition $2 \rightarrow 1$ is the inverse of the transition probability A_{21}

$$\tau_2 = \frac{1}{A_{21}} \,.$$

(5.89)

In the case of different decay channels the lifetime is the inverse of a sum over all transition probabilities

$$\tau_2 = \frac{1}{\sum_m A_{2m}} \,.$$

(5.90)

We now want to define an emission cross section. If we consider an ideal system with a single nondegenerate transition and no nonradiative decay channels, the emission and absorption cross sections are identical $\sigma^{\text{abs}} = \sigma^{\text{emis}}$.

Real systems deviate from this in the following ways:

- The upper as well as the lower laser level are composed of an ensemble of sublevels. Especially in disordered systems such as glasses an inhomogeneous broadening of the energy levels can become

important. Therefore an effective density of states for each level has to be taken into account.
- The spacing of the sublevels is such that thermal occupation has to be considered, i.e. where $\Delta E = h\Delta\omega < k_{\text{B}}T$ where k_{B} is the Boltzmann constant.
- Different degeneracies of the energy levels are involved. If the upper level has a degeneracy of g_2 and the lower level a degeneracy of g_1, the emission and absorption probabilities have to be multiplied by these degeneracy factors. If an energy state is connected with a magnetic moment, a canceling of degeneracies due to crystal field splitting can occur, which leads to an ensemble of sublevels (see above).
- There exist nonradiative processes that empty the upper state and decrease the radiative emission cross section. At high enough energies lattice vibrations (phonons) can empty an excited state in a nonradiative way.

For these reasons the effective emission cross section for a real system deviates from the absorption cross section in a nontrivial way

$$\sigma^{\text{abs}}(\lambda) \neq \sigma^{\text{emis}}(\lambda) \,.$$

(5.91)

An ideal two-level system and a real system are sketched schematically in Fig. 5.22a,b. The emission cross section is related to the transition probability by

$$\sigma^{\text{emis}}(\lambda) = \frac{\lambda^2 A_{21}}{8\pi} S(c/\lambda) \,,$$

(5.92)

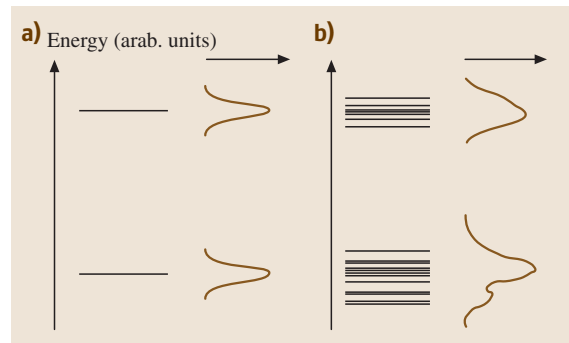
where $S(c/\lambda) = S(\nu)$ is the lineshape function. The lineshape function is normalized to unity $\int S(\nu)\,d\nu = 1$. The


Fig. 5.22a,b In (**a**) the schematic terms for an ideal, only lifetime-broadened emission process from an excited state to the ground state is plotted. Many real systems sketched in (**b**) show a splitting into different sublevels, different degeneracies and nonradiative transitions

question remains if and how it is possible to measure the emission cross section. While for the absorption cross section such a measurement is straightforward, it is far more complicated to complete this process for an emission cross section. The lineshape can be determined by saturating a transition with a light source, then switching off the light and measuring the resulting fluorescence, which is decaying exponentially in time, with a spectrometer. The wavelength dependent signal of the spectrometer is proportional to the emission cross section. If a sample of volume V is irradiated with light until a stationary state is reached, the inversion level $0 < N_2(x) < 1$ is a measure of the excited optical centers. The probability for an emission process to occur in the wavelength range between λ and $\lambda + \Delta\lambda$ is

$$W(\lambda) = \frac{\sigma^{\text{emis}}(\lambda)\Delta\lambda}{\int \sigma^{\text{emis}}(\lambda)\,d\lambda}\,. \tag{5.93}$$

Therefore the light intensity emitted by an infinitesimal volume element $dV(x)$ is given by

$$dI(\lambda, x) = N N_2 \tau^{-1}\,dV(x) h\nu W(\lambda)\,. \tag{5.94}$$

Here again N is the concentration of optical centers and $h\nu = hc/\lambda$ is the energy of each emitted phonon with Planck's constant h. For a measurement of $W(\lambda)$, this intensity, which is emitted with equal probability in all spatial directions, has to be collected in a spectrometer which normally covers only a small part of the spatial angle in which the emission takes place. On the way to the spectrometer the light may also travel through other volume elements causing absorption or stimulated emission. Therefore the absolute signal measured in the spectrometer is related in a nontrivial way to the emission cross section. For measuring cross sections the following special conditions are thus used:

- Excitation and measurement are done close to the surface of a sample to avoid the emitted light traveling through large parts of the sample. This is done either in a backscattering geometry or at a corner of the material.
- The excitation is so strong (e.g., with a laser) that saturation is reached $N_2 \approx 1$. In this way absorption of emitted light traveling through the sample is suppressed.
- Standards are used for a comparison. These are e.g. rare-earth ions of well-defined concentration in single crystals, glasses with well-controlled compositions or fluid organic dyes.

Even if it is a nontrivial task to measure the emission cross sections, it is the most important microscopic quantity for the laser activity of a transition.

Example for Er Ions

As an example we show here the emission and absorption cross sections of Er^{3+} for the transition around 1550 nm. This transition is important for telecommunication applications since it takes place in the wavelength range where silica fibers exhibit minimum light attenuation. The states involved in this transition have the spectroscopic symbols $E_1 - \to\ ^4I_{15/2}$ and $E_2 \to\ ^4I_{13/2}$ which stand for spin, angular and total moment of the correlated eleven 4f electron system which forms the Er^{3+} system. In Fig. 5.23 we plot an example of this transition of Er^{3+}, which is of high technological importance. The value of the emission cross section is influenced by the fact that the ground state is eightfold degenerate whereas the degeneracy of the excited state is sevenfold. It is further influenced by nonradiative decay channels due to lattice vibrations. The spectral shape of the cross sections is formed by the level splitting in the local crystal field formed by the glass environment and the thermal occupation of the different sublevels. In addition there is inhomogeneous broadening due to the disordered structure of the glass.

5.1.7 Volume Scattering

This section deals with the interaction of light with particles inside a certain volume leading to light scattering. Before going into details the term scattering must be defined and explained. Afterwards scattering is subdivided
Fig. 5.23 Plot of the emission and absorption cross section for an Er^{3+}-doped glass

into single scattering, multiple scattering, and coherent scattering.

Definition and Basics

Scattering is defined here as energy absorption of incident light followed by re-emission of part of this light at the same frequency. Thus inelastic effects such as Raman scattering or Brillouin scattering are not discussed in this section.

The *origins* of light scattering are surface irregularities. From this point, volume scattering is scattering at the surface of particles in a certain volume. Surface scattering is discussed in Sect. 5.1.8.

Obviously scattering is strongly related to diffraction, as seen from the definition of scattering. Indeed, diffraction is scattering by a flat particle [5.50].

In the following, volume scattering is subdivided into (Fig. 5.24)

- single scattering,
- multiple scattering,
- coherent scattering.

Volume scattering can be regarded as the sum of single scattering events as long as the density of scattering particles is not too high. Mathematically this is expressed with the packing fraction η defined by

$$\eta := \frac{NV_{\text{scat}}}{V_{\text{vol}}} , \tag{5.95}$$

where N is the number (integer) of the single scatterer, V_{scat} is the volume of a single scatterer, and V_{vol} is the whole volume in which the N identical scatterers are located.

Before now discussing these three different subdivisions of volume scattering a few basic items must be described.

Scattering attenuates light, as does absorption by the medium itself. Both effects together are referred to as *extinction*, where: extinction = absorption + scattering [5.50].

The total (over all directions) scattered power P_{scat} (in units of W) can be calculated from the scattering cross section C_{scat} (in units of m^2) by

$$P_{\text{scat}} = C_{\text{scat}} I_{\text{in}} , \tag{5.96}$$

where I_{in} is the incident light intensity (in units of W/m^2). Typically one wants to know the power scattered in a certain direction (Fig. 5.25) and this is described by the differential scattering cross section $dC_{\text{scat}}/d\Omega$ (Ω: spatial angular)

$$\frac{dC_{\text{scat}}}{d\Omega} = R^2 \frac{I_{\text{scat}}}{I_{\text{in}}} \tag{5.97}$$

where R is the distance from scatterer to observer and I_{scat} is the scattering intensity. The scattering cross section can be obtained from the differential scattering cross section by:

$$C_{\text{scat}} = \int_{4\pi} \frac{dC_{\text{scat}}}{d\Omega} \, d\Omega . \tag{5.98}$$

Unfortunately the scattering cross section and the differential scattering cross section can only be calculated for a few geometries, such as spheres (Mie scattering).

Fig. 5.27 Differential scattering cross section multiplied by 1.5×10^9 particles/mm^3 for a glass sphere ($n_{sphere} = 1.51$) of radius $a = 400$ nm embedded in a medium with $n_{medium} = 1.50$ at a wavelength of 550 nm

Single Scattering (Mie Scattering)

A very important geometry of single scatterers is the sphere. In 1908 *Mie* [5.51] derived an analytic theory that completely describes the scattering from a (conducting or nonconducting) sphere embedded in a nonconducting medium. A compact survey of the formulas can be found in [5.52]. Many basic characteristics of scattered power can be obtained by studying scattering by a sphere. The calculated scattering cross section normalized to the geometric cross section of a glass sphere ($= \pi a^2$ where a is the sphere radius) can be seen in Fig. 5.26.

Figure 5.26 demonstrates the different wavelength dependence of the scattering cross section and thus of the scattered power according to (5.96). Depending on the geometric sphere size (characterized by the diameter $2a$) relative to the wavelength, three important regions can be identified:

- $\lambda \ll 2a/n_{medium}$, region of *geometric optics*. Surprisingly the term $C_{scat}/\pi a^2 = 2$. This effect is called the *extinction paradox* and the factor 2 is due to diffraction effects [5.53, 54].
- $\lambda \approx 2a/n_{medium}$, *resonance effect*, the term $C_{scat}/\pi a^2$ has its maximum. Therefore the highest scattered power can be measured if the geometric size of an object is of the order of the wavelength.
- $\lambda \gg 2a/n_{medium}$, *Rayleigh scattering*. The scattered power is proportional to $1/\lambda^4$. This effect is respon-

sible for the blue sky, where small particles inside the atmosphere scatter blue light (≈ 400 nm) more than red light (≈ 800 nm).

These basic characteristics of a single scatterer – here shown for the special case of a sphere – are typical for all single scatterers of arbitrary geometry. As discussed and shown in Fig. 5.26 different behavior of the scattered power can be observed based on the size of the scatterer relative to the wavelength.

Multiple Scattering

In the preceding section scattering at a single isolated particle has been described. Now, multiple scattering is discussed, which is the weighted superposition of many single scatterers without interference effects. Multiple scattering with interference effects is called coherent scattering and is discussed below.

Multiple scattering can only be described numerically and must be used whenever the packing fraction η is larger than about 0.3. Based on the knowledge of the scattering function (described by the differential scattering cross section) of a single scatterer, the overall scattering function is calculated by tracing rays throughout the volume.

For example, multiple scattering of 1.5×10^9 particles/mm^3 resulting from a packing fraction of $\eta = 0.8$ is calculated here (this can be the case for a glass ceramic, Sect. 5.5). The single scatterer is assumed to be a sphere of radius 400 nm with a refractive
Fig. 5.28 Multiple scattering with $\eta = 0.8$ based on the data from Fig. 5.27. The differential scattering cross section due to multiple scattering inside the volume is totally different from that shown in Fig. 5.27 (the angle is defined in the inset of Fig. 5.27)

Fig. 5.29 (a) An example of the static structure factor, for the case of hard spheres. (b) The scattering vector q

index of $n_{sphere} = 1.51$ embedded in a glass with refractive index $n_{medium} = 1.50$ at a wavelength of 550 nm. The differential scattering cross section of this single scatterer multiplied by 1.5×10^9 particles/mm^3 is shown in Fig. 5.27.

The differential scattering cross section of a single scatterer (as seen in Fig. 5.27) is used to calculate the differential scattering cross section of the whole volume with a packing fraction of $\eta = 0.8$. The result, shown in Fig. 5.28, has been obtained by calculating the multiple scattering numerically.

As shown in Fig. 5.28 most of the power will be scattered in the backward direction (180°). Less power will be scattered into the forward direction (0°) and no power will be scattered in the sideway direction (90°).

By comparing Fig. 5.27 with Fig. 5.28 it can be seen that the differential scattering cross sections are totally different. The reason for that is multiple scattering inside the volume.

Coherent Scattering

Coherent scattering – the phenomenon in which a series of independent single-particle scattering events is replaced by collective light manipulation from an ensemble of different scattering centers – is the focus of this section. When dealing with materials containing scatterers separated by distances greater than the coherence length (the distance necessary for propagating waves to lose their coherence), the scattering events can be treated as independent occurrences even under multiple scattering conditions. Such scattering is called incoherent, and the resulting intensity of such radiation is simply a summation of the intensity contributions of all the independent scattering centers.

However, when the distances between scatterers are on the order of or less than the coherence length, coherent scattering effects must be considered [5.55]. In this case, wave package interference takes place as the package, is capable of interacting with more than one scattering center at a time; several scatterers distort the photon package simultaneously. Thus, a relationship exists between the phases of the light signals arising from the different scatterers. The events are no longer separate; they are correlated, and the resulting intensity of transmitted light is no longer a simple sum. Thus, in coherent scattering, wave packages experience a combined interaction with several scattering centers that affects their transport through the medium. In photon group interference (a quantum effect), the wave package comes apart upon scattering but the different sinusoidal components meet again and interfere. This interference affects the intensity of light transmitted through the sample; thus, coherent scattering studies can yield valuable structural information.

As discussed, scattering is coherent when the phases of the light signals arising from different scattering centers are correlated and incoherent when the phases are not. Hence, the propagation of coherently scattered light depends strongly on the direction of the scattering vector q – the difference between the incident and outgoing wave vectors, $k_{in} - k_{out}$ (Fig. 5.29b) – whereas incoherently scattered light can propagate in any direction regardless of the phase relation between waves from different scattering centers [5.56]. When the average distance between scattering centers (d) is on the order of the coherence length or less,

the interference effects are significant and quantitatively describable by the static structure factor $S(q)$, which gives correlations in the positions of particle centers (Fig. 5.29a). $S(q)$ is the link between the theoretical description of structural inhomogeneities and the actual experimental scattering measurements [5.57]. An extreme case of coherent scattering is a strictly periodic configuration of scattering centers. The scattering intensity shows maxima at Bragg peaks and the structure factor consists of sharp δ peaks. Note that the relation between incoherent and coherent scattering terms is usually expressed via the Debye-Waller factor.

The plot of the structure factor in real space is the pair correlation function, $g(r)$, which gives the probability of finding a pair of centers at a specific distance r apart in a sample. The relationship between $g(r)$ and $S(q)$ is

$$S(q) = 1 + 4\pi\rho \int_0^\infty r^2 \left[g(r) - 1\right] \frac{\sin(kr)}{kr} \, dr , \quad (5.99)$$

where ρ is the density of scattering centers. There is a mathematical connection between the cross section of the scatterers and the structure factor. For the general case of scattering from a correlated group of particles the scattering cross section is

$$C_{\text{scat}} = \frac{1}{k_0^2} \int_0^{2k_0 a} F(y, k_0 a) S(y) y \, dy , \quad (5.100)$$

where $y = qa$, $F(y)$ is the form factor, a is the radius of the scatterer, and k_0 is the incident wave vector [5.58].

Coherently scattered photons have a phase relationship, consequently exhibiting more wavelike behavior. In experiments in which coherent scattering is a prominent effect, the interference between scattering paths must be considered – and can be exploited. For example, light from a monochromatic coherent source scatters from a sample and exhibits a characteristic speckle pattern – an array of bright, non-overlapping spots due to interference effects – based on the composition and structure of the sample, as long as single scattering is the dominant effect [5.56]. Thus, such patterns contain structural information. An additional field is the analysis of backscattering cones. Another example of coherent scattering effects is evidenced by the unexpectedly high transparency of a glass ceramic – a phenomenon that cannot be explained by Rayleigh or Mie scattering theories (Sect. 5.5).

5.1.8 Surface Scattering

This section discusses in more detail light scattering due to surface irregularities. The Rayleigh criterion assesses when scattering is important and must be included. How roughness is related to the scattered light can be estimated by the so called total integrated scatter (TIS). TIS is an integrated (over all directions) value, so the angular dependence of scattering is not covered. The angular dependence of surface scattering can be estimated by assuming a sinusoidal surface roughness. A general (scalar) scattering theory is also briefly discussed.

More details on surface scattering can be found in [5.59, 60].

Basics and Rayleigh Criterion

Perfectly smooth surfaces only reflect light specularly. As stated in Sect. 5.1.7, due to surface irregularities light is also scattered in directions other than the specular one. This is illustrated in Fig. 5.30.

As can be seen from Fig. 5.30 in addition to the specular reflected light, scattered light is also generated due to the rough surface. This stray light is scattered over a wide angle around the specular direction. The rougher the surface the more light is scattered away from the specular direction.

But when is a surface smooth? This is answered by the so called *Rayleigh criterion* [5.60].

As can be seen from Fig. 5.31, a plane wave incident on a rough surface experiences a phase difference between the two outer "rays". If this phase difference Φ
Fig. 5.30 Specular light reflection at a perfectly smooth surface (*top*) and light scattering at a rough surface (*bottom*). *Dotted line* = scattered (reflected) light, *solid line* = incident light
Fig. 5.31 A plane wave incident on a rough surface and its phase difference due to different optical paths
Fig. 5.32 Surface roughness and TIS

is smaller than $\pi/2$, the surface is called smooth (i.e. Rayleigh criterion)

$$\Delta h < \frac{\lambda}{8 \cos \alpha} , \tag{5.101}$$

where Δh is the RMS roughness (standard deviation).

Scattering (TIS) and Surface Roughness

The way in which surface roughness is related to scattered light can be seen in the so called total integrated scatter (TIS). The TIS is the ratio of scattered power P_{scat} (without specular reflected light) in one hemisphere to the specularly reflected power P_{ref}. If the surface roughness is smaller than the wavelength, then TIS is given

Fig. 5.33 Surface roughness plotted against wavelength for various TIS values. Typical roughness values for super and normal polished glass are also plotted. Note the logarithmic scale of the roughness axis
Fig. 5.34 Sinusoidal surface roughness and its parameters for the 1st diffraction order

by [5.59]:

$$TIS = \frac{P_{scat}}{P_{ref}} = \left[\frac{4\pi \cos \alpha_R}{\lambda} \right]^2 (\Delta h)^2 , \tag{5.102}$$

where α_R is the angle of incidence (reflectance) as shown in Fig. 5.30 and Δh is the RMS roughness of the surface (Fig. 5.32).

From (5.102) it can be seen that the scattered power is proportional to the square of the surface roughness and depends as $1/\lambda^2$ on the wavelength. The surface roughness vs. wavelength for various TIS values is plotted in Fig. 5.33. Consider a specific glass surface and incident light at 500 nm. For this wavelength, only a thousandth part of the reflected light should be allowed to be scattered (TIS $= 10^{-3}$). For this wavelength and TIS value the RMS roughness is just 1.3 nm. This value is between normal and super-polished glass surface. Hence, normal polishing is *not* sufficient here. Therefore, a more expensive super-polishing must be used.

The TIS can also be used for estimating the surface roughness. By measuring the TIS at a determined wavelength, as described in [5.59, 61], the surface roughness can be calculated with the help of (5.102).

Angular Scattering from a Sinusoidal Surface Roughness

As already mentioned TIS is an integrated value, and thus angular dependencies of the scattered can not be described by TIS. But in many cases the direction of scattered light must be known, e.g. to determine the scattered contribution perpendicular (90°) to the incident light. To get a feeling for the angular dependence the easiest form of surface roughness – a sinusoidal surface – is considered (Fig. 5.34). An arbitrary surface roughness can be regarded as the superposition of sinusoidal rough surfaces. This approach is used in [5.60]. As already mentioned, scattering is strongly related to diffraction.
Such a sinusoidal grating diffracts (scatters) light into many orders. Light scattered into the m-th diffraction order is given by [5.59]

$$P_{\text{scat}}^m \propto \left(\frac{\Delta h}{\lambda}\right)^{2|m|} , \quad (5.103)$$

where the scattering angle belonging to this m-th order can be calculated from the grating equation

$$\sin \Delta\alpha_m = m\frac{\lambda}{d} . \quad (5.104)$$

$\Delta\alpha_m$ is the diffraction angle measured relatively to the direction of specular reflection. Here we will restrict the following considerations to the case of normal incidence, i.e. $\Delta\alpha = \alpha$. As an example, the case of a smooth surface is considered.

Smooth surface, i.e. $\Delta h/\lambda \ll 1$ and thus only the first-order diffraction need to be considered, as can be seen in Fig. 5.34. For that case the angle of the first diffraction order is only determined by the periodicity d and wavelength of the grating – *not* by the roughness Δh. The scattered power is proportional to $(\Delta h/\lambda)^2$, as it was obtained from TIS (which is valid only for smooth surfaces). The scattering angle $\Delta\alpha$ depends only on the periodicity d and the wavelength λ. Here three cases are of special importance:

- $\lambda/d \ll 1$, the periodicity is much larger than the wavelength and thus according to (5.104) with $m = 1$, the angle $\Delta(\alpha)$ equals 0. This means that the light will mainly scatter in the specular direction.
- $\lambda/d \approx 1$, the periodicity is of the order of the wavelength and so the scattering angle equals 90°.
- $\lambda/d < 1$, the periodicity is larger than the wavelength and light will be scattered between 0° and 90°.

All three cases for a smooth surface are illustrated in Fig. 5.35, which clearly shows the angular light scattering difference for different periodicities d (compared to the wavelength).
Fig. 5.35 Angular scattered light of a smooth surface for different periodicities d

Unfortunately, reality is much more complicated and a sinusoidal surface roughness cannot be found. But, as previously explained, a random surface roughness can be decomposed into a superposition of sinusoidal surfaces. This is done in much more detail in [5.60]. The angular scattering behavior of a surface is normally measured by the so called angular-resolved scatter (ARS). These measurements can be used to extract the angular scattering characteristics (the bidirectional scattering distribution function, BSDF) used in simulation tools for predicting scattering characteristics.

General Scalar Scattering Theory (First Born Approximation)

If the geometry of the roughness and the different refractive indices are known, then a general theory for calculating the scattered electric field can be developed. This theory is accurate for small refractive index changes (the so called first Born approximation), but after iterative use of the result stronger changes in the refractive index can also be calculated.

The total electric field $U(\mathbf{r}, \omega)$, i.e. the incident field U^i and the scattered field U^s ($U = U^i + U^s$), obeys the following differential equation [5.62] (in SI units):

$$\Delta U + \left(\frac{2\pi}{\lambda_0}\right)^2 U = -4\pi F(\mathbf{r}, \omega) U , \quad (5.105)$$

where λ_0 is the free space wavelength, $\mathbf{r}$ is the arbitrary point of observation, and the scattering potential F is

$$F(\mathbf{r}, \omega) = \frac{1}{4\pi}k^2 \left[n^2(\mathbf{r}, \omega) - 1\right] . \quad (5.106)$$

The right-hand side of (5.105) describes the source of the scattering. Thus, as can be seen from (5.106), this source is only determined by the spatially and frequency-dependent refractive index n. Here it is clearly shown that the source of light scattering is the spatially dependent refractive index (rough surface).

As shown in [5.62] the solution of (5.105) for the scattered electric field is given by

$$U^s(\mathbf{r}, \omega) = \int_V F(\mathbf{x}, \omega) U(\mathbf{x}, \omega) \frac{e^{ik|\mathbf{r}-\mathbf{x}|}}{|\mathbf{r}-\mathbf{x}|} d^3x . \quad (5.107)$$

This form has the drawback that the total electric field inside the integral (5.107) must be known. But U also contains the scattered electric field. This problem can be overcome by using the so called first Born approximation (or Rayleigh–Gans theory). The first Born approximation assumes a smooth surface (weak change

in the refractive index) and also a far field [5.62]:

$$U \approx U_1 = e^{i\mathbf{k}_i \mathbf{r}} + \frac{e^{ikr}}{r} \int_V F(\mathbf{x}) e^{i(\mathbf{k}_i - \mathbf{k})\mathbf{r}} \, d^3x \,, \quad (5.108)$$

where $\mathbf{k}_i$ is the wave vector of the incident wave and $\mathbf{k}$ is the wave vector of the origin and point of observation.

Equation (5.108) is the first Born approximation and the scattered electric field is given by

$$U^s = \frac{e^{ikr}}{r} \int_V F(\mathbf{x}) e^{i(\mathbf{k}_i - \mathbf{k})\vec{r}} \, d^3x \,. \quad (5.109)$$

The theory is limited to smooth surfaces, but iterative use of (5.109), as described in [5.54], allows its extension to rougher surfaces.

Unfortunately, the spatial distribution of the refractive index must be known. This is a problem and thus the elegant (5.109) has its limits. Therefore, TIS and ARS measurements are mainly used for describing the scattering of rough surfaces.

5.1.9 Other Effects

In addition to the previously discussed "classical" optical material properties:

- (non-)linear refractive index
- absorption coefficient
- emission cross section
- scattering cross section

there exist numerous effects which occur in optical materials when additional physical fields such as:

- quasi-DC electric field
- quasi-DC magnetic field
- mechanical stress

additionally influence the optical properties of the solid. From these phenomena, the resultant electro-optical and piezo-optical effects are described below.

For some optical materials, incoming light of certain intensity or energy causes (quasi-)permanent changes in optical properties. The unwanted effects of solarization and laser damage are described in Sect. 5.4. On the other hand, the desired permanent property changes one can encounter are:

- photochromism
- photorecordability
- photorefractivity.

Photochromism is briefly introduced here while photorecordability and photorefractivity are extensively discussed in Sect. 5.9.3.

The Electro-Optic Effect

The electro-optic effect [5.63] (Pockels effect) in special crystalline optical materials is the change in the indices of refraction of the ordinary and extraordinary rays (Sect. 5.1.4) that is caused by and is proportional to an applied electric field. The electro-optic effect was discovered by Roentgen and was extensively investigated by Pockels around the turn of the nineteenth century. In principle, the electro-optic effect is a special case of nonlinear optical behavior, where the perturbing electromagnetic field is of quasi-DC type.

The electro-optic effect provides a convenient means of controlling the intensity or phase of the propagating radiation. The linear effect can be characterized by a perturbative expansion of the dielectric tensor (see Sect. 5.1.4)

$$\varepsilon_{ij} = \varepsilon_{ij}^0 + \Delta\varepsilon_{ijk}^E E_k \,, \quad (5.110)$$

where ε_{ij}^0 describes the electric-field-independent contribution to the dielectric tensor and $\Delta\varepsilon_{ijk}^E$ is the first derivative of ε_{ij} with respect to each component k of the applied electric field E.

From symmetry arguments similar to the consideration in Sect. 5.1.4, the 27 different coefficients $\Delta\varepsilon_{ijk}^E$ collapse to only 18 parameters, because $\Delta\varepsilon_{ijk}^E = \Delta\varepsilon_{jik}^E$.

Table 5.5 Properties of most important electrooptical materials (after [5.63])

Material	Electrooptic constant r_{63} (pm/V)	Typical half-wave voltage at 546 nm (kV)	Approximate n_o
Ammonium dihydrogen phosphate (ADP)	8.5	9.2	1.526
Potassium dihydrogen phosphate (KDP)	10.5	7.5	1.51
Potassium dideuterium phosphate (KD*P)	26.4	2.6–3.4	1.52
Potassium dihydrogen arsenate (KDA)	10.9	6.4	1.57
Rubidium dihydrogen phosphate (RDP)	11.0	7.3	
Ammonium dihydrogen arsenate (ADA)	5.5	13	1.58
Fig. 5.36 Longitudinal electrooptical modulator (after [5.63])

These coefficients can be measured and provide the information necessary to compute the electrically induced birefringence. Some of the materials which exhibit the electro-optic effect and are used in electro-optic devices are listed in Table 5.5.

A potassium dihydrogen phosphate (KDP) longitudinal modulator is illustrated in Fig. 5.36. When no voltage is applied, the indices of refraction for the ordinary (o) and extraordinary (e) rays are identical along the optic axis. The incoming beam is plane-polarized with the plane of polarization aligned to the x- or y-axis. When a voltage is applied parallel to the light beam the crystal becomes birefringent. The extraordinary ray is retarded with respect to the ordinary ray and, upon emerging from the output face of the electro-optic crystal, the two polarized beams have acquired a relative phase shift due to the retardation of the light in the plane of the slow axis – resulting in an elliptically polarized beam. The retardation is given by

$$\Phi_{\mathrm{eo}} = \frac{n_{\mathrm{o}}^3 \Delta\varepsilon_{123}^{\mathrm{E}} U}{\lambda} \ , \tag{5.111}$$

where Φ_{eo} is the number of wavelengths of retardation, n_{o} is the ordinary index of refraction, $\Delta\varepsilon_{123}^{\mathrm{E}}$ is the electro-optic coefficient (μm/V), U is the applied voltage (V), and λ is the wavelength of incident light (μm). For the value $\Phi_{\mathrm{eo}} = 1/2$, $U = U_{1/2}$ is defined as the half-voltage (see Table 5.5).

A transverse electro-optic effect is also exhibited by some crystals. In this case the birefringence changes are induced by a voltage applied transversely to the beam propagation.

Materials of prime importance concerning electro-optic properties are ADP, KDP, KD*P, KTN, LiNbO$_3$, LiTaO$_2$, Ba$_3$NaNb$_5$O$_{15}$, Sr$_x$Ba$_{1-x}$Nb$_2$O$_6$, CuCl, ZnSe, hexamethylenetetramine, and Se. Some materials have a quadratic rather than linear electro-optic effect. That is, the retardation is proportional to the square of the applied voltage. Among these are strontium titanate, potassium tantalate, and KTN.

Piezo–Optic Effect

The Piezo-optic effect [5.63] is analogous to the electro-optic effect. When pressure is applied to a piezo-optic crystal, the birefringence of the material changes. Some of these piezo-optic crystals are originally isotropic and cubic, but when stressed become birefringent. If such a crystal is stressed in a direction perpendicular to a light beam, the phase retardation is proportional to the stress. This effect is applied in acoustooptic modulators. These devices function based on the fact that refraction and diffraction effects occur when light passes through a solid medium transversely to a high-frequency (ultrasonic) acoustic field propagating in the same medium. The interaction can affect the deflection, polarization, phase, frequency or amplitude of the optical beam. Ultrasonic waves range from 10^5 Hz (above the upper range, approximately 2×10^4 Hz, of the human ear) to 10^9 Hz. Light passing through such a crystal in a direction transverse to the acoustic-wave direction is modulated by the wave.

Table 5.6 lists some of the more important acoustooptic materials and their characteristics. There are many figures of merit used in comparing these materials, two that are commonly employed are

$$F_1 = \frac{n^6 (\Delta\varepsilon^{\mathrm{P}})^2}{\varrho v^3} \ ,$$

$$F_2 = \frac{n^7 (\Delta\varepsilon^{\mathrm{P}})^2}{\varrho v} \ , \tag{5.112}$$

where n is the optical index of refraction, $\Delta\varepsilon^{\mathrm{P}}$ is the appropriate component of the photoelastic tensor (analogous to $\Delta\varepsilon^{\mathrm{E}}$ in the electro-optic effect), ϱ is the mass density, and v is the acoustic phase velocity. Since $\Delta\varepsilon^{\mathrm{P}}$, v, and ϱ exhibit no extreme variations in the various acoustooptic materials, the candidates of most interest are those with good optical and acoustic qualities with large n, although optical and acoustic parameters are not included in the figures of merit.

In Table 5.6, the longitudinal (L) wave is one where the displacement u is parallel ($\parallel$) to the acoustic wave propagation direction ($\boldsymbol{k}$ vector), whereas the transverse (T) wave is one where the displacement u is normal ($\perp$) to the acoustic-wave propagation direction ($\boldsymbol{k}$ vector).

The polarization of the optical wave is defined as parallel (∥) or perpendicular (⊥) to the plane formed by the acoustic and optic **k** vectors.

Photochromism

As discussed in the previous subsections, the interaction of electromagnetic waves with matter is generally

Table 5.6 Properties of most important piezooptical materials (after [5.63])

characterized by terms such as dispersion, absorption, scattering, refraction etc. Here we deal with absorptive effects which are induced in optical solids by the electromagnetic waves themselves.

Electromagnetic waves can cause electronic transitions from one state to another, create new particles or quasi-particles, or excite vibrations of ions and ensembles of charged particles. These effects are well-known absorption mechanisms. Obviously, the absorption spectrum depends on the electronic and ionic configuration. Consequently, the transition from one electronic or ionic configuration into a different configuration necessarily changes the absorption spectrum of the system under consideration. The control of the absorbance spectrum of any material by photons is called photochromism [5.64], regardless of the spectral range in which the absorbance is changed and regardless of the energy of the photons that induce the photochromism. Following this definition, a rich variety of possible effects exists that can be exploited for photochromism: the famous transition of F-centers into Q- and F′-centers or, more generally, the transformation from one to another color centre by illumination, the photon-induced orientation of color centers (photodichroism), the spectral hole burning as well as photon-induced polymerization or decomposition of compounds and photon-induced bleaching of absorption bands for Q-switching of a laser, just to name a few.

The change in the absorption spectrum, however, is hard to see if it occurs in a spectral region with a large absorption constant. Therefore, one must focus on materials and spectral regions where both the absolute and relative change of the absorbance is large if one wants to exploit the corresponding effect of photochromism

for technical applications. Challenging mass applications of photochromic effects are optical data storage and "smart" windows (see Sect. 5.8.3). However, several qualitative and quantitative requirements must be fulfilled; for instances the requirement of special spectral ranges optimized both for the inducing photons and for the induced absorbance is very important in many applications. It is equally important to discern whether the effect is reversible spontaneously or under irradiation, whether it shows fatigue, and how efficiently the absorption spectrum changes per incident photon. As a consequence, the photon-induced control of the absorbance – which is obviously very intriguing from a theoretical point of view – is reduced to only a few applications in practice.

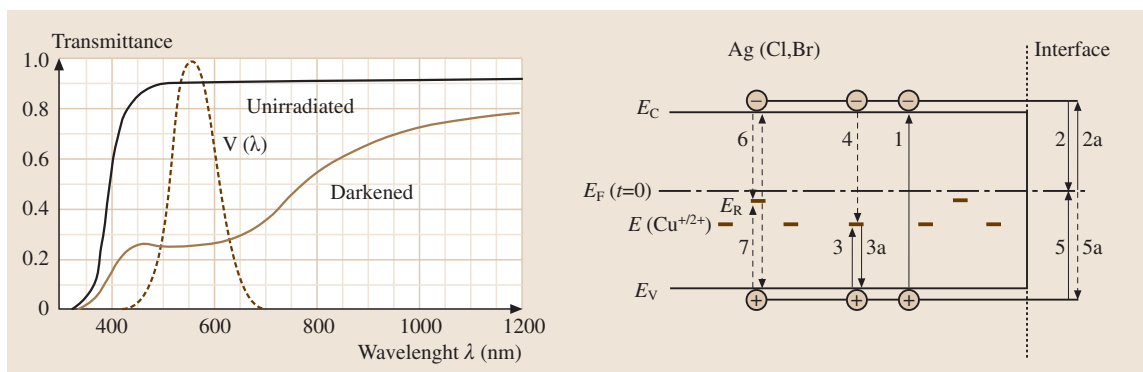
The most prominent and widespread application of a photochromic effect seems to have occurred in photochromic eye-glasses (see Fig. 5.37 left). Although photochromic effects have long been known to occur in glasses, the basis of a material which is useful for photochromic sunglasses was developed by *Armistead* and *Stookey* [5.65] in the 1950s and 1960s. These scientists introduced silver halides into suitable glass melts and succeeded in forming small silver halide precipitates or particles in the glass. The basic effect, namely the photolytical decomposition of silver halides, is very well known in chemistry. In a test tube, the silver halide is decomposed into Ag clusters, which are responsible for the absorbance in the visible spectral region, and volatile halogens. The photolytical decomposition is not reversible in a test tube, however, if the halogens can escape. In a glassy matrix, on the other hand, the photolytic decomposition products remain close together and can recombine into silver halides. The chemical and phys-


Fig. 5.37 *Left*: Transmittance of a commercially available photochromic glass as a function of wavelength before and under solar irradiation after about 15 min. *Right*: Energy band diagram of different photoelectronic processes which can occur in the silver halide particles at the interface between halide particle and vitreous glass matrix. (after [5.64])

ical details of the photochromism of glasses doped with silver halides (Fig. 5.37 right) have been discussed e.g. in [5.64].

Besides silver halides, many other different compounds can be decomposed due to light changing their absorption spectra under irradiation. To list a small ar-bitrary selection of inorganic systems, we mention the Pb-, Cu-, and Cd-halides, the transition metal oxides, and some other compounds. However, most systems are interesting only from a scientific point of view and have little technical potential – or other practical disadvantages reduce their applicability.

5.2 Optical Glass

Every discussion about optical glass, especially an intensive one such as that following, has to start with the definition of the term *optical glass* and its delimitation from other possible types of glasses, e.g. filter glass, technical glass and others.

(Classic) optical glass is the traditional generic term for all glass types which possess the ability to influence the path of transmitting electromagnetic rays in the region between 200 nm to 1500 nm, e.g. to guide light [5.66]. This optical effect, and therefore the optical glass type itself, is usually fixed by the two main optical values: the refractive index (n_d) and the Abbe number (v_d, 1/dispersion) at the wavelength of the spectral d-line (587.6 nm, yellow helium line) [5.66, 67]. The relevant optical range was traditionally seen between $n_d = 1.38 - 2.20$ and $v_d = 18 - 100$. However, actual application trends lead to less extreme regions, so a reduction to $n_d = 1.40 - 2.00$ and $v_d = 20 - 90$ seems to be as suggestive as the prefix "classic". This prefix preserves the delimitation from other types, nowadays often declared as subgroups of optical glass, e.g. color and filter glass and active optical glass. Here this prefix will be neglected, the term optical glass always refers to the aforementioned traditional definition.

Accordingly, optical glass is mainly used for components (lenses, prisms) in light-guiding application fields where there are imaging optics (microscopy, photo objectives, etc.), (digital) projection (color management systems, beamers, cinema objectives), telecommunications (hosting for active elements, ball, and rod lenses, graded index lenses, lens arrays), optical communications engineering (light and image fiber guides, data pick-up systems, read–write systems) and laser technology (laser optics, hosting for active elements).

An overview of available optical glass types is usually given in optical-glass diagrams, wherein they are specified by their two main optical values n_d/v_d only. Those diagrams, provided (currently even by internet) by all well-known glass manufacturers (Schott [5.66], Ohara, Hoya, Sumita, Pilkington, in former times Corning), itemize the glasses independently of possi-ble applications and other optical and physico-chemical properties. Up to now they are divided into historically developed sections, see for example Fig. 5.87.

5.2.1 Chronological Development

The first known optics shops and the early optical industry (ophthalmic, astronomy and microscopy) suffered from the lack of well-defined, reproducible optical glass. To cut a long story short, they had to take and to work with what they obtained from more or less irreproducible pot melts which suffered from poor raw material purity and availability. In addition to the poor optical quality of materials produced in this way, there did not exist any assured knowledge about the relation between composition and properties. At most, raw materials and their effects could be classified by supplier [5.68, 69].

Increasing chemical knowledge allowed the identification of raw material additives and impurities. This enabled, in combination with increasing abilities in chemical separation, the first relations between composition/compounds and properties/defects to be developed. This in turn allowed for the defined adjustment of optical properties, whereas until that time attention was tuned only by the optical position, i.e. the explicit values of n_d/v_d as mentioned above. Otto Schott, a German chemist from a family of glass makers, was the first to investigate the composition/property relation with scientific methods and achieved a fundamental knowledge about melting consistent predeterminable glasses. Ernst Abbe and Carl Zeiss, owners of a firm for high-quality optical instruments, recognized the advantages for their business and, by association with Schott, easily emerged to be the most successful in their profession [5.69].

Prior to 1880, only simple crown and flint glasses were known (approximately 30 types) [5.70]. Crown glasses, consisting of soda–lime silicates, exhibit low refractive indices and high Abbe numbers, although from a current point of view the Abbe numbers would be better judged as moderate. Flint glasses [5.71], with high refractive indices and low Abbe numbers, were

represented solely by lead alkali silicates. The modern borderline between flint and crown is defined by the Abbe number, with flint glasses having $\nu_d < 50$ at $n_d > 1.60$ and $\nu_d < 55$ at $n_d < 1.60$. At that time, the distinction resulted naturally via composition.

From 1880, Otto Schott enlarged the glass map by establishing two new glass formers besides silicate: fluorine (very high ν_d and low n_d) and boron (moderate n_d/ν_d). Additionally he started to work with network modifiers by using BaO as a compound (moderate ν_d, high n_d). So, a variety of new glasses with a broader range of optical positions was generated, which led to the additional classifications: heavy (high refractive index) and light (low refractive index) besides crown and flint (the indication of dispersion/Abbe number) [5.72].

Around 1930 a new era in glass development started, when compounds such as rare earths (especially lanthanum), titania, zirconia and the additional network former phosphorous could be obtained and used in sufficient quantity and quality [5.73, 74]. These glasses led to further new optical positions, whose regions in the Abbe diagram were named by adding the new compound's chemical symbol to the traditional heavy/light crown/flint nomenclature, e.g. PSK (phosphorous heavy crown, the German *phosphor schwerkron*) or LaSF (lanthanum heavy flint, the German *Lanthanschwerflint*) [5.72].

In this context, it is easy to understand that a strong correlation between optical position (n_d/ν_d) and composition evolved, which led to the historical borders in the Abbe diagram and optically defined glass families. Hence, a glass's name, only defined by its optical position followed by a consecutive number, gave strong hints towards its composition.

Even though these boundaries have been valid until now, this strong correlation no longer exists because of the availability of highly pure (classical) raw materials and the accessibility of other, new raw materials obtained through new ways of mining, cleaning, purification etc.. Therefore, it is now possible to reach one optical position by several base-glass compositions, which leads to an increased number of compositional glass families with strong overlaps that cross the traditional boundaries. As a result, the information given by the glass type name (e.g. PSK 54) no longer provides reliable information about the components and glass family and thus about their properties. In this case, one cannot be sure about the existence of phosphorous, because, for example, PSK types can be obtained with and without phosphorous. And though both of these glass families occupy the same optical position

(e.g. Schott's N-LaSF 31A, Hikari's E-LaSF 08 and Hoya's TaFD 30), their physico-chemical properties are quite different (chemical resistance, Knoop hardness, temperature–viscosity profile, etc.).

It remains to remark that mainly the Japanese glass manufacturers Ohara and Hoya recently diverged from this traditional nomenclature and implemented their own representative system of glass naming. Nevertheless they maintained the traditional borderlines in the Abbe diagram.

5.2.2 Compositions of Modern Optical Glass

Today we know of more than 300 different types of optical glasses that can be classified by their chemical composition Figs. 5.38 and 5.87, and Table 5.37). Because of better raw material availability, there exist more than several compositional methods to reach an optical position. Deviation from the traditional base systems and known compositions is often useful because of current enhanced glass-development specifications. Those specifications comprise customer- and process-referred profiles in which it is not unusual to find up to 15 properties, besides the well-known pure optical-position

Fig. 5.38 Today, optical glasses with high quality exist in a broad range of shapes and products

Fig. 5.39 Glass systems of optical glass in the n_d/ν_d plot

specification. Commonly specified properties belong to the following fields:

- *application*: T_g, CTE, specific density, spectral transmission, chemical resistance, solarization, compaction, birefringence coefficient, fracture behavior;
- *pollution control and operational safety*: chemical and thermal reactivity of batch and raw materials, environmental impact of raw materials (mining, cleaning, use, application);
- *melting and hot forming*: viscosity–temperature profile, CTE, adjustment to standard processes, crystallization, aggressiveness against fireproof material;
- *cold working*: CTE, stiffness, hardness, fracture behavior, abrasion rate, chemical resistance;
- *patent law* (very active international patent awareness): adaptation of compositions to relevant legal surrounding, including variations, admixtures, etc.

Increasingly a transition has occurred from developing a) as far as possible an optimized glass out of the traditional optical glass families to b) specially designed single glasses for specific application or process fields arranged on the Abbe diagram only for traditional reasons. Therefore only the most important base systems, as shown in Fig. 5.39, will be discussed in detail.

1. $SiO_2-B_2O_3-M_2O$

This system is formed by the network formers SiO_2 and B_2O_3. Alkaline oxides (M_2O) have been introduced as network modifiers. The presence of B_2O_3 and alkaline oxides is essential, as the glass-forming oxide SiO_2 has melting temperatures that are too high for conventional melting techniques. The addition of B_2O_3 and alkaline oxides facilitates the meltability of these glasses. The optical glass BK 7 is one of the main representative glasses of this system. It is the optical glass

most frequently used and can be produced with extreme homogeneity.

2. $SiO_2-B_2O_3-BaO$ and 3. $SiO_2-BaO-M_2O$

If BaO is used as the main network modifier instead of the alkaline oxide or B_2O_3, this results in two large glass systems. In contrast to other earth-alkaline network modifiers, the introduction of BaO has various advantages. Besides PbO there is no other divalent oxide that increases the refractive index as strongly as BaO. Additionally, BaO neither decreases the Abbe number nor shifts the UV transmission edge significantly to greater wavelengths as PbO does. BaO-containing glasses normally show good abrasion hardness. In some glasses, BaO is partly replaced by ZnO.

4. $(SiO_2, B_2O_3)-M_2O-MO$

To obtain glasses of this glass system, divalent oxides (MO) are exchanged for B_2O_3. From the divalent oxides only CaO, ZnO, and PbO are used in this system. For the production of glasses with high chemical resistance and good crystallization stability, ZnO is particularly important since it increases durability with respect to water and acids much more than CaO, provided that the ZnO content exceeds approximately 10 wt %. It is also possible to reduce the melting temperatures by a simultaneous exchange of ZnO for SiO_2 and to increase the alkaline content without harming durability against weathering. In terms of these characteristics, ZnO is much more effective than B_2O_3. The use of CaO leads to the production of glasses with good mechanical properties and increased abrasion hardness. The chemical durability of these glasses increases with increasing CaO content.

5. $(SiO_2, B_2O_3)-BaO-PbO$

This glass system is a mixture of the glass systems $SiO_2-BaO-M_2O$ and $SiO_2-PbO-M_2O$. Thus these glasses represent a transition from one glass system to the other. In the system $SiO_2-BaO-M_2O$, the exchange of PbO for BaO leads to the production of glasses with a lower tendency to crystallize. Compared with similar BaO-containing glasses, PbO-containing glasses are characterized by lower softening points and higher expansion coefficients. In some glasses of this system, BaO is partly replaced by ZnO.

6. $SiO_2-PbO-M_2O$

Glasses of this system have been known for a very long time. They are widely used for optical glasses and crystal glasses. As a glass component, PbO plays a vital role because on the one hand it increases the refractive in-

dex and on the other it decreases the Abbe number very strongly. Furthermore, PbO significantly affects the partial dispersion of glasses since a high PbO content leads to a positive deviation from the "normal line". High amounts of PbO lead to a high glass density and a rather low chemical resistance, but effects an interesting birefringence coefficient near zero. PbO can be introduced into glasses at more than 80 wt %, which indicates that it does not only have network modifying properties. Normally, if a network modifier is introduced into a glass, e.g. Na_2O into a SiO_2 glass, bridging oxygen atoms are converted into non-bridging oxygen atoms:

$$-Si-O-Si- + Na_2O$$
$$\Rightarrow -Si-O-Na^+ + Na^+-O-Si-.$$
With an increasing content of network modifiers the network progressively weakens and the viscosity of the glass melt decreases. If the content of the network modifiers is increased further, more and more bridging oxygen atoms are converted into non-bridging atoms. For a ratio of network modifiers to network formers of about 1 : 1, a three-dimensional network can no longer be formed and glass formation becomes impossible. However, the glass-forming tendency of binary $PbO-SiO_2$ systems leads to a PbO content of more than 70 mol %. According to *Zachariasen* [5.75, 76] and *Warren* and *Loring* [5.77] these glasses would normally not exist if PbO was only a network modifier. *Fajans* and *Kreidl* [5.78] and *Stanworth* [5.79] explained how the introduction of such a high amount of PbO is possible. In small concentrations, PbO has the same function as any other network modifier. High concentrations of PbO, however, cause an increase in the formation of $[PbO_4]$ tetrahedra. These $[PbO_4]$ tetrahedra can act as network formers and are incorporated into the three-dimensional network. Glasses that contain large amounts of PbO are usually more or less yellow in color. Impurities, such as Fe_2O_3 or Cr_2O_3, have very strong effects on the color of PbO-containing glasses, even stronger than in soda–potash–lime glasses. It was further found that, first, besides the different structures of the PbO-containing glasses, there exists an equilibrium between Pb^{2+} and Pb^{4+} and, second, brown PbO_2 is formed if the melt is supersaturated with oxygen. Unlike the yellow color that is due to impurities, the yellow tint caused by the equilibrium between Pb^{2+} and Pb^{4+} can be reversed by a variation of the redox condition of the melt. For a long time, attempts have been made to increase the chemical stability of optical glasses with high PbO contents. Replacing parts of the PbO content with TiO_2 (in the range of some wt%) has been a common method

to increase the chemical durability. A sufficient TiO_2 content not only improves the chemical durability but, unfortunately, also leads to a transmission loss in the UV range. A solution to this problem is reached by replacing parts of the PbO content with both TiO_2 and ZrO_2. The chemical durability is improved and the optical properties of the original glass ($SiO_2-PbO-M_2O$) are again obtained.

7. $P_2O_5-MO-B_2O_3-Al_2O_3$

Glasses in which P_2O_5 acts as a network former have been known for a long time. P_2O_5 forms glasses with rather low dispersions (high Abbe numbers) and high refractive indices, compared with the classic glasses based on B_2O_3 or SiO_2. Glasses with a high P_2O_5 content have long dispersion spectra in the blue range. These glasses are normally used to correct chromatic aberration. The second and very important property of glasses containing P_2O_5 is their low birefringence coefficient and excellent UV transparency. A disadvantage of phosphate glasses is that their chemical durability is poor compared with the durability of SiO_2-based glasses.

8. $P_2O_5-Al_2O_3-MO-(F_2-O)$

In order to obtain glasses with lower dispersions than those of phosphate glasses, one can introduce fluorine. Most of these glasses are based on a $P_2O_5-Al_2O_3-MO$ glass system which contains high amounts of fluorine. This glass system shows a relatively high chemical durability and a relatively low devitrification tendency. Fluorine takes the places of oxygen atoms so that one oxygen is replaced by two fluorine atoms. The formation of the fluoro-phosphate glasses of this system is rather complex and can be described with amorphous fluoro-alumino-phosphates. As fluorine has a smaller ionic radius and a higher electronegativity than oxygen, the polarization of the cations in these glasses is increased so that the refractive index and the dispersion are decreased. The replacement of oxygen by fluorine leads to glasses that have distinct LgK characteristics, which leads to a long spectrum in the blue spectral region, a significantly positive $\Delta P_{g;F}$ (partial dispersion deviation coefficient) and hence the aptitude for correcting achromatic aberration in combination with a KzF(S) type (short flint) with a short spectrum in the blue spectral region (negative $\Delta P_{g;F}$). The term LgK was neglected for a long time in favor of the systematic terms FK (fluoro crown) and PK (phosphate crown) which both indicate the optical position of fluoro-phosphate types (see Abbe diagram).

9. $(B_2O_3, SiO_2)-La_2O_3-MO$

In connection with B_2O_3, glasses containing large amounts of La_2O_3 form a very extensive glass system. Glasses belonging to this system normally have a high refractive index with a relatively low dispersion. As their chemical resistance is rather poor, their durability can be increased by replacing SiO_2 with B_2O_3 and by the introduction of divalent oxides. In addition, the introduction of ZrO_2 and TiO_2 is another possibility for achieving better chemical properties. In the past, ThO_2 and CdO have also been used to achieve this aim, but for environmental protection these oxides have been eliminated from these glasses. The large disadvantage of these glasses is their poor crystallization stability, especially if SiO_2 is used.

10. $B_2O_3-La_2O_3$

These glasses are based on the $B_2O_3-La_2O_3$ glass system. They all have high refractive indices and high dispersion. In order to obtain high refractive indices, large numbers of oxides that are known to cause a high refractive index, such as Gd_2O_3, Y_2O_3, TiO_2, Nb_2O_5, Ta_2O_5, WO_3, and ZrO_2 are incorporated in the glasses of this system. The large number of network modifiers leads to glasses whose viscosities depend to a high degree on temperature (i. e., they are called short) and which show a very strong tendency to crystallize. On the other hand, these glasses have a distinct hardness and chemical resistance, which increase further with higher refractive indices. In this respect, the glasses differ from those of the system $SiO_2-PbO-M_2O$, which also have a high refractive index.

11. $SiO_2-Sb_2O_3-B_2O_3$

The replacement of PbO by Sb_2O_3 leads to an extensive glass system. Sb_2O_3 reduces the dispersion of the blue part of the visible spectrum. Consequently, short-flint glasses are obtained. The introduction of Sb_2O_3 into a glass gives results similar to those in the case of PbO, although Sb_2O_3 glasses seem to form long chains of $-Sb-O-Sb-O-$ units [5.80].

12. $B_2O_3-PbO-Al_2O_3$

If SiO_2 is replaced by B_2O_3, glasses with primarily very poor chemical properties are obtained. Glasses of this system have an intensive short-flint characteristic, since the PbO content induces absorption in the blue range of the visible spectrum, and B_2O_3 causes strong absorption in the infrared range of the spectrum. Al_2O_3 is added to improve the chemical properties to an acceptable level.

13. $SiO_2-M_2O-TiO_2-(F_2-O)$

The PbO content in glasses of the system SiO_2-M_2O-PbO can be replaced by TiO_2. As TiO_2 causes an increase in the refractive index, glasses of the system $SiO_2-M_2O-TiO_2-(F_2-O)$ are characterized by high refractive indices. The dispersion of these glasses is increased to a higher degree than that of glasses containing the same amount of PbO. The introduction of TiO_2 into glasses is limited, because when the TiO_2 content is increased the glasses tend to crystallize strongly. This should be avoided by the introduction of alkaline oxides into the glass. In spite of the large content of alkaline oxides, these glasses are highly resistant to the influences of water and acids. Glasses with high TiO_2 contents show strong absorption in the UV range. This absorption is stronger than that of glasses containing PbO or Sb_2O_3. Both glass types are characterized by a positive deviation of the partial dispersion from the normal line.

The break up of traditional glass families into ambitious, multi-property specified designer glasses led to rethinking, and thereby to new methods, in glass development. The well-known stepwise successive method has (where suggestive) now been replaced by an intensive field-screening method supported by computer-assisted statistical experimental design (SED; multi-linear regression-driven analysis).

This breaking of traditional borders and innovation concerning methods and materials is the reason for drastic changes in the assortments of optical glasses during the last five to ten years. First, the environmentally driven conversion to lead- and arsenic-free optical glasses took place [5.81] (see next section). In combination, a simplification of the assortments has been carried out. Old glass types with small market volume have been eliminated and high-performance glasses which were offered by several glass manufacturers were slightly redesigned to be optical interoperable. This led to a remarkable shrinking of the available glass assortment. In contrast the development of new glass types with opportunity for less crystallizing types and better application- and production-fitted glasses expanded the list of available glasses. Presumably, this will proceed in cycles in the future.

5.2.3 Environmentally Friendly Glasses

New recipes for many traditional optical glasses have recently been developed by all the major glass suppliers to make them ecologically friendly. The primary elements of attention in the development of ecologically friendly optical glasses are arsenic and lead, although other toxic elements have also required attention. For example, in 1980, the use of ThO_2 was stopped completely and the use of CdO was restricted to colored optical glass.

In the late 1980s, when the public became increasingly sensitive to health problems caused by Pb, the whole glass-producing industry started developing PbO-free glasses as a first step towards the production of environmentally friendly glass. Apart from the health aspect, the reduction and replacement of PbO in the glass composition led to a considerable weight reduction, which is advantageous in several respects for outdoor applications. Since 1995 the use of another substance, As_2O_3, has been restricted; it is used as a refining agent in trace amounts only. With the intention of replacing PbO and As_2O_3, the glass manufacturers initiated a comprehensive program that has not yet been completed [5.81].

The main target has been to redesign all glass types so as to preserve n_d and v_d while gaining a Pb- and As-free composition. Moreover, the partial-dispersion values $P_{g,F}$ and $\Delta P_{g,F}$ have been preserved for several special glasses. There are, however, some special glasses whose optical properties cannot be preserved without the addition of PbO. Of course, these glass types will be available in the future in their known quality and composition. They will be clearly marked as Pb-containing products. The bio-availability of the pure toxic substances in the products that are finally sold is negligibly low. For example, even high amounts of PbO in the composition of a glass would not cause any health problems. But although there is no objective reason, the customers' negative associations regarding Pb or As lead to a strong rejection of products containing these substances. There are, however, serious problems caused by hazardous compounds that make expensive and time-consuming development necessary. High amounts of fine dust are produced during acquisition of the raw material and during batch preparation. Of course, the dust does not contain a higher percentage of toxic substances than the base material, but it has a very much larger specific surface. This large surface in combination with the fact that dust tends to deposit in the lung tissue in large amounts causes a bio-availability of the toxic compounds that is in the latent-toxic range. High yields of grinding waste result from finishing processes, particularly from grinding and polishing. These must be disposed of at high costs on hazardous-waste disposal sites. Experience in this field shows that there is a high risk of incorrect handling and a tendency towards illegal disposal be-

cause of the high costs. Improving technical measures to protect directly affected persons from the unhealthy effects of dust and waste is theoretically possible, but hard to control. In particular in foreign production, for example in developing countries, safety could not be guaranteed [5.81].

For these reasons, there has been a tendency to dispense with these substances and to use TiO_2, Nb_2O_5, ZrO_2, WO_3 and others instead of PbO and As_2O_3 as a refining agent is replaced by Sb_2O_3. All glass compositions reformulated in this way are designated by a prefix to the original name, e.g. "N-" with Schott, "E-" with Hikari, "S-" with Ohara. For 50% of all glass compositions originally containing As_2O_3 but no PbO, replacing As_2O_3 by Sb_2O_3 does not change their properties.

For the compositions originally containing As_2O_3 and PbO (up to 80%), some physical and optical properties are significantly changed upon the replacement of both elements. Besides improvements, these changes also include some disadvantages. Improvements are: better chemical resistance; higher Knoop hardness; higher T_g point; lower density. Disadvantages are: higher tendency of crystallization; higher T_g, reduced transmission in the UV region; changed values for $P_{g,F}$ and $\Delta P_{g,F}$ (except for the N-KzFS series).

5.2.4 How to Choose Appropriate Optical Glasses

In this section practical guidelines for choosing appropriate glasses for optical applications are given. As stated above, optical glasses are ranked by refractive index and dispersion. However, during this selection process, not only the optical properties but also mechanical and chemical properties should be considered. We present each mechanical and chemical property individually along with a brief explanation of its importance.

Transmission and Absorption
Absorption in optical glass can be expressed in a number of ways and the reader is referred to Sect. 5.1.3 of this text for a more rigorous treatment. We simply state here that most optical glass manufacturers list for their glasses internal transmission values that neglect the losses from reflection at air–glass interfaces, and absorption values are thus conveniently calculated according to $\alpha = -\ln(\tau_1/\tau_2)/\Delta x$, where τ_1 and τ_2 are the internal transmission values for samples of thickness x_1 and x_2 ($x_1 > x_2$), Δx is the difference in thickness between the two samples, and α is the absorption coefficient (expressed in units of cm^{-1} when x is in cm).

Partial Dispersion
Since the refractive index varies with wavelength, not all colors are focused at the same point with a simple single-component lens. This effect is referred to as chromatic aberration. For the fabrication of optical systems, achromatic and apochromatic systems are often employed. In an achromatic system, chromatic aberration is minimized for two colors, e.g., red and blue. The other part of the visible spectrum remains uncorrected and is referred to as the "secondary spectrum". The chromatic aberration in an apochromatic system, however, is corrected through the whole visible region. Most optical glasses show normal dispersion where the partial dispersion of refractive index varies nearly linearly with the Abbe number. These glasses are not suitable for the construction of apochromatic systems. Therefore, glasses that deviate from this normal dispersion behavior are required for the construction of apochromatic systems. As a result, glasses with a high dispersion (short) in the blue region of the visible spectrum have been developed. Deviation of partial dispersion from the normal, or linear, behavior is described by a series of partial dispersion deviation coefficients, $\Delta P_{X,Y}$, where X and Y indicate the wavelengths of interest.

Photoelastic Constants
The refractive index of glasses is altered by the application of stress. The change is generally different for light linearly polarized in a plane parallel to the direction of stress than for light linearly polarized perpendicular to the stress. The magnitude of the change is given by

$$n_\parallel = n_0 + K_\parallel S \quad \text{and } n_\perp = n_0 + K_\perp S \qquad (5.113)$$

where n_0 is the refractive index in the absence of applied stress, S, and $K_\parallel$ and $K_\perp$ are the photoelastic constants and $n_\parallel$ and $n_\perp$ are the refractive indices for light linearly polarized parallel and perpendicular to the direction of stress, respectively. The commonly used stress optic coefficient (K) is the difference between the two photoelastic constants.

Thermal Expansion
Inorganic glasses expand upon heating and shrink upon cooling. The coefficient of linear thermal expansion α is defined as $\alpha = \Delta L/L_0\Delta T$, where ΔL is the change in length of a material of length L_0 that experiences a temperature change of ΔT. The value of α is generally a function of temperature. The coefficient of thermal expansion values found in optical glass catalogs represent only a linear fit and care must be taken when comparing

two glasses that the expansion information is taken over the same temperature range.

Thermal expansion is an important property since it is one indicator of the extent to which a particular glass will be prone to thermal fracture. Higher expansion values are generally an indicator that a glass is relatively weak against thermal shock.

Transformation Range

The thermal expansion curve for glasses begins to deviate significantly from a roughly linear shape over a temperature interval referred to as the transformation range. Other temperature-dependent glass properties also change rapidly with temperature over this same range. In addition, if cooling through this range takes place rapidly or unevenly, permanent residual stresses can be imparted to the glass due to unequal amounts of thermal contraction.

The transformation temperature, T_g, is found in glass catalogs and can be used as an indication of where the transformation range exists and what processing or environmental temperatures need to be avoided to avoid changes in surface figure or the creation of residual stresses that can reduce the quality of a transmitted optical wavefront through stress birefringence effects. In this regards, as a rule of thumb, parts should not be heated above a value of $T_g - 200\,°C$.

Softening Point

Similar to the transformation temperature discussed above, another characteristic temperature for glass is the temperature at which the glass begins to deform under its own weight. The corresponding material viscosity is $10^{7.6}$dPa.

Thermal Properties

Additional thermal properties include heat capacity, c_P, and thermal conductivity, λ. The former provides information on the quantity of heat, $\mathrm{d}Q$, required to raise the material temperature by an amount $\mathrm{d}T$: $c_P = \mathrm{d}Q/\mathrm{d}T$; and the latter on the heat flux, Q, that will pass through a slab of material of thickness L, in a time period t, when placed across a thermal gradient generated by a temperature difference ΔT; $\lambda = QLt/\Delta T$. Another thermal property found in some optical glass catalogs is the thermal diffusivity K, which is related to the thermal conductivity, heat capacity and glass density ϱ by $K = \lambda/\varrho c_P$.

All three thermal properties discussed above have a weak dependence on temperature up to values just below the transformation range. As with thermal expansion

information, comparison of glasses in critical situations requires that property information be stated at the same temperature.

Elastic Properties

When a glass bar is placed under tension it stretches. The amount of stress, S, and strain, ε, experienced by the bar are related by $S = E\varepsilon$ where E is the Young's modulus of the material (i. e. Hooke's law). The ratio of lateral to longitudinal stress in the bar is Poisson's ratio, μ. In the case where a compressive stress is applied, the proportionality constant between stress and strain is now the bulk modulus, K. Finally in the case of an applied shear stress, the proportionality constant is the shear modulus, G.

Young's modulus and Poisson's ratio values are typically provided in optical glass catalogs. These elastic constants are interrelated such that if any two are known the remaining pair can be readily calculated. We have for example, $K = E/[3(1 - 2\mu)]$ and $G = E/[2(1 + \mu)]$.

Hardness

The classic hardness scale (Moh scale) is based on a series of minerals and their ability to scratch one another. Modern hardness values are collected based on indentation methods using points of prescribed geometry applied at specific load levels and times. Two common hardness measurement methods, with different indentor geometries and load condition, lead to values of Knoop and Vickers hardness. Because test conditions vary between different techniques it is important to make comparisons only between measurements employing the same standard.

Chemical Resistance

Selection of glasses based on chemical properties, commonly chemical resistance test results in optical glass catalogs, is difficult at best since a wide range of different test standards exist among the various suppliers. Consequently, only a brief introduction is provided here, based on some of the more common types of chemical durability tests with some examples of specific test recipes.

Please note that there are some optical glasses that show no staining or other evidence of chemical attack in one test type, but have a low chemical resistance in one or more other tests. Consequently it is important when evaluating the chemical behavior of optical glasses to consider all resistance test results.

Climate Resistance Test. Climate resistance is intended to give guidance concerning the sensitivity of a glass to

water vapor in ambient air. Typically, but not always, a slow process, this form of chemical attack gradually leads to the formation of a cloudy surface film that cannot be wiped off. An accelerated procedure is thus typically used for testing the climatic resistance of glasses.

In one possible test technique, polished uncoated glass plates are exposed to a water-vapor-saturated atmosphere the temperatures of which are alternated between $40\,°C$ and $50\,°C$ on an hourly basis. Since the temperature increase in the glass plates follows that of the atmosphere, water condenses on the glasses during the warming phase. In the cooling phase the temperature of the atmosphere initially falls faster than that of the glass plates causing a drying of the glass surface. After an exposure time of, for example, $30\,h$ the glasses are taken out of the climatic chamber. The difference, pH, between the transmission haze before and after testing is used as a measure of the resulting surface change. Classifications can then be done based on the transmission haze increase, pH, after the test period has been completed.

Resistance to Staining. The test procedure gives information on possible changes in the glass surface (stain formation) under the influence of lightly acidic water (for example perspiration, acidic condensates) without vaporization. The class of stain resistance is typically determined by placing a plane-polished glass sample in contact with a test solution (for example a standard acetate at pH $= 4.6$ or a sodium acetate buffer at pH $= 5.6$, depending on the relative durability of the glass) using a prescribed temperature and exposure time.

Interference color stains develop as a result of decomposition of the surface of the glass by the test solution. One possible measure for classifying glasses is the time which elapses before the first stain occurs. This change in color indicates a chemical change in the previously defined surface layer of 0.1mm thickness.

Resistance to Acids. When an acidic aqueous medium reacts with the surface of a glass stains can form, the glass can be decomposed, or both can occur. In contrast to the staining resistance tests discussed above, acid resistance testing provides information concerning dissolution since testing is done with larger quantities of solutions, often at lower pH.

ISO 8424 is a standard for evaluating acid resistance of glass. Here, the time required to dissolve a layer with a thickness of 0.1mm serves as a measure of the resistance to acids. Two aggressive solutions are used in determining the resistance to acids: a strong acid, nitric acid, pH 0.3 is used for the more resistant glass types and a weak acidic solution with a pH value of 4.6 (standard acetate) is used for glasses with lower acid resistance.

Resistance to Alkali. These tests concern resistance to alkalis and are provided because many fabrication processes occur in water-based media (for example, grinding and polishing compounds) that usually become increasingly alkaline through the chemical reactions of the water and the abraded glass particles over time. This particularly applies when such solutions are recycled.

ISO 10629 is a standard for evaluating alkali resistance of glass. This test also takes into consideration the fact that higher temperatures can occur as a result of the polishing process through abrasion. The alkali resistance classes indicate the resistance of glasses to alkaline solutions and therefore as a warning signal to finishers of glass of possible problematic materials. As with the acid resistance testing discussed above, alkali resistance is based on the time required to remove a layer thickness of glass of 0.1 mm in an alkaline solution (sodium hydroxide, $c = 0.01\,mol/l$, pH $= 12$). In ISO 106529, the layer thickness is calculated from the weight loss per surface area and the density of the glass.

5.3 Colored Glasses

5.3.1 Basics

Color in glass arises from the selective attenuation or amplification of the incident light within special regions of wavelength in the visible part of the spectrum, i.e. in the range from about $380\,nm$ to $780\,nm$ [5.82]. Generally, the shape of the transmission curve versus the wavelength λ is described by (5.114) (see

also Sect. 5.1.3)

$$\tau_i(\lambda) = \exp\sum_m \left(-\varepsilon_{\lambda,c,m}c_m d\right)\ , \tag{5.114}$$

$$\tau_i(\lambda) = \frac{(\Phi_{e\lambda})_{ex}}{(\Phi_{e\lambda})_{in}}\ , \tag{5.115}$$

$$\tau(\lambda) = \frac{(\Phi_{e\lambda})_\lambda}{\Phi_{e\lambda}} = P\tau_i(\lambda)\ , \tag{5.116}$$

where ε and c are the extinction coefficient and the concentration of the coloring species m, respectively, d is the thickness of the probe and τ_i the internal transmission. The internal spectral transmittance $\tau_i(\lambda)$ in (5.115) is the ratio of the emerging spectral radiant flux $(\Phi_{e\lambda})_{ex}$ to the penetrating radiant flux $(\Phi_{e\lambda})_{in}$. It describes the transmission of a homogeneous absorbing filter material without allowing for reflection losses; $\tau(\lambda)$ characterizes virtually every optical filter, regardless of its structure or mode of action. The extinction coefficient for a given base glass is a function of the wavelength, the coloring species m and, in some cases, the concentration of this species. Keep in mind that one coloring ion in two different oxidation states acts like two different species (e.g. Fe^{2+}, Fe^{3+}).

Unfortunately, there is no way to calculate ε from theoretical considerations so it must be taken from experiments for every coloring species. Some data have been compiled by *Bamford* [5.83], but not for all elements and combinations. Additionally, all data taken from the literature depend on the special base-glass composition. So, for a given new problem, the extinction coefficients must first be established experimentally.

In many cases (5.114) can be simplified. Very often, glasses are colored by only one species in one oxidation state and the extinction coefficient is not a function of concentration. This is especially true if the concentration of the species is low. Then (5.114) can be written as (Lambert–Beer law)

$$\tau_i(\lambda) = \exp(-\varepsilon_\lambda cd) \ . \tag{5.117}$$

From this equation, the transmission plots for different concentrations of the coloring species and different probe thicknesses can easily be calculated from one experiment, since ε is then a constant for a given wavelength.

As already mentioned, the color of a glass can be taken from a plot of its internal transmission against wavelength. A translucent body showing an internal transmission of $\tau_i = 1$ at every wavelength in the visible range is called colorless (see Fig. 5.40); the usual optical glasses are examples of these. When the internal
Fig. 5.40 Transmission spectra of white and blue glasses

transmission at a range of wavelengths is attenuated by any of the mechanisms discussed in Sect. 5.1.3, a color arises. The color depends on the part of the spectrum missing (Table 5.7).

Figure 5.40 shows the internal transmission plot of a white glass and a blue glass. The color of the blue glass is obtained by doping with Cu^{2+}. This kind of representation is chosen for scientific applications and construction of optical instruments because it advantageously shows the spectral distribution of transmitted light. Another way to describe the color of the glass is the use of color coordinates. When this method is used, the color is defined by two coordinates x and y, which are obtained by weighting the $\tau(\lambda)$ curve of the glass with the intensity distribution of the standardized light source for the colors red, green and blue. In the ideal case, the color portions of the light source add to clear white light. The procedure has been extensively described by *Bamford* [5.83].

Figure 5.41 shows the distribution coefficients for the red (P_x), green (P_y), and blue (P_z) part of a special standardized light source (illuminant D65) as has been set up by the International Commission on Light-

Table 5.7 Relation between color and absorbing wavelength range

$\lambda_{absorbed}$ (nm)	400	425	450	490	510	530	550	590	640	730
Color of light$_{absorbed}$	violet	indigo blue	blue	blue green	green	yellow green	yellow	orange	red	magenta
Color of light$_{resulted}$	green yellow	yellow	orange	red	magenta	violet	indigo blue	blue	blue green	green

Part A | 5.3
Fig. 5.41 Distribution coefficients for red (P_x), green (P_y), and blue (P_z) part of light of illuminant D65 (standardized light source)

ing (CIE). After multiplication of the transmission curve by the distribution coefficients, and normalization of the sum to unity, one obtains the color coordinates. The "z" coordinate has been omitted because it can easily be calculated from the condition that $x + y + z = 1$.

This method is used when the color impression is needed; e.g. for traffic signs and glasses for artists.

From the chemical point of view, the base-glass composition of colored glasses ranges within the compositional region of normal optical glasses, as discussed in Sect. 5.2. Historically, colored glasses have been developed from optical glasses by the empirical addition of so called "coloring elements". There has been a lot of experimental work on this topic, of which a survey has been given by *Weyl* [5.84] and to some extent by *Vogel* [5.85]. The coloring elements additionally present in the base glasses, transition metals and lanthanides, contain partly filled d and f electronic shells. For some special applications, the elements of the sixth (S to Te) and seventh (Cl to I) main groups are used in combination with zinc and cadmium or copper and silver, respectively, in addition to the transition metals and lanthanides.

5.3.2 Color in Glass

The mechanisms of generating colors have been described in [5.86]. From these 15 mechanisms, only four are very important for practical use in inorganic oxidic bulk glasses: ligand field effects [5.82, 87–91], charge-transfer effects [5.82, 92], metal colloids [5.93–95] and semiconductor-doped glasses [5.85, 96–98]. These are in essence described in Sect. 5.1.3 and [5.82]. Therefore we will not explain this mechanism here.

The usual colors of some of the more important ions are listed in Table 5.8 [5.84], which can be described by ligand field effects.

The color of glass is determined by several parameters such as the kind of coloring species, its valency, the coordination of colored species, and the base glass.

The influence of the base glass on the spectra can be attributed to two items. The first is the intensity of the absorption band caused by the transition. This is influenced by the probability of electron transfer. Different base glasses show different coupling modes and therefore different extinction coefficients for a given coloring ion. Commonly, phosphate glasses show lower extinction and the color of a given ion is fainter than in silicate glasses [5.87]. The second reason is the difference of absorption peak maxima between silicate, phosphate and borate glasses. If it is only about $1-2\%$ the arrangements of the coloring ion ligands stays unchanged. The differences between the peak maxima positions are much more pronounced. Some transitions show no correspondence at all. The explanation follows from changes in the coordination. The coordination, for instance, of Ni^{2+} in silicate glass is unexpectedly fourfold (tetrahedral), resulting in a purple color, whereas the dark yellow of Ni^{2+} in the phosphate glass results from the normal octahedral coordination [5.87].

Another coloring species of great importance is $Fe^{2+/3+}$. The interpretation of the spectra of iron is quite a complicated task. One not only has to consider two oxidation states with different peak positions but also that these two species each appear in tetrahedral as well as in octahedral positions. Adding further confusion, parts of these bands can occur at nearly the same wavelengths. Additionally, charge-transfer bands of Fe^{3+} with oxy-

Table 5.8 Usual colors of some ions in glasses, according to [5.84]

Element	Valency	Color
Fe	2+	Green, sometimes blue
Fe	3+	Brown
Cu	2+	Blue, turquoise
Cr	3+	Green
Ni	2+	Violet (tetrahedral)
Ni	2+	Yellow (octahedral)
Co	2+	Blue
Mn	2+	Pale yellow
Mn	3+	Violet
Pr	3+	Green
Nd	3+	Violet
Er	3+	Pale red
Fig. 5.42 Semiconductor-doped glasses: Band structure and absorption of light for II–VI semiconductors

gen occur. The color of the glass depends strongly on the redox conditions during melting. By the application of a low oxygen partial pressure the glass becomes very pale green to blue according to the transition at about 1100 nm. Under oxidizing conditions the glass turns brown because of the manifold bands of trivalent iron present all over the visible and UV range of the spectrum.

Beside the colored glasses described above, which are based on absorption bands, there are also long-pass filters, which are prepared by doping with semiconductors such as ZnS, ZnSe, ZnTe, CdS, CdSe, and CdTe followed by an additional annealing process to grow semiconductor crystals in the glass. These semiconductor-doped glasses show very differ-

Table 5.9 Band-gap energies for some semiconductor crystals (macrocrystals)

Compound	E_g(eV)/λ_c (nm)	E_g(eV)/λ_c (nm)

CdSe	1.7/729	1.73/717
CdTe	1.5/827	−/−

ent behavior with interesting spectral properties. The absorption mechanism is explained in Sect. 5.1.3.

The essential properties of the transmission spectrum are the wavelengths λ_c, λ_s and λ_p. The wavelength λ_c is defined as the middle of the maxima between the blocking and the pass area ($\tau_i = 0.5$). In the blocking part ($\leq \lambda_s$) all light will be absorbed and at the pass part ($\geq \lambda_p$) the incident light will be transmitted.

Commercially available filter glasses of this series have absorption edges from about 400 nm to 850 nm. As indicated in Fig. 5.42 the band gap, and therefore the absorption edge, depend on the chemical composition and size of the crystals. The transition from Zn to Cd and from S over Se to Te leads to an increasing red shift of λ_c. Decreasing the size of the crystals also moves the effective band gap to higher energies and creates a corresponding blue shift of λ_c. The exact energies of the band gap can be taken from Table 5.9.

By annealing [5.99, 100], influencing the diameter of the crystals, and by mixing appropriate amounts of the pure compounds, all values for λ_c between 350 nm and 850 nm can be achieved.

5.4 Laser Glass

5.4.1 Common Laser Glasses and Properties

Laser glass is a solid-state material with the ability to amplify light by stimulated emission of radiation. In its most common form it is a multicomponent oxide glass doped with a lasing ion such as neodymium. In this section we deal predominantly with multicomponent glasses in contrast to the rare-earth-doped fused silica such as that commonly employed in Er-doped fiber amplifiers.

Although the dominant commercial market for laser glass is in large laser systems for inertial confinement fusion research with application to fusion energy and weapons physics science [5.101], these materials

have also found their way into a number of industrial and laboratory environments. For example, one leading application is in the field of laser shock peening [5.102].

Commercial laser glasses fall into three broad categories depending on the operating regime of the applied laser system. Laser glass composition development is a mature field and for each specific application glass compositions and/or processing details of these glasses have already been identified by suppliers that provide optimized properties for each situation.

There are, for example, laser glasses designed for high peak power. Here, laser properties have been op-

timized to offer the highest possible stored energy and extraction efficiency, resulting in high peak powers in single shots that are separated in time. Repetition rates of such systems are at most a few Hertz, and more commonly are one to several laser shots per day.

There are also laser glasses for high average power applications where repetition rates can be in the range of 1–20 Hz. Such laser systems are in general aggressively cooled to remove heat deposited into the glass during repeated optical pumping. In addition to good laser properties, these glasses also possess enhanced thermomechanical properties consistent with high thermal loading without part fracture.

Still another example are glasses developed for guided wave optics. Here, glass compositions are selected for high stability to devitrification during redrawing into fibers or for compatibility with structuring technologies, for example ion exchange, used in preparing planar waveguide structures. Figure 5.43 shows representative laser glass parts, the largest being a slab more than 1 m along on its diagonal axis for use in high peak power laser fusion research.

Another way laser glasses are categorized is by the glass type. The first laser glass to be identified was a glass based on silica (commonly called a silicate glass) [5.103]. Today, the multicomponent glasses of greatest commercial value are phosphate types and the compositions are essentially free of any silica. In addition, there are glasses based on other glass forming systems, as well as glasses that contain, in addition or in place of oxygen, other anions such as fluorine.

Fig. 5.43 Laser glasses

Today, the most commonly employed multicomponent laser glasses are based on phosphorous. These glasses are available in high optical quality from a number of commercial vendors with a wide range of dopants and doping levels, and in particular offer superior performance for resistance to laser damage when operated in high-fluence applications.

Although neodymium is the most common dopant and lasing ion, through selection of various dopant ions, either alone or in combination, a wide range of lasing wavelengths are possible. When more than one active ion is selected, usually one or more ions acts as a sensitizer for the primary lasing ion. The classical case is the codoping of laser glass containing erbium with ytterbium. Table 5.10 lists typical lasing wavelengths available in common glass hosts along with common sensitizing ions. The emission wavelength is, however, a function of glass composition so these values should only serve as a rough guide.

Specification of Laser Glass Doping Level

A common problem in identification of the optimal laser glass composition is the selection of the doping level of the lasing species or other sensitizing ions. The doping level is largely driven by two factors: the need to pump the entire laser glass volume uniformly and the avoidance of a phenomena called concentration quenching, in which two neighboring lasing ions in the glass can exchange energy by a radiationless process that steals available energy from the laser beam of interest. A rough guideline for dealing with the former case is provided in Table 5.11, which lists typical doping levels as a function of rod diameter for typical flashlamp pumped laser systems that provide nominally uniform excitation of the complete active volume.

Table 5.10 Laser wavelengths from selected active ions in glass

Active ion	Approximate emission wavelength (μm)	Sensitizing ion(s)
Nd^{3+}	0.93, 1.06, 1.35	Cr^{3+}, Mn^{2+}, Ce^{3+}, Eu^{3+}, Tb^{3+}, U^{3+}, Bi^{3+}

Tb^{3+}	0.54	Ce^{3+}, Cu^{+}
Pr^{3+}	0.89, 1.04, 1.34	

Table 5.11 Guidelines for neodymium dopant level for various rod diameters

Rod diameter (mm)	Nd concentration in phosphate laser glass (wt% Nd_2O_3)	Nd concentration in silicate laser glass (wt% Nd_2O_3)
≤ 5	8.0	3.5
5 to 7	6.0	3.0
6 to 10	4.0	3.0
9 to 13	3.0	3.0
12 to 16	2.5	3.0
15 to 20	2.0	2.0
20 to 26	1.5	2.0
≥ 27	1.0	2.0

Figure 5.44 shows the effect of concentration quenching for neodymium where the lifetime of the excited state used in the laser transition is shown to decrease with dopant level for some representative neodymium-doped laser glasses. The effect of concentration quenching is often estimated by the following equation

$$\tau = \tau_0 / \left[1 + (N/Q)^n \right] , \tag{5.118}$$

where τ is the lifetime at neodymium concentration level N (in units of 10^{20} ions per cm^3), τ_0 is the effective lifetime for a negligible doping level in the glass and Q is a concentration quenching factor that corresponds to the doping level at which the lifetime value falls to $\frac{1}{2}$ of τ_0. The value of n is generally equal to 1 or 2, and depends more on the amount of data available to determine the fit to (5.118) than on material considerations. The concentration quenching effect varies with glass type, and in
Fig. 5.44 Typical concentration quenching curves

particular is less pronounced in phosphate compositions than in silicate glasses. Table 5.11 also lists different optimal doping levels for both the silicate and phosphate glass types.

Rare-earth ion concentration is expressed in a number of ways, most commonly as either a weight percent of oxide in the glass or as the number of active ions per cubic centimeter. It is straightforward to convert between these two values if one knows the density of the glass. For the case of various lanthanide cations the following conversion formulae between lanthanide (Ln) ion density, in units of $10^{20}/cm^3$, and weight percent of the lanthanide oxide can be employed:

$$\text{Ln ion density} = \varrho F(\text{wt\%Ln}_2O_3) , \tag{5.119}$$

$$\text{wt\%Ln}_2O_3 = \text{Ln ion density}/(\varrho F) , \tag{5.120}$$

where ϱ is the glass density in g/cm^3 and the value of F for a number of common rare-earth elements is given in Table 5.12.

Glasses for High Peak Power

Glasses for high peak power are generally characterized by enhanced laser properties. This can perhaps be expressed as having a large value of the following laser figure of merit $\text{FOM}_{\text{laser}}$,

$$\text{FOM}_{\text{laser}} = \sigma Q/n_2 , \tag{5.121}$$

where σ is the cross section for stimulated emission and Q is the concentration quenching factor (see p. 294), which together are a measure of the laser gain available in the glass, and n_2 is the nonlinear index, a measure of glass weakness to resist damage when transmitting a high-intensity pulse of laser light (see Sect. 5.4.2). These properties for some typical commercial high peak power laser glasses are given in Table 5.13.

Glasses for High Average Power

Glasses for high average power are generally characterized by enhanced thermomechanical properties as well as good laser properties. This is often expressed as having a large value of the following thermomechanical figure of merit FOM_{tm},

$$FOM_{tm} = K_{IC} K (1 - \nu)/\alpha E , \qquad (5.122)$$

where K_{IC} is the fracture toughness, K is the thermal conductivity, ν is the Poisson's ratio, α is the thermal expansion and E is the Young's modulus of the glass. These properties for some typical high average power commercial laser glasses, along with the laser properties discussed earlier, are given in Table 5.14.

Planar and Fiber Waveguide Lasers and Amplifiers

The glasses described in the previous sections can also be drawn into fiber form for preparation of fiber lasers and amplifiers. In addition, a number of glasses are also available for preparing planar waveguide structures by techniques such as ion exchange. The ion-exchange structuring technique is normally performed at temperatures below the transformation point of the glass. Properties of some of these glasses specifically devel-

oped for planar waveguide applications are provided in Table 5.15. Since these glasses have been commonly employed in the preparation of active planar guided-wave devices based on the erbium emission in the 1540 nm telecommunications region, Table 5.15 contains some associated properties for this active ion.

Estimating Refractive Index

Glass manufacturers typically report refractive index and dispersion as measured at wavelengths near 587.6 nm. It is a common requirement to estimate the refractive index of laser glass at additional wavelengths, for example for purposes of coating design at a pump or lasing wavelength. In addition, refractive index is a function of doping identity and content, so that catalog index values and those listed here in Tables 5.13, 5.14, and 5.15 are only rough guides. For this, a useful relationship for the refractive index at a different wavelength $n(\lambda)$ is

$$n(\lambda) = n_D - [(n_D - 1)/V_D]\left(1.5079 - 523\,640/\lambda^2\right) \tag{5.123}$$

where n_D is the refractive index at 589.3 nm, V_D is given by

$$V_D = (n_D - 1)/(n_F - n_C), \quad \text{(see Sect. 5.1.2)} \tag{5.124}$$

and n_F is the index at 486.1 nm, n_C is the index at 656.3 nm, and λ is in nm. The accuracy of (5.123) is given as ± 0.001 in the cases where index measurements are accurate to ± 0.0001, but there is no applicable wavelength range provided [5.104].

Alternatively, a similar equation based on index data measured at the mercury d-line at 587.6 nm is the following:

$$n(\lambda) = n_d - [(n_d - 1)/V_d]\left(1.5079 - 523\,640/\lambda^2\right), \tag{5.125}$$

where n_d is the refractive index at 587.6 nm, V_d is given by

$$V_d = (n_d - 1)/(n_F - n_C), \tag{5.126}$$

and n_F is the index at 486.1 nm, n_C is the index at 656.3 nm, and λ is again in nm. Equation (5.125) is expected to be accurate to ± 0.003 for IR wavelengths up to 2.3 μm in the cases where index measurements are accurate to ± 0.00002.

5.4.2 Laser Damage

Advances in high-power and high-energy laser systems have made power densities in excess of 10^9 W/cm^2 available. At such power levels a number of different damage mechanisms come into play that can lead to temporary or even permanent changes in the optical quality of optical materials, including laser glass. Such changes may occur at a surface or within the bulk material, and can both render an optic unusable and/or alter the transmitted beam profile in such a way as to place other downstream components in an optical system at increased risk of damage.

Transient Thermal Effects

Since the refractive index is generally a function of temperature, thermal gradients within laser glass parts can lead to optical distortion of propagating light through inhomogeneous changes in the optical pathlength. For some applications, it is possible to have laser glasses that behave essentially as an athermal component in which the thermal expansion of the glass offsets the change in optical pathlength due to the variation of index with temperature.

For a laser glass component within a cavity of an otherwise fixed length (for example as defined by a frame constructed from near zero expansion materials such as Zerodur or Invar), the variation in optical pathlength

Table 5.15 Properties of typical waveguide laser glasses

Glass type	Schott IOG-10 Silicate	Schott IOG-1 Phosphate	Hoya LHG-5 Phosphate	Kigre MM-2 Phosphate

Part A | 5.4

with temperature, dS/dT, is given by

$$dS/dT = \alpha(n-1) + dn/dT ,\qquad (5.127)$$

where the glass is characterized by a thermal expansion value of α, refractive index of n, and temperature change of refractive index, relative to air, with temperature of dn/dT.

An alternative situation occurs if the laser glass part is coated in such a way as to define the length of the optical cavity, as in the case where the end mirrors of a laser oscillator cavity are directly applied to the ends of a laser rod. In this case the cavity length variation with temperature is given by

$$dS/dT = n\alpha + dn/dT .\qquad (5.128)$$

Typical values for α, n, and dn/dT are included with other laser glass properties in Tables 5.13–5.15.

Surface Damage

Surface damage on active (and also passive) optical materials in high-intensity laser systems normally appears as circular elevations (pustules) or depressions (pits) on transmission surfaces. The number density and size of these features is somewhat determined by the laser energy density and pulse length, respectively. Laser glass surfaces are vulnerable to laser damage since they typically become contaminated through routine storage and handling as well as the gradual accumulation over time of airborne particles. Surface contamination serves as a nucleation point for damage. The initial preparation of the surface can potentially play a critical role in determining the likelihood of experiencing laser damage. After polishing of a surface is completed, there can still exist residual scratches, defects, and subsurface flaws that can retain contaminants of polishing compounds and cleaning materials. Such sites on optical material surfaces serve as additional nucleation points for laser damage.

Induced damage on beam exit surfaces is often correlated with absorption of laser energy at such surface defect sites, followed by formation of a plasma which in turn can enhance reflection of the laser light back on itself, further increasing the local electric field intensity associated with the laser beam. Finishing vendors for high-damage-threshold optics need to avoid leaving residue of polishing compounds that absorb strongly at the intended wavelength of exposure. Surface damage threshold is also clearly improved by proper cleaning of optical surfaces and subsequent protection from atmospheric contaminants, including water, which can alter surface properties through condensation and diffusion.

Self–Focusing Damage

Self-focusing occurs due to the dielectric breakdown of an optical material from localized focusing of a propagating laser beam by increase of the refractive index with the applied light intensity. This effect leads to one or more threadlike damage sites oriented along the main optical axis that are often referred to by a number of different terms including *tracks* or *angel hair*.

The damage event often begins as a localized hot spot within a laser beam that causes an increase in local refractive index within the glass. Since the optical pathlength is increased at such a hot spot, and drops towards the original value away from the high intensity region, this portion of the laser glass essentially acts as a positive lens. This artificial lens further converges the laser beam, compounding the effect. This convergence continues until the electric field associated with the laser increases to a point that atoms are ionized and a plasma is produced within the glass. An example of such self-focusing damage is shown in Fig. 5.45.

The phenomena of self-focusing is driven by the laser glass nonlinear refractive index n_2, the accumulated optical pathlength, and the presence/absence of localized hot spots in the laser beam. Internal optical quality of laser glass has improved over time to the point that meter-class sections are available that are essentially free of all bubbles and inclusions that can cause localized fluctuations in beam intensity through diffraction effects, so the nonlinear index plays a prominent role in determining if laser damage of this type will occur. It is for this reason that n_2 appears in (5.121) for FOM_{laser} in Sect. 5.4.1. In addition to selection of a laser glass with low n_2, laser cavity and beamline designs need to minimize the possibilities of high-fluence locations in
Fig. 5.45 Self-focusing damage in laser glass

beams passing through laser glass components, i. e. the laser energy should be spread out over as large an area as practically possible.

Multiphoton Induced Damage

Multiphoton transitions involve two or more photons whose energies are combined to a value sufficient to excite a real transition in a material. High-fluence laser sources provide high photon flux levels that make these low-probability multiphoton transitions in glass observable. Damage from multiphoton absorption can occur when electrons are excited into an optical material's effective conduction band, where they then migrate to stable traps in the material and induce structure and property changes. Damage takes two principle forms: as a localized discoloration and/or as a permanent change in the refractive index of the damaged region. This type of laser damage is almost always viewed as problematic and the observed absorption characteristics as a function of wavelength are generally similar to that observed with high-energy radiation damage, such as that found with UV, X-ray, or particle (proton, electron, etc.) exposure.

For a particular laser design, the extent of multiphoton damage is determined by the number of laser photons required to achieve a combined energy sufficient to lead to damage. As a rough guide, one can use an effective band gap of the laser glass, as calculated from the onset of absorption in the high-energy end of the electromagnetic spectrum, compared to the energy available from a single photon at the laser wavelength.

Point–Defect Laser Damage

Nearly all optical materials, including laser glass, contain some level of localized microscopic bulk defects including bubbles, dielectric inclusions, and precious metal particles. All such defects have some relationship to the original manufacturing process. Most inclusions and metal particles represent either unmelted compounds from the original glass melt or portions of the manufacturing equipment that were incorporated into the final laser glass component. Bubbles by themselves are not typically linked with the creation of localized damage sites, however they can cause diffraction of a propagating laser beam with associated small-spatial-scale high-intensity power spikes that can then damage other optical elements in a laser system through nonlinear effects (see for example the discussion in the subsection on surface damage).

Metal particles, chiefly platinum, remain in laser glass since for optical quality reasons these glasses are produced within pots and crucibles made of precious
Fig. 5.46 Particulate damage in laser glass due to a platinum particle

metals and their alloys. Subsequent particulate-related damage from these inclusions appears as isolated damage sites within a bulk optic. Figure 5.46 shows a magnified image of such a damage site that measures 0.25 mm in diameter. The damage mechanism is believed to be direct absorption of laser radiation by the dielectric or conducting-defect site, followed by heating of the particle to above its boiling point, with subsequent crack nucleation and growth from both the vaporization-related shock wave and localized thermal-induced stress occuring [5.105].

Since the initial discovery of the laser in 1960, the largest single improvement in laser glass damage-threshold performance has been the development of manufacturing technologies capable of producing meter-class phosphate laser glass components completely free of all inclusions or internal defects capable of becoming particulate damage sites [5.106]. The specification of such platinum-particle-free glass should be made when laser fluence levels approach the damage threshold, a condition approximated for pulsed 1.064 μm laser exposure by

Damage threshold in J/cm^2 =
$$2.5 \times (\text{pulse length in ns})^{0.3} . \tag{5.129}$$

Although laser damage is an extensively studied field, there is no comprehensive database of the enormous amount of accumulated experimental data on this subject that would make it possible to predict the laser damage level for a particular situation. Interested readers are referred to several textbooks that deal exclusively with this field of investigation [5.107, 108]

Part A | 5.4

5.4.3 Storage and Handling of Laser Glass

Laser glasses are typically brittle materials that are easily chipped or broken upon thermal or mechanical loading. As a result, heating and cooling of glass parts should be at rates not exceeding 20–30 °C/h. Laser glasses with good laser properties are generally of compositions that also exhibit low chemical durability. The low durability can sometimes be used to an advantage, since deliberate chemical etching [5.109] or chemical ion-exchange processes [5.110] can be used to enhance mechanical strength.

There exists no universal method for evaluating all possible chemical attack paths and laser glass compositions. However, as a general rule, the presence of water is nearly always a prerequisite for the chemical attack of glass. As a consequence, long-term storage of sensitive glasses is best accomplished within a closed, and preferably evacuated, environment containing a desiccant material.

Methods to Enhance Part Strength

Laser glasses can be strengthened by techniques such as acid etching and ion exchange. In the former, surface removal by etching is accompanied by blunting of crack tips left following fabrication or mechanical handling. Blunted crack tips require a higher energy level to propagate into cracks or fractures, effectively increasing the strength of the glass part to breakage. Ion exchange involves the substitution of a smaller cation within the glass structure by a larger cation, effectively placing the surface of the glass under compression. To experience
Fig. 5.47 Chemical durability in EtOH/water mixtures

fracture, the applied stress must now exceed not only the initial strength level of the glass but the compressive surface stress as well. Both processes involve some level of chemical attack to the glass surfaces and are not suitable for polished optical surfaces.

Liquid Cooling of Laser Glasses

Solid-state laser systems employing laser glass as the gain medium are typically cooled by a recirculating liquid coolant system. Chemical attack by the coolant solution is a variable to be considered, in particular when phosphate laser glasses are employed and the component is to be left in contact with coolant during periods of no operation. In this case, it has been shown that addition of ethylene glycol to water can provide improved protection to chemical attack, as seen in Fig. 5.47.

5.5 Glass–Ceramics for Optical Applications

5.5.1 Overview

Glass–ceramics – glasses that are crystallized via a deterministic and controlled process – combine the relative ease of manufacturing associated with glass with the added functionalities that exist only in crystalline states of matter [5.111, 112]. For example, the combination of a crystalline phase that exhibits negative thermal expansion, a relatively rare occurrence in nature, with the normal positive expansion for glass has led to the development of ultra-low thermal expansion glass–ceramics used for such things as telescope mirrors, IR-transparent cooker tops, and reflectors for digital projection [5.113]. Dental glass–ceramics combine high strength with the proper amount of controlled translucency to mimic

natural teeth precisely [5.114]. And a wide variety of nonlinear phenomena have been demonstrated in glass–ceramics, including ferroelectric and pyroelectric behavior [5.115], second-harmonic generation [5.116], upconversion [5.117], and scintillation [5.118].

Contrary to one's first impression, the presence of crystals in a glass framework need not significantly inhibit transmission. The ability to control the crystallization process often allows one to keep crystal sizes small relative to the wavelength of the incident radiation, thereby minimizing scattering losses, particularly at longer wavelengths. In addition, the precipitation of very small, insoluble crystals in a soluble matrix allows one to form crystals in compositions that are otherwise difficult if not impossible to control. For ex-

ample, *Beall* [5.119] developed a Cr-doped forsterite ($Cr:Mg_2SiO_4$) glass–ceramic; stoichiometric forsterite glass by itself is extremely unstable and only very special processing techniques are able to form it [5.120]. However, by relying on phase separation to create Cr-doped, forsterite-like sub-domains which subsequently crystallized, Beall was able to combine the ease of glass production with the formation of a desired crystal. This tactic is a familiar one in glass–ceramic development.

Glass–ceramic production begins with the formation of suitable glass castings using now-standard manufacturing techniques [5.124]. Detailed inspection techniques are then used to determine the internal quality of the part owing to the inherent high transparency of glass. After inspection, a controlled thermal cycling program, termed "ceramization", is used, whereby the glass part is partially or wholly transformed into a glass–ceramic. Typical thermal histories take advantage of the disparate temperature regimes in which crystal nucleation and subsequent growth take place [5.125]. At a minimum, three heating/cooling ramp rates and two pairs of temperature/time conditions need to be specified in a ceramization process (Fig. 5.48). This, coupled with the fact that both nucleation and growth are thermally activated processes with inherently strong nonlinear dependencies on temperature [5.126], can make ceramization a challenging process.

5.5.2 Properties of Glass–Ceramics

Compared to their precursor glasses, glass–ceramics typically have increased strength and higher elastic constants. Thermal expansion, on the other hand, can be either higher or lower than the precursor glass. Glass–ceramics normally exhibit less dielectric loss than their glassy precursors, due in part to tying up the more mobile species in a more rigid, crystalline framework (though
Fig. 5.48 Schematic temperature–time path used for the production of glass–ceramics, a process termed ceramization; q_i refers to heating and cooling rates, T_i and t_i refer to temperatures and time used during crystal nucleation and growth stages, respectively

exceptions are known [5.111, 127]) whereas relative permittivities are generally higher in glass–ceramics. Finally, chemical durability is typically enhanced over glass, in some cases quite dramatically [5.112].

Thermomechanical Properties
Thermal Expansion. Coefficient of thermal expansion values (CTE) for glass–ceramics range from nearly -10 to $+25 \times 10^{-6}\,°C^{-1}$, a remarkably wide range few materials can approach (Table 5.16) [5.111]. Expansion matching to most metals (including Si) has been accomplished thereby allowing for the production of multi-material devices under stress-free or stress-controlled conditions (Fig. 5.49) [5.111,128,129]. A possible complexity with glass–ceramics arises from the often nontrivial expansion curves for the crystalline phases. For example, glass–ceramics that contain a silica polymorph typically show a pronounced change

Table 5.16 Comparison of optical and physical parameter values for a range of glass–ceramic materials

Material	n	T_i (%)	λ (nm)	Thickness (mm)	CTE (ppm/°C)	T range (°C)	E (GPa)
Zerodur [a]	1.52	99.6	1550	1	0 ± 0.05	0 to 50	90
SA-O2 [b]	1.56	≥ 98	1550	1	1.8	30 to 500	98
WMS-15 [b]	1.52	99.9	1550	1	11.4	-30 to $+70$	96
NEX-C [b]		99.3	1550	10	-2	-40 to $+80$	94
Oxyfluoride [c]		99.99	1500	1			
Telluride [d]	2.1	≈ 80	800	1			
Pyroceram [e]					5.7	20 to 320	120

(Sources: [a] Zerodur product brochure, [b] Ohara product brochure, [c] [5.121], [d] [5.122], [e] [5.123]; note that Pyroceram, while opaque in the visible region, is transparent in its operative, radio-frequency region)

Part A | 5.5
Fig. 5.49 Range of thermal expansion curves ($\Delta L/L$) attainable with glass–ceramics. Also plotted are expansion curves for typical metals (here, α is the CTE of the material). (After [5.111])

Fig. 5.50 Example of the range of CTEs that can be attained in glass–ceramics for a single composition. The curve labeled "glass" is for the unceramized precursor glass whereas those labeled "Ex. 1" and so on are for 3 different ceramization protocols. The large bump in CTE near 175 °C is due to the polymorphic transition of a cristobalite solid-solution phase

in slope in a plot of CTE versus temperature, associated with a polymorphic transition of the silica phase (Fig. 5.50). This can be dealt with, in principle, through a suitable choice of the particular crystalline phases that most modify the CTE relative to the glass precursor. Additionally, the value of CTE can be tuned over fairly substantial ranges for a single bulk composition through proper choice of heat treatment conditions (Fig. 5.50). To a fairly good degree, the CTE of a glass–ceramic depends linearly on the relative amounts of the various phases, though more complicated treatments exist [5.130]. Cryogenic thermal expansion data are known for only a few glass–ceramics [5.131].

Elastic Constants. Due to their lack of crystalline order, most glasses have elastic moduli and related parameters (e.g., Young's modulus E, sound velocities) considerably lower than those of their crystalline counterparts. Thus, glass–ceramics commonly have E values between those of crystals and glasses (e.g., 80 to 150 GPa),

though in some cases nearly double that of their precursor glasses (Table 5.16) [5.111]. As for CTE, the Young's modulus also displays a nearly additive relationship with respect to the phase content [5.132].

Strength, Hardness, and Fracture Toughness. Enhanced strength is one of the hallmarks of glass–ceramics. Here, the moduli of rupture measured via four-point bend tests or associated techniques can be double or more those of the precursor glasses [5.133], though surface flaws still ultimately control the maximum attained strength values. Unlike thermal expansion and elastic properties, strength is not only controlled by the proportion of the various phases present, but also by the internal microstructure, particularly at or near the surface [5.112, 134]. The presence or absence of interlocking crystals, preferred crystalline orientation, or even the slip system associated with the crystalline phases present can all play a role in dictating glass–ceramic strength.

As a brittle material, the fracture behavior of glass–ceramics is commonly characterized by hardness and fracture toughness values. The former is normally quantified via diamond micro-indentations and the latter by the propagation of either a preexisting flaw of known dimensions or the development of indentation fractures [5.135, 136]. Here too crystal content and microstructure play dominant roles [5.137].

Electrodynamical Properties

Dielectric Properties. Dielectric property characterization – typically restricted to sub-optical frequencies and often grouped with physical properties – is analogous to refractive index and absorption characterization at optical frequencies. Dielectric properties are generally restricted to GHz and lower frequencies (microwaves and radio-frequency), whereas optical characterization is normally restricted to tens of THz and above (infrared, visible and UV primarily). Little is known about the response of glass–ceramics, or of many substances for that matter, in the so called terahertz regime (0.1 THz to 10 THz) [5.138].

The most important dielectric parameters in the GHz and below regime are the dielectric constant (relative permittivity) and dielectric loss (loss tangent). The power absorbed per unit volume P may be written:

$$P = \frac{1}{2} E_0^2 \omega \varepsilon_0 \varepsilon_r \tan \delta \ , \tag{5.130}$$

where E_0 is the magnitude of the electric field, ω is the frequency of the field, ε_0 is the permittivity of vacuum, ε_r is the *relative* permittivity of the material (not to be confused with the permittivity of the material, given by the product of ε_r and ε_0), and $\tan \delta$ is the loss tangent [5.139]. The relative permittivity of the dielectric material is related to its refractive index via

$$\varepsilon_r = n^2 \ . \tag{5.131}$$

Note that this latter expression is only strictly true if the frequency with which both permittivity and refractive index are made are equivalent, or, somewhat more loosely, if the polarization loss mechanisms are unchanged between the two measurements. Thus, ε_r is related to the speed of propagation within the dielectric whereas $\tan \delta$ is a measure of the absorption. Typical values for permittivity start at values similar to glass (≈ 5) but can exceed 1000 for glass–ceramics containing ferroelectric crystals [5.140–142]. Loss tangents also

start close to glass values (e.g., 0.0002) and range up to nearly 1 (Table 5.17) [5.111]. The dielectric strength of glass–ceramics – the magnitude of the electric field just sufficient to initiate breakdown of the dielectric – is generally superior to that of ceramics and comparable to that of glasses (Table 5.17).

Refractive Index and Absorption. Optical properties of glass–ceramics are quite similar to those of their glass precursors and the crystalline phases contained therein. As introduced in Sect. 5.1.1, the two fundamental quantities, refractive index and absorption, can be described collectively via the complex refractive index

$$\tilde{n}(\omega) = n(\omega) + i\kappa(\omega) \ , \tag{5.132}$$

where n, the refractive index, and κ, the bulk absorption, are both frequency dependent [5.143]; κ is in turn related to the more often used absorption per unit length α via

$$\alpha = \frac{2\omega\kappa}{c} \ , \tag{5.133}$$

(see Sect. 5.1.3) where c is the speed of light and α is used to characterize the total transmission T through a sample via

$$\frac{I_t}{I_0} = T = RT_i = R \exp(-\alpha z) \ , \tag{5.134}$$

(Fig. 5.10) where I_t is the transmitted intensity $(\mathrm{W/m^2})$, I_0 is the incident intensity, T_i is the internal transmission (not including surface reflection losses), R is a factor that accounts for reflection losses, and z is the sample thickness [5.144].

Refractive indices of most glass–ceramics are in the range 1.5 to 2.0 across much of the visible and infrared region, whereas transmission values are strongly dependent on the wavelength of interest (Table 5.16). In some applications, absorption across a wide range of

Table 5.17 Dielectric properties of various glass, glass–ceramic, and ceramic materials

Material	ε_r	$\tan \delta$	Test frequency	Dielectric strength (kV/mm)	Test frequency (Hz)
Lithium–zinc silicate glass-ceramic [a]	5.0	0.0023	1 MHz	47	50
Fused silica [b]	3.8	0.0004	1 MHz	36	100
Alumina (99.5%) [c]	9.7	0.0001	1 MHz	8.7	60
Y-stabilized zirconia [c]	9.0	0.001	1 MHz	9.0	60
Steatite [d]	6.1	0.0008	1 MHz	9.1	60
Pyroceram [e]	5.5	0.00033	8.5 GHz		

(Sources: [a] [5.111], [b] GE Quartz commercial literature, [c] Coors Ceramics Company commercial literature, [d] CeramTec commercial literature, [e] [5.123])

wavelengths is of interest. For example, in the characterization of dental glass–ceramics with controlled translucency, standardized tests exist that quantify a material's integrated absorption in the visible region when recorded against a white or black background [5.114] and may be quantified with respect to standardized color coordinates [5.145].

Scattering. Volume scattering (see Sect. 5.1.7) of radiation by crystals is one of the most interesting aspects of glass–ceramics. Glass–ceramics have in fact been used recently as test materials for wavelength-dependent scattering experiments and analysis in the UV–VIS portion of the spectrum [5.146]. Depending on the application, the wavelength of light may be greater or less than the average crystal size. This distinction, among other factors, leads to a variety of phenomena that dictate the ultimate utility of glass–ceramics for optical applications. The theoretical basis for scattering in condensed matter began over a hundred years ago with the work of Rayleigh and with important generalizations some twenty years later by Mie (Sect. 5.1.7). More recent efforts relevant to glass–ceramics have been devoted to tying the early, theoretical work to the particular set of conditions that glass–ceramics present.

Based on the theoretical arguments of Sect. 5.1.7, we consider here the most important type of scattering for optical glass–ceramics: pure Rayleigh scattering, in which the size of the particle is less than that of the wavelength of light and the scattering cross section is defined by [5.147–149]:

$$C_{\text{scat}} = \pi a^2 Q_{\text{scat}} , \qquad (5.135)$$

where a is the particle radius and Q_{scat} is the scattering efficiency factor. The latter is in turn defined by

$$Q_{\text{scat}} = \frac{8}{3} \left| \frac{m^2 - 1}{m^2 + 2} \right|^2 x^4 , \qquad (5.136)$$

where m is often approximated by the ratio of the refractive index of the particle to that of the matrix (but see [5.149]), and x is a size parameter defined by

$$x = \frac{2\pi a}{\lambda} , \qquad (5.137)$$

where λ is the light wavelength. Taken together, we can write for the scattering cross section (cm^2):

$$C_{\text{scat}} = \frac{128}{3} \pi^5 \frac{a^6}{\lambda^4} \left| \frac{m^2 - 1}{m^2 + 2} \right|^2 . \qquad (5.138)$$

The λ^{-4} dependence is a hallmark of Rayleigh scattering as is the strong dependence on particle size.

An alternative definition, based on a quasi-continuum model due to *Hopper* [5.150], is given by

$$C_{\text{scat}} = \left(6.3 \times 10^{-4} \right) k^4 \overline{w}^3 \left(\overline{n} \Delta n \right)^2 N_{\text{V}}^{-1} , \qquad (5.139)$$

where k is the wavenumber $(2\pi/\lambda)$, $\overline{w}$ is a mean width, here taken as the particle radius (but see explanation in [5.150]), $\overline{n}$ is the mean refractive index, and N_{V} is the number of particles per unit volume. Here we have used Hopper's equation (70) and the definition of the absorption due solely to scattering, sometimes called the turbidity τ (cm^{-1})

$$C_{\text{scat}} = \frac{\tau}{N_{\text{V}}} . \qquad (5.140)$$

The often cited subcase of Rayleigh–Gans scattering has a further stipulation that there is negligible reflection at the particle–matrix interface. In this case, (5.136) is modified [5.149]

$$Q_{\text{scat}} = |m - 1|^2 x^4 \int_0^{\pi} G^2(u) \left(1 + \cos^2 \theta \right) \sin \theta \, d\theta , \qquad (5.141)$$

where

$$G(u) = \frac{2}{u^3} (\sin u - u \cos u) \qquad (5.142)$$

and

$$u = 2x \sin \frac{\theta}{2} . \qquad (5.143)$$

Another definition of the scattering cross section has no dependence on particle size, but is dependent on the particle number density [5.151]

$$C_{\text{scat}} = \frac{8}{3} \left(\frac{\pi (n^2 - 1)}{N_{\text{V}} \lambda^2} \right)^2 . \qquad (5.144)$$

Finally, work by *Hendy* takes recent findings in structure factors in phase-separated media into account to arrive at a scattering cross section with quite different dependencies on both particle size and wavelength but which explicitly includes the volume fraction crystallized φ [5.152]

$$C_{\text{scat}} = \frac{14}{15\pi} \varphi (1 - \varphi) k^8 a^7 \left(\frac{\Delta n}{\overline{n}} \right)^2 N_v^{-1} . \qquad (5.145)$$

To relate scattering cross sections to experimental measurables, we make use of the equation that relates the normalized transmitted intensity to the path length z [5.151]

$$\frac{I_{\text{scat}}}{I_0} = \exp \left(-C_{\text{scat}} N_{\text{V}} z \right) , \qquad (5.146)$$

where here (5.146) ignores losses due to absorption and reflection.

As an example of scattering in a glass–ceramic, we will analyze data from the nanocrystalline glass–ceramic Zerodur. This material, described more fully below, contains approximately 70 vol. % of 50 nm crystals. The number density for the microstructure is $\approx 10^{16}$ crystals/cm^3 [5.153]. Figure 5.51 plots uncorrected transmission data for both glassy and ceramized Zerodur. Note that the composition of these two samples is identical and so the difference between the two curves should be dominated by scattering losses. Figure 5.52 plots this difference, here normalized to remove the reflection losses which are virtually identical for both glassy and ceramized material. Rearranging (5.146) we have

$$-\ln\left(\frac{I_{\text{scat}}}{I_0}\right) = C_{\text{scat}}N_{\text{V}}z . \tag{5.147}$$

The measured quantity on the left-hand side (LHS) of this expression is directly proportional to the scattering cross section. Dividing the LHS of (5.147) by the path length (≈ 5 mm) and by the crystal number density for Zerodur, we arrive at the scattering cross section itself (small symbols in Fig. 5.53). Note the nearly linear appearance when plotted on this semilog scale, suggesting a power-law dependence on wavelength (the best-fit slope to data in the range 450 to 800 nm is -4.3, consistent with Rayleigh scattering). The rea-

son for the small deviation from the λ^{-4} dependence at short wavelengths (< 425 nm) is not clear. Also plotted in Fig. 5.53 is the prediction of the Hopper cross section (5.139). We used an estimated ratio of indices (m) of $1.55/1.5 \approx 1.03$ for this example. For comparison, note that the observed cross section at 500 nm was 1.2×10^{-17} cm^2. Although both the Rayleigh and Hopper equations predict the observed λ^{-4} dependence of the cross section, the pure Rayleigh model is some three orders of magnitude too high (3.3×10^{-14} cm^2), whereas the Hopper model predicts 1.0×10^{-17} cm^2, very close to
Fig. 5.52 Pure scattering effect on the transmitted intensity in Zerodur. The difference spectrum from the transmission curves in Fig. 5.51 were renormalized to remove reflection losses common to both samples. The subtraction process itself removes common absorption losses. What then remains, and is plotted here, is only the modification to the observed intensity due to scattering

Fig. 5.51 Raw transmission data for glassy and ceramized Zerodur (thickness $= 5.05$ mm for both samples). Note the high transmission of both samples through the visible region (400 to 800 nm) and the nearly identical values for both ceramized and unceramized (glassy) samples at wavelengths greater than ≈ 1000 nm
Fig. 5.53 Measured and calculated scattering cross sections in Zerodur

the observed value. The particle-size-independent model (5.144) gave comparable results to the pure Rayleigh model at 500 nm (6.6×10^{-14} cm^2). Numerically integrating the Rayleigh–Gans equations (5.141–5.143) yielded 1.4×10^{-14} cm^2 at 500 nm, a fairly small correction from the pure Rayleigh value. The model of Hendy yielded 3.3×10^{-17} cm^2, quite close to the measured one near 500 nm. However, the Hendy model predicts a too steep, λ^{-8} dependence, refuted by the very close agreement between the data in Fig. 5.53 and those models that predict a λ^{-4} dependence.

Nonlinear Properties (Electro–Optic, Pyroelectric, SHG, etc.). Although nonlinear crystals have been in use for over 100 years [5.143], the use of glass–ceramics as a host for such crystals has only been known for some 50 years. *Herczog* [5.140] reported the crystallization of microcrystalline $BaTiO_3$ from suitable borosilicate glasses and the production of glass–ceramics with relative permittivities exceeding 1000, whereas *Borrelli* et al. [5.159] and *Borelli* [5.160] reported quadratic electro-optic behavior in $NaNbO_3$-containing glass–ceramics. Nanometer-sized crystals in related transparent glass–ceramics that previously failed to exhibit ferroelectricity were shown to exhibit pyroelectricity, thereby confirming their status as active crystals but revealing a size dependence on the glass–ceramic's measured functionality [5.115]. More recent work regarding transparency requirements in systems containing ferroelectric crystals has focused on crystal number densities, sizes and refractive index contrasts [5.161, 162].

A wide variety of compositional families that contain nonlinear crystals have been explored, including transparent titanate- and tantalate-bearing glass–ceramics [5.161, 163]. Telluride systems offer the advantage of a relatively small refractive index contrast between the high-index active crystals and the high-index residual glass matrix [5.122, 164–166]. Transparent bismuth–borate glass–ceramics have been developed to yield materials that exhibit second-harmonic generation [5.155, 167, 168] as have potassium–niobate [5.154] and potassium–titanium phosphate compositions [5.169]. Results on glass–ceramics containing superconducting $Bi_3Sr_2Ca_2Cu_3O_{12-x}$ crystals have been reported [5.170] as have glass–ceramics for X-ray scintillators [5.118, 171].

Glass–ceramics have been developed to serve as frequency upconverters, luminescent materials, laser hosts, Q-switches, and optical amplifiers (Table 5.18) [5.117, 172–177]. The typical design goal is to partition all elements that participate actively in the nonlinear process into the crystal phase, as in the *Beall* example noted earlier [5.119], thereby increasing the efficiency of the active process (e.g., narrowing a laser linewidth). Although early reports of Nd-doped $Li_2O-Al_2O_3-SiO_2$ glass–ceramics reported lasing [5.178, 179], subsequent work showed that Nd was not incorporated into the crystal [5.180], thereby limiting the advantage of the glass–ceramic route. Much recent work has focused on high-transparency rare-earth-doped fluoride- and oxyfluoride-based compositions for optical amplifiers [5.181–191]. Q-switching has been demonstrated in Co-doped $MgO-Al_2O_3-SiO_2$ glass–ceramics [5.177, 192, 193]. Long-lasting (> 12 h) phosphorescence has been reported for Mn^{2+}-doped $ZnO-B_2O_3-SiO_2$ glass–ceramics [5.194]. Cr-doped mullite-containing glass–ceramics have been developed for solar energy concentrators and laser hosts [5.195]. These have met the criteria for good absorption in the visible with luminescence in the near-IR suitable for conversion to electrical energy by Si photovoltaic strips, although the conversion efficiency is too low at present to make a viable alternative to existing solutions [5.112].

5.5.3 Applications

This section will highlight optical glass–ceramic applications that have actually made it to the commercialization stage, a stringent feat for any materials development program. The list includes glass–ceramics

Table 5.18 Examples of active functionalities attained in glass–ceramics

Material	Active feature	Characteristic feature
$K_2O-Nb_2O_5-4SiO_2$[a]	Second-harmonic generation	Up to 600 times that of quartz
$Li_2B_4O_7-Bi_2WO_6$[b]	Relative permittivity	Up to 10^6 at 673 K (100 Hz)
(Na, Sr)NbO_3[c]	Kerr constant (electrooptic)	$\approx 2 \times 10^{-17}$ m^2/V^2
$BaO-GeO_2-TiO_2$[d]	Piezoelectric	$d_{33} \approx 6$ pC/N
$Li_2O-SiO_2-B_2O_3$[d]	Pyroelectric	$p_3 \approx -8$ μC/m^2/K
$BaO-B_2O_3$[e]	Second-harmonic generation	0.12 times that of urea

(Sources: [a] [5.154], [b] [5.155], [c] [5.156], [d] [5.157], [e] [5.158])

used for both reflective (e.g., mirror) and transmissive (e.g., coating substrates) applications.

Reflective

One of the cornerstone applications for glass–ceramics is for mirror substrates. Typically this calls for ultra-low-expansion materials due to the exacting dimensional tolerances that must be attained to ensure satisfactory optical resolution in semi-controlled ambient environments such as an astronomical observatory. The use of negative-expansion high-quartz solid-solution crystals embedded in a positive expansion glass matrix to induce a nearly zero CTE has a long history [5.112, 196]. One of the most widely used low-expansion glass–ceramics for mirrors is Zerodur, developed by Schott Glas nearly 40 years ago [5.153]. In addition to control of the dependence of CTE on temperature [5.197], studies have reported precision polishing of Zerodur substrates using both conventional and ion-beam finishing [5.198, 199] although much knowledge on this topic remains proprietary to individual finishing houses. A common and nonproprietary technique to remove microcracks formed during grinding is the use of an HF−HCl acid etch to physically and chemically remove material [5.124]. Although HF is a well known and effective etchant of silicate glasses and glass–ceramics, the use of HCl is equally important to prohibit the precipitation of insoluble fluoride compounds on the surface of the material being etched. Recipes are also known for the removal of standard mirror coatings [5.124].

Although there are many examples of large Zerodur mirror blanks currently in service in astronomical observatories around the world, one is particularly noteworthy: the very-large telescope (VLT) array in Chile. There, four 8.2 m Zerodur-based telescopes use state-of-the-art adaptive optics and interferometric techniques to attain very high optical resolution with tremendous light-gathering capability [5.200, 201].

Transmissive

One of the earliest applications of glass–ceramics coincides with the emergence of glass–ceramics as a new material. *Stookey* [5.202] at Corning was able to fabricate a radio-frequency-transparent high-strength cordierite glass–ceramic called Pyroceram. This material is still used on the radar domes (radomes) of hypersonic missiles and has extremely low levels of rain erosion at these speeds; a chemical etch is used to increase the strength of the material [5.123].

Robax, a VIS-transparent, low-expansion glass–ceramic manufactured by Schott Glas, is widely used in oven and fireplace sight panels. The high transparency of the material (similar to Zerodur noted above), high thermal shock resistance and extremely high maximum service temperature (680 °C continuous, 750 °C for short times) has allowed Robax to replace borosilicate glass in many applications [5.124].

Telecommunication technologies have also driven glass–ceramic developments. Ohara has released IR-transparent high-Young's-modulus (E) high-CTE glass–ceramics called WMS-13 and WMS-15 for dense-wavelength-division multiplexing (DWDM). These materials also feature excellent chemical durability and the ability to achieve low RMS roughness values through superpolishing. The somewhat atypical combination of high E *and* high CTE while maintaining good chemical durability – required for the use of these materials as substrates for thin-film interference filters in field-based applications – is considerably more difficult to achieve in glass.

Thin-film, transparent protective glass–ceramic coatings couple good transparency with extremely good wear resistance. *Rother* and *Mucha* [5.203] report using SiO_2 and Al_2O_3 powders and an electron beam evaporator to deposit a 3 μm coating on automobile wheel demonstrators. The mechanically stable coatings will undergo further testing before widespread commercialization.

5.6 Nonlinear Materials

5.6.1 Overview on Nonlinear Optical Materials

In Sect. 5.1.5, we have mentioned that, even among the second-order nonlinear (NL) materials [5.204–211], not many made their way into industrial application (because of disadvantages that NL materials are suffering

due to other intensity dependent effects besides the desired one).

The materials with the highest nonlinearities can be found among the (photonic) crystals, such as the ferroelectrics ADP and KDP used in electrooptical and acoustooptical devices where the first crystals were applied for frequency conversion. Due to their lack

of a center of symmetry, these crystals show rather high second-order susceptibilities, which are suitable for applications like frequency upconversion and others. Substitution of cations of an intrinsic nonlinear crystal (e.g.: Gd in Gd–Ca–Oxyborate) by optical active cations, like rare-earth cations (e.g. Nd^{3+}), results in self-frequency doubling crystallites, which combine the active ion with the nonlinear host. Photorefractive crystals can be used for many applications including phase conjugation, image amplification, information processing and optical computing. In the past, most of the experiments concerning optical nonlinearity have been performed on $BaTiO_3$ single crystals, which have excellent photorefractive properties, but are difficult to grow. One of the present leading crystals is K–Na–Sr–Ba–Niobate (KNSBN) because of its large electrooptic coefficients. Two further advantages of this material are that there is no room temperature phase transition and that there is a possibility of doping with Mn, which enables the formation of deep level centers for charged carrier recombination. On the other hand, single crystals, which are very expensive, are needed to avoid scattering effects [5.205, 212–216]. The high costs, and thus economic disadvantages, of crystalline materials arise due to the extreme difficulties to grow them. Nevertheless crystalline materials, especially the niobates will still be among the major materials for all-optical applications. But on the other hand, the limitations of Li-niobates will result in the research into materials like novel ceramic crystals, polymers and even fullerenes.

Other materials with high nonlinear refractive index and near resonance nonlinear effects are organic molecules, such as dyes, polymers (p-toluene-sulphonate), aromatic molecules, and molecules of the pyridine family, the stilbene family, and others which have extremely high $\chi^{(3)}$ values in the direction of the polymer chain, or chiral conjugated polymers and dendrimers (e.g. polydiacetylens) The disadvantages of these materials are their thermal instability, their softness, and the difficulty to get crystals of sufficient size. Furthermore, because of the mostly resonant nonlinearity, the response time for optical switching of these materials is rather low. A possible way to stabilize the organic molecules against degradation and to achieve larger sample sizes is to dope a glass host with these molecules. Glasses doped with organics will be further discussed Sect. 5.6.5 [5.205, 217, 218].

Currently it seems rather clear that the main improvements will come out of the field of organic crystals, as there exist the best possibilities to develop new high potential systems, whereas no real developments are expected to come from the field of inorganic crystals. Composites may also offer new possibilities to overcome the problems of the current materials.

An overview over many common NL materials is given in Table 5.19. Table 5.20 then lists some of the most common NL materials and their proposed (and sometimes already commercially realized) applications. Table 5.21 presents nonlinear susceptibilities for a wide range of exemplary inorganic and organic crystals.

According to *Hirao* [5.204, 219, 220] and others [5.221, 222], for the development of high efficient optical devices the following points have to be taken into account:

- Increase of the upconversion-efficiency and the transition probability of the radiating transition of RE-ion dopands by selection of glass hosts with low multiphonon emission rates.
- Processing speed ("turn-off" times in a time range < ps)
- Phase matching
- Operating power and fraction of power, which can be switched: low switching energy and rapid switching times
- Nondispersive
- Heating stability
- Improvement of the crystallization stability
- Enhancement of IR-transparency and chemical resistance
- Avoiding release of toxic and aggressive substances
- Development of low cost fabrication methods
- Control and measurement of traces of contamination during the fabrication process

In contrast to the materials named above, materials which posses inversion symmetry (isotropic materials), like glass, have no second-order contribution of the optical susceptibility. Nonlinear glasses can be found among the oxide- halide- and chalcogenide glasses (intrinsic nonlinearity) and the semiconductor (SC), metal particle and organic dye-doped glasses (extrinsic nonlinearity) These materials have been intensively investigated in bulk structure as well as in waveguide and fiber structure and have shown many interesting properties: SC-micro-crystal doped films emit electroluminescence, dye-doped polymers exhibit SHG and Faraday effect glasses can be used for magneto-optical switches. Furthermore, methods for the fabrication of long period optical fiber gratings have been developed [5.204, 219, 220].

Table 5.19 The most important and other less important nonlinear optical materials [5.210]

Specialty **ceramics**: Li-, K-Niobate, K-Titanylphosphate (KTP, also very successful: used for doubling to Nd:YAG laser frequency to 532 nm), Li-Tantalate, Sr-Ba-Niobate, B-Ba-Borate, Li-Triborate (Other ceramic NLO materials: Ce-doped Sr-Ba-Niobate, Bi-silicon dioxide, Ba-Titanate)

Rare-earth elements doped in silica: Er and Pr in optical fiber amplifier (OFA)

Nanophase materials made from micrometer-sized powders: especially important, when used in composites

Polymers (including third-order NL-optical polymers, NL-dye functionalized thermoplastics)

Silicon-plastics: polysilicates and polysilynes

Liquid crystal polymers

Compound SC: transparent in the IR region

Ceramics

Semiconductors: excitation of carriers changes the optical properties, but difficult to find materials with low activation energies and large NLO properties, also difficult production.

Superlattices: excitation of carriers in the narrow bandgap part leads to migration of the carriers into the wide bandgap part, which creates a large charge separation. Possibility of tailoring the optical properties. But also difficult to produce.

Organic materials: disadvantages: thermal (operation temperatures about 80 °C) and chemical instabilities, but easy manipulation. Leading candidates are the Methacrylates (properties similar to $NiBO_3$, low cost production, but poor strength and easy evaporation), Poly- (di-) acetylenes (good NLO properties, but unstable, hard to dissolve), Nitroanilins, . . .

Table 5.20 Applications and proposed nonlinear materials [5.222]

Application	Material
Communications	
Modulation and switching	$LiNbO_3$, KTP, II–V-SC, MQW's
Directional couplers	$LiNbO_3$
Lenses	$LiNbO_3$ with As_2S_3-glass

The third-order susceptibility of glasses is generally much smaller than the second-order contributions of the crystalline material mentioned above. Additionally, the third-order nonlinearity makes a variety of processes possible, such as THG, FWM, DFWM (optical Kerr effect), as well as intensity dependent refractive index changes. But glass also shows some advantages compared to other second and third-order nonlinear materials [5.204, 206, 207, 222]:

- roducible with high optical quality and transparency/homogeneity even in large sizes
- easy fabrication of fiber and film waveguides with high quality
- high transparency over large spectral ranges
- high chemical, thermal and mechanical stability and durability, high optical damage threshold
- adjustable compositions
- quicker production process
- potential lower cost

A correlation between nonlinear properties and material structure would allow us to predict the nonlinear prop-

erties of new materials. A kind of quality coefficient can be used as a measure for the nonlinear properties of the materials. There are many suggestions for appropriate figures of merit for nonlinear materials, most of them reflect besides $\chi^{(3)}$, the absorption α and the response time τ of the material

$$F = \chi^3 / \tau \alpha . \tag{5.148}$$

For instance, the optical glass SF59 has a relative high figure of merit (FoM), not because of high nonlinearities (compared to typical second-order materials), but because of extremely low absorption and insensitivity to thermal effects [5.206, 207].

Due to the usually low third-order nonlinearities of glassy materials, nonlinear optical devices for signal processing or logic circuits for optical computing have to be produced in waveguide geometry to increase the power density. Optical waveguides can be produced via sputtering, CVD (Chemical vapor deposition), sol–gel coating, ion implantation and ion exchange. Besides the planar or channel waveguides, optical fibers are ideal for the study of nonlinear interactions as well as for

the desired applications, because they combine strong beam confinement and low loss for propagation over long distances [5.206].

We now describe in more detail two representitive research areas for nonlinear materials, all optical switching and observation of second-harmonic generation in the isotropic material glass. Followng this is a discussion of the many glass systems, which have been intensely investigated for nonlinear effects over the last 20 years.

5.6.2 Application: All 0ptical Switching

All-optical switching [5.204–206, 219, 220, 223] is a technique based on the optical Kerr effect (linear electrooptical effect) and means the switching of a light beam by using a pump beam which changes the optical communication signal to be switched. The first ultra fast all-optical switch was demonstrated on a silica glass fiber. Silica is known to have only a small nonlinear susceptibility, but also a very small absorption coefficient at the operating wavelength. This allows all-optical switching between two waveguides embedded in the same fiber simply by controlling the pulse intensity. Generally, for optical switching at THz frequencies, there are several important material requirements besides $\chi^{(3)}$, interaction length, and light intensity that need to be present [5.205, 212]

- high damage threshold or thermal stability,
- low power switching threshold and minimal (two photon) absorption,
- wavelength tunability,
- sub-ps- nonlinear response times,
- compatibility with waveguide fabrication process.

The efficiency of a switching device is induced by confinement of the beam into the waveguide over a macroscopic distance. The "turn-on"-time of all nonlinearities is instantaneous, even for the thermal related effects. Thus, the most important parameter for optical switching is the relaxation time of the nonlinear index change. To avoid crosstalk, this relaxation time has to be significantly shorter than the time between two pulses. Two of the fastest switching speeds among the nonlinear materials, besides the organic para-toluene sulphonate, are found in the systems $Au:SiO_2$ and $Cu:SiO_2$. Generally, chalcogenide glasses, as well as metal and semiconductor doped glasses also are prospective materials for all-optical switching devices.

A figure of merit (FOM) for ultrafast photonic switching expresses the ratio of fast index change to the resultant thermal index change and is an indication for the number of switching operations that can be performed within the thermal lifetime [5.206, 207]:

$$F = n_2 c_p \varrho / \tau \alpha (\mathrm{d}n/\mathrm{d}T) . \qquad (5.149)$$

Due to this FOM, the ideal material for all-optical switching has high nonlinearities, fast response and minimal absorption. For instance, the lead silicate glass SF59 has a relative high FOM because of extremely low absorption and insensitivity to the thermal effects. SC-doped glasses show large and relatively fast NL-absorption changes, but the switching value of these SC-doped glasses is too low for practical application. Dye doped glasses have higher nonlinearity, but their response times are too slow for application. Another limitation of the resonant nonlinear materials for all-optical switching is two-photon-absorption (TPA).

Among the other nonresonant, nonlinear glasses, Bi_2O_3-glass with response times of ≈ 100 fs and a repetition rate of switching of about 1.6 THz is a very prospective candidate for all-optical switching. Other candidates are chalcogenide glass fibers (response time ≈ 200 fs) One disadvantage of these glasses may be a structural change occuring when irradiated with light near the bandgap wavelength. Additionally, photonic bandgap materials, like Au-doped, poled glasses are considered for optical switches [5.204, 219, 220].

Like the diffractive and the holographic optical elements, the switchable optical elements can be used in a great variety of advanced devices; from everyday consumer products (eyeglasses, cameras, CD-players, animated holograms and real time holographic display systems) to commercial instrumentation (tunable grating elements, fiber optic crossbar switch, tunable Bragg grating for DWDM) Many patents exist for applications from biochip reader to flexible flat-panel displays. Three existing kinds of optical switches are:

- **Directional coupler**: switching into one or the other channel; characteristics are controlled by the beam itself.
- **Mach–Zehnder interferometer**: switching is controlled by one or two separate control beams.
- **Nonlinear mode sorter**: a multi-mode beam is split into two channels. By varying the input power, the phase difference between two modes can be tuned. Thus, depending on the power of the signal, the

modes were separated and the output switched from one channel to another.

5.6.3 Second Harmonic Generation in Glass

Besides the Ge:SiO$_2$ fibers discussed in Sect. 5.1.5, other glasses which show photo-induced second-harmonic generation are Tm-doped alumosilicate fibers (resonant enhanced SHG) [5.224] and semiconductor microcrystallites-doped glasses [5.225], whereas Ce-doped lead germanate glasses show only low intensities (Table 5.22) [5.226].

SHG in HMO-Glass
Ionic bonds are believed to play a major role for encoded photoinduced SHG. Thus, it is not surprising that the SHG intensity in binary lead germanate glasses is found to be zero in contrast to binary lead silicates. Addition of Ce to the glass resulted in observation of saturable SHG. Low-Pb glass has a very low photoinduced SHG efficiency saturation level. On the other hand, for higher Pb-concentration the damage threshold of the glass decreases significantly. Further, the induced grating can be erased by an IR reading beam after some seconds. Comparison of lead silicate, Ce-Pb-germanate and Ge:silicate shows that high SH efficiencies can be achieved with Pb-containing glass at much lower preparation powers.

SHG in Rare Earth-Doped Glasses [5.227, 228]
Due to the absorption peaks near the SH wavelength, only a limited number of REs are suited for SHG with 1064 nm as fundamental wavelength. Furthermore, two or three photon absorption processes have been observed e.g. for Tm-doped glass, which lead to luminescence e.g. at 470 nm. Temporal and thermal stability is also a crucial factor in these glasses. As the formation of the $\chi^{(2)}$ grating is based on photooxidation, thermal and temporal stability of the gratings can be rather low, as the electron traps are usually rather shallow.

SHG in CdSSe-Doped Glasses [5.226]
SHG with pumping at 1064 nm was found to be more intensive for OG550 than for GG495. But GG495 is expected to be less sensitive to pumping and readout index changes. For instance, the SHG-intensity for OG550 (7.7×10^{-2} s^{-1} for 2 W) is found to rapidly decrease with time (optical erasure), whereas there is only a small decay for GG495 (1.5×10^{-2} s^{-1} for 2 W). Smaller decay effects due to heating are also found. Damage threshold of the glass is about 500 W/µm^2.

5.6.4 Glass Systems Investigated for Nonlinear Effects

Oxide Glasses Without Heavy Cations
The glasses of this group usually show only small nonlinearities, which are directly correlated with the nonbridging oxygen content [5.205, 206, 212, 229]. Measurements of various groups showed that the nonlinearity of nonbridging oxygen is significantly higher than that of bridging oxygens.

Despite the low nonlinearities of the oxide glass system, there have been recent experiments with silicon nanocrystals embedded in SiO$_2$ matrix. These samples show a $\chi^{(3)}$ of about 10^{-9} esu, dependent on the nanocrystal size. A much more interesting system, which is a kind of link to the heavy metal oxide glasses, is silica doped with various amounts of germania. The increase of the linear refractive index with increasing germania content consequently increases the nonlinear part of the refractive index. For about 50 wt % of GeO$_2$, a nonlinear refractive index of 1.1×10^{-13} esu has been found. Hydrogen-treatment even increases this value. Germania-doped silica fibers show photo-induced refractive index changes of up to 10^{-3} through exposure to UV light [5.230].

Heavy Metal Oxide Glasses (HMO)
The HMO-cations [5.231–233], like Pb, Bi and Ga posses large polarizabilities and therefore strong optical nonlinearities. Elements heavier than Bi might have larger NL-properties, but have disadvantages, such as their high toxicity, radioactivity and the sometimes poor optical quality of the resulting glasses, which make them useless for any practical application. Ba and La seem not to be responsible for nonlinearities. Tl$^+$ contributes strongly to the nonlinearity, for instance in the Tl-germanate, Tl-tellurite and Tl-antimonite glasses. It is the only metal which is a post-transition element and therefore forms bonds with large polarizability. In spite of this, Tl-containing glasses are not suitable for practical application, mainly due to the high toxicity.

Among the HMO-glasses, the Bi-oxide glasses and the Bi–Ga-oxide glasses are the most prospective for nonlinear devices. For example a Pb–Bi-Gallate glass was found to have the largest nonlinearity among the oxide glasses. In this glass system, Pb and Bi have an equivalent influence on the nonlinearity. Optical Kerr shutter experiments on Bi-glasses have shown that the response times of these glasses are in the range of 150 fs and THz optical switching can be performed. Thus, the conclusion was drawn, that these glasses are prospec-

tive materials for the realization of ultra fast response and high frequency switching (ultrafast switches, optical isolators and in advanced computing).

As a rule of thumb, one can say that the larger the linear refractive index, the higher the third-order susceptibility. Glasses with refractive indices higher than 2 have a $\chi^{(3)}$ larger than 10^{-13} esu. Typical ranges of $\chi^{(3)}$ for HMO-glasses are 10^{-12} to 10^{-11} esu, which are almost the same for all HMO-glasses. Due to the electronic nature of the nonlinearity, the response times of HMO-glasses lie in the sub-ps range. This makes the HMO-glasses good candidates for all-optical switching applications. For incident light with optical frequencies, possible present nuclear contributions would be mitigated, because of slower response times of nuclear motion.

Transition Metal–Doped Glasses

Oxide glasses show an increase in the NL-indices when they are doped with transition metal cations or index raising conditional network formers, like Ti, Ta and Nb, due to the high hyperpolarizability of these ions [5.206, 234–236]. Ions with an empty or unfilled d-shell (d^0 electron configuration), like Nb or Ti (i. e. Ti−O entities), contribute most strongly to the hyperpolarizabilities [5.231]. On the other side doping, for instance with rare earths, can lead to a strong increase of the absorption coefficient in some of the commercially interesting spectral regions (e.g. telecommunication windows) Thus, rare-earth- (RE) doped glasses were are prominent for their application as laser glasses (upconversion lasers) or optical amplifiers.

Compared to the heavy metal cations, the nonlinearity of this group seems to be caused by another mechanism. This is due to the fact that (e.g.) TiO_2-dopands are found to be responsible for nonresonant NL-effects in glass. However, the combined effect of Ti and HM-cations, like Bi and Tl, show NL-effects not higher than 10^{-18} m^2/W. An explanation might be the fact, that glasses with high concentrations of Ta, Ti and Nb are found to have negative electrooptic coefficients, in contrast to Pb^{2+}. Therefore Ti^{4+} can be used to balance the positive electrooptic contribution of Pb^{2+}.

Studies with Nb-containing oxide glasses have shown that the d^0-transition metal is located in a (Met−O)^6-configuration, with the oxygen electrons strongly delocalized towards the transition metal. This delocalization results in a large hyperpolarizability and thus large nonlinearity, which is found to be directly proportional to the concentration of (Met−O)^6-entities [5.235].

Non–Oxide Glasses

Among the halide glasses, the fluoride glasses have the smallest NL, and the bromide and iodide glasses have the largest NL [5.206, 231, 237]. However, bromide and iodide glasses show very low glass-transition temperatures and poor chemical durability. Thus, they are not attractive for nonlinear applications, although the significant laser oscillation of the fluoride glasses at 1340 nm cannot be covered by oxide glasses.

Among the chalcogenide glasses, S glasses as well as Se and Te glasses show much higher nonlinearities than oxide glasses. As_2S_3 glass has shown the highest third-order susceptibility of all intrinsic nonresonant nonlinear glasses. Further examples of chalcogenide glasses with very high nonlinear susceptibilities are: $As_{40}S_{57}Se_3$, $As_{40}S_{60}$ and $As_{24}S_{58}Se_{38}$. Closer inspection of the origin of the nonlinearity of this glass exhibits a ratio $\chi^{(3)}_{2121} / \chi^{(3)}_{1111}$ of nearly zero, which is much smaller than the expected value for nonresonant NL of $1/3$, the expected value for purely electronic contribution. The result of further investigations showed, that a kind of resonant contribution due to two-photon absorption is responsible for the high nonlinearity of this glass. Due to their very short response times, chalcogenide glasses are prospective materials for use as optical memory, switching devices, and (Bragg-) gratings in planar waveguides ($\Delta n \approx 10^{-4}$) Experiments with these glasses have shown that high quality, low loss waveguides for optical applications can be easily formed.

Tellurite and antimonate are both known as network formers, which contribute to $\chi^{(3)}$ via their stereochemical lonestanding electron pair in 5s (e.g. structural unit TeO_4) Both tellurite and antimonate glasses show a very good IR-transmission as well as very good chemical durability. Tellurite glasses have a nonlinear refractive index of 30−70 times that of silica. Pure tellurite containing glasses are difficult to prepare, thus, most of the investigated glasses have tellurite concentrations of about 70% [5.231].

5.6.5 NL–Effects in Doped Glasses

With the exception of the transition metal-doped glasses, all the glasses discussed above have intrinsic nonresonant nonlinearities [5.206]. Due to the fast response time of the usually electronic nonlinearity and the low absorption coefficient, the figures of merit of these materials can be rather high, despite the low $\chi^{(3)}$. In contrast to these glasses, the glasses discussed in the next part of the chapter have extrinsic resonant nonlinear optical prop-

erties, which are usually higher than the nonlinear ones at least in the spectral regions of fundamental absorption (Table 5.23).

Semiconductor–Doped Glasses

Among the studied nonlinear glasses, semiconductor-doped glasses [5.205, 208, 212, 223, 238, 239], especially the Schott filter glasses based on $Zn_yCd_{1-y}S_xSe_{1-x}$, have been studied extensively. Other semiconductor dopants, besides CdSSe, are CuCl, CuBr, Cu_xSe, Ag(Cl, Br, I), CdTe, III–V compounds, Bi_2S_3, PbS, HgSe, In_2O_3, In_2Se_3, SnO_2 and AgI. Among all these glasses, the best materials for ultrafast switching, based on a FOM, are ZnTe, CdTe and GaAs. In some experiments, the optical switching is done with different pump and probe wavelengths. As a result, it has been found that one gets a larger $\chi^{(3)}$ for the small loss in the near resonance region.

Semiconductor-doped glasses exhibit large nonlinearities based on optical Kerr effect at photon energies near the bandgap. The NL-behavior of these materials is characterized by intensity dependent changes in absorption and related changes in the refractive index ($\Delta n \cong 10^{-4}$) with relaxation times in the range of ns or ps. A strong dispersion in the electronic nonlinearity is found near the two-photon absorption (TPA) edge. The nonlinear refractive index increases as the TPA-edge is approached and eventually becomes negative at higher energies. The nonlinear properties of CuCl-doped glasses are based on an enhancement of the nonlinearity in the resonance region of the CuCl Z_3-exciton [5.207]. The advantages of semiconductor-doped glasses (SDG) compared to the bulk semiconductor (SC) are [5.238, 239]:

- fast (ns–ps) response time,
- high threshold,
- weak absorption losses (for working wavelengths still near high absorption wavelengths!)
- possible usage at room temperature (but binding energies of these glasses are usually in the range of a view meV, thus, devices based on these materials better have to be operated at low temperatures).

On the other hand, the nonlinear optical effects in SDGs are smaller than those in bulk SC: χ^3 of the doped glasses is typically in the range of 3×10^{-9} to 10^{-4} esu. For example for CuCl-doped glasses, $\chi^{(3)}$ is in the range of 10^{-3} to 10^{-8} esu, depending on the crystallite size. Changing the crystallite size, doping with other semiconductors or metal colloids like Au or Ag, or changing the glass host composition may improve the nonlinear properties. Decreasing the size of the nanocrystallites, and thus enhancing the confinement, enhances the nonlinearity.

Metal–doped Glasses

Glasses containing very small metal particles exhibit an efficient, fast optical Kerr-effect [5.204, 206, 212, 219, 220]. The enhancement of the intrinsic $\chi^{(3)}$ arises from the surface mediated plasmon resonance, analogous to the SER-effect. The observed Kerr susceptibility or electronic nonlinearity of these materials includes contributions from intraband (transition into the conduction band), interband (saturation of interband transitions between d levels and the conduction band) and hot electron transitions (creation of photoexcited hot electrons due to the surface plasmon absorption) The maximum of the nonlinear susceptibility is found to be near the surface plasmon resonance.

Metal-doped glasses are expected to be good candidates for optical bistability and optical switching. Silver and gold particles dispersed in glass show NL effects, such as optical phase conjugation.

Gold-doped glasses: For gold spheres, $\chi^{(3)}$ is positive and found to be independent of particle size, with response times in the ps-regime. The nonlinear response of gold nanoparticle-doped glasses has been found to be as fast as 240 fs [5.240].

Silver-doped glasses: Glasses doped with silver nanoparticles exhibit an ultrafast nonlinear response of 360 fs and a $\chi^{(3)}$ of about 7.6 to 15×10^{-8} esu [5.204, 208, 241].

A nonlinearity of thermal origin has been reported for Mn doped glass. Due to a theoretical calculation, Al is suggested to have a larger nonlinearity than Ag and Au. By preparing core-shell systems, an enhancement of the nonlinearity by a factor of 10^8 might be possible [5.206]. Metal-doped glasses can be produced via sol–gel-technique, ion exchange, ion implantation or electrolytic coloration. Various metal-doped silica glasses, such as copper-, silver-, gold-, platinum-, lead-, tin-, iron-, germanium-, and phosphorous-doped glasses have been investigated. Of these glasses, the tin-implanted glasses have the highest nonlinear susceptibility. The size and the shape of the metal clusters can be modified by thermal treatment or by ion implantation with another element [5.206, 241].

Organic (Dye–) doped Glasses

Organic dyes, polymers and solvents, like 4-(N,N-diethylamino)-β-nitrostyrene (DEANST), acridine, fluorescein and rhodamine 590, have intense singlet–singlet-

Table 5.22 Poling of glass for second-harmonic generation [5.225, 227, 228, 242]

Glass	Poling	Parameters		SHG coefficient d (pm/V)
Fused silica, containing Na, OH	Thermal	275 °C	5 kV	1 (in a 10 μm layer)
GeO_2-SiO_2 , Herasil	Thermal + electric	280 °C	4.3 kV	1
Ge-silicate "half"-fiber	Thermal + electric	275 °C	−5 kV	0.3
Ge-silicate optical fibers	Electric, thermal electric and UV			0.002 to 6

GeO_2-SiO_2 sputtered film	Optical + electric field	ArF 100 mJ/cm^2/pulse	Electric field	up to 12.5
15.7 GeO_2−84.2 SiO_2 (mol%)	Optical + electric field	ArF: 10–100 mJ/cm^2/pulse	3×10^5 V/cm	7×10^{-3}–2
Ge-silicate	fs-encoding	810 (960 mW)	405 nm (200 fs, 200 kHz)	
Er-, Tb- and Sm-doped Al-silicate fibers, Er-doped Ge:SiO$_2$ fiber	Optical	1065 nm (30–50 GW/cm^2)	Seed: 532 nm	Conversion effic.: 10^{-6} to 10^{-3}, 8×10^{-3} in Ge-silicate
Ce- and Eu-doped Al-silicate fibers	Optical	Nd:YAG: 1064 nm	Seed: 532 nm	Conversion effic.: 2×10^{-6} to 1.5% for Ce-doped fiber for 200 W pump
Tm-doped aluminosilica fiber	Optical	Nd:YAG: 1064 nm	Seed: 532 nm	SH output e.g. 4.6×10^{-2} W for 240 W pump at 1064 nm and 4.6×10^{-2} W for 55 W at 844 nm
Ce-doped lead germanate glass	Optical	1065 nm Nd:YAG	Seed: 532 nm KTP	
CdSSe-doped: GG495–RG630	Optical	1065 nm (3 W)	532 nm (1 W) pulsed laser	10^{-4}
Chalcogenide glasses: GeAsS	Optical	Nd:YAG 1064 nm	Seed: 532 nm	α(532 nm) = 1.99 cm^{-1} conversion effic.: 10^4x that of $TeO_2-Nb_2O_5$-glass
Fused silica fibers containing impurities: OH, Na, Fe	Gamma ray	^{60}Co source (10^6 rad at 400 rad/s)	1064 nm (Nd:YAG, 50 ns, 10 Hz, 1 kW) and 532 nm seed (300 W), 1 h	2×10^{-4} (natural SiO$_2$) 9×10^{-3} (Ge:SiO$_2$ + Ce) 2×10^{-2} (Ge:SiO$_2$ + Ce)

Table 5.23 Nonlinear susceptibilities of commercial glasses

Glass system	$\chi^{(3)}$ (10^{-14} esu)	Wavelength range
Heavy metal (Tl–Pb–Cd–Ga)	up to 56	High frequency
Pb-silicate	up to 16	
Ge–Ga–S	3000–27	600–1250 nm
Semiconductor doped (CdSSe)	up to 5 000 000	Near exciton absorption peak
Nb–Te-oxide	9.4	
Bi-oxide	930	
Chalcogenide	174	
Noble metal doped glass	up to 10 000 000	Near plasmon absorption
Dye doped glass	up to 1.4×10^{14}	Near absorption

transitions, which contribute to a high second-order susceptibility [5.204, 206]. The doping of glasses with dyes, polymers, and other organic materials also results in high nonlinearities, several orders of magnitude larger than that of inorganic glasses. Thus, these glasses are attractive candidates for various low power optical devices, such as optical power limiters, phase conjugated mirrors or optical logic gates. The large nonlinearities are caused by saturation of the near resonant intensity dependent ground state absorption. The

excited dyes may return to their ground state either radiatively or nonradiatively or be transferred to the lowest triplet state by intersystem crossing. Triplet-singlet-transitions are forbidden, thus the triplet state has a lifetime many orders of magnitude longer than the singlet states. For sufficient intense excitation, the electrons accumulate in the triplet state and the ground state absorption is saturated. This produces a change in the refractive index via the Kramers–Kronig relation.

Dye-doped glasses are made by impregnation of porous silica or sol–gel-methods or require low melting glass hosts, such as lead–tin–fluorophosphate- (good optical quality and chemical stability) or boric acid-glass, because of the thermal degradation or decomposition of the dyes.

5.7 Plastic Optics

Injection moulded precision plastic optics in high volumes were first produced during the 1960's. After the development of sophisticated measuring and manufacturing methods in the late sixties also precise aspheric surfaces were as easy to make as spheric contours. Today plastic optics are a widely used low-cost option compared to glass with even more degrees of freedom for optical and component design. Polymer optical systems at present are used in sensor applications, visual systems, cameras (mobile phones, video-conferencing cameras), scanners, security systems and so on.

Of course the properties of glass materials are very different from that of plastic materials. But glass and plastic optics both offer unique advantages and help to solve various engineering problems.

Generally speaking, glass materials are harder and more durable than plastic materials. Glass materials are also more stable (temperature and humidity) than plastic. The variety of optical glass available from well-know suppliers comprises hundreds of different materials. Compared with this the choice for plastic materials is limited only to about 10 different materials (and even less optical parameter variations). The large selection of glass materials allows the designer to choose materials with desirable optical properties to gain better optical performance. However, plastic optics offers other design freedoms that are not achievable with glass optics.

The manufacturing technologies for glass and plastic optics are totally different. Glass lenses are made by a grinding and polishing process whereas precision plastic lenses are in the whole made by injection-moulding or compression moulding. Because of the materials characteristics and the manufacturing process plastic optics have some unique advantages.

- **High production numbers at low costs**
  Injection moulding is ideal for high volume production with low unit costs. Moderate raw material costs and multi cavity moulds (up to 32 cavities) allow large production volumes at a reasonable unit price. In spite of normally considerable tooling costs the cost break-even compared to glass design versions can be relatively low.
- **Lightweight and hardiness**
  For a given volume glass is much heavier than plastic (by a factor of 2.3 to 4.9). Plastic materials are relatively shatter and impact resistant. These features are important, e.g. for head-mounted systems.
- **Design potentials**
  Injection moulding makes it economical to produce sophisticated optical shapes such as aspheres, diffractive optical elements or even freeform surface structures. From the design point of view, the more sophisticated surface shapes reduce costs or obtain better performance or even performance unrealisable by optics in glass (Fresnel structures, lens arrays, diffractive optical elements).
- **Optical systems and component assembly**
  For typical optical systems, the optical components (mirrors, lenses, prisms etc.) must be fixed in a mounting. With plastic optics, it is possible to mould mounting elements, posts or alignment notches integrally with the optical component. This can reduce part and assembly costs considerably.
  Technologies adapted to plastic materials like ultrasonic and laser welding, gluing and integrated snap-in structures allow fast and cost efficient automated and manually operated assembling solutions. Two component injection moulding is the choice for integrating optical elements and mounts in one injection cycle.

5.7.1 Moulding Materials

As already mentioned, the choice for plastic optical material is limited only to about 10 different types
Fig. 5.54 Abbe diagram

of material. Optical properties (Abbé value, refractive index, Fig. 5.54) as well as mechanical, thermal and humidity boundary conditions are decisive for the material choice. Different to glass during plastic injection moulding the process affects not only the geometry but also the inner properties like refractive index and birefringence.

Optical Properties

Fundamental optical properties are defined by optical transmission, refractive index and dispersion. For plastic optics birefringence is an important parameter too. Although the total number of plastic materials has increased in recent years, the range of refractive index and dispersion characteristic is limited to almost two major groups – crown-like materials as acrylic (PMMA), polyolefin (COC, COP) and Flint-like materials as polystyrene, polycarbonate and SAN. This strongly limited variety of plastic optical materials restricts the optical design that can be made in plastic considerably.

Physical Properties

Important physical properties are weight, impact and abrasion resistance and thermal properties like temperature resistance and thermal expansion (Table 5.24).

Already during system design both mechanical and thermal properties have to be taken into consideration. The thermal expansion of optical plastics is approximately ten times higher than that of glass materials. In an optical system this effect has to be compensated by optical design and mounting.

Typically most of optical plastics can withstand temperatures up to 90 °C. The maximum service temperature of polycarbonate and polyolefine materials reaches 120 °C. The specific gravity of plastic optical materials ranges from 1 to 1.3. Polycarbonate has the highest impact resistance of all optical plastics and is used for windshields and crash helmets. Acrylic has the best abrasion resistance.

Most Common Materials

Some of the most common optical polymers are:

PMMA (Polymethyl methacrylate). Acrylic is the most commonly used optical plastic. It is moderately priced, easy to mould, scratch resistant and not very water absorptive. Its transparency is greater than that of most optical glasses. Additives to acrylic (as well as to several other plastics) considerably improve its ultraviolet transmittance and stability. So acrylic is used in almost 80% of all plastic optical applications.

(Poly–)Styrene. Polystyrene is a low-cost material with excellent moulding properties. Styrene has a higher index and a lower numerical dispersion value than other plastics. It is often used as the flint element in color-corrected plastic optical systems.

Compared with acrylic, styrene has lower transmission in the UV portion of the spectrum: It does not have the UV radiation resistance nor the scratch resistance of acrylic.

Because its surface is less durable, styrene is more typically used in nonexposed areas of a lens system.

NAS Copolymer. NAS is a copolymer of certain fractions of polystyrene and acrylic (typically 70/30). This allows to adjust refractive indexis a low-cost material with excellent moulding properties.

PC (Polycarbonate). Polycarbonate is very similar to styrene in terms of such optical properties as transmission, refractive index and dispersion. Polycarbonate, however, has a much broader operating temperature band of up to 120 °C. For this reason, it is used as the flint material for systems that have to withstand severe thermal conditions.

Another advantage is the high impact resistance of polycarbonate. Safety glasses and systems requiring durability often consist of polycarbonate.

Cyclic Olefin Polymer and Copolymer (COP/COC). Cyclic olefin (co-)polymer provides a high temperature alterna-

Table 5.24 Plastic material properties

Material / Properties	Characteristics	Acrylic (PMMA)	Poly-styrene (PS)	Poly-carbon-ate (PC)	Styrol–Acryl-nitril (SAN)	Cyclo-olefine (ZEONEX)	Polyether-sulfone (PES)	Acrylnitril–Butadien–Styrolcopoly-mere (ABS)	Optical glass (BK7)

tive to acrylic. Its refractive index and transmittance are similar but the heat distortion temperature is about 30 °C higher than for acrylic. Its water absorbtion capability is significant smaller.

5.7.2 Manufacturing Methods

The manufacturing processes for glass and plastic optics are totally different [5.243–247]. Glass lenses are made by grinding and polishing process. By contrast typical manufacturing methods for precise technical plastic optical parts are diamond turning, injection and compression moulding. Other methods like casting have their application in special fields like ophthalmics (eyeglasses). In any case, processing transparent plastic

materials for optical purposes should take place in a clean environment.

Diamond Point Turning

Diamond point turning is an ultraprecision machining process carried out on special high performance, modular set up, multi-axis, linear motor driven, ultraprecision diamond CNC-machining systems.

In combination with vibration isolation systems, digital signal processor based machine control and integrated measuring systems an one nanometer programming resolution is possible.

This method can be expanded to full 3-D-milling systems. With such an arrangement the generation of free-form surface profiles is possible. Because of

the long production time and the high machine costs, this technology is used for prototyping in plastic and nonferrous metals, mould inserts and series production plastic parts – which can not to be manufactured by injection moulding (because of size or precision demands).

Injection Moulding

Injection moulding produces several parts per shot (moulding cycle) in single or multicavity tools. This production method is used for most of the plastic optic parts. Other fabrication techniques are used only when moulding is inappropriate.

A plastic injection-moulding machine consists of a fixed platen, a moving platen, a clamping unit and an injection unit. Moulding of optical parts requires special machine configurations and auxiliary equipment.

Compression Moulding

Compression moulding is used for making of Fresnel lenses or other microoptical structures. The material is pressed between heated platens with accurately defined temperature cycling during pressing. Mould inserts are formed by electroplated copies, replicated from master structures. These masters can be, for instance, diamond turned structures or diffraction gratings made by holographic methods. The compression moulding process allows to realize small structures with high aspect ratios and tight angular and positioning tolerances.

5.7.3 Manufacturing Process

Optical and System Design

On the one hand optic design [5.243–249] for plastic optics in principle uses the same mathematical algorithms than optic design for glass. On the other hand, designing plastic optics requires a profound understanding of the material properties and the manufacturing processes [5.245, 248, 249]. Knowledge of production technologies, material characteristics and assembling methods together with design expertise are needed to fully exhaust what precision plastic optics can be.

Simply substituting the indices of refraction and re-optimising the design will not succeed. Expert design assistance is essential at this stage.

Designing plastic optics with modern design tools allows great design freedom. The advantage of combining integral mounting structures with the optical surfaces to create mounting flanges, alignment and snap features provides the ability to automated assembly. Aspheric, cylindric, or toroidal surfaces are as easy to realize as spherical ones. Microstructures such as diffractive optical elements can be integrated too.

Prototyping

After designing a plastic optical system, lens prototypes can be made by diamond point turning in various plastic materials. The best surface finishes can be obtained with PMMA. Materials such as polycarbonate, pleximid or Zeonex do not yield very smooth surface finishes.

A major problem is the availability of semifinished plastic blocks in various materials. For PMMA a wide variety of bars or plates is available. For other materials or colored options semifinished items have to be made by injection moulding.

Because of the high manufacturing costs diamond point turning is only recommended for making a limited number of prototypes to verify functionality of the optical design and to perform first tests.

In this stage optical systems are normally assembled from single elements. Housing parts often are made from aluminium. The resulting surface quality and system performance can not be a validation of the manufacturability by injection moulding. To get reliable knowledge about this, making a moulded prototype from a single-cavity prototype mould is recommended.

The Injection Mould

A high quality injection mould is obviously essential for precise plastic optic parts. The parts never can be better than the tool - but good tooling, however, does not guarantee good parts. A strong understanding of the whole manufacturing process is the key to producing precision plastic components.
Fig. 5.55 Injection mould

Table 5.25 Tolerances of optical components

	Unit	Injection molding	High-end injection molding	Single-point diamond turning
Radius	% (+/-)	5	2	0.5
Refractive index	(+/-) (PMMA)	< 0.0005	< 0.0005	< 0.0005
EFL	% (+/-)	5	2	1
Thickness	mm (+/-)	0.13	0.05	0.02
Diameter	mm (+/-)	0.13	0.05	0.02
Surface figure	Fringes per inch of diameter	$< 10f$ (5λ)	$< 8f$ (4λ)	$< 2f$ (1λ)
Surface irregularity	Fringes per inch of diameter	$< 5f$ (2.5λ)	$< 3f$ (1.5λ)	$< 1f$ (0.5λ)
Surface rms error	nm	< 10	< 5	< 2
Surface S/D quality		80/50	60/40	40/20
Wedge (TIR)	mm	< 0.025	< 0.015	< 0.010
Radial displacement	mm	< 0.100	< 0.050	< 0.020
Diameter/thickness ratio		> 2 : 1	> 3 : 1	> 5 : 1
Repeatability	Focal length (part to part in one cavity)	< 2%	< 1%	< 0.5%
DOE depth	μm (+/-)	***	0.25	0.1
DOE min groove	mm	***	0.05	0.01

Any injection mould consists of three main parts. The upper half, which is affixed to the injection-side platen, the lower mould half, which is affixed to the ejector-side platen and the mould-ejection mechanism. Guide pins and taper locks ensure proper alignment of the mould halves.

Production volume and precision required from a tool influences the selection of mould materials and built-in maintanance features.

Transmission T (%)

Double side coated

Single side coated

PMMA uncoated
Fig. 5.56 Abbe values

Single-cavity and multi-cavity moulds from 2 to 8, 16, or even 32 cavities are used for plastic optic parts.

Thermoplastic material shrink during cooling down in the mould. This geometric effect has to be compensated for in the injection mould. Exact shrink rates can be calculated and the tool can be modified. For manufacturing optical plastic parts by injection moulding the optical surfaces (plano or aspherical shapes, diffractive, conical, lenticular and cylindrical surfaces) are generated as separate inserts in the tool.

Aspheric inserts are manufactured by two steps. First a best-fit curve is generated on a stainless steel substrate. The substrate is then subjected to a nickel plating process (electroless nickel) that deposits a thin layer of nickel (up to 500 μm). In the second step single-point diamond turning produces the final aspheric or diffractive curve in the nickel. Because the hardness of a nickel-plated insert is less than that of a steel spherical insert, it will be more susceptible to scratch defects.

Pre-Production

A pre-production stage is recommended to check the manufacturing process. Typically this is done by using a single-cavity prototype mould. This mould can be used to find optimal moulding conditions. Optical an mechanical design can be verified with real moulded

components and design revision is possible to affordable conditions. Often the prototype moulds is used to start limited production since production tooling may take much more time.

Series Production

For series production of high volumes multi-cavity production moulds are required. Depending on quality, volume, throughput and cost, the production tool may have 2, 4, 8 up to 32 cavities. The production moulds function for at least several hundred of thousands of injection cycles.

5.7.4 Coating and Component Assembly

Coating

Because of their limited temperature and UV resistance plastic lenses must not be coated in an elevated temperature and radiation environment. During the deposition of thin films onto plastic, the coating chamber temperature is significantly lower than that for glass optics. This requires deposition techniques such as ion-assisted deposition to apply antireflective, conductive, mirror and beamsplitter coatings.

Today multi-layer dielectric coatings are routinely deposited on plastic components. Typical broad band anti-reflection coatings reduce reflection to about 0.5% per surface across the entire visible spectrum. Narrowband, multilayer antireflection coatings can achieve surface reflectances less than 0.2%.

Multi-layer dielectric coatings can be modified easily to scratch resistant designs for front lenses and windows.

Several front and back surface reflector coatings are available for plastic substrates. Standard coating metals include aluminium, silver and gold. Aluminium coatings provide surface reflectances greater than 88% across the visible spectrum, and gold coatings greater than 95% for the near infrared region.

Component Assembly

Many advantages of using plastic optics will come out in particular in manufacturing components. The integration of optical, mechanical and electronic elements allows to build low cost polymer optical components like small camera lenses or scanner heads f.i.

Plastic optical assemblies are usually done in a clean room environment by manual, semi or fully automated processes. The components have to be designed to ensure ease of assembly. Snap-on features, UV-cementing, heat-staking and ultrasonic and laser welding can also be employed with plastic materials.

Since most optical tolerances are additive, it is essential to establish quality check points in the manufacturing process to sort out non-conforming sub-assemblies. Automatic in-line optical performance monitoring such as MTF testing can be implemented. SPC techniques should be used here to ensure the process is not drifting out of the controllable range.

Component Tolerances

The high repeatability of the injection moulding process yields components with little dimensional variability. But the specific tolerances for an optical component strongly depend upon the part geometry and size, the plastic material, the mould design and the production process stability.

5.7.5 New Developments

In the last years several new developments in the field of plastic optics took place. The permanent improvement process in tooling technologies in combination with diamond turning, milling and grinding led to new design and tolerance levels. New materials like the cyclo-olefins led to better material performance and coating stability.

The fabrication process for diffractive elements (done primarily by single-point diamond turning) has improved considerably. Micro- and nanostructures like moth-eyed surfaces can be achieved by injection moulding and compression moulding and allow functionalised surfaces.

Even calibration structures for scanning probe microscopy applications can be replicated by injection moulding up to 25 nm structures.

Plastic optic technology permanently expands its traditional limits and fields of application. On the one hand plastic optic is still limited by material properties but on the other hand design and assembling freedoms allow new approaches.

5.8 Crystalline Optical Materials

In the following section we will discuss a few crystalline materials [5.250–252] that are used for optical applications. Among the oxides we want to focus on Sapphire, we mention the class of halides where CaF_2 is the most prominent example and we discuss a few semiconductors. The following subsections summarize material properties and fields of application. In each subsection, tables summarizes the optical and mechanical materials properties.

5.8.1 Halides, CaF$_2$

Halides are crystals whose anions are halogens, the elements of group seven in the periodic table, namely fluorine, chlorine, bromide and iodine. Halides tend to have rather simple ordered structures with a high degree of symmetry. The most famous halide is rock salt, NaCl. Halides can generally be synthesized as single crystals from molten salt by Czochralski process.

Table 5.26 Basic properties of CaF_2 crystals

Formula	CaF_2					
Max. sizes (diameter (mm))	180					
Transmission range, μm	0.15–9.0					
Density (g/cm^3)	3.18

Part A | 5.8
In optical applications two candidates are of particular importance: MgF_2 and CaF_2 (Table 5.26 and Table 5.27). These materials transmit well into the UV region and are used for most UV-optics. MgF_2 is an excellent material for eximer lasers. MgF_2 is slightly birefringent as can be seen from the data in Table 5.27.

CaF_2 is also an excellent material in laser optic field. It has a wide transmission range from $0.13–9.5\,\mu m$ and an especially high transmission in the IR range. CaF_2 is widely used in laser, IR, and UV optics. It is slightly soluble in water and is susceptible to thermal shock.

CaF$_2$ and all halides are rather soft materials which are generally not very dense $(3.18\,\text{g/cm}^3)$. CaF$_2$ belongs to the cubic class and its cleavage plane is the 111-plane. In particular CaF$_2$ has been focused on as the material for future micro-lithography applications in the semiconductor industry because of its high transmission in the UV region. The band gap is larger than 11 eV. Further applications are laser windows and optical elements in the visible region. In addition CaF$_2$ has a low refractive index and its mechanical properties allow for rather easy polishing.

5.8.2 Semiconductors

Semiconductors have a wide range of applications in optical devices. In the following we will focus on Si (Table 5.28),Ge and CdTe as materials of interest in IR-transmitting elements. The crystal structure is cubic, and in the case of Si the diamond structure.

Silicon is commonly used as substrate material for infrared reflectors and windows in the 1.5–8 μm region. The strong absorption band at 9 μm makes it unsuitable for CO$_2$ laser transmission applications, but it is frequently used for laser mirrors because of its high thermal conductivity and low density. Silicon is also useful as a transmitter in the 20 μm range.

Germanium is used primarily in the 2–12 μm spectral region. Ge has a good thermal conductivity and excellent hardness and strength. It is the material of choice as a substrate for a variety of filters. One disadvantage of Ge over Si is its greater tendency to become opaque at higher temperatures due to its relatively low band-gap of 0.75 eV. This lower band-gap results in easier stimulation of electrons from the valence band to the conduction band. Cadmium telluride (CdTe) has an IR-transparent region from 1–25 μm. It is a very soft material and a low thermal conductivity. It is an excellent substrate material for filters in the 12–25 μm region in which many other materials have decreased transmittance due to the presence of absorption bands.

Gallium arsenide (GaAs) used for lenses and beam splitters provides an alternative to ZnSe in medium and high power CW CO$_2$ laser systems (Table 5.29). It is most useful in applications where toughness and durability are important. Its hardness and strength make it a good choice where dust or abrasive particles tend to build up on or bombard the optical surfaces. When frequent cleaning by wiping is required, GaAs is excellent. The material is nonhygroscopic, safe to use in laboratory and field conditions and is chemically stable except when in contact with strong acids.
Fig. 5.57 Transmission of sapphire

Further areas of interest where semiconductor materials are used as optical materials are the LEDs and laser diodes. Depending on the spectral properties one is interested in the semiconductors of III–V type. Famous candidates are InAs or GaN as material for blue LEDs.

5.8.3 Sapphire

Sapphire is the leading material for highly sophisticated optical applications that require reliability, strength, and a wide range of light transmittance. Sapphire transmits light over a broad wavelength range spanning from 0.15 to 5 μm (Figs. 5.57, 5.58 and Table 5.30).

This unique ability to transmit over a broad range combined with its mechanical strength makes sapphire the material of choice for many applications. For imaging optics it is desirable for the refractive index of an optical material to have a low dependence on temperature. Because of its low dn/dt, a temperature gradient across a window will not cause image blur and foresight error. The United States National Bureau of Standards has extensively researched the index of refraction of sapphire. Recently a model was developed by *Thomas* et al. at the Advanced Physics Laboratory to predict dn/dt from 0.7 to 5 μm.

Sapphire is a single crystal material from aluminium oxide, Al$_2$O$_3$. It has a hexagonal/rhombohedral structure. Optically it is a negative uniaxial crystal in the visible region with a small birefringence.

Sapphire has a band-gap of approximately 10 eV, which is one of the largest for an oxide crystal, permitting optical transmission in the above mentioned range. Like other crystals sapphire can be synthesized by a Czochralski process. Sapphire has a high melting point and is a very hard material which allows it to be used in applications of extrem temperature conditions. Sapphire is used in laser windows – in particular for ap-

plications where high transmission in the IR-region is required. Its hardness and stiffness make it a suitable substrate material. In the semiconductor industry sapphire is used as a substrate to grow GaN on it for the production of blue LEDs.

5.8.4 Optic Anisotropy in Cubic Crystals

According to the Sect. 5.1.4 optical anisotropy would not be expected in a cubic crystal. Birefringence in cubic solids should only be caused by deviations from the cubic symmetry. There is, however, an effect that makes cubic solids optically anisotropic. In these crystals

a symmetry breaking is provided by the electromagnetic radiation of the light wave. This is called induced spatial dispersion. Here the dependency of the dielectric function on the wavevector of the incident radiation $\mathbf{k}$ becomes important.

Let us try to estimate the order of magnitude of optical anisotropy which we can get due to the symmetry breaking of the light. Because of the extremely large velocity of the light, $c = 2.9979 \times 10^8$ m/s the corresponding wavevectors are very small

$$E_{light} = \hbar\omega = ck \; . \tag{5.150}$$

For visible light, e.g. at 600 nm, the photon energy is about 2.1 eV and this translates, using the dispersion relation (5.150), to $k = 2\pi/\lambda = 0.01$ nm^{-1}. This has to be compared with the size and usual wavevectors occurring for electronic degrees of freedom in the solid. For a lattice constant of $a = 5.2$ Å $= 0.52$ nm (CaF$_2$) the maximum wavevector at the edge of the Brillouin zone results to $k_{BZ} = 2\pi/a = 12.1$ nm^{-1}. There are more than three orders of magnitude between the length scales on which the electromagnetic field is varying (λ) and the length at which the lattice is varying (a).

The spatial dispersion is the influence of the inhomogeneity of the electromagnetic field on the optical response of a system. This causes a non-locality. For perfectly homogeneous fields ($\lambda \to \infty$, $k \to 0$) the optical response of the cubic system is isotropic.

Let us assume now that our system allows for an expansion of the dielectric function around the zero wavevector [5.253]. Taylor expanding the (inverse) dielectric function with respect to the wavevector of the light gives an idea how the anisotropy enters into the optical response

$$\epsilon_{ij}^{-1}(\mathbf{k}, \omega) = \epsilon_{0ij}^{-1}(\omega) + h_{ijkl}k_k k_l + O(k^4) \; . \tag{5.151}$$

The term linear in $\boldsymbol{k}$ vanishes due to the inversion symmetry of the cubic crystal. In order to obtain an upper boundary for the expected anisotropy one can do the following estimate [5.254]. Responsible for the anisotropy is the deviation of the electromagnetic field from uniformity along the elementary cell of the crystal. This is the quantity

$$\frac{a}{\lambda} = \frac{k}{k_{\mathrm{BZ}}} \ . \tag{5.152}$$

This means we get, using the k^2 dependency from (5.151) and the magnitude from (5.152) as an upper boundary for the magnitude of the expected anisotropy

$$\left| \epsilon_{ij}^{-1}(\boldsymbol{k}, \omega) - \epsilon_{0ij}^{-1}(\omega) \right| \ll \left(\frac{k}{k_{\mathrm{F}}} \right)^2 = \left(\frac{a}{\lambda} \right)^2 \ . \tag{5.153}$$

Since $k/k_{\mathrm{BZ}} = 8 \times 10^{-4}$, the anisotropy in ε is smaller than 10^{-6}. This effect can be only observed with extremely accurate high resolution interference measurements.

In the vicinity of a strong absorption in the material the physics changes. This was first described in 1958 by the 2003 nobel laureate *Ginzburg* [5.253]. The reason is that not the wavelength in vacuum as in (5.152)

has to be compared with the length of the elementary cell but the wavelength in the medium $\lambda_{\mathrm{m}} = \lambda / n$. Since the refractive index n becomes large in the vicinity of a strong absorption (Sect. 5.1.1) the spatial dispersion induced optical anisotropy becomes better observable near an absorption in the material.

In semiconductor materials, the enhancing resonance can be provided by the vicinity of a band edge and has been shown in [5.255] for silicon and [5.256] for GaAs. It has also been measured in alkali halide crystals [5.257]. In strongly ionic crystals deep excitonic electron–hole bound states are present. For the strongly ionic crystal CuCl the exciton resonance was identified as the enhancing absorption [5.258]. Recently the effect of spatial dispersion induced birefringence became of special importance for the crystal CaF_2 [5.259]. This material is used for UV lenses employed for microlithographic structuring of semiconductors. Here a direct connection between the exciton resonance and the spatial dispersion was made [5.260].

Finally, one has to note that – opposite to usual birefringence with according to Sect. 5.1.4 a maximum of two – the spatial dispersion induced birefringence in a cubic crystal has seven optical axes.

5.9 Special Optical Materials

5.9.1 Tunable Liquid Crystal Electronic Lens

The lens is a key element for use in optical systems. A conventional lens made by shaping a medium with a fixed refractive index brings light to focus. Glass, polymers and other transparent solid materials are commonly used for fabricating lenses. One major characteristic of the solid lens is that it has only one focus. To change the focal length, a zoom lens has been developed. A zoom lens system usually consists of groups of lenses. The separation distances between the lenses are mechanically adjusted. However, the adjusting processes are complicated, bulky and even inefficient. Therefore, developing a compact, lightweight, low-cost, and efficient tunable lens is highly desirable and urgently needed.

Due to high birefringence of nematic liquid crystals (LCs), which can be controlled by the applied voltage, an electrooptical effect based on the reorientation of LC molecules can be easily obtained. In addition to displays, adaptive optical components using LC materials have been demonstrated and application increased during the past decades. Among these photonic devices,

tunable-focus LC lens is particularly attractive for optoelectronics, machine vision, imaging, and eyeglasses applications.

The use of nematic LCs for making tunable lenses was proposed as early as 1977 by *Bricot* [5.261]. Since then, various approaches have been developed, such as surface relief profile [5.262–265], hole-, line- or spherical patterned electrode [5.266–269], modal addressing [5.270–272], Fresnel zone lens [5.273–275], as well as LC/polymer UV pattern irradiation technique [5.276–278]. Each method has its own merits and demerits. In this chapter, we classify those LC lenses into three groups according to the underlying lens structure. In each group, we will choose a typical cell structure as an example for discussion. Especially, we put emphasis on the newly developed LC lens using the simple UV exposure technique. We describe the fabrication method and performance of this kind of lens in details.

Types of LC Lens

Similar to a conventional LC cell for displays, the LC lens is composed of LC material sandwiched between
Fig. 5.59 A tunable-focus lens with an inhomogeneous LC layer

Fig. 5.60 A tunable-focus lens with striped electrodes and a homogeneous LC layer

two glass substrates. To obtain a switchable gradient profile within LC layer, several methods have been proposed. According to the device structure, we can classify LC lens into three different categories.

Curved Cell Gap. In some LC lenses, LC layers can have concave, convex or Fresnel lens structure [5.261–265]. Figure 5.59 shows such a structure. One glass substrate has plano-concave surface and the other is flat. The inner surfaces of the indium-tin-oxide (ITO) glass substrates are coated with thin polyimide layers and then rubbed in order to get a homogeneous alignment throughout the LC bulk. LC lens with such a structure can be operated in two modes.

In the voltage-off state, the incident unpolarized light can be separated into two polarization components: parallel and perpendicular to the LC director. The beam with polarization parallel to the LC directors is called extraordinary ray and the perpendicular one is called ordinary ray. The extraordinary and ordinary rays will be focused onto two different but fixed focal planes. Their focal lengths are given by $f_e = R/(n_e - n_g)$, and $f_o = R/(n_o - n_g)$, respectively, where R is the radius of the concave lens substrate, n_g the refractive index of the glass substrate, and n_e and n_o are the extraordinary and ordinary refractive indices of the LC material.

When a certain voltage is applied to the electrodes, the LC directors are reoriented along the electric field direction. Under such a circumstance, the extraordinary ray sees an effective refractive index (n_{eff}). In this case, the focal length is given by

$$f_{eff} = R/(n_{eff} - n_g) . \tag{5.154}$$

In (5.154), n_{eff} is equal to n_e at $V = 0$ and is reduced to n_o as $V \to \infty$. Therefore, the focal length can be

tuned between f_e and f_o by the applied voltage. For the ordinary ray, it always sees the ordinary refractive index n_o regardless of the applied voltage. Thus, its focal length is not tunable by the applied voltage.

Because of the curved cell gap, liquid crystal in different positions will exhibit a different switching speed. The LC in the thicker area usually has a slower response time and presents light scattering due to the worse alignment. Another drawback of this kind of lens is the focal length can only be tuned between f_o and f_e. To widen the focal length, one has to use a high birefringence LC.

Planar Cell Gap. Several methods have been reported using a planar LC cell to realize the tunable-focus lens. To create a gradient refractive index profile within the LC layer, three different approaches have been explored. *Patterned Electrodes*. Several patterned electrodes, such as line-, hole-, spherical pattern electrode [5.266–269], and modal addressing have been consideredy [5.270–272]. A classical electrode structure is shown in Fig. 5.60. A homogeneous nematic LC layer is sandwiched between an ITO plate and a ground ITO plate. The ITO plate is a glass plate with a group of addressable discrete transparent ITO stripes. The ground plate is a glass plate with uniform ITO electrode covering the entire plate. Each electrode stripe on the glass substrate is individually addressed with voltages chosen so that the refractive index across the cell forms parabolic shape such that the incident light is brought to focus at a selected plane. From Fig. 5.60, one can see that only the light with its polarization axis parallel to the LC directors is affected. This kind of lens with linear electrode belongs to the cylindrical lens. The focal length has the following

expression:

$$f = \frac{x_0^2}{2d(n_e - n_{eff})} , \qquad (5.155)$$

where x_0 is the maximum aperture distance and n_{eff} is the effective refractive index.

Since $n_o \leq n_{eff} \leq n_e$, f can be tuned in the following range

$$\frac{x_0^2}{2d(n_e - n_o)} \leq f \leq \infty . \qquad (5.156)$$

To get a true spherical lens, four cylindrical lenses are required to combine together. By designing the electrode with hole-, hybrid- or spherical pattern, or using modal addressing, a spherical LC lens is realized. The focal length of the spherical lens is expressed by

$$f = \frac{\pi r^2}{(\delta_c - \delta_e)\lambda} , \qquad (5.157)$$

where r is the radius of the lens, λ is the wavelength, and $\delta_c - \delta_e$ is the phase difference at the lens center and edge.

The lens with a planar cell gap has several advantages. For instance, the focal length can be tuned within a wide range, be fabricated with large size, and the switching speed is uniform across the whole lens. The drawback of this type of LC lens is that the cell fabrication process is complicated and the addressing technique is difficult.

Spherical Electrode within a Planar Substrate. To fabricate an adaptive lens with a wide range tunable focal length, a new lens structure as shown in Fig. 5.61 is considered. The upper planar substrate actually consists of a convex and a matched concave spherical surface. One of the spherical surfaces is coated with indium-tin-oxide (ITO) as electrode. The lower substrate has a transparent electrode coated on its inner surface. Homogeneous LC layers are aligned between the substrates. In the null voltage state, no focusing effect occurs provided
Fig. 5.61 A tunable-focus lens with a spherical electrode and a homogeneous LC layer
Fig. 5.62 Measured spot intensity profiles for the LC lens shown in Fig. 5.61. *Top*: $V = 0$; *middle*: $V = 18\,V_{rms}$; and *bottom*: $V = 35\,V_{rms}$. Lens diameter: 6 mm

that the refractive index of the upper convex and concave substrates is the same. When a voltage is applied across the LC layer, a centro-symmetrical gradient distribution of refractive index is generated. As a result, the LC layer causes light to focus. By controlling the ap-

Part A | 5.9

plied voltage, the focal length of the lens is continuously tunable.

A sample LC lens was fabricated according to the design sketched in Fig. 5.61. The diameter of the lens is 6 mm and the LC cell gap is 40 μm which is filled with UCF-2 ($\Delta n = 0.4$) nematic LC mixture. The height from the top spherical electrode to the liquid crystal layer is $d = 1.03$ mm. The 3-D focal length intensity was measured using a CCD camera at different voltages. The distance between the LC lens and CCD camera is 78 cm. Results are shown in Fig. 5.62. At $V = 0$, the light intensity of a collimated He–Ne laser passing through the lens cell is very weak. As the voltage is increased to $V = 18$ V$_{rms}$, a tightly focused spot appears. As the voltage is increased further, say to $V = 35$ V$_{rms}$ the measured light intensity decreases. This means that the focus is somewhere between the LC cell and CCD camera. The focal length of this spherical lens can be tuned continuously from ∞ to 0.5 m by controlling the applied voltage. The response time is ≈ 200 ms for the 40 μm cell gap employed.

UV Exposure through Photomask. Tunable lenses using polymer dispersed liquid crystal (PDLC) and polymer network liquid crystal (PNLC) have been demonstrated recently [5.276, 277]. This kind of lenses is prepared using photo-polymerization induced phase separation

Fig. 5.63a,b Device fabrication of an inhomogeneous PNLC using a patterned photomask

Fig. 5.64a–c Photographs of the PNLC sample at different operating voltages. **(a)** $V = 0$, **(b)** $V = 2$ V$_{rms}$, and **(c)** $V = 35$ V$_{rms}$

technique. A unique feature of these polymer dispersed LCs is that the larger LC domain exhibits a lower threshold voltage. If LC presents an inhomogeneous centrosymmetric LC domain dispersed in a polymer matrix, then the applied homogeneous electric field would induce a gradient refractive index profile, which reveals a lens-like character.

A PNLC lens using UV exposure fabrication technique has been proposed. Fig. 5.63a illustrates the fabrication method of a positive PNLC lens. The key element is the patterned photomask. To obtain a PNLC cell with an inhomogeneous centrosymmetric polymer network profile, a circular continuously variable optical density is used as the photomask, as shown in Fig. 5.63b. Its optical density increases outward radically from a minimum at the center to the maximum at the edges. When a uniform UV light passes through the photomask, the output intensity varies in parabolic profile across the LC sample. The area with a stronger UV light would accelerate the polymerization process and produce a higher polymer concentration. Conversely, the area with a weaker UV exposure would have a lower polymer network concentration. As a result, an inhomogeneous centro-symmetric polymer distribution is formed.

The PNLC cell with convex refractive index profile functions as a positive lens. When a uniform electric field is applied, the LC directors are reoriented to different degrees. The area with looser network packing (edges) has a lower threshold voltage than that of a denser zone (center). Thus, the convex refractive index is generated. As the applied voltage increases, the curvature of the gradient lens decreases. In the high voltage regime, nearly all the LC directors are aligned along the electric field direction. The gradient direction no longer exists and the lens effect vanishes.

To fabricate a positive PNLC lens, a mixture of 5 wt % UV curable monomer BAB-6 (containing 2% photoinitiator IRG-184) in a LC host (W-1331, $\Delta n = 0.229$) was injected to a homogeneous ITO coated LC cell. The monomer has a common rod-like structure with a reactive double bond at both sides. The inner surfaces of the LC cell were coated with thin polyimide layers. The cell gap of the homogeneous cell is 16.5 μm. The diameter of the photomask is 1.7 cm. The measured UV intensity after the photomask is 14 mW/cm^2, and the exposure time is 60 min.

The prepared sample is highly transparent in the voltage-off state. By observing the birefringence colors on a light table, one can check the gradient refractive index. Three photographs of the PNLC sample
Fig. 5.65 Spatial phase profile of the positive lens at various voltages

cell at $V = 0$, 2 and 35 V_{rms} were taken, as shown in Fig. 5.64a–c, respectively. The rubbing direction of the cell was orientated at 45 °C with respect to the fast axis of the linear polarizer. The analyzer is crossed to the polarizer. At $V = 0$, the color is relatively uniform. As the applied voltage exceeds the threshold, color starts to change from the borders and gradually extends to the center, like a swallowing spot. A circular color ring was shown in Fig. 5.64b at $V = 2\,V_{rms}$. This implies that the central area has a higher threshold voltage than that of the edges. One the contrary, decreasing voltage changes the birefringence color from center to borders, like a vomiting spot. This cell acts as a positive lens.

The measured phase retardation of the cell is plotted in Fig. 5.65. At 2 V_{rms}, $\Delta\delta = 0.8\pi$ which corresponds to 120 meter focal length. As the voltage increases, $\Delta\delta$ decreases so that the focal length increases. Due to the long focus, this lens is suitable for satellite imaging and astronomy applications. To shorten the focal length, several methods can be chosen, such as improving the photomask pattern, using high birefringence LC material, increasing the cell gap, or reducing the diameter of the curved spot.

To fabricate a negative lens, one can choose a photomask with reversed optical density. By using patterned UV exposure method, both positive and negative lenses can be fabricated. Since the lens is a single pixel device, the fabrication process is simple and the lens size depends upon the photomask design.

Like the aforementioned LC lens, PNLC lens is polarization dependent too. To overcome this polarization dependence, two cells with orthogonal alignment directions should be considered. The PDLC with sub-wavelength droplet size is another technique for solving the polarization dependent problem for LC lens [5.276]. The drawbacks of the nano-PDLC lens are the high operating voltage and small refractive index change which results in a long focal length.

Besides the patterned photomask, exposure using a UV laser beam with Gaussian intensity distribution to the LC/monomer cell has been studied [5.278]. The cured spot presents a lens-like character under the action of a homogeneous electric field. The concern for this technology is that a high power laser is needed for scaling up the lens aperture.

Fresnel Zone Plate. In comparison with the above refractive lens, Fresnel zone plate lens belongs to the diffraction lens. It can be fabricated with large aperture size. Fresnel lenses are suitable for long distance optical communication, optical distance measurement and space navigation. In a binary-phase planar Fresnel lens, the phase difference between the adjacent zones can be tuned by the applied voltage. Maximum diffraction occurs when the phase difference is equal to an odd multiple of π while no diffraction occurs for even multiple of π. Through diffraction, the Fresnel zone plate works as a focusing element.

Due to higher-order Fourier components, Fresnel lens has multiple foci at f, $f/3$, $f/5$, etc. However, the majority of the incident light diffracts into the primary focus. The primary focal length can be expressed by $f = r_1^2/\lambda$, where r_1 is the innermost zone radius. The radius of the nth zone (r_n) is given by $r_n^2 = nr_1^2$, n is the zone number. Theoretically, the diffraction efficiency of the primary focus for the binary phase Fresnel lens is 41%.

A method of fabricating LC Fresnel lens was proposed by *Patel* and *Rastani* [5.273]. The idea to fabricate the lens is to make the neighboring zones with orthogonal LC directors on one substrate, and homeotropic alignment on the other. Another method of fabricating LC Fresnel lens is to etch the ITO electrode by photolithographic to form a zone plate [5.274]. However, the two fabrication methods are rather complicated.

Using UV pattern irradiation technique, one can simplify the device fabrication process [5.275]. A method of fabricating Fresnel lens using patterned photomask is similar to that as shown in Fig. 5.63, except that the photomask was produced with transparent odd zones and opaque even zones.

To fabricate a nanoscale PDLC Fresnel lens, 26 wt % LC E48 and 74 wt % UV curable prepolymer NOA81 were mixed and injected into a homogeneous empty
Fig. 5.66a−c Imaging properties of the PDLC Fresnel lens recorded by a CCD camera. **(a)** without sample, **(b)** with sample near the focal spot, and **(c)** with sample at focal point

cell. The cell gap is $15\,\mu$m. A photomask was produced by etching a chromium oxide layer using electron beam lithography. The radius of the innermost zone is 0.5 mm, and the zone plate consists of 80 zones in 1 cm aperture. The photomask is in proximity contact with the LC cell substrate during exposure to the UV light.

To evaluate the image quality of the PDLC Fresnel lens, a black cardboard with transparent alphabet **R** was placed before the sample. A collimated He–Ne laser has 1 cm diameter which fills the entire zone plate. A CCD camera was set at ≈ 25 cm behind the sample. Figure 5.66a and Fig. 5.66b show the photos without and with sample, respectively. When the sample is absent, no focusing effect occurs. Once the LC Fresnel lens is in position, a clear but smaller image is observed, although some circular noises exist due to diffraction. When the CCD camera was moved to the focal point, a tight spot appeared in the center, as shown in Fig. 5.66c. These results indicate that the sample indeed behaves like a lens.

The light efficiency of the PDLC Fresnel lens is about 32% at $V = 0$. As the applied voltage is increased, the diffraction efficiency is increased. At $180\,V_{rms}$ (or $12\,V/\mu$m), the diffraction efficiency reaches nearly $\approx 39\%$. Further increasing the voltage, the diffraction efficiency will decrease. Because of the sub-wavelength PDLC droplets, the Fresnel lens is transparent in the voltage-off state, polarization independent, and its switching speed is in the sub-millisecond range. However, the operating voltage of this kind of lens is relatively high. To decrease the operating voltage, PNLC
can be considered. The PNLC contains a lower polymer concentration than PDLC. As a result, its operating voltage is much lower except the PNLC lens is polarization dependent.

Microlens Arrays

Two-dimensional microlens array has a wide range of applications, including information processing, optoelectronics, integrated optics components and optical communication systems. The hole-patterned electrode, hybrid-patterned electrode as well as surface relief profile can be used to demonstrate microlens arrays. To fabricate microlens arrays, we continue to use the UV exposure through a patterned photomask. According to diffraction theory, when UV light passes through a tiny hole, it will be diffracted and the diffracted intensity presents a parabolic-like profile. Therefore, when the UV curable monomer doped in LC host is exposed using the diffracted UV light, an inhomogeneous centro-symmetrical PNLC can be obtained. Similar to the results as shown in Fig. 5.64, the cured spot acts as a lens.

An example of fabricating LC lens array is demonstrated using PNLC technique. A mixture of $3\,wt\%$ monomer BAB6 (with a small amount of photoinitiator IRG-184) and $97\,wt\%$ LC E48 was injected to a homogeneous cell composing of ITO glass substrates. The inner surfaces of the cell were coated with polyimide layers and then buffed in the antiparallel direction. The LC cell gap and the substrate thickness are $15\,\mu$m and 1.1 mm, respectively. A chromium layer with circular aperture array deposited on a glass substrate is then placed on the top of the cell. The diameter of each aperture is $25\,\mu$m and the distance between the neighboring pixels is $85\,\mu$m from center to center. The cured UV intensity from the photomask side was $40\,mW/cm^2$ and the curing time was 45 min.

The cured sample was observed using a polarizing microscope. The rubbing direction of the cell was oriented at $45°$ with respect to the axis of a linear polarizer and the analyzer was crossed to the polarizer. Three photographs were taken at $V = 0$, 5 and $20\,V_{rms}$ and results are shown in Fig. 5.67a–c, respectively.

At $V = 0$, the UV exposed array spots is very weak and cannot be observed clearly. The cured spot size is about $50\,\mu$m due to the diffraction effect. When the sample cell was rotated gradually, the array spots will disappear, this means that the PNLC cell is homogeneous and polarization dependent. When the applied electric field is increased slowly, a clear spot array appears as shown in Fig. 5.67b. In the mean time, a color

Fig. 5.67a−c Photographs of the PNLC sample cell at different operating voltages: **(a)** $V = 0$, **(b)** $V = 4\,V_{rms}$ and **(c)** $V = 30\,V_{rms}$

change occurring starts from the spot borders, and gradually shrinks to its center. This implies that the spot center has a higher threshold voltage than that of its borders and the cured spot acts as a positive lens. As the applied voltage is sufficiently higher than the threshold, most of the bulk LC directors are orientated perpendicular to the substrates. Under such a circumstance, the spot profile becomes very weak, as shown in Fig. 5.67c.

To characterize the light focusing properties of the sample cell, A collimated He–Ne laser beam ($\lambda = 633$ nm) was normally incident on the sample with its polarization direction parallel to the cell rubbing direction. The laser beam was expanded to 5 mm diameter before illuminating the LC sample. A 10 times beam expander was positioned between the CCD and the LC sample in order to clearly resolve the output intensity. A CCD camera at $2cm$ behind the sample cell was used to record the light focusing ability. Figure 5.68a–c show the photos for $V = 0$, 5 and $20\,V_{rms}$, respectively. One can see in the voltage-off state, no focusing effect occurs at the exposed spots. At $5\,V_{rms}$, the light passing through the exposed spots was focused. The spots become bright, as shown in Fig. 5.68b. However, the focusing point is relatively large. When the voltage was increased to $20\,V_{rms}$, a tightly focused spot appeared in the center of each cured spot, as shown in Fig. 5.68c. These results indicate that each spot indeed behaves like a lens.

The voltage-dependent focal length of the microlens arrays was measured and results were shown in Fig. 5.69. As the applied voltage increases, the focal length increases too. This is because the lens profile becomes shallower with increasing voltage.

The focal length of the lens is expressed as $f = \pi r^2 / \lambda \Delta \delta$, where r is the radius of the lens, λ the wavelength and $\Delta \delta$ is the phase difference between the lens center and border. Since $\Delta \delta$ can be adjusted by the applied voltage, the focal length is tunable. Theoretically, sufficiently high electric field would reorient the bulk LC directors perpendicular to the substrates so that $\Delta \delta \approx 0$ and $f \approx \infty$. However, in our microlens arrays the polymer networks exert the weakest stabilization on LC molecules at the border of the microlens, thus the radius of the microlens has the tendency to shrink at high voltage. In this condition, the focal length cannot be lengthened, it will gradually saturate as the voltage exceeds $10\,V_{rms}$, as shown in Fig. 5.69.

Comparing with other microlens technologies, the PNLC advantages are in uniform cell gap and using single electrode on both substrates. The tunable gradient profile is induced with the help of electric field. Like conventional PNLC cells, the PNLC lens has reasonably
Fig. 5.68a−c Focusing properties of the PNLC lens arrays recorded by the CCD camera. **(a)** $V = 0$, **(b)** $V = 4\,V_{rms}$, and **(c)** $V = 6.7\,V_{rms}$

fast switching speed, wide range tunable focal length by optimizing the cell structure and UV curing conditions, and relatively low operating voltage. This kind of microlens is easily realized with a long focal length and, therefore, is suitable for optical fiber switches and incoherent correlator applications.

In summary, three basic mechanisms have been proposed to fabricate LC lens. They are: inhomogeneous electric field on inhomogeneous LC media, inhomogeneous electric field on homogeneous LC media, and homogeneous electric field in inhomogeneous LC media. Each technique has its own merits and demerits. In terms of fabrication process, the patterned UV exposure technique seems to be the simplest. Depending upon the specific photomask patterns, positive and negative spherical lens, elliptical lens, cylindrical lens, microlens array, prism, and prism grating can be fabricated. The nano-PDLC approach offers advantages in polarization independency and fast response time. However, its operating voltage exceeds $10\,V/\mu m$. On the other hand, polymer network has a lower polymer concentration. As a result, its operating voltage is reduced to $2\,V/\mu m$, except that the focusing effect is dependent on the light polarization.

5.9.2 OLEDs

For over 100 years, people have been obtaining light from light bulbs. Unfortunately, the majority of the energy involved is converted into heat and only a tiny fraction actually produces light. In an attempt to overcome this inefficiency, very competitive technologies such as sodium pressure and fluorescent lamps and inorganic light-emitting diodes (LED) were developed. LEDs are highly efficient and available in all colors. Recently, a promising technology to convert electricity into light was developed by depositing thin layers of appropriate materials between two electrodes and applying an electric field (Fig. 5.70) [5.279–281].

The emissive material between the electrodes is an organic semiconducting material, and hence the entire device is now called an organic light-emitting diode (OLED). OLEDs combine the advantages of LEDs with those of organic materials, which include mechanical flexibility, full color availability and large lighting areas. To couple light out from the device one electrode must be transparent. Indium-tin-oxide (ITO) on glass or plastic substrates with a layer thickness of 100–200 nm is the most common transparent and conductive electrode.

This brief review cannot replace a physical textbook and not all elementary processes in an operating OLED can be examined herer intensively. However, the physics of a single layer OLED can be simplified. ITO works well, with its large work-function, as an anode and injects positive charge carriers (holes) into the organic semiconductor. On the other side of the organic layer, a metal electrode simultaneously injects electrons. After migration in the emissive layer, a hole and an electron combine to form an exciton. This neutral excited state is
Fig. 5.70 Multi layer setup of an organic light-emitting diode

Table 5.31 Relation of energy gap of HOMO and LUMO, emission color, and wavelength of emitted light

Energy gap in emitters (eV)	Color	Wavelength (nm)
1.9–1.6	Red	650 780
2.3–1.9	Yellow	530–650
2.5–2.3	Green	490–530
3.1–2.5	Blue	420–490

a high energy state far from thermal equilibrium. Unfortunately, this surplus energy cannot be released solely as radiation (light), but is also dissipated as heat. The emission color (wavelength, Table 5.31) is a material property and depends on the difference between the energy levels of the first electronic excited state and the ground state, i. e. the energy difference between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of the molecule.

An excited state can be generated by the absorption of light of suitable wavelength as well as by applying a voltage to an OLED device. Independent of the kind of excitation, the radiative decay of the excited state is physically identical and thus both emission spectra have the same shape. The processes are called photoluminescence (PL) and electroluminescence (EL), respectively.

Properties such as flatness and brightness, combined with the possibility of high resolution (pixelation) of the device, make OLEDs a very promising and competitive technology for liquid crystal (LC) displays. Extremely lightweight, full color and flexible displays are likely to be produced within a few years to penetrate the huge market dominated by LC, LEDs, and plasma technology. In recent years, enormous improvements upon OLED emitters allow the production of large bright areas, which will be interesting and useful for lighting applications. Developing a suitable coating technology is the key for making self-luminating large areas with low manufacturing costs. Although a few products equipped with OLED-technology are already available, several technical challenges still remain to be solved.

Emitter Materials

In the pioneering work by *Tang* and *van Slyke*, EL was first discovered in 1987 by using an aluminum quinolate (Alq$_3$) as an emitter material [5.282]. A second milestone in the field of organic EL occured when polymers were brought into the action in 1990, after workers at Cambridge University evidenced the generation of light from poly-para-phenylenevinylene (PPV) [5.283].

The discovery of light emission from organic materials has led to tremendous research activity. As a consequence, the number of materials employed as the emitter material in OLEDs is vast, and a comprehensive list can not be published within the scope of this book. All organic materials used as emitters in OLEDs must combine several properties. First of all, they need to be of high purity and chemically and thermally stable. Secondly, they must exibit a high quantum yield. Finally, the materials need to be processible and have the ability to form thin films.

The most common classification for emitter materials used in OLEDs is "Small Molecules" (SM) versus "Polymers" (Fig. 5.71 and Fig. 5.72). The main difference between the two is the processing of the materials for fabrication of devices. SMs (compounds with a low molecular weight) are evaporated in a high vacuum process to deposit a film – ranging in thickness from a few layers to a few nanometers – on a surface. Due to the large molecular weight of polymer chains, a vacuum process cannot be used. Advantage can be taken of good solubility in various solvents to obtain homogeneous films by spin-coating or printing techniques. These solution coating processes offer enormous advantages concerning thin films on large areas. It is difficult to compare both classes so only advantages and drawbacks with regard to processability and OLED performance are considered.

Purification of the materials is an important issue since it is well known that tiny amounts of impurities can dramatically impair device performance. Deposition of pure low molecular weight compounds in high vacuum serves as an extra purification step during the OLED process itself. In contrast, polymers must be purified as well as possible before the coating process. For efficient devices, the number of positive and negative charge carriers in the emitter layer must be equal. This goal can be achieved by pursuing the following two strategies described. Using an evaporation process for SM, several materials can easily be deposited on top of each other. This process allows the manufacture of multilayer devices, in which each layer has its own function, such as hole injection or transport, light emission, electron transport or blocking, etc. Efficiency is optimized by material choice and order, layer thickness, co-evaporation, etc.

Polymeric multilayer devices are more difficult to produce due to polymer solubility in multiple solvents. Most two layer devices are made utilizing water soluble polyethylenedioxythiophene/polystyrylsulfonat (PEDT/PSS), which is rendered insoluble
Fig. 5.71 Chemical structures of representative luminescent conjugated polymers
Fig. 5.72 Chemical structures of representative hole transport materials

(even in water) after baking the film. In this case the emissive polymer can easily be deposited on top of PEDT/PSS by a solution coating process. Due to limitations on the number of polymeric layers that can be stacked, the ideal emitter should have a balanced number of holes and electrons during operation. Furthermore using appropriate electrodes gives nearly balanced electron and hole injection leading to efficient OLEDs.

Fluorescence and Phosphorescence

An important point to keep in mind is the fact that singlet and triplet excitons exist. Whereas during photoexcitation generally singlet excitons are formed, the spin statistics predict the ratio of singlet to triplet excitons created in an operating OLED device should be 1 : 3.

Part A | 5.9

After the formation of singlet excitons by the combination of oppositely charged carriers, it is impossible to distinguish singlet excitons created by charge carriers from single excitons formed by photoexcitations. Without going into further details, the radiative decay of a singlet state is physically permitted and fast (lifetime $\approx 10^{-9}$ s). The transition from a triplet excited state to the ground state is strictly forbidden and only occurs under certain circumstances like spin–orbit coupling in the presence of heavy atoms, with lifetimes ranging from 10^{-6} s up to hours. To improve the efficiency of devices it is desirable to include radiative decay of both kinds of excitons by adding phosphorescence emitters like organic-heavy metal complexes.

Color

Yellow, red, and green emitters are already commercially available in large quantities. Recently, material suppliers are focusing on synthesizing long-lifetime blue and white emitters. In fact, it is the lack of stability in both blue and white emitters that prevents full color products with long lifetimes even under moderate operating conditions. Due to the high energy band gap of blue emitting materials, they are particularly unstable and side-reactions often damage the molecular structure.

Problems for full color displays are caused by the different lifetimes of the emissive colors, leading to a color shift over a short period of time. For example, white emitting devices – which are always a combination of several emission colors – show a slow change of hue during device operation.

Conjugated Polymers

Film formation, quantum yield, device efficiency, lifetime, and emission color can be tuned by modifying the chemical structure of the emitting materials. Since the discovery of EL in polymers many derivatives of poly-para-phenylenevinylene (PPV) as well as other classes of luminescent polymers have been synthesised and used successfully in OLEDs. PPV itself is an insoluble polymer. To make devices with PPV, a soluble non-conjugated precursor form must be coated on the device. The precursor is subsequently thermally transformed to PPV. PPV emits yellow-green light with a peak wavelength of 510 nm. For the sake of purification and processing a soluble polymer is highly desirable. Introducing side groups onto the polymer chain cannot only make the polymer soluble, but can also modify the electrical and optical emission characteristics. Poly[2-methoxy-5(2-ethylhexyloxy)-1,4-phenylenevinylene] (MEH-PPV), a material

investigated and used in OLEDs in 1991 is one of the first examples of this approach. This molecule shows an emission in the orange-red region of the spectrum [5.284].

A disadvantage of PPV is the easy oxidation of the vinylene bridge between two phenylene-rings. This undesired side-reaction, which can occur during synthesis or device operation, breaks the conjugation and leads to a reduction in device efficiency. Again, two ways were identified to improve the oxidative stability: substitution at the vinylene carbon position or replacing the double bond by a triple bond ending with poly[2,5-bis(hexyloxy)-1,4-phenylene-(1-cyanovinylene)] (CN-PPV) [5.285] and poly(para-phenyleneethylene) (PPE), respectively [5.286].

Poly-para-phenylene (PPP) derivatives were synthesized to obtain stable blue emitters [5.287], however, conjugation in the polymer chain is reduced due to non-planar alignment of adjacent phenylene rings. Improved planarity is realised by bridging two phenyl rings with a methylene-group to form polyfluorene (PF). PF is a blue emitter which can be color tuned over the visible spectral range by adding different monomers during the polymerization of PF-precursors [5.288–290].

Researchers in Germany synthesised a PPP derivative where all adjacent rings are bridged, namely the ladder-PPP (LPPP)[5.291, 292]. The phenylene-rings are completely planarised and the stiff chains show high persistence lengths that are responsible for the relatively high mobility of charge carriers in this semiconducting polymer.

Another approach in polymer OLEDs is the application of polymer blends [5.293–295]. At least two polymers are mixed: a polymer for charge carrier transport and an emissive polymer. Recent research has been done on avoiding the problem of phase separation. For the polymer blend approach, either a copolymer possessing all properties of the blend itself is synthesized or the chains of the two polymers are crosslinked after processing as a thin film in the device.

The synthesis of polymer chains with defined chain ends has led to more stable derivatives in comparison to the polymer without defined chain ends. Such "end-capped" emitter polymers (for instance attached to a hole transport molecule at the chain end) show better device performance.

Along with conjugated polymers, other classes of organic materials are noteworthy. Heterocyclic polymers like polythiophene (PT) [5.296], polypyridine [5.297], and many others were synthesized and countless derivatives were investigated in OLEDs.

Small Molecules

Thermal stability is required in an evaporation process to deposit a molecule on a surface without decomposition. Furthermore, formation of stable and amorphous films of one or more functions, such as charge injection and transport, and emission must be combined within the material (Fig. 5.73) [5.298].

Promising compounds with reasonably efficient emission are organo-metallic complexes. In this case emission comes from either the ligands or the metal-center. The prototype for ligand emission is the aluminum triquinolate (Alq$_3$) [5.282] shown in Fig. 5.72. Many materials have been found to generate light of all colors. Rare-earth-complexes emit through electron transition in the metal atom [5.299]. These spectra are very narrow compared with polymer emission spectra, however short wavelength emission is hard to realise and quantum efficiency seems to be lower than in ligand-emission complexes, too.

In efficient SM devices multilayer systems are used. For a balanced number of oppositely charged carriers in the emissive layer and for decreasing the on-set voltage, injection and transport materials are necessary for holes and electrons in addition to device setup optimization.

Material improvements for SM-OLEDs can be shown exemplary at hole transport materials, where the most widely used compounds are aryl-amines. To ensure the final materials are high temperature stable glassy films (instead of crystalline layers) many derivatives have been synthesised, including N,N'-diphenyl-N,N'-bis-(3-methyl-phenyl)-(1,1')-biphenyl-4-4'-diamine (TPD) [5.300] and N,N'-diphenyl-N,N'-denaphthyl-(1,1')-biphenyl-4,4'-diamine (NPB). An other large arylamine, the so-called starburst amine (MTDATA), shows a glass transition temperature (T_g) around 160 °C [5.301].

Two other approaches to increasing the T_g are raising the molecular weight or modifying the molecular structure of the material. The former approach is limited by the need to increase the evaporation temperature for higher molecular weights. In recent years *spiro*-compounds have been synthesized [5.302] to obtain materials with a high T_g. An advantage of this molecular element is the inhibition of crystallization to produce materials in a stable glassy state.

For generating light in an OLED, small fluorescent molecules are also used for doping both electron and hole transport materials. Due to the lower excited state energy of the dopants (as compared to the host), excitons formed in the binder are immediately transferred to a dopant which acts like an exciton trap. By optimizing the dopant/host ratio, emission only comes from the dopant. However, if the dopant concentrations are too high (> 2–3%), performance actually suffers due to concentration quenching of the luminescence. Examples of fluorescent dyes are perylene [5.303], 4-(dicyanomethylene)-2-methyl-6-(p-dimethylaminostyryl)-4H-pyran (DCM) [5.304, 305], and chinacridone [5.306].

Mechanism of Degradation and Device Failure

Depending on the desired properties of an OLED a long lifetime (ten thousands of hours) and/or a high brightness $(1000$ to $5000 \, \text{Cd/m}^2)$ have to be achieved (Fig. 5.74).

Two kinds of failure can be observed: a sudden death, where a short circuit prevents light emission, or a slow decrease, where the lighting area becomes inhomogeneous (black spots) and/or darker.

Immediate failure of the device occurs by connecting the ITO anode directly to the metal cathode during fabrication. In this case a large amount of current flows through this defect and the area becomes hot, damaging the metal and polymer alike. Interestingly, it was found that shorts can also arise during operation by a currently unknown mechanism. Non-emissive regions on the lighting area have to be avoided. These so-called black spots are very tiny in the beginning and grow larger with time. It was shown by different spectroscopic techniques that a large particle (in comparison to the film thickness) in the middle of such a spot can cause a pinhole in the cathode. These damages are supposed to be preferred channels for the penetration of reactive species like oxygen and water into the sensitive materials. This idea is also supported by the constant circular growth of these spots [5.307]. Clean room conditions during OLED preparation and manufacturing of a thin film of suitable polymer like PEDT/PSS to smooth the ITO-surface can prevent failure by shorts.

Lifetime is typically defined as the reduction of brightness to 50% of the initial brightness at constant current and depends strongly on the operation conditions. The brighter the device and the more charge carriers go through the layers the shorter the lifetime due to generating more light and heat in the device. Lifetime depends also on the emission color. Red, yellow and green emitters are stable for more than 20 000 h. Blue and white emitters are being improved intensively, but are still not appropriate for long life products yet.

A typical lifetime curve for a PPV-derivative such as that shown in Fig. 5.73 reveals two areas. During the first phase the brightness shows an "initial drop". After this short period the reduction of brightness be-
Fig. 5.73 Chemical structures of representative Small-Molecules luminescent dyes

Fig. 5.74 Typical accelerated lifetime measurement of a PPV derivative at a high and constant current and high brightness (started at $3500\,\mathrm{Cd/m^2}$ and cancelled at $1750\,\mathrm{Cd/m^2}$ after several 100 h segments)

comes slower. Although a stable level is never reached and the brightness decreases continuously, lifetimes of PPV derivatives can still reach several 10 thousand hours under moderate conditions ($100\,\mathrm{Cd/m^2}$ at room temperature). The initial drop is often called burn-in and is not fully understood, whereas the slow reduction of brightness is attributed to slow degradation mechanisms.

OLEDs are generally very sensitive to water and oxygen; therefore the whole device must be hermetically encapsulated to minimize material damages. Thin metal cathodes are supposed to react with traces of water to decrease the ability of electron injection, particularly under operating conditions. Oxygen reacts with emitter polymers due to its potential for photooxidation of the conjugated polymer. Cleavages of polymer chains have been observed, consequently breaking the conjugated system [5.308–310]. But air is not the only oxygen source – ITO is another [5.311]. Again a dramatic improvement in lifetime was found by introducing a PEDT/PSS layer on top of ITO. A further advantage of this polymer coating is the prevention of indium migration in the device. Ion migration is also known to be

a general problem in operating devices [5.312]. Several scenarios are described concerning this issue. First, the ion remains in his charge state and counteracts the applied electric field. Second, ions damage the materials by oxidizing and reducing. Third, the ions can react at the electrode and generate impurities which prevent the charge carrier injection. These descriptions of ion migration fit the observation that devices driven in a pulsed mode (forward/reverse bias) show slower aging than direct current driven devices.

A further drawback of organic materials is their sensitivity to UV-light. Formation of highly reactive radicals, cleavage of chemical bonds and polymer chain decomposition have negative effects on device performance. UV protection of OLEDs is necessary particularly for outdoor applications.

Summary

LEDs can be made of organic materials. These OLEDs possess a layer setup and are made of either Small Molecules or polymers, or a mixture of both. Thin amorphous films of Small Molecules are deposited chiefly by vacuum processes, whereas polymer films are obtained by wet coating techniques. All emission colors are available, including white. However, lifetimes of blue and white emitters (compared to red, yellow and green) are still too short for long life products and full color applications, respectively. A further issue is the color shift during device operation, which depends strongly on the device operation conditions. An encapsulation increases the device lifetime tremendously – however, hermetic protection against environmental impact is not available yet. Emitter materials, particularly polymers, have been improved astonishingly in the last decade. Detailed

understanding of the device physics and the degradation mechanisms is necessary to furter develop material properties and device design.

For high-end products, some technical problems must still be solved. But visible progress has been made over the last decade in all the important fields like effi-ciency, color portfolio brightness, and lifetime to make OLED devices already competitive in some niches. Time will tell whether the replacement of spot lights (like light bulbs) by lighting areas made of diffuse OLEDs in applications will take place.

5.9.3 Photorefractive Crystals

Light-induced refractive index changes, so-called photorefractive effects, in inorganic electrooptic crystals were discovered by *Ashkin* et al. in 1966 [5.313]. Though in the beginning these effects seemed to be very undesirable ("optical damage"), *Chen* et al. recognized only two years later the significance for holographic storage [5.314]. In 1975, *Staebler* et al. reported the recording of 500 thermally fixed volume phase holograms in $LiNbO_3 : Fe$, each hologram with more than 2.5% readout efficiency [5.315]. The method is based on the Bragg condition allowing the superposition of many volume ("thick") holograms at the same site under different angles.

During hologram recording a light pattern has to be transposed into a refractive index pattern. Interfering light beams generate bright and dark regions in an electrooptic crystal. When light of suitable wavelength is chosen, charge carriers – usually electrons [5.316] – are excited in the bright regions and become mobile. The charge carriers migrate in the crystal and are subsequently trapped at new sites. By this means electronic space–charge fields are set up that give rise to a modulation of refractive index via the electrooptic effect. Figure 5.75 illustrates the photorefractive process. Index changes up to 10^{-3} are obtained. The trapped charge can be released and the field pattern erased by uniform illumination or by heating. On the one hand, this reversibility is highly desired for, e.g., erasable holographic memories or adaptive optical components; on the other hand, the problem of destructive readout arises.

Photorefractive effects have been observed in many electrooptic crystals, among them $LiNbO_3$, $LiTaO_3$, the ferroelectric perovskites $BaTiO_3$, $Ba_{1-x}Ca_xTiO_3$, $KNbO_3$, and $KTa_{1-x}Nb_xO_3$ (KTN), the tungsten–bronze-type crystals $Ba_2NaNb_5O_{15}$ and $Sr_{1-x}Ba_x Nb_2O_6$ (SBN), the nonferroelectric sillenites $Bi_{12}TiO_{20}$ (BTO), $Bi_{12}SiO_{20}$ (BSO), and $Bi_{12}GeO_{20}$ (BGO), the semiconductors GaAs and InP, and others. Very early crucial influences of dopants and thermal treatments were discovered [5.317, 318]. Photorefractive crystals are of particular interest for many unique devices, such as self-pumped phase-conjugating mirrors, parametric amplifiers and oscillators as well as static and dynamic
Fig. 5.75 Photorefractive process in electrooptic materials. A light intensity pattern $I(x)$ illuminates a photorefractive material. Here as an example we use a sinusoidal light pattern with the period length Λ as it is generated by interference of two plane waves. The light excites free charge carriers; e.g., electrons from traps are excited into the conduction band. The free-carrier distribution $N(x)$ yields currents due to, e.g., diffusion. For pure diffusion charge transport, the charge carriers move into the darker areas where they are captured by empty traps. An effective charge density distribution $\rho(x)$ builds up with missing electrons and effective positive charge in the bright and excess electrons and effective negative charge in the dark areas. This charge distribution yields a space–charge field $E(x)$ and, because of the linear electrooptic effect, also a refractive-index modulation $n(x)$

optical filters [5.319, 320]. They are also considered for holographic data storage [5.321].

In the following we describe the charge transport processes that critically determine the performance of the material. Figures of merit for the hologram storage properties will be introduced, the limits will be evaluated, and the crystals mentioned above will be discussed. Finally, fixing techniques will be briefly reviewed.

Charge Transport

The charge driving forces are well known: diffusion, bulk photovoltaic currents [5.322], and drift of charge carriers in external or pyroelectric fields [5.323] generate the space–charge field. Compensating drift currents arise, and saturation is achieved if they are as large as the driving currents. Application of large external electric fields is of interest mostly for crystals with a relatively high conductivity, and large pyroelectric fields occur only in the case of high light intensities. Thus diffusion and the bulk photovoltaic effect are of major importance.

Extrinsic or intrinsic defects occurring in more than one valence state are sources and traps of the charge carriers. Figure 5.76 shows different charge transport situations in a band diagram. The energetic positions of the levels shown correspond to the thermal energy required to excite a charge carrier from the filled level. Photon energies necessary to release electrons are typically larger because of the Franck–Condon principle. The simplest and for many applications the desired mechanism is provided by a "one-center system" with monopolar conductivity (shown in Fig. 5.76 for electron conductivity). One impurity type occurs in two different valence states, and charge is redistributed via

Fig. 5.76 Charge transport processes in a photorefractive crystal. *Arrows* indicate excitation and recombination of electrons (for details see text)

either conduction or valence band [5.324]. An example is iron-doped $LiNbO_3$ at usual continuous-wave laser intensities. Iron ions occur only in the valence states 2+ and 3+ [5.325]. Electrons are excited from Fe^{2+} to the conduction band and trapped by Fe^{3+} elsewhere.

Electron–hole competition may complicates the situation [5.316, 326, 327]. Electrons and holes can be created at the same center, as shown in Fig. 5.76, but it is also possible that an additional independent center is present that generates holes. In any case, diffusion currents of electrons and holes compensate each other which is disadvantageous for hologram recording.

Many materials show more complicated transport mechanisms, because two or more photorefractive levels participate in the charge transport simultaneously. Additional independent centers [5.328, 329] or impurities occurring in three or more valence states [5.330] may be the origin of these additional levels. We have to distinguish between so-called deep and shallow levels. "Shallow" indicates here that charge can be released thermally from this level, which is practically impossible for a deep site. A system with the simultaneous presence of a deep and a shallow energy level (shown in Fig. 5.76 for electron conduction) has detrimental consequences for hologram recording. The shallow levels are empty in the dark because all charge carriers have been thermally excited and trapped by deep sites. Upon illumination, the shallow levels trap charge carriers from either the conduction or the valence band. As a consequence, the response time grows (smaller photoconductivity [5.331]) and, moreover, often the absorption increases, too, because the filled shallow traps absorb light effectively [5.329].

Deep and shallow levels exchange charge via conduction or valence band. Direct exchange of charge is possible, if the concentrations are large enough that different centers are located closely together. This may occur in the case of intrinsic defects [5.332]. For very high defect concentrations additional bands are created, because centers of the same type couple and exchange charge directly [5.333, 334]. More details about the charge transport may be found in a review [5.335].

The charge transport situation can be influenced by doping, thermal annealing, and selection of experimental parameters (light intensity and wavelength, crystal temperature). Thus it is possible to establish in many materials the desired one-center charge transport situation. We will concentrate in the following on a one-center system, because we are interested in the performance limits of different materials. Iron-doped lithium niobate ($LiNbO_3 : Fe$) will be used as an example to describe
in more detail the ongoing processes and the resulting dependences. However, most of the theoretical consideration is valid for any photorefractive crystal.

Quantitative description of the formation of the space–charge pattern under nonuniform illumination requires the solution of the Maxwell equations, together with the current and the rate equations. Generation and recombination of conduction band electrons are described by $(dN_e)/(dt) = +SIc_{Fe^{2+}} - \gamma c_{Fe^{3+}} N_e$, where N_e is the concentration of electrons in the conduction band, S is the photon absorption cross-section, I is the light intensity, $c_{Fe^{2+}}$ and $c_{Fe^{3+}}$ are the concentrations of Fe^{2+} and Fe^{3+} ions, and γ is the recombination coefficient. The general problem leads to a system of coupled nonlinear differential equations that cannot be solved analytically [5.324]. Reasonable approximations reveal that simple exponential evolutions govern build-up and decay of the space–charge field. Analysis yields the steady-state amplitude E_{sc} of the space–charge field [5.324]

$$E_{sc} = m\left(E_D^2 + E_{phv}^2\right)^{1/2}, \quad E_D = \frac{k_B T}{e} K,$$

$$E_{phv} = \frac{\beta \gamma}{e \mu S} c_{Fe^{3+}}, \tag{5.158}$$

where m is the modulation degree ("visibility", "contrast") of the interference pattern, E_D is the diffusion field, E_{phv} is the bulk photovoltaic field, k_B is the Boltzmann constant, T is the temperature, e is the elementary charge, K is a typical spatial frequency of the hologram (2π/period length of the interference pattern), β is the bulk photovoltaic coefficient [bulk photovoltaic current density/($c_{Fe^{2+}} I$)], and μ is the charge carrier mobility. In the following we will assume a fully modulated light pattern, i.e., $m = 1$. The field E_{sc} might be reduced by space–charge limiting effects ($E_q < E_D$ or $E_q < E_{phv}$ with the space–charge limiting field $E_q = [e/(\varepsilon\varepsilon_0)](1/K)N_{eff}$, dielectric constant ε, permittivity of free space ε_0, and effective trap density N_{eff}).

The bulk photovoltaic effect dominates in $LiNbO_3$ and $LiTaO_3$ crystals containing 0.01 wt % or more Fe, but diffusion is the major transport mechanism in many other materials. We have to distinguish between different geometries, e.g., transmission and 90° geometry (Fig. 5.77). Typical spatial frequencies in these geometries are $2\pi/0.4\,\mu m^{-1}$ and $2\pi/0.15\,\mu m^{-1}$, respectively. These values will be used in the following if we refer to transmission or 90° geometry. The corresponding diffusion fields at room temperature are 4 kV/cm and 10 kV/cm. Bulk photovoltaic fields in $LiNbO_3$ can reach values up to 100 kV/cm [5.322]. Larger fields cannot be created because electric breakdown takes place [5.336]. We will treat in the following the situation where the light is polarized perpendicularly to the plane of incidence (ordinary polarization), if nothing else is mentioned. In-plane polarization yields recording beams of crossed polarization in the case of the 90° geometry, and no intensity pattern is present. Extraordinary polarization can be used in the transmission geometry, and electrooptic coefficients, dynamic range and sensitivity might be higher, but extraordinarily polarized light tends to create strong holographic scattering [5.337], which is unacceptable for many applications.

The refractive index is modulated via the linear electrooptic effect [5.338], and the refractive index changes are

$$\Delta n = -\frac{1}{2}n^3 r E_{sc}, \tag{5.159}$$

where n is the refractive index and r is the effective electrooptic coefficient. Proper n and r values must be selected considering the material symmetry, the crystal cut, the polarization of light, and the direction of the space–charge field E_{sc}. For example, $LiNbO_3$ with ordinarily (o) or extraordinarily (e) polarized light and a field along the optical axis corresponds to $n = n_o$ and $r = r_{113}$, or $n = n_e$ and $r = r_{333}$, respectively.

Useful figures of merit are required in order to allow comparison and evaluation of the materials in terms of storage performance.

The *dark decay* of the refractive index modulation typically follows a monoexponential function $\Delta n(t) = \Delta n(t = 0)\exp(-t/\tau_{dark})$. Large dark storage times τ_{dark} are usually desired.

Monoexponential growth of the space–charge fields and refractive index changes, $\Delta n(t) = \Delta n_s[1 - \exp(-t/\tau)]$, is characterized by the *response time τ*, which depends on light intensity according to $\tau = \varepsilon\varepsilon_0/\sigma_{ph}(I)$, where σ_{ph} is the photoconductivity.
Fig. 5.77 Transmission and 90° recording geometries. The black *arrows* show the direction of the crystallographic *c*-axis
Fig. 5.78 Normalized refractive index modulation $\Delta n/\Delta n_s$ vs. normalized time t/τ for an exposure schedule that yields holograms of equal strength. Hologram Nr. 1 (*dashed curve*) is recorded into saturation. Recording of hologram Nr. 2 (*dotted curve*) erases part of hologram Nr. 1. Recording is stopped as soon as both holograms approach equal strength. At this point both holograms have both a Δn of $\Delta n_s/2$. Recording of hologram Nr. 3 (*full curve*) then erases the holograms Nr. 1 and 2 and so forth

Here Δn_s is the saturation value of the amplitude of a single hologram.

Subsequent superposition of several holograms requires a special exposure schedule, if holograms of equal efficiency are the target [5.352]. The diffraction efficiency (ratio between the intensities of diffracted and incident light) of an individual of M multiplexed holograms will be $\eta(M) = [(M\#)/M]^2$, if M is large enough to ensure that η is much smaller than 1. Figure 5.78 illustrates the required exposure schedule and derives graphically that for M holograms of equal

strength the Δn per hologram is just $\Delta n_s/M$. Considering $\eta \propto \Delta n^2$ [5.353], we end up with the formula $\eta(M)$ given above.

The $M\#$ is a useful measure for the *storage density* and *capacity* of photorefractive crystals [5.354]. It is given by

$$M\# = \frac{\pi \Delta n_s d}{\lambda \cos \Theta} \exp(-1) \quad \text{for} \quad \alpha d = 2, \qquad (5.160)$$

if the time constants for recording and erasure are equal. Here d is the thickness of the crystal, λ is the vacuum wavelength of the light, Θ is half the angle between the recording beams in the medium, and α is the intensity absorption coefficient. Build-up of Δn requires the presence of excitable electrons, which cause absorption. Considering this trade-off, the largest $M\#$ is achieved for $\alpha d = 2$. The photon budget determines the minimum efficiency η necessary to read a hologram. Assuming, e.g., $\eta = 10^{-6}$, an $M\#$ of 10 indicates that 10 000 holograms can be multiplexed. However, the number of useful holograms can be reduced significantly owing to hologram cross-talk, light scattering, or homogeneous bulk photovoltaic fields.

There are various ways of defining the *sensitivity*. A useful measure is $W_{\eta=1\%}$, the exposure density (laser-light intensity multiplied by the recording time) required to record a hologram of 1% diffraction efficiency. Recording and erasure of the refractive index changes Δn are governed by monoexponential functions [5.324]. Using *Kogelnik's* equation [5.353] for small diffraction efficiencies $\left(\eta \approx [(\pi \Delta nd)/(\lambda \cos \Theta)]^2 \exp(-\alpha d)\right)$ we end up with

$$W_{\eta=1\%} = \frac{1}{10} \frac{\tau(I)I}{M\#} \quad \text{for} \quad \alpha d = 2. \qquad (5.161)$$

Table 5.32 Refractive index n_o for light polarized perpendicularly to the optical axis, electrooptic coefficient r, and dielectric coefficient ε for fields along the optical axis for different photorefractive crystals (light wavelength 514 nm; room temperature values)

Material	n_o			r (pm/V)			ε_{33}

GaAs	3.45	2	[5.351]	1.4	+2	[5.339]	12	[5.339]

[a] Ba$_{0.77}$Ca$_{0.23}$TiO$_3$, [b] KTa$_{0.52}$Nb$_{0.48}$O$_3$, [c] Sr$_{0.61}$Ba$_{0.39}$Nb$_2$O$_6$, [d] Bi$_{12}$TiO$_{20}$, * r_{113}, + r_{231}, 1 633 nm, 2 1150 nm

Small response times τ and large values of $M\#$ are required to achieve good sensitivities (small $W_{\eta=1\%}$ values). In addition to $W_{\eta=1\%}$ another measure for the sensitivity is also commonly used

$$S = \frac{\sqrt{\eta}}{Idt}\bigg|_{t\ll\tau}, \tag{5.162}$$

where η is the diffraction efficiency that the hologram reaches after the recording time t. For small recording times ($t \ll \tau$) we can write $\sqrt{\eta} = M/\#\times(t/\tau)$. From this the simple relation $S = (10dW_{\eta=1\%})^{-1}$ can be derived. For a sample of, e.g., $d = 1$ cm thickness and a $W_{\eta=1\%}$ of 10 mJ/cm^2 we end up with $S = 10$ cm/J.

Performance Limits

There is no obvious theoretical limit to the *dark storage time*; very large values up to 10 y have been extrapolated [5.355]. For strongly doped crystals tunnelling of electrons between traps may reduce the dark storage time [5.333].

Crystals with thicknesses d up to 1 cm are available, and are supposed to have the highest *storage density*. Absorption is limited to $\alpha = 2/d = 2$ cm^{-1}, which determines the concentration Fe$^{2+} = 4.3\times10^{17}$ cm^{-3} [5.325]. Thus the largest possible E_{sc} (all electrons are redistributed) is $E_{sc} = E_q = [e/(\varepsilon\varepsilon_0)](1/K)N_{eff} = 180$ kV/cm and 66 kV/cm for transmission and 90° geometry, respectively (ε, Table 5.32). A field of 180 kV/cm is above the break-down threshold, but the $M\#$ describes the multiplexing properties, and the amplitude of each single

hologram is well below the break-down field if many holograms are superimposed. We get $\Delta n_o = 13\times10^{-4}$ and $\Delta n_o = 5\times10^{-4}$ ((5.159), n_o and r_{113} from Table 5.32), which yields according to (5.160) the $M\#$ values 30 and 16 for transmission and 90° geometry respectively ($\lambda = 514$ nm, $\Theta = 45°$, $\alpha d = 2$). A similar estimate holds for LiTaO$_3$. However, in diffusion-controlled media the space–charge fields are lower, and limited by $E_{sc} = E_D$. The $M\#$ can be estimated using (5.158–5.160). $M\#$s range from 0.3 to 10 for different materials (Table 5.33).

Regarding *response time and sensitivity*, we have to consider the quantum limit, i.e., each incident photon moves in the optimum situation one electron to the desired position. Considering green light (photon energy 2.4 eV) and an energy difference of about 1 eV between the impurity level and the band, about 1.4 eV remains to move the electron against the space–charge field. Supposing a typical period length of 0.4 µm (transmission geometry), we have to move the electron about 0.2 µm against the field. Thus the energy of one photon is sufficient to move the electron against fields of up to 70 kV/cm. The fields are larger in the 90° geometry, but the transport lengths are smaller. From this perspective it is reasonable to treat the situation where each photon redistributes one electron. In this case we can replace $\tau(I)$ by $(\varepsilon\varepsilon_0/e)K(hc/\lambda)dE_{sc}(1/I)$, where h is the Planck constant and c is the vacuum speed of light, and get for $I = 1$ W/cm^2 and parameters of LiNbO$_3$ the result $\tau \approx 100$ ms (ε from Table 5.32, $K = 2\pi/0.4$ µm^{-1}, $\lambda = 514$ nm). This yields $W_{\eta=1\%} \approx 0.3$ mJ/cm^2.

Table 5.33 Various storage parameters for different photorefractive crystals (light wavelength 514 nm; room temperature values; Trans., transmission geometry; 90°, 90° geometry). The values for $M\#$ and $W_{\eta=1\%}$ are calculated from (5.158–5.161)

Various Crystals

Table 5.32 summarizes important parameters, and Table 5.33 presents typical hologram recording characteristics of various inorganic photorefractive crystals.

Hologram recording performances of $LiNbO_3$ and $LiTaO_3$, of the perovskites $BaTiO_3$, $Ba_{0.77}Ca_{0.23}TiO_3$ (BCT), $KTa_{0.52}Nb_{0.48}O_3$ (KTN), and $KNbO_3$, of the tungsten–bronze structure $Sr_{0.61}Ba_{0.39}Nb_2O_6$ (SBN), of the sillenite $Bi_{12}TiO_{20}$ (BTO), and of the semiconductor GaAs are summarized in Table 5.33. *Dark storage* and *response time* may vary by orders of magnitude for the same material depending on doping (elements, concentrations), annealing (oxidation, reduction), and experimental conditions (light intensity, crystal temperature, etc.). Thus the values shown are only typical numbers. It is possible to improve one value at the expense of another. For example, the response time of $KNbO_3$ can be decreased to a few ms by electrochemical reduction [5.371], but simultaneously the dark storage time is decreased by orders of magnitude.

The largest possible *storage densities* are calculated [(5.158–5.160), Table 5.32] considering bulk photovoltaic charge transport for $LiNbO_3$ and $LiTaO_3$, and diffusion for the other materials. $LiNbO_3$ and $LiTaO_3$ have larger storage densities in the transmission geometry because more charge per interference fringe is available to build-up the space–charge field. However, the 90° geometry is advantageous for diffusion recording, because higher spatial frequencies yield larger diffusion fields. Using the response time τ and the storage capacity already determined, the *sensitivity* is estimated based on (5.161).

The number of holograms that can be multiplexed may be reduced significantly in many samples by several undesired effects. For example, light scattering reduces the visibility of the interference pattern, and therefore the fields and the dynamic range are also lowered. The required exposures $W_{\eta=1\%}$ [5.355, 372] for recording in $LiNbO_3$ and $LiTaO_3$ are one order of magnitude larger than the values presented in Table 5.33. It is also known that the measured refractive index changes in, e.g., $BaTiO_3$ and KTN crystals are often about 4 to 5 times below the calculated values [5.346, 373]. The numbers for storage capacity and sensitivity in Table 5.33 are optimum values which may be achieved in carefully selected and optimized samples.

Table 5.33 clearly shows which material is the best for which application. Crystals of the lithium-niobate family ($LiNbO_3$ and $LiTaO_3$) are the favorites for long-term high-capacity storage of holograms. The performance of the rarely used $LiTaO_3$ exceeds that of $LiNbO_3$, but the drawback in this case is that ultraviolet light is required. Good availability, excellent homogeneity, and high robustness are further advantages of $LiNbO_3$ and $LiTaO_3$. Furthermore, the processes occurring in $LiNbO_3$ are well understood, e.g., the proportionality between the space–charge field and the concentration of Fe^{3+} ions (5.158) is verified [5.356]. The crystals can be tailored for applications by optimization of the Fe concentration, by annealing and by additional doping. For example, doping with two deep independent levels which can be addressed with light of different wavelength allows optical fixing of the information [5.374]. Doping with large amounts of Mg increases the conductivity and improves the sensitivity [5.356]. More details about the specific properties of $LiNbO_3$ and other photorefractives can be found in a review [5.375].

The perovskites have shorter hologram lifetimes, but they are well suited for, e.g., holographic double-exposure interferometry [5.376]. The properties of all sillenite-type crystals $Bi_{12}TiO_{20}$ (BTO), $Bi_{12}SiO_{20}$ (BSO), and $Bi_{12}GeO_{20}$ (BGO) are very similar with one exception: The optical activity of BTO is much smaller than that of BSO and BGO [5.349], which is of importance especially for thick samples. Parameters of the semiconductor GaAs are shown for completeness. Small dark storage times and small storage capacities make GaAs unattractive for many photorefractive applications. However, perovskites, SBN crystals, crystals of the sillenite type, and photorefractive semiconductors can be of great interest for dynamic components because of the relatively large sensitivity that allows fast optical processing, fast adaption of optical components, and fast refreshment of storage systems.

The sensitivities of the materials are orders of magnitude away from the quantum performance limits, and the low sensitivity is indeed the major drawback of inorganic photorefractives. A detailed study of the properties of cerium-doped SBN revealed the reasons [5.377] which apply for many photorefractive crystals. Only a few percent of the photons release electrons; most of the light energy is immediately transferred to heat. Trapping of electrons is very efficient because of Coulomb attraction which limits the life-time and the transport lengths. It is unlikely that these problems can be completely overcome by a new inorganic photorefractive crystal.

Laser technology may solve the remaining problems of speed. The available output power of continuous-wave lasers increases rapidly. Pulsed systems become smaller and cheaper. Recording and reconstruction of
Fig. 5.79 *Thermal fixing*. During or after recording the crystal is heated. Ions become mobile and screen the electronic space–charge field. In the example shown, electrons are moved into the darker areas. This charge is compensated by H^+ ions. After cooling back to room temperature the ions are almost immobile. Now illumination moves part of the electrons back because of spatially inhomogeneous excitation, and a space–charge field appears that modulates the refractive-index through the electrooptic effect. Further erasure of the electronic pattern is impossible because drift of electrons in the space–charge field cancels all erasure currents. *Electrical fixing*. Similar to thermal fixing, but instead of heating and ions, external electrical fields and switched ferroelectric domains are involved. The *arrows* indicate the directions of the switched ferroelectric domains

Fig. 5.80 Two-photon persistent holographic recording: The first photon excites an electron from a ground state into an excited state. This illumination can be, e.g., spatially homogeneous. Exposure with a holographic interference pattern of the recording wavelength excites in the illuminated areas electrons from the excited state into the conduction band where they move and recombine elsewhere with traps either through the excited state into the ground state or directly into the ground state. The wavelengths for the first and second transition must be carefully selected to make excitations through real levels possible. For reading, homogeneous light of the recording wavelength must be present. However, this light fails to excite the electrons from the ground state into the excited state because of insufficient photon energy. Thus no electrons are released, and the hologram is stable against further illumination

holograms in photorefractives by, e.g., femtosecond light pulses has been demonstrated [5.378]. Another approach to solve the problem of insufficient sensitivity is the usage of multiple-quantum wells [5.379, 380]. Electric space–charge fields yield large absorption changes which modulate the refractive index due to the Kramers–Kronig relations. Multiple-quantum wells are fast, and there seems to be a lot of room for further improvements.

Nondestructive Readout

The retrieval of information stored in electrooptic crystals requires homogeneous illumination and thus leads to erasure effects. In many cases asymmetries in the recording and read-out processes that are simply achieved by a reduction of the read-out light intensity are not sufficient. For this reason several methods have been developed to stabilize volume phase holograms versus the readout light.

Thermal fixing has already been discovered in $LiNbO_3$ in 1971 [5.381]. By heating, a hologram re-

sulting from electronic and ionic charges is formed which is stable against homogeneous illumination. Protons (H^+) play the major role as mobile ions in the thermal fixing process [5.336, 382]. Electrical fixing has also been demonstrated [5.383, 384]. An external electric field slightly smaller than the coercive field has been applied to convert the space–charge pattern into a domain pattern. Figure 5.79 illustrates these fixing processes.

To preserve the possibility of desired optical erasure, the use of two-photon excitation has been proposed for hologram recording [5.385]. Then readout without erasure is possible using reduced light intensity [5.386]. Similar methods that avoid large recording intensities are based on the population of shallow levels [5.387] or of photochromic centers [5.374]. A general picture about two-photon persistent holographic recording is shown in Fig. 5.80.

There seems to exist a simple possibility for reading volume holograms nondestructively: the use of readout

light of low photon energy, insufficient to excite charge carriers. However, information losses then arise because of the Bragg condition. A method has been proposed to improve the situation with the help of anisotropic diffraction [5.388]. Another solution to increase the bandwidth of the readout light has been developed [5.389, 390], based on a spectrum of spatially adapted wave vectors. Finally, the use of frequency-difference holograms has been suggested and demonstrated for nondestructive readout [5.391, 392]. The spatial frequency shift is achieved by nonlinear mixing of a hologram with a carrier frequency grating, but recording with two different wavelengths is required.

Conclusions

Good availability, excellent homogeneity, robustness, large dark storage times, large storage capacities, reversibility and the availability of efficient and convenient fixing techniques make $LiNbO_3$ and $LiTaO_3$ the favorites among the photorefractive crystals for applications that involve long-term storage of many strong holograms. This is the reason why many demonstrators are based on this material. Tungsten–bronze- and sillenite-type crystals are more sensitive, but small dark storage times and low storage capacities limit their applicability to short-term, high-resolution storage of images, e.g. for the purpose of holographic interferometry. Knowledge about the charge transport nowadays enables tailoring of the crystals considering system issues such as the desired Bragg selectivity, the light wavelength and the light intensity. Concentrations and valence states of impurities may be adjusted by doping or thermal annealing.

Holographic storage is only one of many possible applications of photorefractive crystals. Lithium niobate and lithium tantalate are, e.g., excellent to realize fixed Bragg wavelength filters for telecommunication. Materials like the perovskites barium titanate and potassium niobate, tungsten-bronze type and sillenite type photorefractive crystals as well as semiconductor photorefractive crystals can be of high interest for dynamic holography, optical signal processing, realization of adaptive optical components, for phase conjugation, and for many other advanced applications.

5.9.4 Metal Mirrors

Mirrors can be fabricated from any number of materials with an emphasis for high performance applications on near-zero expansion materials such as ULE^{TM} [5.394] and Zerodur$^®$ [5.395]. However, metals and ceramics, primarily silicon carbide, are now being used in many applications. When designing a mirror, there are many metals from which to choose. After considering the properties with respect to the requirements, fabricability, compatibility with other components and dimensional stability must be considered. Metal and silicon carbide mirrors and support structures need to be as stable as their dielectric counterparts. After a brief discussion of dimensional stability – its causes and prevention, properties, selection criteria and recommended fabrication methods are given. More complete treatments have been given by *Paquin* [5.396, 397] and others [5.398].

Dimensional Stability

Dimensional stability of a component is determined by the amount of instability, recognized as dimensional change or distortion leading to reduction of system performance. Stability can only be achieved and controlled when the causes and sources are understood.

Instability Types. Basically there are two types of dimensional instability. First there are permanent changes such as temporal and hysteresis instabilities, and second, changes that may be permanent that happen when the environment is changed. Temporal instability is a dimensional change or distortion that occurs over time in a constant environment, while hysteresis is a change measured at constant conditions before and after changes in the environment such as temperature cycling or vibration (mechanical cycling). Thermal instability can be a change that is seen at a different temperature but returns to the original at the original temperature, or a change that depends on the rate of change of temperature and is not the same when returned to the original conditions.
Fig. 5.81 Interferograms of an optical flat at $26\,°C$ (*left*) and $85\,°C$ showing thermal instability due to severe inhomogeneity of thermal expansion. The figure repeats no matter how many cycles are performed [5.393]

Instability Sources. The sources of these dimensional instabilities are the material, the fabrication process, the environment or a combination of them.

The Material

The material from which a component is fabricated is often the source of instability due to anisotropy and/or inhomogeneity. Anisotropy is direction dependent property variation and inhomogeneity is random spatial property variation looking like the material is "poorly mixed" as shown in Fig. 5.81 [5.393]. The result is thermal instability that is permanent in that the inhomogeneity and/or anisotropy is permanently in the material and cannot be changed, and repeatable in that the distortion at any temperature is repeatable time after time. To avoid this form of thermal distortion, the material selected must be homogeneous and isotropic. Single crystals are intrinsically homogeneous, but are uniformly anisotropic in some properties depending on crystal structure.

Metals can have microstructural changes from exposure to heat from any number of sources, such as processing operations or exposure in use. Amorphous metals such as as-deposited electroless nickel can crys-

tallize and shrink, heat treatable metals such as 6061-T6 aluminum can overage and lose strength and metals with a low annealing temperature such as OFC copper can soften. Fabrication methods to eliminate or minimize these effects are discussed for each material in Sect. 5.9.4.

Another form of thermal instability is thermal mapping where the distortion is proportional to the intensity of impinging radiation and thermal properties of the material. This instability can be minimized by choosing materials that have low coefficient of linear thermal expansion (CTE or α), high thermal conductivity (k or λ) and high specific heat (c_p).

Fabrication

The most common instabilities are temporal and hysteresis. They are both caused by decrease of residual stress and associated strain. Machining and/or grinding operations induce residual stress, sub-surface damage and strain in the cut surface. This layer must be removed or the part will be unstable and subject to further surface damage from high energy laser impingement. Chemical etching can remove the damaged layer and heat treatment can reduce or eliminate the stress.

Temporal instability is the dimensional change associated with stress relaxation. The rate of decrease in stress (s) is proportional to the amount of stress present, that is,

$$(-\,\mathrm{d}s/\,\mathrm{d}t)\tau = s \tag{5.163}$$

and

$$s = s_o\,\mathrm{e}^{(-t/\tau)}\ . \tag{5.164}$$

The relaxation time (τ) is the time (t) at which the stress has dropped to 0.37 of the original stress (s_o) and the decay is exponential. Similar equations can also be formulated for change in strain or surface figure. Stress relaxation is also a thermally sensitive process so that the rate at which the stress decreases, increases exponentially with increasing temperature,

$$1/\tau \propto \mathrm{e}^{(-E/kT)}\ . \tag{5.165}$$

These relationships are used in fabricating components to relieve stress, thereby increasing dimensional stability. *Lokshin* [5.399] has shown the effects of both thermal cycling and isothermal exposure on stress relaxation as shown in Fig. 5.82. Note that thermal cycling is more effective in reducing stress than isothermal treatment for the same elevated temperature.

Since thermal cycling effectively reduces residual stress it is obvious that hysteresis instabilities are caused by reduction of residual stress.

Curve	Thermal conditions

2	Isothermal; 190 °C
3	Isothermal; 400 °C
4	Isothermal; 600 °C
5	Cycled from −70 °C to +400 °C
6	Cycled from −196 °C to +400 °C
Fig. 5.82 Comparison of the effects of thermal cycling and isothermal exposure on stress relaxation in stressed pure beryllium. For Be, thermal cycling reduces stress more than isothermal treatment at the same upper temperature. (Thermocyclic stabilizing treatments) (After [5.399])
Fig. 5.83 Dependence of coefficient of linear thermal expansion on temperature for several mirror materials [5.400]

Fig. 5.84 Dependence of thermal conductivity on temperature for several mirror materials. (After [5.400])

Minimizing residual stress in fabrication of metal optics is best achieved in the fabrication process by using low stress machining/grinding techniques, chemical etching to remove damaged layers, annealing to eliminate stress, and thermal cycling to stabilize. Thermal cycling should be carried out between temperature extremes that are higher and lower than those the part will see in subsequent fabrication and assembly operations, shipping and storage, and in service.

Environment
A mirror's environment includes externally applied stresses incurred during fabrication and assembly, the attachment stresses, thermal stresses in storage and finally the use environment. To resist deformation due to these stresses, the material must be strong enough, both on a macro and micro scale and not be subject to temperatures that will cause any of the instabilities discussed above. Athermalization of systems to minimize thermal distortions is described elsewhere in this volume.

Mirror Materials. The room temperature properties of metal mirror materials are compared with those of

other common mirror and structural materials in Table 5.34. The properties were obtained from many sources and are believed to be the most accurate at the time of preparation. Care should be taken in using these properties as they are typical and should not be used for design purposes. Properties vary with temperature, as shown in Figs. 5.83 and 5.84 [5.400], and the table values should not be assumed for other temperatures.

Some of the properties that may be unfamiliar are:

- Yield strength: stress at which plastic strain is 0.2% or 2 parts in 10^3
- Microyield strength: stress at which plastic strain is 1 ppm or 1 microstrain
- Steady state thermal distortion coefficient: distortion per unit of power in micrometers/watt
- Transient thermal distortion coefficient: related to the time in seconds for a distortion to reach steady state, per unit volume and unit temperature

Aluminum (Al)
The most readily available of the metals for use in mirrors and structures, Al is available as wrought or cast and heat treatable or not. Properties and heat treat temperatures are given in Table 5.35.

The most versatile alloy is the wrought, heat treatable 6061, the commonly used alloy for optical systems. The similar, but purer 6081 yields higher quality diamond turned (SPDT) surfaces. For either alloy the preferred fabrication sequence, as described in a study by NASA Goddard Space Flight Center [5.401], is: rough shape (forging preferred), solution treat, quench (in polyalkylene glycol/water solution) and age, followed by further machining, re-age, thermal cycle and then complete optical fabrication. The aircraft alloys 2024 and 7075 have

much higher strength, but are harder to stabilize and undergo dimensional changes during aging [5.402]. For large components with section thickness greater than 7.0 cm, the non-heat treatable alloys of the 5000 series are recommended, e.g., 5056 [5.403]. These alloys can be repeatedly annealed and still retain yield strengths of 150 MPa or more. For applications requiring minimal strength, 1100 is the preferred alloy for SPDT since it is 99% Al with no alloying that forms hard particles.

Cast alloys are generally more difficult to stabilize. The most commonly cast Al is A356, A357 being a cleaner version with tighter specificationss. A201 has lower alloying and when carefully cast can be SPDT finished directly. Alloys 713 (Tenzaloy) and 771 (Precedent 71A) are Al/Zn alloys that machine well and can be precision cast. Tenzaloy is usually not heat treated whereas Precedent 71A is. Precedent is the most stable of these alloys but requires special considerations in casting i.e., silicon free crucibles, chlorine purging and ceramic filters. Castings can be hot isostatic pressed (HIP'ed) to close porosity and increase properties, but is only cost effective in production.

Mirrors can be fabricated with bare surfaces finished by SPDT and/or polishing, but are usually plated with either electroless nickel (EN) that can be turned and/or polished, or electroplated Al for elimination of bimetallic thermal distortions [5.404]. Systems with Al mirrors and structures are a low cost approach for fully athermalized performance.

Beryllium (Be)

Beryllium is the lightest structural metal, with high elastic modulus, thermal conductivity and infrared reflectance, and is transparent to X-rays. The primary optical applications are space optics and structures, applications requiring low moment of inertia, and X-ray windows. All Be materials are made from powder, with HIP the preferred consolidation method [5.405]. The optical grade, O-30, is HIP'ed from spherical powder produced by gas atomization [5.406], is the most homogeneous and isotropic Be material, and is recommended for bare polished mirrors. Instrument grade I-220H, as used for the 1.1 m chopping secondary mirrors of the VLT telescopes [5.407], is a fine grained, high strength Be material made from HIP'ed impact ground powder that is often used for electroless nickel coated mirrors requiring higher strength than can be obtained with O-30 or other grades, e.g., S-200FH, S-65 or I-70H. Prior to the availability of O-30, I-70H, HIP'ed from impact ground powder, was the preferred mirror material as used for SIRTF [5.408], an all Be telescope launched in 2003.

The typical fabrication method for Be components requires machining the shape from a HIP'ed billet,
Fig. 5.85 Coefficient of linear thermal expansion of I-70H HIP'ed beryllium. Low-temperature data from *Swenson* [5.412]. High-temperature data from *Touloukian* et al. [5.413]

followed by chemical etch and anneal before finish machining. There are other near-net-shape fabrication techniques that can produce open or closed back mirrors or even integral cooling channels [5.405, 406, 409–411], but as yet, none of these methods has been extensively employed. Beryllium mirrors can be polished bare or with an EN coating that can be SPDT finished and/or polished.

Although Be has high CTE of 11.4 ppm/K at room temperature, it drops rapidly to 0.1 ppm/K at 50 K as shown in Fig. 5.85 [5.412, 413]. Combined with its exceptionally high thermal conductivity, peaking at 150 K with 300 W/m K, as shown in Fig. 5.83, Be has exceptional cryogenic performance when bare polished and can be made very stable when careful fabrication methodology is strictly followed [5.414].

AlBeMet®162 is an alloy of 62% Be, 38% Al, that has been used for space structural applications [5.415] but is now also being used as a mirror substrate material [5.411]. It is typically produced from atomized powder and extruded. It can be machined and welded much like Al and in mirror form must be plated to achieve an optical surface. Modifications of this alloy have been cast, but with mixed success due to porosity and segregation of the Be and Al phases.

Handling Be materials in solid form poses no health risk but inhalation of airborne Be may cause a serious lung disorder in susceptible individuals. The Brush Wellman website [5.416] contains extensive information on Be health and safety, specifications for all Be grades and a complete guide to designing with Be.

Copper

Copper has traditionally been used for high energy applications because of its high thermal conductivity. The two principal Cu alloys in use are commercially pure oxygen free copper (OFC) and dispersion strengthened GlidCop®. While OFC has the highest thermal conductivity, it loses most of its strength when brazed. It is this loss of strength that drove the selection of GlidCop®, a high strength Cu alloy with near OFC thermal conductivity, for brazed heat exchanger components [5.417, 418]. The preferred grade is GlidCop®Al-15 LOX, dispersion strengthened with 0.3% Al_2O_3 in the form of 5–15 nm particles that retains > 70% of strength at temperatures up to 800 °C. Other grades have higher Al_2O_3 content but are more difficult to braze. Brazing is readily accomplished, but takes some care. Several brazing methods have been demonstrated [5.417, 418] both without and with a pure Cu plated layer, and with either Ti/Cu/Ni or Au/Cu braze alloys. The former method seems simpler. Mirrors made from GlidCop®are usually EN plated and polished.

Ferrous Alloys

There are many uses for ferrous alloys in optical systems, but few mirrors are fabricated from these alloys. Among these are 17-4 PH precipitation hardening stainless and AISI 1010 mild steel [5.417]. The processing of 17-4 PH is simple when material is obtained in the solution treated and cold finished form. After machining to shape, a precipitation treatment of one hour at 480 °C with air cool to condition H900 provides a dimensionally stable substrate that can then be ground, thermal cycled, lapped and polished bare to very low roughness levels. Mild steel in the fully annealed condition has good strength and reasonably good thermal conductivity, but requires an EN coating for polishability.

Invar 36 and super invar have the lowest thermal expansion and therefore best thermal distortion performance of any metal in the temperature range of 0–80 °C. To achieve this low CTE and dimensional stability at the same time, the material must have < 0.02% carbon, low silicon and manganese and be given the three-step heat treatment developed by *Lement* et al. [5.419]. The recommended treatment is:

1. heat to 830 °C for 30 min and quench in polyalkylene glycol/water solution,
2. heat to 315 °C for 1 h and air cool,
3. heat to 95 °C for at least 48 h and air cool.

The fabrication/heat treat schedule then follows [5.417]. Shaping is be done before step 1) and finish machining after step 2), after which step 2) is repeated. Thermal cycling, not exceeding $300\,°C$, should also be performed in the final stages of fabrication. Step 3) should only be carried out after all fabrication steps are complete, and then that temperature, $95\,°C$, should never be exceeded.

Super invar has a somewhat lower expansion coefficient by virtue of a substitution of about 5% cobalt for some of the normal 36% Ni. It is fabricated and heat treated the same as regular invar 36, but undergoes a phase change at low temperatures that results in a sudden expansion and substantial increase in CTE. The phase change temperature is normally $\leq 80\,°C$, but if the material is to be used below about $-40\,°C$, it should be dilatometrically tested.

Other Metals

There are many other metals that have been utilized in optical systems, chief among them being molybdenum (Mo). Many water cooled and uncooled Mo mirrors have been fabricated for use in high power laser optical systems. The preferred grade is low carbon vacuum arc cast, where fine grain material can be brazed and polished bare. Other grades (Mo 0.5% Ti and TZM) containing titanium (Ti) and/or zirconium (Zr) have fine particulates that make brazing more difficult and a fine polish impossible. Sputtered Mo coatings on Mo mirrors have produced the best finishes. For further information on Mo and its fabrication see the many papers in the proceedings of the Laser-Damage Conferences [5.420–424].

Titanium has also been used for some mirrors, primarily in high stress, low mass applications. In the 6Al4V alloy it has a very high strength-to-weight ratio. Very little has been published, but it is known to be difficult to polish well and also difficult to plate with Ni. Various schemes to improve plating adhesion include grit blasting the substrate, putting on a thin Ni or other electroplated metal strike followed by a diffusion anneal, and other proprietary methods used by various plating companies.

Polishable Coatings

Electroless nickel (EN) is the primary coating used to make metal mirror surfaces more polishable (including SPDT). It has been used on a variety of substrate materials including Al, Be, Cu, invar, steels, Ti and others. It is an alloy of Ni and phosphorous (P) and its properties depend on a number of factors including % P and post-plate bake time and temperature [5.425]. It deposits

Table 5.36 Major types of silicon carbide

SiC type	Structure/composition [a]	Density	Fabrication process	Remarks
Hot pressed	$\geq 98\%\ \alpha +$ others [b]	$> 98\%$	Powder pressed in heated dies	Simple shapes only
Hot isostatic pressed	$> 98\%$ SiC + others	$> 99\%$	HIP encapsulated preform	Complex shapes can be formed; high equipment cost for large sizes

as an amorphous coating at P contents of 6–15%, but with baking at moderate temperatures of 150–190 °C, the lower concentration alloys devitrify. Alloys above 10.5% P remain amorphous to greater than 300 °C and with a 2 h, 190 °C bake, they are ideal for SPDT. Lower concentration coatings are harder and are better for polishing. The CTE of EN varies inversely with % P from approximately 18 ppm/K at 6% P to 9 ppm/K at 13% P, all after baking.

All EN coatings have residual stresses [5.426] that come from three sources: intrinsic from deposition process, bimetallic from cooling from plating temperature (≈ 90 °C) with CTE mismatch to substrate, and from shrinkage during post plate baking. The stresses can be measured [5.427] and controlled. For optical applications, great care must be taken to control the process parameters tightly to prevent variation in % P as plating progresses and to provide a cover on the bath to prevent contamination. Further details on processing are given by *Howells* and *Paquin* [5.417].

A more recent finishing method for virtual elimination of residual stress and bimetallic stress is electrolytic Al plating, a 99.9% pure Al coating called Alumiplate^{TM} [5.428] that can be diamond turned. It was used on cryogenic Al mirrors for the Gemini Near Infrared Spectrometer with great success [5.429]. It has also been applied to Be mirrors.

Silicon Carbide

There are many types of silicon carbide (SiC) as can be seen from those shown in Table 5.34. The differences are substantial, both in the properties and in the fabrication methods as shown in Table 5.36.

Silicon carbide exists in two forms: alpha (α), the more common form with hexagonal crystal structure and anisotropic CTE and elastic properties, and beta (β), the face centered cubic form, isotropic in CTE but anisotropic in elastic properties. The α form is stable at all temperatures while β converts to α above about 1600 °C. Most properties of the two forms are within a few percent of each other. The fabrication methods described in Table 5.36 for the many SiC types yield combinations of α, β, Si and C that provide substantial differences in the usefulness and/or applicability for optical components.

Hot pressed SiC has been used for substrates in heat exchanger mirrors but while it is not normally used for optics, some applications have been reported [5.430]. HIP methods can provide small complex components, but have not been used because the extremely high temperatures and pressures needed require a large capital investment for an autoclave of practical size. Chem-

ically vapor deposited (CVD) SiC [5.431] is extremely pure β, so it can be polished to very low roughness levels [5.432, 433], but can only be deposited as thin shells or plates. Many small mirrors have been fabricated, but attempts to produce large mirrors with lightweight back structure have been only partially successful. CVD SiC is used extensively to coat multiphase SiC types and has many other uses.

Sintered SiC has been used to fabricate a number of different optical forms and systems [5.434] including the 3.5 m diameter Herschel primary mirror of twelve brazed segments and the RocSat2 all SiC telescope with 600 mm primary. Fabrication consists of cold isostatic pressing a billet of α SiC with sintering aids, machining the part to near finish quality allowing for shrinkage ($\approx 15\%$, but known precisely) vacuum sintering and final grinding of critical surfaces. The finished surface contains approximately 2% voids of 2 µm average size and is typically coated with CVD SiC for final optical surface finishing.

Reaction bonded SiC, also known as reaction sintered or silconized SiC, is a two phase material consisting of interpenetrating networks of Si and α-SiC. Properties depend on the amount of Si that can be 10 to 50%. The process is flexible as practiced by numerous companies. The simplest form, siliconized SiC [5.435], uses a cast preform that is prefired, machined and final fired in the presence of Si to infiltrate to near full density. Higher SiC content provides improved properties, but requires more steps in the process. Carbonaceous material can be added at several points in the process, but these can lead to inhomogeneity. Preforms can be fabricated from reusable tooling to reduce cost of production parts. Meter-class mirrors have been fabricated [5.436]. Finishing can be performed on the bare two phase surface, but is usually performed on an amorphous PVD Si or CVD SiC surface [5.435, 437].

The multiphase short carbon fiber reinforced ceramic Cesic$^{\circledR}$ [5.438] is an innovative approach to relatively rapid, low cost SiC optics and structures. Short fiber carbon felt is processed to graphitize it to a lightweight porous body that is readily machined. It is then infiltrated with Si that reacts with the carbon matrix and surfaces of the carbon fibers to form SiC. There is no noticeable shrinkage in the conversion process. Surfaces are not suitable for polishing, and components are slurry clad with material of the same composition but with a much finer microstructure allowing polishing to surface roughness of 2 nm rms. Mechanical properties, as shown in Table 5.34, are somewhat lower than other SiC types.

The SuperSiC® materials [5.439] are perhaps the simplest and quickest to get from raw material to finished optical component. A proprietary graphite body is machined to near finish dimensions and then converted to pure β SiC that has about 18% porosity. The porosity can be filled with Si. In either case, a coating of CVD SiC is applied to all surfaces. A complete list of properties is not yet available for this material.

5.10 Selected Data

6. Thin Film Optical Coatings

Within the scientific conception of the modern world, thin film optical coatings can be interpreted as one-dimensional photonic crystals. In general, they are composed of a sequence of single layers which consist of different transparent dielectrics with a thickness in the nanometer scale according to the operation wavelength range. The major function of these photonic structures is to adapt the properties of an optical surface to the needs of specific applications. By application of optical thin film coatings with optimized designs, the spectral characteristics of a surface can be modified to practically any required transfer function for a certain wavelength range. For example, the Fresnel reflection of a lens or a laser window can be suppressed for a broad wavelength range by depositing an antireflective coating containing only a few single layers. On the basis of a layer stack with alternating high- and low-refracting materials, high reflectance values up to 99.999% can be achieved for a certain laser wavelength. In addition to these basic functions, optical coatings can realize a broad variety of spectral filter characteristics according to even extremely sophisticated demands in modern precision optics and laser technology. Moreover, recent developments in optical thin film technology provide the means to combine selected optical properties with other features concerning, for instance, the thermal, mechanical or chemical stability of a surface. The latest progress in ophthalmic coatings even includes the integration of self-cleaning, photoactive or anti-fogging functions in antireflective coatings on glass.

As a consequence of this enormous flexibility in adjusting the properties of functional surfaces, optical coatings can be found in nearly every product and development of modern optic today.

In order to keep pace with the rapid development of optical technology, innovations in the design, deposition processes and handling of optical coatings are some of the crucial factors. Also, high demands in respect to precision and reproducibility are imposed on the control of layer thickness during the production of the coating systems. For certain applications in fs lasers or optical measurement systems the individual layer thickness has to be controlled within the sub-nanometer scale, which can be only achieved on the basis of advanced in situ monitoring techniques of the growing layers. These skills have to be complemented by extended knowledge of characterization, because optimization and marketing of optical coatings can only be performed on the basis of reliable and standardized characterization techniques. The present chapter addresses these major aspects of optical coatings and concentrates on the essential topics of optical coatings in their theoretical modeling, production processes, and quality control.

Part A | 6

6.1 Theory of Optical Coatings

Photonic structures were present in nature long before mankind. During their evolution, butterflies and other insects developed a variety of nanostructures on their wings and bodies for camouflage, deterrence or attraction [6.1]. The beginning of technical engineering of optical surfaces can be dated back to the Greek culture, when metal surfaces were polished to mirror quality. Tracing the history of optical coatings through the medieval times, the production of Venetian mirrors by covering glass with an amalgam during the 16th century can be considered as the first application of optical thin films. The first observation of an antireflective effect for transparent thin films may be assigned to *Fraunhofer* [6.2] who performed studies in aged glass surfaces and observed a reduction of reflectivity by the tarnish layer in the year 1817. In the same century, *Dennis Taylor* [6.3] investigated adapted etching techniques to achieve antireflective effects on different glass materials used in optical devices during these times, and *Augustin Jean Fresnel* (*1788; †1827) published his well-known equations describing the optical function of a single boundary. As a milestone in optical thin film technology, the conception of the Fabry–Perot theory [6.4] in 1899 opened the way towards the theoretical description of multilayer structures. This basic theory describes the interference of partial waves reflected from two parallel optical surfaces, which can be considered as the fundamental element of all coating systems (Fig. 6.1): layers of different dielectric materials are deposited in a defined sequence on the surface of the optical component. At least two layer materials with different refractive indices have to be selected to adjust the spectral transfer
function of the layer stack to the specification defined by the application. Besides transparency in the operation wavelength range, major aspects for the choice of the coating materials include the contrast in the indices of refraction as well as their chemical and mechanical stability. The sequence of the materials and their corresponding thicknesses is often referred to as the design of the optical coating system and comprises all information for modeling of the spectral characteristics.

For the theoretical description of optical thin films, the application of the Fabry–Perot theory to a single layer (Fig. 6.2) can be considered as the starting point. In this approach a single layer of thickness d_1 and refractive index n_1 is formed by two boundaries between two semi-infinite media with indices of refraction n_0 and n_2, respectively. In the classical model, the light interacting with this structure is described by the function of a plane wave (point x, time t) with amplitude E_0 and wave number $k = 2\pi/\lambda$ incorporating the wavelength λ and frequency ω:

$$E(x, t) = E_0 \exp[-\mathrm{i}(kx - \omega t)] . \tag{6.1}$$

To calculate the spectral transfer function, this plane wave is followed on its way through the single layer, and the contributions of the individual partial waves are calculated and accumulated to form the total transmitted and reflected wave. At the first interface, a part of the incident plane wave is directly reflected with an amplitude of $A_0 = E_0 r_1$ (order zero), where the reflection coefficient r_1 can be calculated by the Fresnel formulae. The reminder of the wave is transmitted through the first

Fig. 6.1 Basic structure of a thin film system: transparent layers of at least two different materials (n_H, n_L) are deposited on a substrate with refractive index n_T
Fig. 6.2 Schematic path of a plane wave incident onto a single layer with refractive index n_1. The reflection and transmission coefficients for the amplitudes at the interfaces $m = 1, 2$ are denoted by t_m and r_m, respectively. A prime added to the coefficients indicates a transfer of the wave opposite to the direction of incidence

boundary (coefficient t_1), partially reflected back by the second boundary (coefficient r_1) and then reaches via the first boundary the incident medium with an amplitude $A_1 = E_0 t_1 r_2 t_1'$. On its double path through the layer the considered partial wave also undergoes a phase shift δ_1 which is dependent on the thickness d_1 and the refractive index n_1 of the layer:

$$\delta_1 = \frac{2\pi n_1 d_1 \cos\theta_1}{\lambda} \ . \tag{6.2}$$

In (6.2), the case of an arbitrary angle of incidence θ_1 in the layer is taken into account, which has to be calculated by Snellius' law. On the basis of the preceding considerations, the amplitude A_1 of the first partial wave emerging from the layer can be written as:

$$A_1 = t_1 t_1' r_2 E_0 \exp(-\mathrm{i}2\delta_1) \ . \tag{6.3}$$

In this notation t_1' indicates the transmission coefficient for waves passing the first boundary in the direction opposite to the incident wave. If this notation is applied in the same sense to the part of the wave reflected back into the layer by the first boundary (coefficient r_1'), the amplitude A_2 of this partial wave after back-reflection by the second boundary and passing the first boundary is given by:

$$A_2 = t_1 t_1' r_2 E_0 \exp(-\mathrm{i}2\delta_1) r_1' r_2 \exp(-\mathrm{i}2\delta_1) \ . \tag{6.4}$$

In addition to the expression for the first-order amplitude, the second-order partial wave includes a factor $r_2 r_1' exp(-\mathrm{i}2\delta_1)$. Obviously, this additional factor appears for every further order of reflection, and therefore, the amplitudes A_k of a partial wave of the order k can be determined:

$$A_k = t_1 t_1' r_2 E_0 \exp(-\mathrm{i}2\delta_1)[r_1' r_2 \exp(-\mathrm{i}2\delta_1)]^{k-1} \ . \tag{6.5}$$

To calculate the reflectance of the layer, all partial waves emerging from the layer into the incident medium have to be added to determine the total amplitude A_{tot} of the reflected contributions. This sum can be expressed in closed form, because the partial waves follow the rule of a geometric expansion:

$$A_{\mathrm{tot}} = \left(r_1 + \frac{t_1 t_1' r_2 \exp(-\mathrm{i}2\delta)}{1 - r_1' r_2 \exp(-\mathrm{i}2\delta)}\right) E_0 \ . \tag{6.6}$$

Finally, the reflection coefficient r_S of the single layer is determined by the ratio between the total amplitude of the reflected wave and the amplitude of the incoming wave

$$r_s = \frac{A_{\mathrm{tot}}}{A_0} = \frac{r_1 + r_2 \exp(-\mathrm{i}2\delta)}{1 + r_1 r_2 \exp(-\mathrm{i}2\delta)} \ . \tag{6.7}$$

In this expression, the coefficients r_1' and t_1' have been replaced by using the following relations, which can be derived from the conditions of continuity valid for the amplitude at the boundaries:

$$t_1 t_1' = (1 - r_1')(1 - r_1) = (1 - r_1)(1 + r_1) = 1 - r_1^2 \ . \tag{6.8}$$

In view of the fact that only field intensities but not amplitudes can be measured, it is worthwhile to convert the expression for the amplitude reflection coefficient into the corresponding reflectivity value:

$$R_s = \frac{r_1^2 + 2r_1 r_2 \cos(2\delta_1) + r_2^2}{1 + 2r_1 r_2 \cos(2\delta_1) + r_1^2 r_2^2} \ . \tag{6.9}$$

In principle, (6.9) provides all the means for the description of the spectral transfer function for a single layer also including the cases of an arbitrary angle of incidence and an absorbing layer material. For this general case, the refractive index has to be expressed in its complex form with $n_1 = n_1 + \mathrm{i}k_1$, where k_1 denotes the extinction coefficient of the layer material, and the Fresnel formulae as well as Snellius' law have to be applied in their complex form.

In order to get a deeper insight into the fundamental operating principle of coatings the discussion of a few special configurations is of particular interest. In optical thin film technology the layer thickness D_i is often expressed in units of quarter-wave optical thickness (QWOT) at the design wavelength λ_Z:

$$D_i = \frac{4n_i d_i}{\lambda_Z} \ . \tag{6.10}$$

If the layer thickness is an integer multiple of 1 QWOT, the phase shift of a wave with the design wavelength traveling perpendicularly through the layer corresponds to multiples of $\pi/2$. Evaluating (6.9) for a 2 QWOT of any dielectric material on the basis of the Fresnel formulae for normal incidence results in:

$$R_s = \left(\frac{r_1 + r_2}{1 + r_1 r_2}\right)^2 \ ,$$

with

$$r_1 = \frac{n_0 - n_1}{n_0 + n_1} \ , \quad r_2 = \frac{n_1 - n_2}{n_1 + n_2} \ ,$$

$$R_s = \left(\frac{n_0 - n_2}{n_0 + n_2}\right)^2 \ . \tag{6.11}$$

Apparently, the expression for the reflectance is reduced to the Fresnel formulae for an interface between the incident medium and the carrier medium, demonstrating that

the single 2 QWOT layer has no influence on the spectral transmittance of the structure. For the case of a layer with a thickness of 1 QWOT at the design wavelength, (6.9) can be written in the form:

$$R_s = \left[\frac{n_2 n_0 - n_1^2}{n_2 n_0 + n_1^2} \right]^2 .$$

(6.12)

The reflectance of the single layer on the substrate can be totally suppressed if the condition $n_1^2 = n_0 n_2$ is fulfilled. For a further illustration of the effects typical for a single dielectric layer, corresponding reflectance spectra are depicted for different refractive indices in Fig. 6.3. Considering the reflectance values at the design wavelength λ_Z the cases $n_1^2 = n_2$ (zero reflectance), $n_1 < n_2$ (reflectance lower than the reflectance of the uncoated substrate), $n_1 = n_2$ (reflectance equal to the reflectance of the uncoated substrate), and $n_1 > n_2$ (reflectance higher than the reflectance of the uncoated substrate) can be distinguished. As a function of the wavelength, a cyclic behavior of the spectra with a period of one octave can be observed, which shows common points of tangency at the reflectance level of the bare substrate. These points can be attributed to the wavelength positions, where the layer thickness is according to an even multiple of QWOT resulting in the special condition described by (6.9). Thus, on one hand, a single 1 QWOT layer of a material matched to the refractive index of the substrate can be employed as an antireflective coating. On the other hand, a layer with a high index of refraction is suitable for an enhancement of the reflectance to a certain limit given by the availability of high-refracting materials. Actually, single-layer coatings can still be found nowadays on many optical components for laser applications, where only one wavelength has to be controlled.

In principle, the outlined theoretical approach for the single layer can also be transferred to the calculation of multilayer systems. However, considering the enormous number of partial waves, which increases exponentially with the number of layers in a stack, the resulting equations become extremely complicated and difficult to handle. For example, the expression for the reflectance of a three-layer system would already fill one printed page of this book. Therefore, the idea of a formalism assigning a matrix to each layer of the design was a substantial step forward to an understanding of thin film design. This so-called matrix formalism, which was born in the 1940s, can be deduced on the basis of the boundary conditions of the electric and magnetic field at the interfaces between the layers in
Fig. 6.3 Spectra calculated for a 1 QWOT single layer ($\lambda_Z = 1000$ nm) of different materials on a the surface of a Nd:YAG rod ($n_2 = 1.78$, ambient refractive index $n_0 = 1$). The refractive indices are typical values for e-beam deposition of the corresponding deposition materials: MgF_2: $n_1 = 1.38$, Al_2O_3: $n_1 = 1.62$, Y_2O_3: $n_1 = 1.76$, HfO_2: $n_1 = 1.95$, TiO_2: $n_1 = 2.25$. The line corresponds to the reflectivity of the uncoated substrate material

a system [6.5–8]. Besides the clear representation of each layer by a single matrix M_i, this approach offers a second major advantage which is related to a consecutive multiplication of these single-layer matrices to calculate the transfer function of a multilayer system. Thus, considering a stack, which is formed by a number K of single layers with layer 1 located at the first interface in respect to the incoming wave, the transfer matrix M_S of the entire stack can just be determined by the following multiplication:

$$M_S = M_1 M_2 M_3 \ldots M_i M_{i+1} \ldots M_K .$$

(6.13)

The elements of the single-layer matrix M_i can be derived from the boundary conditions in the layer structure relating the electric (E_{i-1}) and magnetic (H_{i-1}) field strength at the front face to the field strength values (E_i and H_i) at the rear face of the layer:

$$\begin{pmatrix} E_{i-1} \\ H_{i-1} \end{pmatrix} = M_i \begin{pmatrix} E_i \\ H_i \end{pmatrix}$$

$$= \begin{pmatrix} \cos \delta_i & \frac{i}{n_i} \sin \delta_i \\ i n_i \sin \delta_i & \cos \delta_i \end{pmatrix} \begin{pmatrix} E_i \\ H_i \end{pmatrix} .$$

(6.14)

In this formalism, the matrix elements M_{ij} contain the refractive index n_i of the layer and the phase shift δ_i, which are exclusively parameters of the layer number i. For a calculation of the reflection coefficient r_{SK} of the entire structure comprising also the substrate (index

of refraction n_T) and the ambient medium (index of refraction n_0), again the ratios of the amplitudes have to be considered:

$$r_{SK} = \frac{n_0 M_{11} + in_0 n_T M_{12} - iM_{21} - n_T M_{22}}{n_0 M_{11} + in_0 n_T M_{12} + iM_{21} + n_T M_{22}} \quad (6.15)$$

In order to demonstrate the elegance of the matrix formalism, the reflectance of a high-reflecting dielectric mirror will be considered in the following. The standard design of such a mirror is a periodical 1 QWOT stack (see also Fig. 6.1) of two coating materials with a high n_H and a low index of refraction n_L. For an efficient description of the designs, a notation in capital letters, which indicate a 1 QWOT layer of a certain layer material, is often used in optical thin film technology. For example, a mirror stack with 11 layers in the described structure is represented by the sequence HLHLHLHLHLH (H: refractive index n_H L: refractive index n_L) or even more condensed by $(HL)^5H$. For the more general case of N layer pairs (design: $(HL)^N H$) the matrix M_{DM} of the dielectric mirror can be expressed by:

$$M_{DM} = \begin{pmatrix} 0 & i/n_H \\ in_H & 0 \end{pmatrix} \begin{pmatrix} 0 & i/n_L \\ in_L & 0 \end{pmatrix}$$
$$\times \underbrace{\begin{pmatrix} 0 & i/n_H \\ in_H & 0 \end{pmatrix} \dots \begin{pmatrix} 0 & i/n_H \\ in_H & 0 \end{pmatrix}}_{(2N+1) \text{ matrices}} \quad (6.16)$$

Obviously, the single matrices for the 1 QWOT-layer reduce to simple expressions containing solely the refractive index of the materials for this special case of normal incidence. Executing the matrix multiplication, applying (6.15) and calculating the reflectance $R_{DM} = r_{DM} r_{DM}^*$ results in:

$$R_{DM} \approx 1 - 4n_0 n_T \frac{n_L^{2N}}{n_H^{2(N+1)}} . \quad (6.17)$$

This expression is an approximation for a large number N of QWOT-layer pairs, which is typical for practical systems involving 10 to 40 layer pairs. An interpretation of this estimation (6.17) indicates that the contrast (n_L/n_H) between the indices of refraction governs the number of layer pairs necessary to achieve a defined reflectance value. A high contrast does not only reduce the number of layer pairs, but also results in a more extended reflection band in the spectrum of the QWOT stack (Fig. 6.4). In Fig. 6.5 the development of the reflectance spectrum is illustrated for the QWOT stack defined in Fig. 6.4 for different angles of incidence.

The shift of the spectra towards shorter wavelength can be explained on the basis of a reduction of the phase difference between the partial waves in the layer structure. For arbitrary angles of incidence the spectra of p- and s-polarization have to be considered separately in the matrix formalism resulting in a broader reflectance band for the s-polarization compared to the p-polarization. These effects have to be taken into account if a dielectric mirror designed for normal incidence is operated under arbitrary angles of incidence in an application.

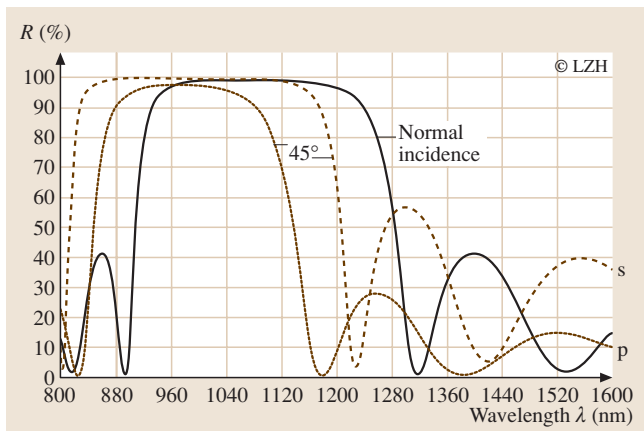
Besides the described high-reflecting stacks, antireflective coatings are often applied in laser technology to reduce reflection losses of windows, laser rods, or lenses. Compared to the mirror designs, antireflective (AR) coatings are regularly built only of a few layers, but often of more than two materials, especially to accomplish the demands of lowest residual reflectivity for a broad spectral range. For laser technology with its dominant single-wavelength applications and challenging specifications concerning the losses and the power-handling capability of the coatings, single layers or two-layer AR coatings are mainly employed. On the basis of two layers, a total suppression of the Fresnel reflection of most substrate materials can be accomplished for one wavelength. Such coatings, which are often called V-coatings according to the shape of their
Fig. 6.4 Reflectance spectra calculated for 1 QWOT stacks ($\lambda_Z = 1064$ nm) of different high-refracting materials in conjunction with SiO$_2$ ($n_L = 1.46$) as the low-index material on a quartz surface ($n_T = 1.46$, refractive index of the ambient $n_0 = 1$). The refractive indices of the high-index layers are typical values for electron-beam deposition of the corresponding deposition materials: Al$_2$O$_3$: $n_H = 1.62$ (green), CeO$_2$: $n_H = 1.80$ (blue), HfO$_2$: $n_H = 1.95$ (magenta), TiO$_2$: $n_H = 2.25$ (black). The number of layer pairs is kept constant at $N = 6$ for all depicted spectra


Fig. 6.5 Reflectance spectra calculated for 1 QWOT stack with parameters according to Fig. 6.4 and TiO_2 ($n_H = 2.25$) as the high-index material. Besides the spectrum for normal incidence, the reflectance is depicted for an angle of incidence of 45°. For arbitrary angles of incidence, s- and p-components have to be distinguished

spectra, offer the advantage of lowest total thickness providing minimum losses and highest laser-induced damage thresholds [6.9].

In regard to the important role of losses and stability of coating systems for laser technology, the designs are often also optimized with respect to the distribution of the electrical field strength in the structure. In view of the fact that the matrices associate the field strength values at different positions in the layer system, the calculation of the field strength distribution can be readily accomplished using the matrix method. Moreover, an implementation of the formalisms into modern computer algorithms, which allow for the calculation of all transfer parameters including many other important aspects in laser technology, such as absorbance, phase shift or group delay dispersion, is an uncomplicated task. In the course of the rapid development of computer technology, extensive software tools are available nowadays, which even allow for an inverse synthesis of multilayer designs. As input parameters of these modern optimization tools the desired spectral characteristics can be entered, and appropriate design solutions are developed on the basis of sophisticated algorithms. In summary, the challenges of optical thin film technology are no longer concentrated on the theoretical modeling and the calculation of designs. Present and future problems are coupled to the reproducible and precise production of coatings with high optical quality and environmental stability.

6.2 Production of Optical Coatings

Looking back, the production of optical coatings exhibits a long and successful technical history. Besides the already mentioned early aging and etching experiments of Fraunhofer and Taylor, in 1852 *Grove* described the sputtering effect, as it was later called, in a gas discharge apparatus [6.10]. In 1857, *Faraday* vaporized gold wires by high electrical currents and studied the optical properties of the deposited material, although he was mainly interested in the finest particles [6.11]. *Wright* reported in 1877 "on the production of transparent metallic films by the electrical discharge in exhausted tubes" [6.12]. In 1884, *Edison* filed an application for a patent, which described thermal evaporation within a vacuum vessel as well as arc vaporization to "plate one material with another" and was granted in 1894 (Fig. 6.6) [6.13]. In the following decades, a multitude of publications documented the development of industrial production methods for optical coatings, starting with single layers and resulting in increasingly complex multilayer systems [6.14, 15]. Within the scope of the present article, a short overview of the most common production tech-

niques for optical thin film filters from the basics to some of the latest developments will be given. Further information about optical coating technology can be found in a variety of comprehensive technical books [6.9, 16–19].

Concerning the industrial production, there are fundamental demands on the deposition process, although their priorities depend on the specific applications. High reproducibility of the optical properties of the thin films is needed, as well as of the mechanical characteristics. Large areas have to be coated homogeneously, using high deposition rates with simultaneous realization of a precise layer thickness determination and termination. Furthermore, a high level of automation, a short process time, and inexpensive, nontoxic deposition materials are economically relevant. With regard to the thin film material choice, specific requirements also have to be fulfilled [6.20]. Dielectrics for use in multilayer coatings have to be transparent in the spectral region desired by the specific application. Therefore, besides an appropriate refractive index contrast, a low extinction coefficient has to be realized. In addition, an adequate
Fig. 6.6 Illustration from Edison's patent *Art of Plating One Material with Another*, granted in 1894 [6.13]. The conductive coating material is vaporized within a vacuum chamber by a continuous arc between the electrodes (*a*). For coating mirrors, Edison placed glass plates on the inner side of the apparatus. Furthermore, the patent describes thermal evaporation by resistive heating

mechanical and environmental stability must be ensured. Finally, the materials have to be technically controllable within the chosen deposition process, and have to exhibit the potential to form amorphous, compact thin film microstructures. In the visible and near-infrared spectral region, these requirements are covered best by the material class of oxides. Common examples are the low-refractive-index materials SiO_2 or Al_2O_3 and the high-refractive-index metal oxides Ta_2O_5, Nb_2O_5, or TiO_2. Going down to the ultraviolet and vacuum ultraviolet wavelength ranges, the oxides are complemented and successively replaced by fluorides, e.g., AlF_3, MgF_2, and LaF_3. In contrast, the mid- and far-infrared spectral region is the domain of materials such as Ge, Si, ZnSe, ZnS, and the radioactive ThF_4, which is still in use, mainly for high power CO_2 laser optics.

6.2.1 Thermal Evaporation

Within the most common deposition processes for optics, thin films are produced under vacuum conditions. In general, these processes are divided into two clas-

sification groups: on the one hand, the physical vapor deposition (PVD), comprising thermal vaporization as well as sputtering, and, on the other hand, chemical vapor deposition (CVD).

One of the basic ways to realize PVD is thermal evaporation of the thin film material by direct or indirect heating of the deposition material within a vacuum chamber. The evaporated material condenses on the substrates to be coated, which are usually located on a rotating spherical calotte above the evaporator. If the uniformity of the layer thickness distribution across the calotte does not fulfil the requirements on the basis of the given geometrical set up, additional masks are used. Under vacuum conditions, the evaporation rate exhibits a strong dependency on the temperature, and is mainly determined by the temperature-dependent equilibrium vapor pressure p^* of the evaporant. On the basis of the experimental work of *Hertz* [6.21] and *Knudsen* [6.22], a theoretical description of the evaporation rate became known as the Hertz–Knudsen equation:

$$\frac{dN_e}{A_e\, dt} = \alpha_e \frac{p^* - p}{\sqrt{2\pi m k_B T}} \, , \qquad (6.18)$$

with

dN_e/dt number of evaporating atoms per time unit,
A_e surface area of the evaporation source,
α_e evaporation coefficient (sticking coefficient for vapor atoms onto the surface),
p^* equilibrium vapor pressure of the evaporant,
p hydrostatic pressure of the evaporant within the vacuum chamber,
m atomic mass,
k_B Boltzmann's constant,
T temperature.

The strong temperature dependency of the evaporation rate results from the equilibrium vapor pressure as an exponential function of the temperature

$$p^* = p_0 e^{-\frac{L_0}{k_B T}} \, , \qquad (6.19)$$

where p_0 is a constant factor and L_0 is the latent heat of evaporation per atom or molecule.

With the focus on technical aspects, a variety of evaporation sources has been developed. In practice, unwanted contamination effects of the films with contact material from the evaporation source, as well as its significant corrosion, can occur due to chemical reactions at the required high temperatures. Furthermore, high evaporation temperatures between some hundred to several thousand Kelvin have to be reached within the evaporation source.

An elementary, but not often used, method is the sublimation of a conducting material by direct current heating. This technique is not applicable to many materials; potential examples are C, Cr, Fe, Ni, Rh, and Ti. An early developed and widely applied way to realize thermal evaporation is indirect heating of the coating material by a resistively heated reservoir. The characteristic shape of the reservoir gave this process variant its name: boat evaporation. Evaporation boats are made of conducting high-temperature resistant materials, e.g. W, Mo, Ta, or C, in addition partially equipped with a ceramic insert (liner). Obviously, the maximum evaporation temperature is limited by the melting point of the boat material. In a slightly modified alternative, the boat is reduced to a filament, wetted by molten material, which is kept in place by surface tension. However, due to the thermal inertia of the boat and the molten coating material, a nearly real-time rate control is difficult to realize. Furthermore, the melting can exhibit disadvantageous spatter behavior, leading to coating defects. This effect can be partially suppressed by equipping the boats with perforated caps or chimney constructions.

Another technical possibility to melt conductive materials is the application of induction heating. While inductive heaters are frequently used for large molten masses, e.g., in the field of crystal growth, this solution is rarely used for the deposition of optical coatings.

Today, the most common thermal evaporation method in the industrial production of optical coatings is the direct heating of the coating material within a crucible by an electron beam (Fig. 6.7). The characteristic parameters of the electron beam, which is directed by magnetic fields into the water-cooled crucibles, are an acceleration voltage of $6-10\,\mathrm{kV}$ and currents of $0.1-1.5\,\mathrm{A}$. In order to achieve uniform evaporation, the electron beam can be swept across the coating material by deflection coils, optionally combined with a rotating crucible. In addition, multi-crucible electron-beam sources allow the sequential evaporation of different coating materials within one process; otherwise the deposition plants are equipped with two or more sources. Compared to boat evaporation, the electron-beam heating technique offers important advantages. Due to its high power densities, high-melting-point materials can be evaporated and, furthermore, the cooled crucible prevents contamination. With regard to rate control, electron-beam sources benefit from a low inertia in combination with the high reliability of today's technical solutions. However, it must be pointed out that high local temperatures may lead to decomposition, if chemical compounds are used as coating materials. In the case
Fig. 6.7 Electron-beam evaporation source. The electrons are accelerated by a potential difference of several kV and are directed by a magnetic field into the water-cooled crucible. Additional deflection coils allow for the beam to write adapted patterns on the material to achieve uniform evaporation

of oxides, an additional oxygen inlet can overcome this problem. In common deposition systems, stoichiometric films can be attained applying a typical oxygen partial pressure range of 1 to $3\times10^{-2}\,\mathrm{Pa}$. Thermal evaporation in the presence of reactive gases such as oxygen, nitrogen, or even fluorine is sometimes referred to as reactive evaporation.

Regarding the layer properties, thin films produced by thermal evaporation exhibit characteristic microstructures depending on the individual process parameters. The typical thermal energies below $0.3\,\mathrm{eV}$ of the condensing particles result in packing densities lower than the density values of the corresponding bulk materials. As a consequence of limited surface mobility of the condensing particles and shadowing effects, a columnar growth containing microstructural voids is most common for evaporated films [6.23, 24]. Derived from experimental studies, approved structure zone models have been developed that describe characteristic zones depending on the ratio between the substrate temperature and the melting point of the coating material [6.25]. Usually, the process parameters are optimized to achieve maximized packing densities to minimize voids, which results in the need for an additional substrate heating, typically in the range of $300\,^\circ\mathrm{C}$. Besides increasing mechanical stability, an enhanced packing density affects the optical layer properties, e.g., leading to higher refractive indices in most cases. A major disadvantage of the

presence of microstructural voids in the thin films is the ingress of moisture from the environmental atmosphere. On the one hand, the adsorbed water and bonded OH groups result in optical absorption losses, especially in the near- and mid-infrared (MIR) wavelength range. On the other hand, water adsorption influences the effective refractive index of the layer. As a result of the varying water content, the spectral characteristic of a porous multilayer interference filter shows a strong dependency on environmental parameters such as temperature and humidity.

Furthermore, the microstructure of the growing layer is affected by the surface structure of the substrate in all deposition processes for optical filters. As a higher surface roughness of the substrate increases the roughness of the layer surface, the substrate should be chosen in view of the application to avoid unacceptably high optical scattering losses. In addition, cleanroom areas are indicated in optical thin film production, due to the fact that particle contamination results in serious layer defects.

6.2.2 Ion Plating and Ion−Assisted Deposition

As discussed above, thin films produced by thermal evaporation processes exhibit a distinct microstructure as a consequence of the low kinetic energies of the condensing molecules and atoms. Besides the thermal energy deposited into the growing layer by substrate heating, additional energy deposit by ion impact was quickly identified as a promising alternative. In the beginning, reactive evaporation processes were optimized by the application of ionized oxygen [6.26, 27]. In 1967 a process concept was patented, in which a negative bias voltage accelerated positive ions onto the substrates [6.28]. Applied ion species included inert gas directly provided to maintain a discharge, as well as ionized evaporated coating material. In the course of further technological progress, this method was enhanced and became known as the ion plating process, which found its way into the optical thin film industry in different variations. An established concept is the reactive low-voltage ion plating (RLVIP) system, shown schematically in Fig. 6.8 [6.29]. In addition to the conventional thermal evaporation configuration, an argon discharge is directed from a hot cathode source mounted on a chamber wall into the crucible of the electron-beam evaporator, which acts as anode. As a consequence of the interaction with the argon plasma, the evaporated coating material is ionized and accelerated

together with argon ions towards the substrates by the self-bias voltage of the electrically insulated substrate holder. This negative self-bias voltage usually ranges between -5 to -30 V with respect to the plasma potential and depends on the plasma parameters as well as the geometrical conditions. As a consequence of the additional energy input and the effective activation, thin films produced by reactive low-voltage ion plating, exhibit a compaction of the microstructure and optimized stoichiometry, respectively.

Employing ions to enhance the optical and mechanical thin film properties as well as the process stability, ion-assisted deposition (IAD), also referred to as ion-beam-assisted deposition (IBAD), represents a widely used process concept. As depicted in Fig. 6.9, the IAD process is characterized by a separate ion source, integrated in addition to the evaporation sources into the process chamber. The ion beam is superimposed upon the flux of condensing particles and leads to the desired densification of the growing layer. The dominant densification mechanism is attributed to momentum transfer, which was verified by calculations on the basis of collision cascade models in accordance with experimental results [6.30]. However, excessive ion energies
Fig. 6.8 Schematic diagram of a reactive low-voltage ion plating (RLVIP) system. An argon discharge is directed from a plasma source into the crucible of an electron-beam evaporator. The ionized coating material and a part of the argon ions are accelerated towards the substrates by the self-bias voltage of the electrically insulated substrate holder

may lead to ion-induced stoichiometry defects by the preferential sputtering effect, which results from different sputtering efficiencies of the single components of a compound [6.31]. In the case of the widely used metal oxides, the preferential sputtering of oxygen atoms results in an oxygen deficiency and consequently, in an increase of the optical absorption losses [6.32]. In practice, ion energies covering the range of several $10\,\mathrm{eV}$ to several $100\,\mathrm{eV}$ are applied within typical IAD processes. The usual ion-source operating media are inert or reactive gases, in the latter case, in particular, oxygen to assist oxide coatings. Consequently, besides the densification effect, the stoichiometry of oxides benefits from the reactive ions, resulting in homogeneous layers with reduced optical losses.

Concerning the IAD process environment, some central demands on the ion source can be stated. High ion currents at low ion energies are needed, and the ion current distribution across the calotte has to be extensive and homogeneous. The ion source must exhibit a high stability and reliability, even at long process times. An independent control of ion current and energy within a wide parameter field is also advantageous. Furthermore, contamination of the growing layers by material originating from the ion source has to be avoided. And finally, options for reactive gases that can be used, low levels of maintenance, and low operating costs are relevant. Nowadays, a variety of gridded and grid less ion sources, fulfilling nearly all these requirements for standard IAD applications, are commercially available [6.33, 34].

In the following, the positive effects of ion-induced layer densification are illustrated briefly. With regard to the microstructure, the aforementioned structure zone models for thermally evaporated films have been extended to integrate the dense structures resulting from ion-assisted deposition processes [6.35]. As the microstructural densification by the ions counteracts the void development of the columnar growth, the high optical losses attributed to adsorbed water can be prevented by applying IAD concepts. In Fig. 6.10, the optical losses of a SiO_2 single layer deposited with a thermal evaporation process are compared to those of a SiO_2 single layer produced within an ion-assisted deposition process. The plotted extinction coefficients are calculated from spectrophotometric transmittance and reflectance measurements and indicate optical losses in the range between 10% and 20% for the thermally deposited layer. Using spectrophotometric measurements, no water could be detected in the IAD coating. Besides the reduction of absorption losses, another positive effect of the dense and water-free microstructure is the drastic increase in thermal spectral stability of the coatings. Ion-assisted deposition can reduce the relative wavelength shift $\Delta\lambda/(\lambda°C)$ of the spectral characteristic from several hundred ppm/°C for a thermally deposited coating to a few ppm/°C [6.36].

Furthermore, ion-assisted deposition offers the possibility to tune the mechanical intrinsic stress of a coating from tensile to compressive stress, which can improve the layer adherence and the dimensional accuracy of critical optical components [6.37–39]. And finally, the implemented ion source enables options for substrate precleaning process steps.

6.2.3 Sputtering

Sputtering represents an established and versatile class of energetic vacuum deposition processes, applying condensing particles with significantly higher energies than those resulting from thermal evaporation methods. Its basic principle, derived from the early gas discharge experiments in the 19th century, is depicted in Fig. 6.11. Within a vacuum chamber at a pressure of about $1\,\mathrm{Pa}$, a glow discharge is maintained by a direct-current (DC) voltage in the kV range between the anode, carrying the substrates to be coated, and the cathode. The cath-
Fig. 6.9 Principle arrangement of an ion-assisted deposition (IAD) process. Besides the electron-beam evaporators, an ion source is implemented in the vacuum chamber. The substrates are exposed to the low-energy ion beam, which results in an additional energy transfer into the growing layer
Fig. 6.10 Comparison of the optical losses of SiO$_2$ single layers: thermal evaporation versus ion-assisted deposition (absorption band of adsorbed water). The optical losses are calculated from measured spectrophotometric transmittance and reflectance data

Fig. 6.11 Schematic diagram of a direct-current sputtering process. A glow discharge is driven by a DC voltage in the kV range. Coating material is sputtered from the target on the cathode and is deposited on the substrates positioned at the anode

ode consists of the coating material which has to be electrically conductive (*target*). In the discharge area, positive working gas ions, e.g., argon ions, are generated by impact ionization and accelerated towards the target. Ions impinging on a solid surface, besides other interactions, eject atoms, molecules, and clusters by collision cascades. This effect is called sputtering; its efficiency depends on the target material and microstructure as well as on the species, the energy, and the angle of incidence of the ions. Within the depicted DC discharge process, the particles sputtered from the target condense on the substrates and form a layer. As a consequence of the high kinetic energies of the adatoms in a typical range of several eV (maximum energy of several tens of eV), sputtered coatings exhibit a higher density in comparison to evaporated thin films.

A way to overcome the DC sputtering limitation to conductive targets was found in the technology of radio-frequency (RF) sputtering. In a common set up, the DC electrodes shown in Fig. 6.11 are converted to RF coupling electrodes. Choosing a geometrical arrangement in which the surface area of the substrate electrode exceeds the area of the target electrode, a DC potential with a negative target electrode results from the self-bias effect. Due to this DC potential, the sputtering occurs on the target, and not on the substrate electrode [6.40].

Today, magnetron sputtering is an important sputtering technology for the industrial production of optical coatings. The term magnetron is derived from a magnetic field, crossing the electric field of a DC discharge,

and confining the plasma within the region in front of the target (Fig. 6.12). Resulting from the increased degree of ionization, a significantly higher deposition rate provides a reduction in process time. Furthermore, the layer quality benefits from the less intensive interaction with the plasma as well as from the reduced pressure, in the range of 10^{-1} Pa. However, the application of the DC magnetron source within a reactive process environment is linked to some limiting complications. The reactive gas interacts with the target material and the generated compounds form an insulating layer on the target surface, an effect called *target poisoning*. Due to the differences in sputtering efficiency of metals and, for example, oxides or nitrides, the deposition rate decreases strongly while the target is poisoned. Also a modification of the discharge conditions is attributed to the formation of an insulating layer, which can lead to arcs or even a termination of the discharge. Besides the poisoning of the target cathode, the whole chamber, acting as an anode, is covered successively by the insulating compound – the so-called disappearing anode. To overcome these limitations, the magnetron process can be driven in a transition mode between the metallic and the non-metallic mode. However, as this transition mode exhibits considerable instability, a complex active process control has to be implemented to stabilize the relevant parameters, e.g., on the basis of lambda probes for reactive oxygen [6.41].

A second technological approach is the sequential processing concept, in which the magnetron sources work in the metallic mode. Separated from the magnetrons, plasma sources provide a subsequent treatment of deposited sublayers, consisting of a few monolayers,

Part A | 6.2
Fig. 6.12 Basic principle of the magnetron sputtering process. A magnetic field, crossing the electric field of a DC discharge, confines the plasma within a region in front of the target. An optional bias voltage applied to the substrate holder allows for an additional energy input into the growing layer

with activated reactive gases. In technical implementation, the magnetron and plasma sources are often located in a circular geometry with a fast rotating cylindrical substrate holder in its center [6.42, 43].

Important advances have been achieved on the basis of dual-magnetron (also called twin-magnetron) configurations, applying medium-frequency voltages in a typical range of 20–100 kHz [6.44]. In a dual-magnetron arrangement, both target electrodes working alternately as the cathode and anode, preventing electrostatic charging as well as the disappearing anode effect, mentioned above. Furthermore, improvements have been made by operating magnetrons in pulse mode, since the limiting thermal load on the target is decreased by this technique.

Nowadays, inline magnetron sputter systems are standard for the large-area deposition in the application fields of architectural glass, photovoltaic, and displays, whereas sequential processing concepts in combination with dual magnetrons are currently finding their way into precision optics.

6.2.4 Ion–Beam Sputtering

Ion-beam sputtering (IBS) represents its own class of sputtering deposition technology, applicable for the highest-quality optics. The basic principle of an ion-beam sputtering process is illustrated schematically in Fig. 6.13 [6.45]. Within a vacuum chamber, a separated ion source is directed to the target, which is consequently not in contact with the ion-generating plasma. The set

up provides a rotating substrate holder for the condensing thin films in the geometrically preferred direction of the sputtered particles. Under typical process conditions, argon ions with kinetic energies in the rage of 1 kV are employed for sputtering, while an additional reactive-gas inlet provides an option for depositing compound layers from metallic targets. In some cases, a second ion source is directed to the substrates, and allows for assistance of the growing layer (compare IAD) as well as precleaning of the substrates.

In comparison to the described DC approach, alternating-current (AC) and magnetron sputtering processes, ion-beam sputtering offers a variety of advantages. A low working pressure (reactive $\approx 10^{-2}$ Pa, nonreactive $\approx 10^{-3}$ Pa) in combination with the absence of interactions between the substrates and the plasma result in high-quality thin films with minimum contamination and defects. However, the decisive factor for the excellent optical and mechanical film quality in ion-beam sputtering is the high energy (up to 100 eV) of the layer-forming particles. IBS coatings are dense, amorphous, and suitable for ultra-low-loss components, as total optical losses in the range of 1 ppm are achievable [6.46]. Furthermore, ion-beam sputtering is an extremely stable process, which allows for a high degree of automation. Also, energy and current density of the sputtering ions can be adjusted independently within a wide range.

Nevertheless, ion-beam sputtering is less often used in the industrial mass production of optical coatings. This niche position results from distinct economic disadvantages, namely a low deposition rate and technical difficulties in coating larger areas homogeneously. Compared to thermal evaporation or magnetron sputtering processes for precision optics, typical IBS deposition rates are 10 times lower (in the range 0.5 Å/s instead of 0.5 nm/s). Major current market segments for ion beam sputtering include high-end precision optics for special applications, mainly in the research and science sector, e.g. complex chirped mirrors for femtosecond lasers as well as next-generation lithography [6.47, 48].

6.2.5 Chemical Vapor Deposition (CVD)

Similar to the PVD processes described above, chemical vapor deposition offers a range of process variants. All CVD processes share the basic principle that the deposited layer is a product of a chemical reaction of gaseous reactants (precursors) [6.49]. This reaction is activated within various process types by different kinds of energy input, covering thermal, plasma, and radiation-
Fig. 6.13 Schematic illustration of the ion-beam sputtering process. A separate ion source is directed to a target, the sputtered particles condense on the rotating substrates. Automatically changeable targets allow for the production of multilayer coatings

induced CVD. Except for the coating material, all further reaction products have to be gaseous, as they have to be exhausted from the process chamber. Chemical vapor deposition is widely applied in hard coatings for wear-protection purposes, besides being the most widely used deposition method in the semiconductor industry. In the production of optical coatings, CVD processes still play a minor role in comparison with PVD technologies.

Chemical vapor deposition distinguishes two layer-forming mechanisms. In heterogeneous nucleation, the coating material is generated on the substrate surface. In homogeneous nucleation, the chemical reaction producing the coating material takes place above the substrate surface. Subsequently, the reaction product diffuses to the surface of the substrate, where the film is formed. Since coatings produced by homogeneous CVD processes in most cases are less dense and exhibit a lower layer quality than coatings by heterogeneous CVD processes, the latter variant is standard. However, some process concepts combine both types by applying a homogeneous gas-phase reaction to produce a reactant for the final heterogeneous layer-forming reaction. In all cases, complex gas dynamics have to be controlled by adaptation of the gas inlets, and a balanced flow and pressure control.

The classic way to perform chemical vapor deposition is by thermal activation of the reactions by heating of the substrates. Most of these reactions require high temperatures, typically exceeding $450\,°\mathrm{C}$, which are incompatible with optical coatings on substrates for precision optics or on plastics. As an example, in the semiconductor industry the pyrolysis of silane is used to deposit silicon (g: gaseous, s: solid):

$$\mathrm{SiH_4(g)} \xrightarrow{\approx 600--700°C} \mathrm{Si(s)} + 2\mathrm{H_2(g)} \,. \tag{6.20}$$
Applying additional oxygen, silica coatings can be produced:

$$\mathrm{SiH_4(g)} + \mathrm{O_2(g)} \xrightarrow{\approx 450°C} \mathrm{SiO_2(s)} + 2\mathrm{H_2(g)} \,. \tag{6.21}$$
Thermally activated chemical vapor deposition processes are driven at atmospheric pressure (APCVD) or, more commonly today, in low-pressure reactors at a typical pressure range of 10^1–10^3 Pa (LPCVD). Atmospheric-pressure CVD offers higher deposition rates than LPCVD, which, in contrast, provides higher uniformity and a better covering of nonplanar geometrical shapes.

Another way of energy input is used in plasma-enhanced chemical vapor deposition (PECVD), a process variant rapidly gaining importance in many applications [6.50]. The PECVD technique offers the advantage of much lower process temperatures than those needed in thermally activated CVD. As a result of the applied DC, RF or microwave plasma excitation, the gaseous precursors can react while the substrate temperature stays below $300\,°\mathrm{C}$. In Fig. 6.14, a basic RF-driven PECVD reactor is shown.

A special pulsed PECVD concept is based on microwave impulses and is therefore called plasma impulse CVD (PICVD) [6.51]. The PICVD process offers a feasible technical solution to apply coatings on complex-shaped surfaces, in particular on the inner surfaces of tubes, reflectors, or even bottles. Process pressures in the range of a few 10^{-2} Pa result in short pumping times. On the other hand, the pumping time is minimized by the smallest reactors, as, in the case of inner surfaces coatings, the process chamber is often geometrically defined by the substrate itself. Examples of this modularly scalable PICVD concept are cold light mirrors on halogen-lamp reflectors as well as barrier coatings on the inner walls of polyethylene (PET) bottles or of ampoules for pharmaceutical packaging. As every microwave pulse deposits a sublayer of a reproducible thickness in a few milliseconds, a precise thickness control can be realized by pulse counting. Consequently,
Fig. 6.14 Basic reactor set up for RF-excited plasma-enhanced chemical vapor deposition (PECVD). The plotted substrate heater is an option to assist the layer-forming mechanism. Without the RF electrode the CVD process can be driven as a non-PECVD process by thermal activation only

the deposition rate, which can exceed 10 nm/s for metal oxides, is determined by the pulse repetition rate and the conditions of the chemical reaction. For example, SiO_2 coatings are derived from a $SiCl_4$ precursor by the overall reaction:

$$SiCl_4(g) + O_2(g) \xrightarrow[\rightarrow \text{ plasma}]{\text{microwave pulses}} SiO_2(s) + 2Cl_2(g) \,.$$

(6.22)
In the process chamber, this reaction is divided into two parts. In a first homogeneous gas-phase reaction SiO is produced ($SiCl_4 + (1/2)O_2 \rightarrow SiO + 2Cl_2$), which diffuses to the surface and is oxidized in the final heterogeneous reaction ($SiO + (1/2)O_2 \rightarrow SiO_2$).

In an alternative approach for activation, the CVD reactions can be induced by laser radiation [laser CVD (LCVD)]. This process variant is based either on a pyrolytic, i.e., thermal, interaction or direct photolytic activation [6.52]. In contrast to the other mentioned CVD techniques, LCVD is normally not applied for optical coatings. Laser CVD is primarily suitable for micro-technical applications, as structures in the range of several 10 microns can be deposited selectively, e.g., for circuit or mask repair in the field of electronics and lithography, or for the creation of three-dimensional objects such as carbon fibres [6.53, 54].

Generally, chemical vapor deposition plays a minor role compared with physical vapor deposition in optical thin film technology. However, with regard to coatings on complex surface geometries, CVD processes are superior to PVD technologies, as diffusion is an undirected

effect. Furthermore, the precursor chemistry offers the possibility to obtain intermediate refractive indices, e.g. for the production of rugate filters, by varying the mixture [6.55]. In this connection, it has to be mentioned that these chemicals are mostly toxic and often difficult to handle.

6.2.6 Other Methods

Besides the introduced common deposition techniques in the fields of precision, laser, and consumer optics, a variety of processes for special applications is available today. Analogous to the laser CVD mentioned above, a laser PVD process has been developed, which has become known as pulsed laser deposition (PLD). In PLD, target material is ablated by the laser pulses within a vacuum chamber and is subsequently deposited onto the substrates positioned in the plasma plume. The PLD process is mainly employed in laboratory-scale systems and offers superior reproduction of the target stoichiometry in the produced thin films of organic and inorganic compounds [6.56]. However, up-scaling of this technique to large coating areas and high deposition rates is problematic and still too cost-intensive.

A more common deposition method that is used in some application fields of optical coatings is the sol–gel process. Starting from a colloidal solution (sol), in most cases of silicon or metal alkoxides, a transition leads to a gel phase, which is the base material for the coating. In the case of dip-coating, the layer is formed by dipping the substrate into the solution. In the spin-coating process, the layer is produced by spreading the solution on the spinning substrate to achieve a uniform thickness distribution, which depends on material-specific parameters and the speed of rotation. Furthermore, the solution can also be applied by spraying, in a laminar-flow-coating process, using capillary forces, or by printing techniques. A densification of the initially porous sol–gel films is often done by baking at temperatures of up to 1000 °C. The domain of the sol–gel technology in optics is the production of large-area antireflection coatings, especially for high-power lasers [6.57].

6.2.7 Process Control and Layer Thickness Determination

With regard to the nanometer precision demanded in optical coating production, process control plays a key role in modern production environments. Recent trends to realize advanced process control strategies are often based on in situ monitoring techniques of important deposition

parameters and coating properties. The central requirement for the production of optical interference filters is a precise thickness control of the growing layers.

In a straightforward approach, the layers can be terminated by time, if the deposition rate of the process is stable enough to fulfil the required thickness accuracy, e.g., in some sputtering processes. An exceptional position is taken by plasma impulse CVD, where the thickness can be determined by counting microwave pulses.

A widespread technical solution to measure the actual deposition rate and the layer thickness in the production of thin films is a quartz crystal monitoring system [6.58]. Since the resonance frequency of the oscillating quartz varies with the material deposited on its surface, the rate can be determined from the change in oscillation frequency on the basis of material-specific constants (e.g., specific weights). As a consequence of a position of the quartz crystal monitor differing from the substrate holder location, another calibration factor, called the tooling factor, has to be considered for an accurate determination of the deposition rate. In particular, these factors depend not only on coating materials and the process parameters, but often also on the layer thickness as a result of the developing microstructure in the growing thin films.

As indicated above, the performance of a multilayer filter depends on optical thicknesses, which are the products of the physical thicknesses and the refractive indices of the included single layers. Thus, monitoring methods that provide in situ analysis of the optical thickness of the growing layer are often superior to systems monitoring mass deposition, especially under the conditions of small variations in the optical properties. The natural way to determine optical thickness is a direct optical access in the form of a transmittance or reflectance measurement [6.59]. The theoretical analysis of a single layer reveals a cyclic behavior of the transmittance or reflectance at a fixed wavelength with increasing optical thickness. This effect can be employed to determine the actual optical and, moreover, the actual physical thickness of the deposited layer on the basis of the known optical constants. Especially, for desired single-layer thickness values of integer multiples of QWOT at the monitoring wavelength, the termination points are extremal values of the measured curves. Since certain wavelengths are distinguished, the monitoring wavelength has to be chosen in accordance with the coating design, and often multi-wavelength monitoring systems are applied. In most cases, the measurements are performed on a centred

test substrate, which remains stationary, in contrast to the products to be coated.

In the course of the rapid development of computer and spectrometer technology, advanced optical broadband monitoring systems have been implemented in deposition process environments [6.60]. These techniques allow for direct broadband in situ transmittance measurements on the moving substrates for each rotation of the calotte. For example, a spectral range of 350–1060 nm can be covered by a fibre-coupled charge-coupled device (CCD) spectrometer system in combination with a free-beam measurement set up inside the vacuum chamber (Fig. 6.15). Each in situ spectrum recorded can be calibrated, because three single measurements are typically performed during each revolution of the calotte: a dark measurement on an opaque part of the calotte, a reference measurement through an open position in the calotte, and the measurement through the substrate to be coated. Based on these three measurements, the absolute transmittance spectrum of the substrate is calculated. Furthermore, the online monitoring software calculates the current layer
Fig. 6.15 Schematic view of the online monitoring system for optical broadband in situ transmittance measurements, realized within an IAD process environment. A halogen lamp mounted above the calotte inside of the process chamber is used as the light source, and the light is coupled into the detector fibre through a window in the chamber bottom

thickness on the basis of the known optical parameters of the coating material (dispersion values and extinction coefficients). Provided with a target multilayer design, the online system can control the deposition plant, determine the end of the layer currently being deposited, and start the next layer. Because of the large databases available, broadband monitoring systems are also useful as a supporting tool for process development and quality management in the production of modern optical coatings. In contrast to the test substrate arrangement in conventional single- and multi-wavelength optical monitors, broadband measurements on the moving substrates make calibration factors and test runs redundant, if there are only the smallest deviations between the vacuum spectra and the spectra after venting (the *vacuum-to-air shift*). Therefore, an appropriate combination of an adequate deposition process and monitoring concept has to be chosen, e.g., an IAD

process providing an extremely low vacuum-to-air shift, as shown above.

Besides a precise layer thickness determination, in the development and control of coating processes for optics, a variety of optimization criteria has to be taken into account. Large areas have to be coated homogenously in flexible and fast processes. Besides the optical quality, the coatings have to exhibit good adherence, low mechanical stress, high abrasion resistance, and adequate environmental stability. Parameters to be controlled are, for example, substrate temperatures, deposition rates, partial pressures of process gases, or ion current densities and energies. Finally, it has to be mentioned that the thin film processing concepts presented are not only applied for optical coatings, including precision, laser, and consumer optics, but also in the fields of electronics, semiconductors, displays, medical technology, tribology, and even decorative coatings.

6.3 Quality Parameters of Optical Coatings

For the application of optical coatings in laser technology, a variety of quality parameters have to be taken into account [Table 6.1, [6.61–68]]. The spectral characteristics are the fundamental properties of the coating system and have to be adjusted primarily for the optical functioning of the laser system or optical device [6.69]. But, as soon as high laser powers or requirements concerning the precision are involved, additional quality parameters describing the optical losses and the stability of the coatings have to be evaluated. For many applications of high-power lasers, the absorbance, which transforms a fraction of the impinging radiation energy into heat, inducing a temperature increase in the coating, is of major concern. As an effect of absorption a temperature profile is built up in the optical component, which may influence the transfer behavior or even lead to the thermal

Table 6.1 Selected quality parameters of optical coatings and surfaces in conjunction with corresponding ISO standards and measurement principles

Specification	Parameter	Unit	Standard	Measurement principle

destruction of the optical component [6.70]. Besides the technical problems directly related to thermal effects, absorption always implies a loss of expensive laser energy, demonstrating the economical dimension of optical losses in modern laser systems. Absorbance in optical coatings is mainly governed by defects, stoichiometric deficiencies, or contaminants generated in the coating material during the production steps. In particular, dielectrics often suffer from unbalanced stoichiometry with a slight excess of the metal component, which is caused by a decomposition of the coating materials during thermal evaporation or sputtering. Stoichiometric effects influence the absorbance behavior in the short-wavelength region whereas adsorbed water, which is the predominant contaminant in optical coatings, may lead to increased absorption values in the MIR spectral region, particularly at the wavelength $10.6\,\mu m$ [6.71] of the CO_2 laser or the band of the Ho : YAG and Er : YAG lasers in the range $2-3\,\mu m$ [6.72]. A standard procedure for the measurement of absorbance in laser components, which is based on the laser calorimetric principle, is outlined in ISO 11551 [6.62]. For calorimetric absorbance measurement, a temperature sensor is attached to the specimen, which is located in a thermally isolating chamber. According to the standard protocol, the sample is irradiated by a laser beam with known power for a heating time t_B after having reached thermal equilibrium with the environment. As a consequence of the heat flow coupled into the sample by the absorption, an exponential increase in temperature can be monitored by the sensor element. Subsequently, the laser is blocked and the sample temperature decreases in proportion to the heat dissipation into the environment. For the determination of the absorbtance, the recorded heating and cooling curve are evaluated according to the methods described in the standard. The laser-calorimetric measurement technique had been tested in various round-robin experiments [6.73, 74] and offers the advantage of an absolute and sensitive assessment of absorbance [6.75].

Scattering is the second loss channel in optical components and summarizes all effects that deflect the radiation from its specular direction [6.76, 77]. Besides the economic loss of radiation, scatter may induce a reduction of the imaging quality of optical systems and may even appear as a safety problem, if a significant fraction of laser power is diverted into the environment, endangering personal operating the laser device. Scattering losses of optical coating systems can mainly be attributed to microstructural imperfections and inclusions in the coatings as well as to the roughness of the surface and the interfaces between the individual layers [6.76]. Theoretical models on the basis of these effects reveal a scaling of the scattering with the wavelength which can be described on the basis of a $1/\lambda^x$ function with an exponent x of $1-4$. In view of this fundamental relation, high scattering values dominating the losses of an optical component are expected especially for the vacuum ultraviolet (VUV)/UV spectral ranges. Following the wavelength scale towards longer wavelengths, optical scattering decreases and may be even neglected for the MIR spectral range, where absorption losses are more pronounced. During the last three decades, an extended scientific and technical background has been built up in the field of scattering measurements resulting in various standard measurement procedures for angle-resolved scattering (ARS) [6.78] and total scattering (TS) [6.63, 79]. Especially, for the determination of the TS value, which is defined by the total amount of radiation scattered into the 4π fullspace by an optical component, measurement set ups with an Ulbricht integrating sphere [6.80] or a Coblentz collecting sphere [6.81] are described in ISO 13696. The fundamental principle of the Ulbricht sphere is based on the integration of scattered radiation by a white highly diffuse reflecting coating on the inner wall of sphere and a subsequent monitoring of part of the integrated radiation, whereas the Coblentz sphere performs a direct collection and concentration of the scattered radiation onto the detector element. Also, the standard ISO 13696 for the measurement of TS values has been tested in various measurement campaigns [6.82] and has recently been qualified for the DUV/VUV spectral range [6.83, 84].

In particular, high-power lasers impose high demands on the power-handling capability of optical coatings, which is expressed in terms of the laser-induced damage threshold (LIDT). Fundamental parameters limiting the LIDT values of coatings are given by the inherent properties as the melting point, the thermal conductivity or the band-gap energy of the employed materials [6.85]. Besides these intrinsic properties, extrinsic effects related to defects and inclusions in the layer structure or special high-power mechanisms at the layer interfaces have to be taken into account [6.86]. Frequently, defect-induced damage mechanisms are observed in optical coatings (Fig. 6.16), which can be described on the basis of inclusions catastrophically heated under laser radiation [6.87]. In this theory, the generation of heat in the inclusion is modeled by the Mie absorption cross section, which is valid for particles with sizes in the range of the interacting wavelength. The diffusion of heat from the inclusion
Fig. 6.16 Scanning electron microscope (SEM) picture of a damage site initiated by defect mechanisms in a single-layer coating of TiO_2 subjected to an energy density of $10.9\,J/cm^2$ in a Nd:YAG laser beam with a diameter of approximately $200\,\mu m$. The height of the picture corresponds to a scale of $20\,\mu m$

into the surrounding coating material can be expressed by a solution of the heat diffusion equation for this specific geometry with polar symmetry [6.88]. The point of damage is reached when the perimeter temperature of the inclusion attains the melting point of the surround-

ing coating material. During the last two decades, the defect model had been studied by a several working groups, resulting in a deep understanding of the underlying mechanisms and the corresponding properties of the coating defects [6.85, 89]. Besides inclusion-dominated breakdown other mechanisms based on absorption and on electronic effects are discussed for the development of high-power laser coatings. In the picture of absorption-induced damage, the energy is directly coupled into the layer structure by absorption in the interaction area with the laser beam and leads to homogeneous temperature increase until the damage temperature of the structure is reached. The damage temperature is specified by transitions in the crystalline structure, the crossing of a defined coating stress level (Fig. 6.18), or the melting temperature (Fig. 6.17) of the coating material [6.90]. For short laser pulses in the ps and fs time domain, typical diffusion lengths of thermal effects are very small compared with the thickness of the layer structure. As a consequence, thermal effects can be neglected for the modeling of ultrashort pulse damage, which is mainly governed by electronic processes. Present theories start from the assumption that catastrophic damage takes place at a critical electron density of $10^{21}\,cm^{-3}$ in the conduction band of the

Fig. 6.17 Nomarski micrograph (color-enhanced presentation) of a damage site initiated by absorption-dominated mechanisms in a highly reflecting mirror of Ta_2O_5/SiO_2, objected to an energy density of $45.9\,J/cm^2$ in a Nd:YAG laser beam with a diameter of approximately $200\,\mu m$
Fig. 6.18 Nomarski micrograph of a damage site initiated by absorption-dominated mechanisms in an antireflective coating of ZrO_2/MgF_2 on a quartz substrate, subjected to an energy density of $35\,J/cm^2$ in a Nd:YAG laser beam with a diameter of approximately $200\,\mu m$. In this case the catastrophic stress level was reached prior to the thermal deterioration of the coating material

coating material [6.91]. At this point laser energy is coupled efficiently into the electrons, resulting in ionization and disruption of the material. For the description of the development of the electron density in the conduction band before arriving at the critical density, rate equations involving multiphoton excitation and the avalanche effect are employed. The major outcome of these theories is a clear correlation of the damage threshold to the maximum internal field strength in the layer structure and to the band-gap energies of the layer materials involved. These theoretical predictions are supported by experiments on single-layer and coating systems tested with ultrashort-pulse lasers in a broad range of pulse durations [6.92]. Aside the numerous damage mechanisms in the depth of the layer structure, features on the surface of the component may also diminish the power-handling capability of the optical component. For example, the field strength of the incoming wave can be enhanced by more than a factor of two in the vicinity of grooves, cracks or other surface imperfection, leading to weak points on the component (Fig. 6.19) [6.93]. An additional cause of surface-initiated damage is the generation of plasmons, which is correlated to the surface roughness of the component [6.94]. In these models, the damage threshold values decrease with the increasing surface roughness of the layers. Conclusively, even though a variety of damage mechanisms have been identified and understood on the basis of adapted models, the power-handling capability of optical thin films is still a major and vivid research area which plays a key role in the development of high-power lasers and their commercialization.

In many technical applications, the optical component additionally has to withstand a variety of environmental influences, including mechanical abrasion, chemical corrosion or severe climatic conditions. For example, the most severe mechanical and chemical requirements are imposed onto coatings for ophthalmology or consumer optics, which are often cleaned with even abrasive and aggressive cleaning solvents and
Fig. 6.19 Example of damage initiated by a surface imperfection in an antireflective coating of $ThF_4/ZnSe$ on a ZnSe substrate, subjected to an energy density of $12.7\,J/cm^2$ in a $TEA-CO_2$ laser beam. The width of the picture corresponds to a scale of $150\,\mu m$

fabrics. In the course of the individual development of the different optical products a variety of standardized testing procedures has been cultivated in the different market sectors for the qualification of optical components. Some of these procedures originating from ophthalmology, defence and medical applications are compiled in Table 6.1, which illustrates the broad spectrum of test procedures available. In particular, in laser technology the requirements in respect to environmental stability are less demanding and in most cases certification according to the conditioning methods with a lower degree of severity described in the ISO standard series 9211 are sufficient. Typical conditioning methods cover abrasion resistance, which is tested by a series of strokes with a special cheese cloth or eraser applied to the optical surfaces, and climatic stability, which is assessed on the basis of defined conditioning cycles in a climatic chamber.

6.4 Summary and Outlook

Even after more than 60 years of research and development, optical coatings are often still conceived as a technology with a large fraction of *magic art*, which can be mastered only by experience and always leaves a certain probability of unforeseen effects in production. Major challenges include the reliable and

reproducible deposition on the basis of well-defined and stable process concepts as well as sensitive and qualified characterization of the coatings. In view of the rapid development of computer systems, online monitoring strategies of the deposition processes and the optimization of stable deposition processes, significant progress

on the way towards precise and deterministic production of even complicated coating system are expected in the near future. Laser technology has always stimulated the development of coatings to a considerable quality level (Table 6.2) and will also be one of the major pace-setters for future innovations in the field.

Demanding future challenges will be imposed on optical coatings by the commercialization of new laser products and innovative applications, which are dependent on optical coatings with improved optical quality, higher stability and increased complexity in their functioning combining several surface properties. This new technology generation will also require improved flexibility and economy from optical factories, which can only be achieved on the basis of reproducible production processes and adapted characterization techniques. In conclusion, optical thin films will remain an enabling technology which will play a key role for many future applications and products.

Terms and Definitions
(in their order of appearance)

n_T refractive index of the substrate
E_0 amplitude of a plane wave
k wave number of a plane wave $k = 2\pi/\lambda$
λ wavelength of a plane wave
ω frequency of a plane wave
δ_i phase shift of a plane wave in layer number i

d_i thickness of the layer number i
n_i refractive index of the layer number i
θ_i angle of incidence in the layer number i
A_0 amplitude of the partial wave of order zero
A_1 amplitude of the partial wave, order one
A_2 amplitude of the partial wave, order two
t_1, t_1' transmission coefficients of the ambient–layer interface
r_1, r_1' reflection coefficients of the ambient–layer interface
r_2 reflection coefficient at the layer–substrate interface
A_k amplitude of the partial wave of order k
r_S reflection coefficient of a single layer
M_i matrix of layer i
E_i, H_i electric field strength, magnetic field strength at the rear plane interface of layer i
M_S composite matrix of a layer stack of K single layers
r_{SK} reflection coefficient of a layer stack of K single layers
n_0 index of refraction of the ambient medium
D_i film thickness expressed in units of QWOT
QWOT   quarter-wave optical thickness; the unit for the thickness of the layer
λ_Z design wavelength
n_H refractive index of a high-index material
n_L refractive index of a low-index material
R_S reflectance of a QWOT stack

Table 6.2 Selected quality parameters of optical coating systems for laser applications (Types: HR: high-reflecting mirror, AR: antireflective coating, th: thermal evaporation, IBS: ion-beam sputtering)

Laser, wavelength	Type	Absorption ISO 11551	Total scattering ISO 13696	Laser-induced damage threshold, ISO 11254
157 nm, F_2-excimer	HR/th	1–4%	1–4%	
193 nm, ArF-excimer	AR/th	0.7–2.5%	0.2–0.5%	1–2 J/cm² (1on1, 20 ns)
	HR/th	0.4–2.0%	0.2–2.5%	2–4 J/cm² (1on1, 20 ns)
248 nm, KrF-excimer	AR/th		< 0.025%	10 J/cm² (1on1, 30 ns)
	HR/th	< 500 ppm	< 0.2%	> 20 J/cm² (1on1, 30 ns)
	HR/IBS		< 0.1%	> 3 J/cm² (1on1, 30 ns)
633 nm, HeNe Laser	HR/th	< 30 ppm	< 30 ppm	-
	HR/IBS	< 5 ppm	< 5 ppm	-
1.064 µm, Nd:YAG	AR/th	< 20 ppm	< 100 ppm	> 60 J/cm² (12 ns, 0.25 mm)
	HR/th	< 50 ppm	< 100 ppm	> 100 J/cm² (12 ns, 0.25 mm)
	HR/IBS	< 1 ppm	< 1 ppm	> 80 J/cm² (12 ns, 0.25 mm)
10.6 µm, CO_2-Laser	AR/th	< 0.16%	-	> 20 J/cm² (100 ns, 1.4 mm)
				> 2 kJ/cm² (1.2 ms, 250 µm)
				> 3 kW/mm (100 µm)
	HR/th	< 0.10%	-	> 25 J/cm² (100 ns, 1.4 mm)
				> 2 kJ/cm² (1.2 ms, 250 µm)

PVD	physical vapor deposition
CVD	chemical vapor deposition
dN_e/dt	number of evaporating atoms per unit time
A_e	surface area of the evaporation source
α_e	evaporation coefficient
p^*	equilibrium vapor pressure of the evaporant
p	hydrostatic pressure of the evaporant
m	atomic mass
k_B	Boltzmann's constant
T	temperature
p_0	constant factor (pressure)
L_0	latent heat of evaporation per atom or molecule

RLVIP	reactive low-voltage ion plating
I(B)AD	ion-(beam-)assisted deposition
IBS	ion-beam sputtering
APCVD	atmospheric pressure CVD
LPCVD	low-pressure CVD
PECVD	plasma-enhanced CVD
PICVD	plasma impulse CVD
LCVD	laser(-induced) CVD
PLD	pulsed laser deposition
ARS	angle-resolved scattering
TS	total scattering
LIDT	laser-induced damage threshold

7. Optical Design and Stray Light Concepts and Principles

To insure that an optical system performs to specifications, the optical engineer needs to fully consider several aspects of the design process. Each of these tasks can be aided with the use of software tools. The optical engineer needs to understand the strengths and limitations of the available software tools and how to best apply these programs to each design. There are several distinct steps in the implementation of an optical system: the first order optical layout, optimized design of the optical system, performing stray, scattered and ghost analysis, performing a tolerance analysis of the optical system and performing manufacturing analysis. Although each of these steps are often considered separately, and often require the use of several different software tools, it is imperative for the engineer to consider the entire process during each phase of system development so that issues arising from stray light or manufacturing tolerances

do not force a redesign of the system. A thorough understanding of the optical design and analysis process as well as the proper use of available optical software tools are necessary to insure the optimum optical design for each specific application.

The design of an optical system is comprised of several distinct but interrelated steps. The initial phase in the optical design process is the design of the optical system. That is, establishing a set of optical parameters for each necessary optical component so that the design's performance level exceeds the design specifications. Another phase of the design process is to perform a tolerance analysis to verify that the system will still perform to specification when the limitations of material properties, manufacturing and assembly are considered. Another important phase is a separate analysis to consider the effects of stray light due to ghost reflections, scatter, and the design of proper baffling.

The optical designer is aided in each of these steps with computer programs specifically written for these tasks. The design and tolerancing of an optical system is generally performed using software referred to as sequential optical design programs or lens design codes. Stray light analysis is performed using a non-sequential, or unconstrained, optical analysis program. We will consider the capabilities and requirements of each of those optical programs.

7.1 The Design Process

The process of designing an optical system consists of establishing a set of optical components with optical properties, including materials (indices of refraction, dispersions), surface curvatures, element thicknesses and spacing, surface shape, etc., which in combination with system properties such as focal length, focal ratio, field of view, and others requirements, provide a design framework that will meet (or exceed) the required performance specification.

Although a lens design code is the most efficient method of determining the necessary parameter values, it is important for the designer to perform a first-order

Table 7.1 Basic optical system specifications and requirements

System parameters
Focal length
Focal ratio or numerical aperture

predesign before turning the process over to the computer. The predesign serves several purposes. First, it gives the designer another opportunity to consider all aspects of the design specifications closely to ensure that all necessary information and design specifications have been provided and to discuss any missing, incomplete or inconsistent requirements. Understanding the design requirements is a critical step in the design process. If any necessary specifications are uncertain, it is important to discuss any issues with the customer before the design begins. Any judgment call made by the optical designer can be overruled at any time, resulting in redesigns and costly delays. At this time the designer can also make a reasonable determination as to whether or not the desired system is physically realizable.

After determining that all necessary specification information is available, a first-order system layout can be determined (see Table 7.1 for a partial listing). As part of this analysis, it is important to consider any constraints placed on the design that may result in tolerance requirements that may exceed current fabrication limits. Although the full tolerance analysis will be performed after the design has been completed, it is at the designer's peril to ignore these aspects during the initial design phase. A similar warning applies to stray light issues as well.

Some of the system parameters that must be clearly understood before beginning the design include focal length, aperture, focal ratio and field of view (including a clear understanding of how the customer defines this parameter), wavelength band. Another necessary parameter is the actual performance requirement. In other words, how well must the system perform under a given set of operating conditions. The performance specification can be based on an encircled or ensquared energy size, modulation transfer function (MTF) values as well as consideration of some optical aberrations, in particular distortion and field curvature. Additional non-optical constraints may be provided including total footprint, volume and weight. Environmental issues such as humidity, pressure, salinity and temperature can degrade the performance of an optical system and can also limit the choices of optical materials as well as surface shape. As with any engineering task, allowable or measurable cost and time constraints will place limitations on the design. Parameters that can significantly impact the cost include aspheric surfaces, certain optical materials, and components with tight fabrication tolerances.

The stop surface is a critical surface in an optical design. The position and size of the stop significantly affect the ability of the design to perform as required. An optical system consists of a series of lenses and/or mirrors. The finite size of these surfaces limits the amount of light
Fig. 7.1 Aperture stop and pupils

Fig. 7.2 System marginal and chief rays

that can pass through the optical system. There is one surface that will limit the angular extent of a light bundle entering the system from an on-axis point source. This surface is called the system's aperture stop. The stop can be formed directly by an optical surface in the system or by a separate mechanical surface, or iris. The stop can be located anywhere in the optical system. Two other related surfaces are the entrance pupil and the exit pupil. The entrance pupil is defined as the image of the aperture stop as seen from object space. If the aperture stop is at, or in front of, the first optical surface, the entrance pupil and aperture stop are coincident. The exit pupil is the image of the aperture stop as seen from image space. If the aperture stop is at, or behind, the last optical surface, the exit pupil and aperture stop are coincident.

In specifying an optical system in a lens design code, it is necessary for the designer to input information concerning the size and location of the system aperture. Often the entrance pupil size is used, as this is the parameter used to specify the system's focal ratio. When the entrance pupil is used to specify the aperture, the size and location of the actual stop surface can change during the design process. If the stop surface must be of a specific size, then the aperture is defined by the stop. In this case, the size of the entrance pupil will be determined by the magnification between the stop surface and the entrance pupil. Other aperture definitions may be available in the lens design program for use with other constraints. Figure 7.1 shows a typical optical system with an embedded stop and indicating the location of the entrance and exit pupils, which for this design are virtual surfaces.

The first-order optical design is used to provide a starting point for the actual design process. Information concerning the relative location of the system stop, the number of lenses or lens groups, and the effective power of each group is determined. First-order
optics defines the properties of an aberration-free optical system. Many basic optical system parameters, such as focal length, focal ratio, magnification, and others, are derived from first-order, or paraxial, optics.

The first-order predesign locates the aperture stop, as well as the pupil and image locations in the optical design by tracing rays through the system. In particular, two specific rays, the marginal ray and the chief ray are used. The marginal ray is a ray that exits from an on-axis object point and travels through the top of the pupil or aperture stop before re-crossing the axis at the image. The marginal ray is used to determine the location of the image plane, the effective focal length and the focal ratio ($F/\#$). The chief ray is a ray that exits from the top of the object and crosses the optical axis at the aperture stop or pupil locations. The chief ray determines the location of the pupil planes, the field of view and the image height. Figure 7.2 shows the marginal and chief rays for the same optical system.

After performing the predesign to determine the general structure of the system, to include the number of elements, use of lenses and/or mirrors, relative stop location, and the basic system shape, the design of the actual system can be started. The synthesis of an optical system starts from the basic layout determined in the predesign. Using this as the basis, the designer uses the lens design program to determine the optical parameters necessary to meet the required performance specification. The lens design program will then take the information provided by the designer to find the combination of parameter values that best meet the performance goals. During this phase, the designer will need to determine whether the initial basic design had enough free parameters, called variables, to provide an acceptable solution. If not, the process begins anew.

The selection of the initial optical design form is a key role for the optical designer. The lens design program can only search for solutions within the solution space defined by the base design. Often a starting-point design is based on a prior known design used for a simi-

lar problem. In some instances an *off-the-shelf* solution, such as a camera lens or a microscope objective, might be the best option. Patent or literature searches can provide many useful ideas. These can provide information concerning the merits of reflective or refractive designs, the number of optical elements, the relative stop position and other important characteristics. Experience and intuition can also be employed in the predesign.

7.2 Design Parameters

The process of determining the optimal parameter values has become the domain of the lens design program. These programs, when used on a standard computer, can easily trace millions of rays through an optical system in seconds. Provided that the system has been properly defined and a proper set of constraints exist, the program can systematically adjust the parameter values until it reaches a solution that best matches the design goals. At this point, the designer needs to evaluate the information provided by the program to determine if the performance goals have actually been met. If not, a determination needs to be made as to whether the goals as defined to the program were sufficient and reasonable. If there were problems in the definition, then the goals need to be redefined before attempting further optimization. If the system and goals were properly defined and a solution was still not found, this indicates that there were an insufficient number of degrees of freedom in the design for a solution to be found. In this case the basic design needs to be reconsidered to allow for additional free parameters. This could also indicate that the design goals may need to be reevaluated.

In designing an optical system, the first and most frequent question asked should be: *does this make sense?* Design goals must be physically unrealizable. The optical designer needs to be able to recognize these issues and to offer alternative solutions. The designer must also be able to recognize when design goals compromise the performance of the system.

To use an optical design program, it is necessary to provide the program with sufficient information to understand the system under design. Lens design programs are called sequential ray traces because they trace geometrical rays through an optical system in a predefined sequence. These programs are based on a surface, rather than a component, model. Each surface defines a transition from one optical space to the next. Each surface has an object side and an image side. If we consider a simple optical system consisting of a singlet lens, there are four optical surfaces:

1. The object surface
2. The front lens surface
3. The rear lens surface
4. The image surface

Additionally, in this model, either the front or rear lens surface must be designated as the stop surface.

Each ray that is traced through the system starts at the object surface and is then traced sequentially through the front lens surface, the rear lens surface and on to the image surface. Rays cannot go through surfaces in any other order such as 1 to 3 to 2 to 4; this would require non-sequential ray tracing.

The optical design program simply applies Snell's Law to each ray on a sequential surface-by-surface basis. Some of the information the program will consider or provide includes the exact ray path, the effects of reflection and refraction, wavefront phase, aberrations and image quality. Some information concerning polarization effects may also be provided.

Equally important is the information that is ignored during sequential geometrical ray tracing, such as surface and volume scatter, if the system or any particular ray is physically realizable, or if there is any edge diffraction or other non-geometrical propagation of the wavefront.

The following information needs to be available to the optical design program before a system can be analyzed:

1. System aperture type and size
2. Surface information (sphere, asphere, others)
3. Number of surfaces
4. Which surface is the aperture stop
5. Wavelength band and weighting
6. Field of view

Additionally, optimization requires:

1. Variable parameters
2. Merit function

Optical design is an interaction between the designer and the computer program. The designer provides the program with information about the initial design form and the performance goals. An optical design program

is constrained to work within the design space provided. The program can make significant changes to the values associated with any variable parameter, but it cannot add additional variables, or add new parameters, such as additional lenses or aspheric coefficients. The designer needs to use the analysis provided by the design program to determine if any changes need to be made to the design and what the most effective changes are.

As previously discussed, the system aperture is used to determine the size of the entrance pupil, which determines how large a light bundle enters the optical system.

Surface information includes the curvature, thickness or distance to the next surface, the optical material the ray is entering, and possibly other information including aspheric or other shape coefficients.

Wavelength information consists of one or more wavelengths. During optimization and analysis, rays are traced for all defined wavelengths. Wavelengths may be weighted to indicate importance. A common use of weighting would be to apply the photopic or scotopic curves for visual optical systems or an appropriate detector response curve. Rays are only traced at the defined wavelengths, not as a continuum. Additionally, one wavelength is designated as the primary wavelength. This wavelength is used to calculate wavelength-dependent system properties, such as the focal length.

The field of view is also defined as a collection of specific points. Field points can also be importance weighted. Field points serve as source locations for the rays to be traced. Rays from each of the defined wavelengths will be launched from each of the defined field points to perform analysis and optimization. The field of view can be defined in terms of angles or heights in either object or image space. The angle definitions are necessary for infinite conjugates; either angles or heights can be used for finite object distances. For rotationally symmetric optical system, it is only necessary to trace rays from half of the field.

Variables are any parameters in the system that can be adjusted during the optimization process. These include radii, thickness, refractive indices, Abbe numbers, conic constants, aspheric coefficients and others, depending on the type of surface. In some cases, wavelength and field of view can also be appropriate variables. During the optimization process, all of the variables are adjusted. It is important for the designer to limit the ability of the program to change the variables freely to insure a successful design. Common constraints to apply include a minimum and maximum lens thickness.

Although optical design codes can be used to analyze existing designs, the most significant reason to use a design code is optimization. This is the designing part of the process. As indicated earlier, for the program to perform optimization, the designer needs to have provided a set of variable parameters and to have defined a merit function. All lens design programs have multiple algorithms for optimization. The designer needs to determine which, if any, of the native optimization routines is appropriate for a particular design, and if one of these routines is not appropriate, the program needs to allow the designer to create a suitable merit function. Merit functions native to the design program are designed to maximize the image quality of the design. Typically they include procedures to minimize the spot size or wavefront error on either a root-mean-square (RMS) or peak-to-valley (PTV) basis. The spot size or wavefront error will be weighted over all the defined fields and wavelengths. Additionally, it may be necessary to select a point of reference on the image surface for the optimization; usually either the intercept coordinates of the primary-wavelength chief ray or the weighted center position over all the wavelengths, the centroid. The proper merit function depends on the required performance level of the system. For systems that will operate at or near the diffraction limit, wavefront-based optimizations are more appropriate. For designs that do not need to perform at the diffraction limit, the spot-size minimization should be used. In cases where a user-specified merit function is required, such as a merit function based on MTF constraints, it is often more efficient (faster) to begin with a default merit function until the design is nearly finished before switching to the necessary merit function for the final iterations.

The most common optimization algorithms use a damped least-squares process. Let the merit function be defined as:

$$\Phi = \phi_1^2 + \phi_2^2 + \phi_3^2 + \phi_4^2 + \cdots + \phi_m^2 \ . \tag{7.1}$$

In this case there are m items that are being considered or targeted. The contribution of each of these targets to the total merit function is determined by the difference between the actual value and the desired value:

$$\phi_i = v_i - t_i \ . \tag{7.2}$$

In the ideal case, the actual value exactly equals the targeted value, so the contribution of that item to the total merit function would be zero. The goal of the optimization is to determine the set of parameter values that will drive the total merit function value to zero.
Fig. 7.3 Local and global minima

In these equations, each target or operand is given equal weight. In practice, applying weighting factors to each targeted value is necessary for optimal results. In this case the merit function is defined as:

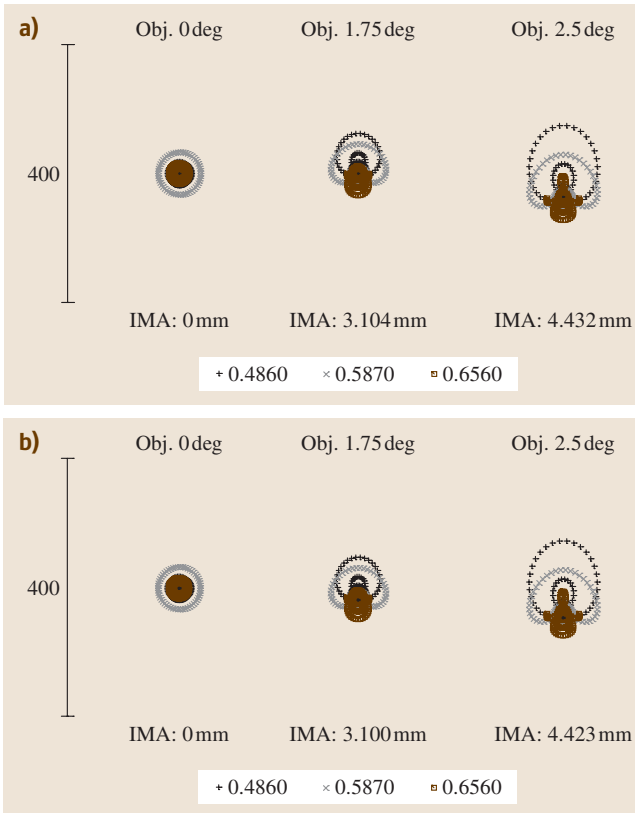
$$\Phi^2 = \frac{\sum\limits_i W_i(v_i - t_i)}{\sum\limits_i W_i} \ . \tag{7.3}$$


Fig. 7.4 **(a)** Spot diagram centered on the centroid **(b)** Spot diagram centered on the primary-wavelength chief ray

The values of each of the variables form an m-dimensional vector X. The goal of the optimization is to find the value for X for which Φ is a minimum. Φ is minimized in a least-squares sense, where the possible movements in solution space are computed by determining the direction where the derivative matrix of X is minimized. Careful sampling of solution space by the design program is necessary to insure that the minimum can be isolated.

There are some inherent problems with damped least-squares optimizations algorithms. The first issue is that the optimization follows a downhill path. That is, the algorithm locates a direction (new location in solution space) where the total merit function is lower than the current merit function and changes the vector X to those coordinates. This process continues until movement in any direction around the final coordinate location results in an increase in the total merit function value. At this point the optimization stops. This value is a local minimum, not necessarily the global minimum. The algorithm cannot search further through the solution space for a better minimum. The solution found depends on the initial starting point. By changing some of the initial parameter values, the optimization could find another local minimum that may be better or worse than that previously found. Figure 7.3 shows a simple two-dimensional (2-D) model of solution space. A, B and C represent possible starting points, with W, X, Y and Z the local minimum values, Z being the global minimum in this space. An optimization starting from point B will most likely find the global minimum value. An optimization from starting point A will stop at the local minimum Y. The starting point C can finish at either W or Z, depending on the direction of the first step.

The second problem that can occur is called stagnation. This occurs when the derivatives of each of the targets with respect to all of the variables is so ill-conditioned that a suitable next step cannot be determined. In this case, the optimization can stop even before reaching a local minimum.

Most optical design programs have global optimization techniques available that can be effectively used to find alternate, better solutions. However, even with global optimization it can never be assumed that the solution is the *true* global minimum.

The key for the optical engineer is to understand that the solution found by the optimizer might not be the best solution. However, it is not necessary to find the best solution, only to find a suitable design form that meets the performance specifications. If not, then the optimization must continue either by changing the

initial parametric values or by adding additional degrees of freedom in terms of additional variable parameters.

In constructing a merit function, the optical designer must perform several tasks. The first is the selection of the proper form of the merit function. As indicated earlier, RMS or PTV minimizations of the spot (blur) size or wavefront departure from spherical relative to either the weighted centroid or the primary-wavelength chief ray are the most common choices. Indeed, an RMS spot size relative to the centroid is often the most appropriate merit function for a design. Even for situations where the final design should be diffraction-limited, this form of optimization is often the best starting point. Figures 7.4a and 7.4b show the blurs for a double Gauss lens design. Although the physical distribution of the rays has not changed, the RMS and geometric values calculated differ for the off-axis field points.

The RMS spot size is a measure of image quality based on tracing geometrical rays through the optical system. Geometric rays propagate through the optical system according to Snell's law, ignoring the effects of diffraction from edges and apertures. The RMS spot size is calculated by tracing a selection of rays of each defined wavelength from each defined field point. The number of rays propagated is adjusted to consider any applied weighting factors. To calculate the RMS spot size relative to centroid, it is first necessary to locate the centroid position. This is the average image position determined by tracing a number of rays:

$$x_c = \sum_1^n \frac{x}{n},$$
$$y_c = \sum_1^n \frac{y}{n}. \tag{7.4}$$

The RMS spot size is then determined using

$$\text{RMS} = \left(\sum_1^n \frac{(x - x_c) + (y - y_c)}{n} \right)^{\frac{1}{2}}. \tag{7.5}$$

In attempting to optimize the design, the result will be a reduction in the aberration in the design usually without specifically targeting aberrations. It is also important for the designer to consider what is actually important in the design. The optimal result, where the total blur size is reduced, generally indicates optimal image quality. In using a native merit function, it is important for the engineer to understand what is and is not considered in the merit function. For example, distortion is not typically considered directly in optimization. If specific constrains
Fig. 7.5 Tangential ray fan

are placed on distortion in the design specifications, it will be necessary for the designer to modify the merit function to include this constraint. Similar requirements may also apply to field curvature requirements.

Additionally, the optical designer may need to add constraints to target specific system properties such as effective focal length, focal ratio or magnification. Boundary limitations also must be considered. Boundary constraints placed on lens components can assure that the lens is physically viable. The center thickness of the lens should be one tenth to one sixth of the lens diameter. Also for lenses with convex faces, the edge thickness needs to be sufficient to prevent chipping and to provide a solid surface for mounting. Often lenses will be oversized and *squared up* to prevent problems. However, if lenses are oversized during manufacture, it is necessary for the designer to insure that all light that could pass through the oversized lens is actually blocked by the lens housing, or the image quality may be degraded by excess light entering the system. Additional constraints that need to be considered and may be appropriate for the merit function include the total length of the system, the weight of any and all components, glass properties and grades, and transmission.

After the design program has reached a minimum solution, several graphical and numerical analytical tools are available to help evaluate the design. These tools provide information to help the designer understand the limitations or dominant aberrations present in the current design form. By understanding the system limitations, the designer can introduce the necessary degrees of freedom to correct for that limit. In terms of aberration correction, particular forms of variables may be effective for controlling some aberrations and be ineffective at correcting other aberrations. Introducing ineffective degrees of freedom can lead to stagnation of the optimization process.

Some of the tools include geometric-ray-based spot diagrams, encircled energy plots, ray fan and optical path difference (OPD) fan plots, wavefront maps, as well as plots of field curvature, distortion, longitudinal aberra-
Fig. 7.6 Sagittal ray fan

Fig. 7.7 Ray fan plot

tion and lateral color. Additional tools may be available that include edge diffraction effects. These tools should be used as the system's performance nears the diffraction limit. These tools include diffraction-based encircled energy plots, MTF plots and point spread function (PSF) plots.

Ray or OPD fan plots show the relative location of linear cross sections of rays through the entrance pupil. Fan plots are generated in the tangential and sagittal direction for each of the defined field points. Each wavelength is plotted separately. Figure 7.5 shows the tangential fan, which is directed along the *y*-axis of the pupil. Figure 7.6 shows the sagittal fan, which is directed along the *x*-axis of the pupil. The coordinate origin of the fan plots is the intercept of the primary-wavelength chief ray. Figure 7.7 shows the ray fan plot for a double Gauss design. The other points indicate how far each of the other rays landed from the chief-ray intercept in either the tangential or sagittal direction. The OPD plot (Fig. 7.8) indicates the difference in optical path traveled for each ray relative to the total optical path of the chief ray.

Although the fan plots are limited to showing information about a pair of linear ray distributions, each is very useful in determining the many first- and third-order aberrations present in the design. Each of these aberrations has a characteristic appearance on the fan plot. By recognizing these traits, the designer can determine which aberrations are limiting the design's performance.

As a system's performance level nears the diffraction limit, it becomes necessary to consider the effects of diffraction from apertures in the performance evaluation. Light has properties of both particles and waves. Rays are used to model particle-like behavior; diffraction and interference characterize wave-like behavior. At optical wavelengths light is a wave phenomenon, and the approximations used in geometric optics may not be sufficient to explain the images formed in such systems. To understand these effects, it is necessary to consider the effects of diffraction from edges and apertures. Although diffraction occurs in all optical systems, it is only necessary to consider diffraction effects when the scale of the image blur due to diffraction is on the same scale as the blur size due to geometric aberrations.
Diffraction theory says that the image formed by a converging wavefront is simply the Fourier transform of the complex wavefront in the exit pupil of the optical system. An important consequence of this is called *compact support*. This tells us that a signal band-limited in the spatial domain cannot be limited in its Fourier domain. As the wavefront passes through a physical aperture, some of the wavefront is clipped off. Because the wavefront is now limited in the spatial domain, it can-

Obj. 0 deg

distribution on a circular aperture is

$$A(\theta_x, \theta_y) = \frac{A_0}{\pi} \iint e^{ik(x \sin \theta_x + y \sin \theta_y)} \, dx \, dy , \quad (7.7)$$

where A_0 is the incident amplitude and π is an area normalization term. Integrating over the distribution yields

$$A(r) = 2A_0 \frac{J_1\left(\frac{kar}{z}\right)}{\frac{kar}{z}} , \quad (7.8)$$

with k being $2\pi/\lambda$, r the aperture radial size and z the image distance and J_1 is a first-order Bessel function. The first root of $J_1(x)$ occurs at $1.22\lambda(F/\#)$. The Bessel function, or Airy disk pattern, describes a pattern of alternating bright and dark zones, with the location of the dark zones determined from the successive roots of the Bessel function. Figure 7.9 shows a cross section of the diffraction image. Figure 7.10 shows a 2-D image. Both figures are plotted on a logarithmic scale to allow further bands to be seen. The central core of the Airy pattern is useful in determining if a design is approaching the diffraction limit. Consider the spot diagrams shown in Fig. 7.11. The circle indicates the Airy disk. In the

not be limited in the Fourier domain. Energy is spread out over all angular space. Due to this spreading of energy, point objects such as stars cannot form point images. The size of the image blur due to diffraction is a function of the focal ratio and wavelength of the system.

$$D = 1.22\lambda(F/\#) . \quad (7.6)$$

Summing the plane waves incident on an optical system a long distance from the aperture gives the far-field diffraction pattern. In the common case of a planar wavefront incident on a circular aperture, the energy distribution is referred to as an Airy pattern. The irradiance

Fig. 7.10 2-D plot of the Airy function
Fig. 7.11 Comparison of the blur size to the Airy disk

spot on the left, the geometric blur is contained within the Airy disk, and the effects of diffraction need to be considered; the size of the image blur will be larger than that calculated using only geometric analysis. For the system on the right, geometrical aberrations dominate the performance and the effects of diffraction can be ignored.

When performing diffraction-based calculations in a lens design code, it is important to understand the process being applied. Ray tracing programs propagate rays through the optical systems. Although each ray represents the normal to the wavefront, the actual wavefront is not propagated. Therefore some form of approximation is often used in diffractive calculations. The optical designer is responsible for determining the validity of the diffraction calculations for any given system.

Although there are situations where geometric or diffractive calculations must be applied, it is important to remember that the two can also be related: if geometric optics predicts a high level of performance for a design, than the system will perform close to its diffraction limit. If geometric optics predicts the blur size is smaller than the Airy disk, then the actual image blur will be near the size of the Airy disk. Also, if the geometric blur is smaller than the Airy disk, there is little value in attempting to reduce geometric aberrations further.

The design of an optical system requires the optical designer to develop a first-order design to insure that all necessary specifications have been provided and make sense. Then the basic system prescription including system parameters such as focal length, aperture, field of view and wavelength data, as well as the basic sequential optical layout with the desired number and types of surfaces and materials, needs to be defined in the lens design program. To perform optimization, variable parameters and an appropriate and well-constrained merit function must be defined. After allowing the optical design program to perform optimization, the designer needs to

consider the appropriate geometrical or diffractive analysis available to insure that the performance goals are truly met. This ends the first and possibly easiest part of optical design.

The next step in designing the optical system is to perform a tolerance analysis. Tolerancing is one of the most complex aspects of optical design and engineering. Tolerance analysis is a statistical process during which changes or perturbations are introduced into the optical design to determine the performance level of an actual design manufactured and assembled to a set of manufacturing tolerances. To perform an optical tolerance is to accept reality. No optical surface will be polished to perfect curvature and figure. No mechanical mount will be perfectly machined. No component will be perfectly positioned. All these, as well as many other error sources will serve to degrade the performance of the assembled system. It is up to the optical engineer to define the fabrication limits properly for each optical and mechanical task. This needs to be done with a consideration for the system performance as well as an understanding of the cost impact of an overly constrained design.

There are several steps to performing a tolerance analysis.

1. Establish a tolerance budget,
2. Perform a test plate fitting,
3. Define a set of tolerance ranges that are easily within fabrication limits,
4. Define compensators that may be used to limit performance degradation,
5. Select an appropriate figure of merit for tolerancing,
6. Evaluate the tolerances to estimate the impact of each perturbation,
7. Generate random designs for statistical analysis,
8. Revise the tolerance ranges as necessary.

The error budget is the total system degradation that is available. If the basic design just met the performance requirement, then it is unlikely that a manufactured system would work to specification, as a system will not be made exactly to the prescription. The available error needs to be shared among all the factors that can impact the system including materials, manufacturing, assembly, environmental, and the residual design error. Table 7.2 lists some of the parameters that should be considered.

Test plate fitting refers to the process of matching the surfaces of all optical surfaces to a set of test plates available to the optician. The curvature of an optical surface is determined interferometrically by comparing the

Table 7.2 Possible tolerance defects

Fabrication errors
Incorrect radius of curvature

Residual design error
System merit function value not zero

surface being polished to a surface of known curvature. If the design can be matched to the available test plates, the cost both in terms of fabrication as well as time will be significantly reduced. If matching all surfaces to test plates significantly degrades the performance, the optical engineer needs to determine if the cost of custom test plates is worth the cost and delay or if a system redesign should begin.

Setting the initial tolerance ranges is a balance: not so tight as to have a cost impact but not so loose that assembly is difficult. Understanding the capabilities of the optical fabrication shop as well as the mechanical fabrication shop is a good starting point for the parameter ranges. Start with readily achievable tolerances and then selectively tighten only those ranges that result in out-of-specification performance.

A compensator is a system parameter that can be adjusted to counteract the effect of an error in another parameter. The ability to use compensators can significantly loosen the parameter ranges, which can be useful in reducing costs. A common compensator is the image distance: the image location is set for each system based on the performance of that system. Compensators represent degrees of freedom, usually mechanical adjustments that need to be available and made during the assembly of the optical design. The cost impact of the compensator needs to be considered before including it in the analysis. A $500 kinematic mount cannot be included with each $7 optical system.

The tolerance figure of merit is usually similar to the final merit function used during the design phase. As each parameter is perturbed within the tolerance range, the compensator value is optimized to minimize the figure of merit. The difference between the original design merit function and the tolerance figure of merit describes the impact of each perturbation on the system performance.

During the tolerance process, each parameter is perturbed individually. This allows the optical engineer to determine which parameters are most sensitive. Parameters that perturb the design outside a portion of the error budget available for fabrication errors need to be more tightly constrained. Tightening constraints adds significantly to the manufacturing costs. Additionally there are some manufacturing limits that cannot be exceeded no matter what the cost. Designs that require such constraints should be deemed unbuildable and the engineer should return to the design process, with careful consideration as to why the design failed.

By generating a series of perturbed lenses, it is possible to determine what the performance level of any manufactured system would be. For these systems, each parameter is perturbed to a value within a specified statistical distribution of the nominal value. The accuracy of this analysis is directly related to the provision by the optical designer of the necessary information to the tolerance algorithm regarding the appropriate distribution. If such information is not available, a Gaussian distribution is normally assumed. This is not always the best choice. Consider the thickness of an optical window. It is unlikely that the window will be polished to the *thin* side. As soon as the component thickness is within the

allowed thickness $+\Delta$, the polishing will stop. The fabricator will not continue to polish to get closer to the nominal value.

After analyzing the statistical information about the random designs, further tightening of the parameter ranges may be necessary to achieve the required pass rate. Again a careful balance needs to be achieved between the success rate (the percentage of the systems that will meet the required performance level) and the cost to increase it.

An optical design is not complete until a tolerance analysis has been carried out. The lens design needs to be manufacturable with some realistic range of parameter specifications to be useful to the customer. The best design is not necessarily the design that best matches the design specification. It is the design that can be built to best match the design specification.

Now that a finalized optical design has been established, it may be necessary to perform a stray light analysis to simulate the real working environment more completely and insure that the limitations imposed by sequential ray tracing have not hidden significant design flaws.

7.3 Stray Light Design Analysis

Years ago a stray light analysis was often an afterthought, if considered about at all. Today it is known that the stray light analysis should be considered along with the conception of the optical design in the very earliest stages of the design study. It might even play a major role in the selection of the starting optical design.

What is a stray light analysis? Stray light analysis is the calculation of how much unwanted radiation reaches the image plane/detector plane. The fine distinction being made here is that in some designs a detector is placed at the exit pupil plane where no traditional image is formed. In this chapter they will be used interchangeably. In a stray light analysis one must consider all the elements in the optical design. It must consider each surface as an independent element that will scatter directly to the image plane or that might create significant non-sequential stray light contributions due to ghost images or total internal reflections off any of its surfaces. In a lens system, all possible combinations of lens and mirror surfaces need to be considered. Each ground or polished edge of the lens elements are potential sources of stray light propagation, and each aperture edge of an optical element creates diffraction. All the mechanical structures that hold the elements in place are potential stray light propagators. Then there are often baffles, the main cylindrical tube-like structures that are used to either enclose the optical system or to baffle the stray light from reaching deep into the system. On these baffles, there are often vane structures to suppress the propagation of the unwanted light further, and those vanes usually have tapered edges, and as fine as they may get, they can sources of scattered stray light and diffracted stray light. These vanes and baffle surfaces are usually coated with paint or light-absorbing material that have a complicated bidirectional scattering function. There is no such thing as a Lambertian black coating at any wavelength. In the infrared there are also potential sources of thermally emitted stray light from the system itself.

In spite of all this complexity, significant stray light suppression design can be accomplished without doing any numerical calculations. Sooner or later one will eventually need a software program to quantify the performance and then a system performance measure to confirm the results of the analysis and fabrication. There are computer-aided design (CAD) tools available that greatly assist in inputting very complicated systems into stray light analysis codes.

Why do a stray light analysis? One needs to perform a stray light analysis and then a measurement when stray light might be a problem in systems that:

1. are in compromising environments that have one or more strong stray light sources
2. observe faint objects
3. make precise measurements
4. require high contrast
5. propagate high-power laser energy, when even small percentages of stray light can damage the system

One carries out the stray light analysis because in many systems it is necessary to assure that the system goals are achieved or even achievable. Stray light analysis usually improves system performance by a factor of 1000 and sometimes by a factor of 100 000 (e.g., in the Hubble telescope).

The adverse effects of stray light in a system are:

1. It can cause such severe problems that the design will not reach its desired optical performance;

4. It produces false artifacts across the image plane that cause false alarms;
5. It causes magnitudinal errors in radiometric measurements;
6. It damages fragile optical components;
7. and stray light can burn out detectors.

Much like in the optical design, the design of stray light suppression in the system starts in the first-order optical design, and with initial specifications determined most often by the purpose, mission and environment of the instrument. The required basic thought analysis of a stray light designer must consider the items the designer considered in Tables 7.1 and 7.2 and some more given in Table 7.3. While stray light design is considered by some to be an esoteric art, it is not. Most good stray light design aspects of a system can be incorporated, in concept, without much precalculation. There are about eight basic principles in stray light design that simplify the process. They are explained in the text. They are:

1. Stray light analysis should be incorporated in the very earliest stages of a preliminary design study. It should play a role in the selection of the starting optical design.
2. Start from the detector.
3. Determine *critical objects*, i. e., objects seen from the image plane.
4. Move it or block it.
5. Trace rays out of the system from the image/detector plane.
6. Trace rays into the system from various field positions to determine the "illuminated" objects.
7. *Only* the aperture stop should not be *oversized*. All other elements have extra imaging surface from any given field point on the image surface. Be concerned about concessions made to oversizing elements for the convenience of manufacturability.

8. One wants and needs to know more than just how much stray light reaches the detector. One needs to know what path it took and the propagation method (scatter, total internal reflection (TIR), diffraction, etc.) in order to improve performance.

The concept is to think out the system before any stray light analysis is performed. It is encouraged to learn and appreciate the concepts so that, when one gets to the computer analysis, it will run faster and will probably produce a more accurate answer. Why?

If one can limit the number of critical paths along which the unwanted stray light propagates there will be fewer interactions that can be miscalculated. Fewer interactions mean that the analyst will probably pay more attention to the fine details, and in the end the software will run faster because there are fewer calculations. Once you know the paths you do not have to make a Monte Carlo zoo of the analysis. After we look at the basic mathematical calculation that needs to be performed we will come back to this point.

7.4 The Basic Equation of Radiation Transfer

The fundamental equation relating differential power transferred from one section on an object, be it a baffle or an optical element, or even a diffracting edge, to another object is determined by

$$d\Phi_c = L_s(\theta_i, \phi_i \, \theta_0, \phi_0) \, dA_s \frac{\cos(\theta_s) \, dA_c \cos(\theta_c)}{R_{sc}^2} \,,$$
(7.9)

where $d\Phi_c$ is the differential power transferred, $L_s(\theta_0, \phi_0)$ is the bidirectional radiance of the source section; dA_s and dA_c are the elemental areas of the source and collector; θ_s and θ_c are the angles that the line of sight from the source to the collector makes with their respective normals. This equation can be rewritten as three factors, which helps simplify the reduction of scattered radiation. With $E(\theta_i, \phi_i)$ being the incident irradiance *incident on the scattering surface*, the three terms are:

$$d\Phi_c = \frac{L_s(\theta_0, \phi_0)}{E(\theta_i, \phi_i)} E(\theta_i, \phi_i) \frac{\cos(\theta_s) \, dA_c \cos(\theta_c)}{R_{sc}^2} \,.$$
(7.10)

The first term is the scatter function, known as the bidirectional reflectance distribution function (BRDF):

$$BRDF(\theta_i, \phi_i; \theta_0, \phi_0) = \frac{L_s(\theta_0, \phi_0)}{E(\theta_i, \phi_i)} \,.$$
(7.11)

The second term is the power on the propagating surface section

$$d\Phi_s = E(\theta_i, \phi_i) \, dA_s \,.$$
(7.12)

The final term has to do with the geometry. It represents the projected solid angle (PSA) of the collector as seen

from the scattering surface, i.e., the source.

$$PSA_{sc} = d\Omega_{sc} \cos(\theta_s) = \frac{dA_c \cos(\theta_c)}{R_{sc}^2} \cos(\theta_s) \,.$$
(7.13)

$d\Omega_{sc}$ is the solid angle of the collector section as seen from the source. Another term used often is the geometrical configuration factor (GCF) introduced by thermal analysis engineers over a century ago. $GCF = PSA/\pi$ because the radiance of an emitting surface was assumed to be Lambertian (it includes the BRDF term).

$$d\Phi_c = BRDF(\theta_i, \phi_i; \theta_0, \phi_0) \, d\Phi_s[d\Omega_{sc} \cos(\theta_s)] \,.$$
(7.14)

In words, the power propagated from one surface area section to another is equal to the power from the surface that is scattering the radiation times the solid angle the collector subtends as seen from the source times the scattering characteristics of the source. So stray light boils down to the repetitive use of the multiplication of just three numbers: the power on the scattering surface, the scatter value for the specific input and output of the scattering surface, and the projected solid angle of the collector. When conceptually designing a system, (7.14) is the equation to keep in mind.

All software programs implement some variation of this calculation, even the ray-based programs. In ray-based programs, the scattered ray is *weighted* by the power on the scattering surface, the BRDF for the directions of the incoming and outgoing ray direction and some form of weighted solid angle. The mathematics of a stray light analysis does not appear to be an overwhelming calculation; it is just the product of three numbers and the BRDF does not seem to be that hard to determine if one has measured data. All of which is

correct. So why does stray light analysis seem so challenging? For one thing, in a typical analysis the equation is calculated 100 million times. No one has the time to do it by hand in detail.

7.4.1 Stray Radiation Paths

Since it is only the third term in (7.14) that can be reduced to zero, it should receive attention first

$$\text{PSA}_{\text{sc}} = \frac{\cos(\theta_{\text{s}})\,\text{d}A_{\text{c}}\,\cos(\theta_{\text{c}})}{R_{\text{sc}}^2} \ . \tag{7.15}$$

How this factor can go to zero is hard to understand at first. The two cosine values can reduce the PSA to zero but seldom can this level of tilt be reached. Usually this is done on lens mounting structures, by tilting them completely out of the way. The diffraction effect remains, but is usually much lower than at the high angle of incidence of the forward-scattering path. For $\text{d}A_{\text{c}}$ the finite area of the collector is always present, so this seldom goes to zero. The PSA can be made to go to zero by moving the collector out of the scattering surface's field of view, in which case it is blocked. In some cases this can be done by a field or aperture stop. Alternatively, this can be achieved by placing vanes on a baffle surface so that the direct forward-scatter path is blocked and two scatterings are present in the path path (each absorbing maybe 99% of the energy with a very good black) and one additional PSA reduction by 90% along the path from the front surface of one vane to the back side of the preceding vane. This then results in a reduction by a factor of about 100 000 in the propagated energy along the path.

This is a crucial point in a stray light analysis. Most analysts make the mistake of working on the BRDF term first. They want the blackest black or the lowest-scatter optical surface without knowing if it will make any measurable difference. A stray light analysis will pay for itself in the long run.

7.4.2 Start from the Detector

Having explained the apparent possibilities for decreasing the PSA_{sc} term, we now consider another concept, by considering the *start from the detector* and the *move it or block it* concepts. By placing baffles, stops, and apertures into a system in the correct places, many critical objects will be removed from the view of the detector. In other cases propagation paths from the directly illuminated surfaces to the critical objects can be blocked. The beautiful part of this is that one does not need to do

the calculation. We all know what zero times something is zero. It is not unusual for an experienced stray light person to reduce the necessary calculations for a software program greatly without reducing the reliability of the result.

What is needed is a logical approach that first blocks off as many direct paths for unwanted energy to the detector as possible and then reduce the list of illuminated objects. Finally the PSA_{sc} for the remaining paths from the illuminated objects to the critical objects is minimized.

Below several stray light paths are pointed out in detail. During the design phase the analyst designs out and reduces the number of critical objects that the detector can see. Then the direct stray light paths from the stray light sources to the illuminated objects are reduced using aperture stops, Lyot stops and intermediate field stops. Every effort is made to use these apertures to block the direct field of view from the image plane completely. Therefore the PSA_{sc} in the above transfer goes to zero, maximizing stray light suppression for these paths.

The next step is to make sure that there is no section of an illuminated object that is both illuminated and seen (i. e., is also a critical object) by the detector. These are single-scatter paths from the stray light source to the detector and must be solved before proceeding. The good news is that, having done this, one more or less knows all the key stray light propagation paths without having done a calculation.

The analysis should not start from stray light sources as, even if some parts of the system are well lit, the emitted photons are not important if they are strongly attenuated before reaching the detector. Unfortunately many engineers first want to determine the destination of the stray light from each source, leading them to choose the best optics and the blackest blacks. This is not the right way to proceed, and the following two points should be borne in mind:

1. Only objects seen by the detector can contribute stray light;
2. The PSA is the only term that can go to zero.

Therefore the approach is first to determine the critical objects that can be seen from the image plane and list all objects that it can see either directly or through the various optics, be they reflective or refraction. This will be covered in detail shortly. The next step is to start moving the critical objects outside the field of view (FOV) or block them with baffles, apertures stops, field stops, or vanes. The PSA should be made to go to zero before

a calculation is considered, with the number of critical objects that can be seen as low as possible.

The next step is to trace the propagation of stray light into the system and determine the illuminated objects. Having done the first step we now know where we do not want any of the direct energy to arrive, i.e., the critical objects, because it will create a single-scatter path to the detector. The significant stray light propagation paths will be defined as the paths:

- from the stray light sources of unwanted radiation to illuminated objects,
- then from these illuminated objects to critical objects,
- then from the critical objects to the detector.

This approach simplifies the analysis immensely and directs attention to the most productive solutions.

With computer software, one can then quantify the power propagated along these paths, which will then reveal which paths are the most significant. The analyst then gains the further advantage of working on the other two terms of (7.14). It is only at the end of the analysis that the analyst considers if the coating will make a difference. Its effect will usually be by less than a factor of five, maybe ten, for any single scatter between a great black and a mediocre black. Blacks are not the secret to good stray light design.

7.4.3 The Reverse Ray Trace

The purpose of a reverse ray trace is to determine what the detector can see. It is only from objects that the detector can see that there can be *any* direct contribution to stray light. An object in this sense can be a diffracting edge and any object seen in reflection or imaged by and through the optical system. This is not an easy calculation for most optical design programs as there is seldom a single aperture that defines the *reverse aperture stop*. Usually there are several apertures that define the limiting size of the ray bundle, so it can be difficult to use those codes.

Take for example a simple two-mirror Cassegrain reflective telescope. The on-axis incoming beam is limited by the aperture of the primary mirror, it is then reflected towards the secondary mirror where the circular beam footprint is then reflected back towards the primary, and often through a hole in the primary to an on-axis beam spot on the image plane behind the primary mirror.

From an off-axis position the incoming beam is again limited by the same aperture of the primary mirror, where it is again reflected towards the secondary mirror

where the circular beam footprint is offset from the center of the secondary mirror and reflected back towards the primary to an off-axis beam spot on the image plane. So the secondary has to be bigger than the beam footprint from any given field position to account for the field of view (FOV) of the sensor. Other than diffraction and aberrational effects, this has little impact on the incoming beam. To the first order, it is geometrically similar, although it may be slightly elliptical.

However, looking out of the system it is dramatically different. All sorts of stray light concepts are involved. Consider the secondary as the aperture stop of the system in reverse; i. e., the full surface intercepts the ray bundle from the on-axis position that is reflected towards the primary mirror. However, when the ray bundle from an off-axis position on the detector reaches the plane of the rim of the primary mirror, it is bigger on one side than the diameter of the aperture of the primary. This is where the primary also becomes the limiting aperture and gives design programs a challenge. Nevertheless, it is because the instantaneous footprint of the *incoming* beam from an off-axis stray light source position needed a bigger secondary mirror aperture to accommodate the beam. The same extra mirror surface needed to accommodate the incoming beam allows the detector to see more in the reverse direction, which is how it sees the baffles, mirror mounts, struts, and (in other systems) the ground edges of lenses, etc. All of these are critical objects and are therefore more sources of scattered and diffracted light to the detector.

The amount of baffle seen increases as the point is moved to an off-axis position on the detector. If there were a baffle one would see much more of the baffle, which could be directly illuminated by a distant stray light source. A source that does not put any direct power on the primary mirror, but does to a black surface with a higher BRDF value is not good.

This concept applies to almost all optical systems. As briefly referred to above, the struts that support the secondary mirror in a typical two-mirror telescope are seen in double reflection off the secondary and them off the primary. As one moves off-axis there is a view to the edges of the struts if they are not tapered out of the field of view. It this case the forward scatter to the detector can be quite high.

These reverse ray traces are not easy in a conventional optical design package because, as the trace starts from the off-axis image plane position, there are often multiple apertures that limit the edge rays in the reverse direction. Once discipline is learned it is often easy, maybe even easier than using a program, to conceptual-

Table 7.4 Comparison of the advantages and disadvantages of a stray light system test and a computer-generated stray light analysis. It shows that every disadvantage of a stray light test is an advantage of a system analysis, and every disadvantage of a stray light analysis is an advantage of a stray light test

Stray light system test advantages	Stray light analysis disadvantages
1 The system is the "as built" system	1 There is the possibility that the system was input incorrectly; operator error. Not all the details are put in. If there are assembly errors they are not usually input into the analysis as they are unknown.
2 The BRDFs are the real coatings	2 The BRDFs are from representative measured data, not the real coatings performance.

Stray light system test disadvantages	Stray light analysis advantages
1 If the system does not pass, then what? A test is almost neveer designed to determine the paths of scatter or if the BRDF along a path is critical.	1 The analysis will easily point out the paths, the flaws, and the magnitudes of power propagated along the paths. You know what to do to fix it. You know what is not important.
2 If the system passes then it appears to have passed the ultimate test; but not in the real environment and the test chamber has been know to affect the results both better and worse than the actual system performance	2 An analysis can predetermine adverse effects resulting from the test chamber environment in comparison to the actual environment in which the system will need to perform in.
3 If the fully built system fails it has been an expensive and time-consuming experience.	3 The rejection of a design on paper is much easier to swallow than a completely built system. And it most often is much less expensive.
4 A stray light test can be relatively expensive and come after the system is built	4 A stray light analysis can be relatively inexpensive and can be performed ahead of time.

ize what would be seen from the various field positions on the detector.

The concept is this: all apertures that are not the aperture stop or conjugate to it will be *oversized* for any given field position and therefore are windows to other surfaces and surface areas; you see critical objects. Once the real hard stop is encountered the detector should not see any more surfaces beyond the ray bundle size. Note that central obscurations and strut-like objects in the field of view will be seen.

7.4.4 Field Stops and Lyot Stops

Field stops have not yet been discussed, but they too have an important role in stray light suppression. If one exists, it is placed at the position of an intermediate image position. Ray bundles traced from an out of for position into the system will be intercepted by this field stop; hence there should not be any directly illuminated objects passed by an intermediate field stop. Field stops limit the number of illuminated objects. Caution should

be exercised in systems that have mirrors, as a beam focused out of field onto a field stop might be seen in the center of a reflection off a mirror, and would then be a bright point source in the field of view of the detector.

A Lyot stop is placed at the image of the aperture stop, often at the exit pupil. Lyot stops are often really *the* stop of the system as they are usually slightly undersized to account for aberrations and diffraction effects. Because they follow the defined aperture stop they are closer to the image plane in the series of optical elements and baffles that follow. Therefore the Lyot stop will limit the number of critical objects seen by the detector.

In detail the concept is more complicated and a software tool is needed to help speed up the calculation. For instance, the image at the intermediate field stop is often not of as high a quality as the final image. That is because the optical parameters are varied to control the final image quality. Therefore aberration will blur the image and increase the spot size, and some stray light might get through the aperture. The same goes for the aperture stop and its Lyot stop. An effect known as pupil

aberration may also occur; if bad enough it will allow extra critical objects to be seen. Usually only a small portion of some new critical object will be seen. However, even if it is only a small piece that is directly illuminated, it could make orders of magnitude difference in the stray light background noise.

After the system is designed and analyzed a stray light system test is performed. One does not just believe the analysis because computers assume a perfect system, a perfectly clean system, a perfectly and completely well-coated system whereas the system will not be ideal. Then why do the stray light analysis at all? Why not just test it? If it does not work, then it can be fixed. However, this approach is not as easy as it first sounds, if you do not know the propagation paths then you do not know what to fix. A trial-and-error approach can be very time consuming and very expensive. It would be unfortunate if you found out that the system was not at fault but that the stray light test was the culprit.

Two comments from experience. In about 20 different stray light system tests on real built systems the test

environment created a problem in 100% of the cases; no exceptions. In some cases the system to the pleasure of the designers exceeded performance goals but that was not correct, and several other times the system test indicated a failure when the failure was in the design of the chamber. It has gone both ways. Fortunately in most of the 20 cases the chamber was pre-evaluated first and a fix to the test procedure was made saving more time and money. In the other cases the program was halted until the fault in the chamber test was found via a stray light analysis. This happens often.

Table 7.4 gives a comparison between a stray light analysis and a system stray light test.

Every stray light analysis should be backed up with a stray light test. The chamber itself should have a performance analysis performed on it before it is used in any particular configuration. The two methods complement each other, the strengths of one cover the weaknesses of the other. Neither one alone should be considered sufficient.

7.5 Conclusion

During the process of the design and analysis of an optical system, it is necessary for the optical designer or engineer to consider many factors that will impact on the performance of the system in operation. These include the actual system design, usually defined using geometrical ray tracing, the effects of diffraction, manufacturing

and material limitations, as well as the effects of stray and scattered light. Software tools are available to help perform these tasks, but it is up to the engineer to understand the strengths and limitations of these programs and to insure that a complete analysis of the system is performed before committing the design to hardware.

8. Advanced Optical Components

This chapter describes a selection of advanced optical components including the underlying physical principles, production techniques and already existing or possible future applications.

Several of these optical elements, in particular variable lenses and photonic crystals, may replace conventional optical systems once their potential for applications has been fully explored. Other components such as high-quality optical fibres, though well established and used worldwide, still undergo a rapid further improvement and integration in communication systems.

Besides increased quality and versatility, a driving force and essential aspect in the development of optical components in general is low cost and mass production.

8.1 Diffractive Optical Elements

Today, the vast majority of optical instruments are based on refractive or reflective optical elements, most often restricted to a spherical shape. On the other hand, the demands on performance, volume and costs of optical imaging systems are increasing dramatically from one product generation to the next, so that the search for alternative design approaches is becoming increasingly important. Significant improvements of the optical performance of imaging systems can be achieved by the substitution of conventional refractive or reflective el-

ements with diffractive optical lenses. Especially, the extremely different dispersive characteristics of diffractive optical elements (DOEs), compared to refractive elements, offer more degrees of freedom in the lens design and allow an advantageous combination of both to form hybrid systems with optimized performance and compactness.

The possible use of the hybrid concept covers a broad application spectrum: in eyepieces the combination of diffractive and refractive optical components allows one to overcome limitations in eye relief, exit pupil, and field of view [8.1–5]. Closely related to eyepieces are head-mounted displays (HMDs), a micro-display application near to the eye, with challenging issues in high-quality ergonomics combined with high optical performance in a minimal volume [8.6–8]. Further application examples of the hybrid concept comprise high-quality camera lenses working over the whole visible spectrum [8.9], optical inspection systems for the semiconductor industry [8.10, 11], and high-resolution microscopy with solid immersion lenses [8.12]. Extremely challenging projects concern space telescopes based on lightweight diffractive lenses with diameters larger than 25 m [8.13, 14] enabling a high resolution observation necessary e.g. for extrasolar planet detection.

8.1.1 The Fresnel Zone Plate Lens

A simple approach to describe the basic principles of the focusing properties of an imaging DOE is based on the analysis of the Fresnel zone plate (FZP) (Fig. 8.1). The FZP is characterized by an axially symmetrical and concentric zone system of alternating opaque and transparent rings. Consider a monochromatic plane wave
Fig. 8.1 Schematic view of the concentric ring system of a Fresnel zone-plate lens illuminated with a plane wave. The convergent first three positive diffraction orders are shown. The optical path length of the light deflected from adjacent zones towards a common focal point differ by an integral multiple of the design wavelength

which is incident onto the FZP. In accordance with the Huygens–Fresnel principle, a common focal point is guaranteed, when the optical path length from two adjacent transparent rings differ by an integer multiple of the wavelength λ. The radius r_j of the j-th transparent ring and the focal length f are related by:

$$r_j^2 = 2j\lambda f + (j\lambda)^2 \ . \tag{8.1}$$

The term $(j\lambda)^2$, which represents spherical aberration, can be ignored in the paraxial approximation for low numerical aperture (NA):

$$r_j \cong \sqrt{2j\lambda f} \ . \tag{8.2}$$

The focal length in this case is determined by:

$$f = \frac{r_1^2}{2\lambda} \ . \tag{8.3}$$

The last relation shows that the focal length scales inversely with the wavelength, which expresses a strong chromatic effect.

In many cases it is of practical interest to express the imaging properties of an FZP such as focal length, numerical aperture, and lens diameter D in terms of wavelength and the fabrication relevant quantities. These involves the total number of periods N and the minimum spatial period $\Delta r = r_N - r_{N-1}$. The derivation [8.15] starts with (8.2) for the outer region of the FZP ($j \to N$) and subtracts as

$$r_N^2 - r_{N-1}^2 = 2\lambda f \ . \tag{8.4}$$

On the other hand when using the definition for Δr with the approximation $2r_N\Delta r \gg (\Delta r)^2$ one can write:

$$r_N^2 - (r_N - \Delta r)^2 \cong 2r_N\Delta r \ . \tag{8.5}$$

The combination of the last two equations results in:

$$D\Delta r \cong 2\lambda f \tag{8.6}$$

with a total lens diameter $D = 2r_N$.

Finally, with the relation $f = r_N^2/(2\lambda N)$ from (8.2) the lens diameter and focal length become:

$$D \cong 4N\Delta r \ , \tag{8.7}$$

$$f \cong 2\frac{N\Delta r^2}{\lambda} \tag{8.8}$$

These important relations show that the focal length of an FZP scales directly with the number of periods, with the square of the minimum period, and inversely with the wavelength. A further essential property of an imaging lens is the numerical aperture (NA), which is defined (in air) as $NA = \sin\theta$, where θ is half of the acceptance angle. From the geometry the NA of a zone plate is given by $NA = r_N/f = D/(2f)$ so that

$$NA \cong \frac{\lambda}{\Delta r} \qquad (8.9)$$

The numerical aperture of an imaging system plays an important role in the determination of both the lateral resolution Δd_{Rayl}, and the depth of focus or axial resolution, Δz. With the famous Rayleigh criterion for lateral resolution and the relation for the depth of focus one obtains:

$$\Delta d_{Rayl} = 0.61 \frac{\lambda}{NA} \cong 0.61\Delta r , \qquad (8.10)$$

$$\Delta z = \frac{1}{2}\frac{\lambda}{(NA)^2} \cong \frac{1}{2}\frac{\Delta r^2}{\lambda} , \qquad (8.11)$$

which means the minimum feature size is the fundamental property that determines the resolution of the FZP.

The mathematical approach of adding a path length difference of exactly one wavelength for constructive interference caused by two adjacent transparent rings in first order can be extended to higher orders ($m = 2, 3, \ldots$) by adding a path length difference of $m\lambda$, leading to the corresponding radius

$$r_{j,m} \cong \sqrt{2jm\lambda f_m} . \qquad (8.12)$$

This implies, in contrast to a conventional refractive lens, that an FZP causes multiple foci at distances of an integral fractions of the basic focal length

$$f_m = \frac{f}{m} . \qquad (8.13)$$

The negative orders correspond to virtual foci of negative focal length. In the case of a transmission grating of equal sizes of lines and spaces only the odd orders occur ($f/3, f/5, \ldots$). If the alternating opaque and transparent structure is replaced by a phase-only diffractive element the light intensity obtained at the focus is increased dramatically. In this so-called Fresnel phase plate the phase difference between neighboring zones is π (180°), which is equivalent to a depth difference of $\lambda/2(n-1)$.

Dispersion Properties of a DOE

An essential difference between imaging DOEs and refractive lenses is their chromatic behavior. The performance of refractive lenses depends on material dispersion. Generally optical materials, e.g., inorganic glasses, crystals or polymers, show normal dispersion, i.e., the refraction index $n(\lambda)$ decreases with wavelength. This means for a refractive lens that the focus corresponding to the blue wavelength is located closer to the lens than the focus of the red wavelength (Fig. 8.2a). Quantitatively this can be expressed by the Abbe number $\nu_{e(ref)}$, where the subscript defines the reference wavelength ($\lambda_e = 546.1$ nm, $\lambda_C = 656.3$ nm, $\lambda_F = 486.1$ nm)

$$\nu_{e(ref)} = \frac{n(\lambda_e) - 1}{n(\lambda_F) - n(\lambda_C)} . \qquad (8.14)$$

The Abbe number of inorganic glasses ranges from 20 for very dense flint glasses up to 90 for fluor-crown glasses. In contrast, the most prominent characteristic
Fig. 8.2a,b Chromatic dependency of refractive and diffractive lenses. The refractive lens (**a**) is characterized by normal dispersion with an increasing focal length for increasing wavelength. The diffractive lens (**b**) shows the reverse behavior, that means decreasing focal length for increasing wavelength

of an imaging DOE is the strong and reversed dispersion, which results in a decreasing focal length with increasing wavelength (Fig. 8.2b). This characteristic can be expressed by an effective Abbe number $\nu_{e(diff)}$ for a diffractive lens, which is determined by the ratio of the wavelengths

$$\nu_{e(diff)} = \frac{\lambda_e}{\lambda_F - \lambda_C} = -3.21 \; . \tag{8.15}$$

Note, the Abbe number of an imaging DOE does not depend on the material or shape of the element but is only related to the application wavelength band.

For applications covering a broad optical spectrum chromatic aberrations are one of the most important factors limiting the optical performance. An elimination of the chromatic aberration for two selected wavelengths can be realized by combining lenses to an achromatic doublet with adapted dispersion properties and optical powers. The optical power of a lens ϕ is the reciprocal of the focal length f ($\phi = 1/f$). When the components of that achromat are in close contact, e.g., cemented or integrated elements, the relevant design equations are the achromatic condition

$$\frac{\phi_1}{\nu_1} + \frac{\phi_2}{\nu_2} = 0 \tag{8.16}$$

and the sum condition for the overall optical power ϕ of the final lens

$$\phi_1 + \phi_2 = \phi \; . \tag{8.17}$$

Here ϕ_1 and ϕ_2 are the values of the optical power of the single elements, and ν_1 and ν_2 are the associated Abbe numbers. The last two conditions allow one to calculate the optical power of the individual elements when the optical power of the final lens is given.

To fulfill the conditions (8.16) and (8.17) in a conventional all-refractive achromatic doublet it is necessary to combine lenses of both positive and negative optical power, which results in a partial compensation (Fig. 8.3a).

In contrast, due to the negative Abbe number of a DOE, a hybrid doublet combines diffractive and refractive components with optical power equal in sign (Fig. 8.3b). This implies that the optical power of each element is less than the total power, which allows a considerable reduction in the amount of material required and also a reduction of the weight and volume of the lens.
Fig. 8.3a,b Schematic view of achromatic lens elements. The refractive approach **(a)** combines positive and negative lens elements fabricated of different materials. In the hybrid diffractive/refractive solution **(b)** a monolithic design is possible

Achromatization with respect to two wavelengths does not allow a complete removal of the color error. The remaining chromatic aberration is known as the secondary spectrum, which tends to be more prominent for hybrid achromats than for all-refractive combinations [8.16]. A reduction of the secondary spectrum – apochromatic correction – could be achieved in the conventional approach by the introduction of a three-lens design, or alternatively in the hybrid approach by combing a single hybrid element with a refractive lens.

Diffraction Efficiency – Efficiency Achromatization

In a diffractive lens, the local grating period determines the direction of the deflected light for the various diffraction orders but it allows no prediction about the amount of light focused into the particular diffractive order. The latter is described by the diffraction efficiency η, which is strongly dependent on the nature of the periodic structure, e.g., geometry and material selection.

As a first example, the efficiency of a simple transmission binary phase grating with equal dimensions of lines and spaces can be calculated for the m-th diffraction order by:

$$\eta_{m,\text{binary,phase}} = \begin{cases} \left(\frac{2}{m\pi}\right)^2 & m \quad \text{odd}, \\ 0 & m \quad \text{even}. \end{cases} \tag{8.18}$$

In Fig. 8.4 the efficiencies for each of the diffraction orders are listed. The exact equivalence of lines and spaces guarantees the suppression of all nonzero even orders, and the phase depth of π results in destructive interference for the zeroth order.

To increase the diffraction efficiency for a selected diffraction order it is necessary to leave symmetric surface relief structures. Here, due to the advantageous realization possibilities, multilevel surface relief gratings are of enormous importance. These stepped gratings can be generated by projection photolithography using several binary masks and subsequent etching processes. When all steps of the N-level structure are of equal height then the number of processing steps can be reduced to $\log_2 N$. The first-order diffraction efficiency of these multilevel structures are given by

$$\eta_{1,N} = \text{sinc}^2\left(\frac{1}{N}\right), \tag{8.19}$$

where

$$\text{sinc}(x) = \frac{\sin(\pi x)}{\pi x}. \tag{8.20}$$

Figure 8.5 shows the calculated efficiencies with the corresponding profile depths d_N for $N = 2$, 4, 8 and 16 phase levels. The strong increase of the diffraction efficiency with increasing phase levels is clearly observable. Note that the total profile depth d_N of the multilevel structure is also increasing with the number of phase levels N, which can be expressed with the relation

$$d_N = \frac{N-1}{N} \frac{\lambda}{n-1}. \tag{8.21}$$

It has to be mentioned that in practice fabrication errors such as etch depth errors and mask-to-mask misalignment result in reduced diffraction efficiencies.

With an increasing number of phase levels, the shape of the multilevel surface relief approaches the geometry of a sawtooth profile. Following the scalar theory, which is valid for grating periods much larger than the wavelength, the sawtooth profile of a blazed diffraction grating possesses the most favorable profile geometry.
Fig. 8.4 Representation of a simple binary phase grating with the corresponding diffraction orders. In the table the efficiencies in dependence on the diffraction orders are listed. The fill factor of 50% guarantees the suppression of all the nonzero even orders, and the phase depth of π is responsible for zero diffraction efficiency into the zero order

Orders	Efficiency (%)
0	0
+1, −1	40.5
+3, −3	4.5
+5, −5	1.6
>+7, −7	3.4

The efficiency η_m in the desired order m for an ideal blazed profile is expressed by [8.17, 18]:

$$\eta_m(\lambda) = \text{sinc}^2(\alpha - m), \tag{8.22}$$

where

$$\alpha = d[n(\lambda) - 1]\frac{1}{\lambda}. \tag{8.23}$$

These equations imply that 100% of the light ($\eta = 1$) will be diffracted into a specific diffraction order m if the denominator of the sinc-function is zero. For a given design wavelength λ_0 and design order $m = 1$

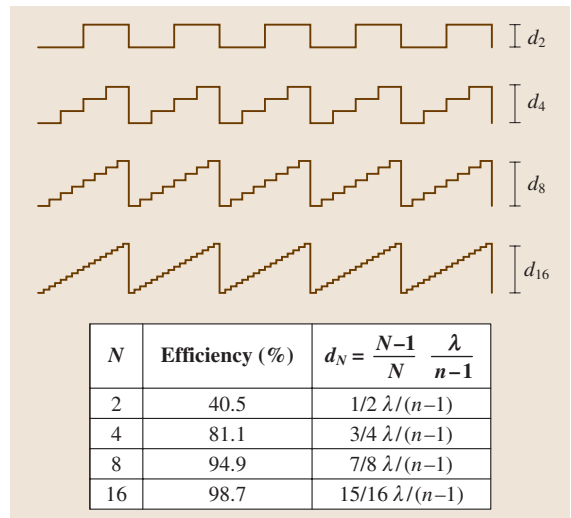
N	Efficiency (%)	$d_N = \dfrac{N-1}{N}\dfrac{\lambda}{n-1}$
2	40.5	$1/2\,\lambda/(n-1)$
4	81.1	$3/4\,\lambda/(n-1)$
8	94.9	$7/8\,\lambda/(n-1)$
16	98.7	$15/16\,\lambda/(n-1)$


Fig. 8.5 Multilevel gratings with 2, 4, 8, and 16 steps. With increasing step number the profile approximates the ideal blazed grating. The first-order diffraction efficiencies with the corresponding profile depths are given in the table
Fig. 8.6 Simple single-layer blazed grating with the interface to air. The diagram shows the calculated scalar diffraction efficiency for the diffracted orders $m = 0$, 1, and 2 and a design wavelength $\lambda_0 = 550\,\text{nm}$ (material: inorganic glass SSK3). The 100% maximum efficiency at the design wavelength slowly decays across the visible spectrum, where it is partly diffracted into the other orders

Fig. 8.7 Schematic view of an NIM DOE with two materials in direct contact at the diffractive interface. The diffraction efficiency was calculated for the combination of SSK3 and polystyrene. The design wavelength is 550 nm and the profile depth 24 μm. The efficiency is nearly 100% over a broad spectral range

the maximum efficiency needs an adjusted profile depth d of:

$$d = \frac{\lambda_0}{n(\lambda_0) - 1} . \tag{8.24}$$

Following (8.22), the calculated efficiencies as a function of the wavelength are shown in Fig. 8.6 for the diffracted orders $m = 0$, 1, and 2 and a design wavelength of $\lambda_0 = 550\,\text{nm}$. Exemplary curves are calculated with the material parameters of the inorganic glass SSK3. The 100% maximum efficiency at the design wavelength slowly decays across the visible spectrum, where it is partly diffracted into the other orders. Nearly all of the energy within the visible spectral band is diffracted into the three orders shown.

This efficiency behavior has a dominant impact on the quality of diffractive or hybrid optical systems. On the one hand, due to the varying efficiency, the images are not generated in true colors and additionally the light transmitted into the zeroth order or into the higher non-design orders may add to the background illumination,

reducing the image contrast. For that reason it becomes an attractive aim to find solutions for diffractive structures which allow a high efficiency (close to 100%) over a broad spectral bandwidth.

Nearly index-matched (NIM) elements [8.19] form one DOE type which show the capability of efficiency achromatization. These NIM-DOEs consist of a diffractive structure with large profile depth, separating two materials characterized by a small difference in their refractive index (Fig. 8.7). Compared to diffractive structures with an interface to air, the NIM concept has the advantage of reduced tolerances on profile depth and surface roughness.

The efficiency as a function of wavelength for this two-media approach shows a similar dependency compared to the previous situation with the interface to air. The important modification is the introduction of the refractive index of the second material

$$\eta_{\text{NIM}}(\lambda) = \text{sinc}^2 \left\{ d_{\text{NIM}} [n_1(\lambda) - n_2(\lambda)] \frac{1}{\lambda} - 1 \right\} . \tag{8.25}$$

Also in this case the profile depth d_{NIM} has to be related to a design wavelength λ_0

$$d_{\text{NIM}} = \frac{\lambda_0}{n_1(\lambda_0) - n_2(\lambda_0)} \ . \tag{8.26}$$

Due to the small difference in the refractive indices of both materials the adapted profile depth requires values in the range of some tens of microns.

In Fig. 8.7 the calculated functional form of the efficiency for this two-media system is shown exemplarily for the glass–polymer configuration of SSK3 and polystyrene (PS). The design wavelength was set to 550 nm, which corresponds to a profile depth of 24 μm. It is clearly observable that the efficiency is nearly 100% over a broad spectral range. A significant reduction occur only below 450 nm. Also remarkable is the asymmetric behavior over the visible spectral range.

From the equations above it follows that in the NIM configuration the dispersion of the two materials must be such that the change of the refractive index, Δn, at the interface remains proportional to λ or

$$\frac{\lambda}{\Delta n(\lambda)} = \text{const} \ . \tag{8.27}$$

This constraint limits the choice of possible material combinations. Furthermore, the material restriction becomes more significant with varying temperature, because dn/dT often differs significantly for the two materials. The need for a large profile depth and a practicable aspect ratio in the fabrication process restrict the minimum zone width of the diffractive structure and therefore limits the diffractive optical power of the NIM-DOEs.

A second approach to realize DOEs with achromatized efficiency uses a multilayer combination of diffractive structures separated by an additional air gap [8.20, 21]. Due to the additional degrees of freedom, the above mentioned constraints on the dispersion properties of the materials are removed.

In one type of multilayer configuration, two single-layer DOE structures are arranged to face each other and are separated by an air gap of a few microns. The two single-layer DOEs are formed to have equal grating pitches but differ in grating heights (d_1, d_2) and in material parameters (n_1, n_2)(Fig. 8.8 top). In the scalar approximation, the efficiency takes the form

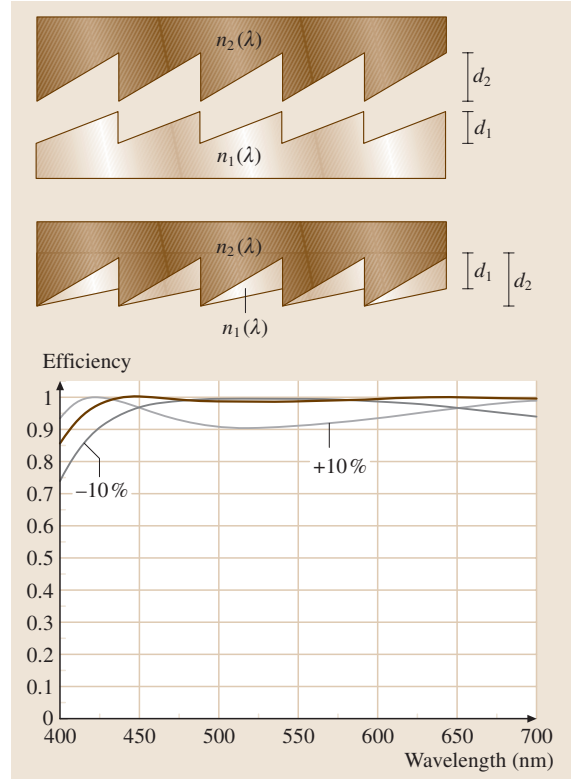
$$\eta_{\text{double layer}}(\lambda)$$
$$= \text{sinc}^2 \left\{ d_1[n_1(\lambda) - 1]\frac{1}{\lambda} - d_2[n_2(\lambda) - 1]\frac{1}{\lambda} - 1 \right\} \ . \tag{8.28}$$


Fig. 8.8 Concepts for multilayer DOEs: *top* – two diffractive structures realized in different media with separating air gap; *center* – diffractive structures in direct contact, air gap moved to the exterior. *Bottom* – calculated diffraction efficiencies for optimum profile depths (*black curve*) and ± 10% deviation from ideal profile depths (*grey curves*)

This equation implies the condition for high diffraction efficiency:

$$d_1 \frac{n_1(\lambda) - 1}{\lambda} - d_2 \frac{n_2(\lambda) - 1}{\lambda} = 1 \ . \tag{8.29}$$

That means, a proper selection of layer materials and corresponding profile depths allows to keep this condition valid over a broad spectral range and therefore guarantees an efficiency achromatization.

Figure 8.8 (bottom) shows the efficiency curve (black) for a double layer system made of an inorganic glass (LLF6; n_{LLF6} (550 nm) = 1.53404, $v_{\text{e,LLF6}} = 50$) and a transparent resin with n_{res}(550 nm) = 1.662 and $v_{\text{e,resin}} = 22$. The optical values of both materials are comparable to the ones discussed in [8.22]. From the design wavelengths $\lambda_{01} = 450$ nm and $\lambda_{02} = 650$ nm

the profile depths were calculated to be $d_1 = 7.26\,\mu\text{m}$ and $d_2 = 4.97\,\mu\text{m}$.

All over the visible spectral range the efficiency is nearly 100%. A slight decay can be recognized below 430 nm.

Additionally Fig. 8.8 contains two efficiency curves assuming both, a positive and a negative 10% deviation from the ideal profile depths. In both cases the efficiency is above 90%. That means, the efficiency achromatization works well, also when the profile depths are not realized in the design optimum.

In an alternative multilayer configuration both materials which form the diffractive structures are in direct contact and the air gap is moved to the exterior of the structure [8.23] (Fig. 8.8 center). The choice of best layer configuration also depends upon polarization-dependent Fresnel losses and fabrication constraints.

The multilayer concept has recently been introduced in consumer camera lenses [8.24]. Compared to a classical dioptric lens design of the same specifications and performance, it was possible to reduce both the overall length by 27% and the weight by 31%.

Athermalization of Diffractive/Refractive Hybrid Lenses

Strong temperature variations may also effect the image-forming properties of optical systems. For example, this concerns high-volume consumer optics based on polymers, and also aerospace and military applications using infrared optical materials. For both application fields, the demands for operating temperature ranges covering 80 °C to 100 °C are not unusual. To describe the influence of temperature variations on the individual optical elements the optothermal expansion coefficient x_f was defined. This parameter relates the change in focal length f of a lens to a change in temperature.

For refractive lenses, the influence of temperature on the optical performance is dependent on two effects. Firstly, the thermal expansion of the lens material changes its geometry, and secondly the refractive index is a function of the environmental temperature [8.25]. For a thin refractive lens, the optothermal expansion coefficient $x_{f,\text{ref}}$ is given by:

$$x_{f,\text{ref}} = \frac{1}{f}\frac{\mathrm{d}f}{\mathrm{d}T} = \alpha_{\mathrm{g}} - \frac{1}{n - n_0}\left(\frac{\mathrm{d}n}{\mathrm{d}T} - n\frac{\mathrm{d}n_0}{\mathrm{d}T}\right), \tag{8.30}$$

where α_{g} is the linear thermal expansion coefficient, n is the refractive index of the lens material and n_0 is the refractive index of the image space. $\mathrm{d}n/\mathrm{d}T$ and $\mathrm{d}n_0/\mathrm{d}T$ express the change of refractive index with the temperature of the lens material and the image space, respectively. The change in focal length is given by

$$\Delta f = f x_{f,\text{ref}} \Delta T . \tag{8.31}$$

In analogy to the previous, for diffractive lenses in the paraxial approximation, it is also possible to derive an optothermal expansion coefficient $x_{f,\text{diff}}$. In this case, the characteristics of $x_{f,\text{diff}}$ are attributed to the expansion or contraction of the zone spacing by temperature variation and also to the change of the refractive index of the image space with temperature [8.26–29]. This dependency is expressed by:

$$x_{f,\text{diff}} = 2\alpha_{\mathrm{g}} + \frac{1}{n_0}\frac{\mathrm{d}n_0}{\mathrm{d}T} . \tag{8.32}$$

Here, it is of particular importance that there is no dependence on the refractive index change of the lens material. This is an essential difference between the thermal characteristics of refractive and diffractive lenses.

Investigations on the influence of temperature variations on the diffraction efficiency show an negligible effect [8.26]. Both variations of the profile height and changes in the refractive index of the material of the diffractive structure make no significant impact to the efficiency.

The comparison of refractive and diffractive elements for selected materials shows different characteristics and quantities in the optothermal expansion coefficients. In Table 8.1 some values for inorganic glasses, optical polymers and infrared materials are listed. The parameters for the inorganic glasses were taken from the Schott glass catalog with the reference wavelength of 546.1 nm (e-line). The change in index of the lens material relative to the change in index of air is related to the temperature range between $+20 - +40$ °C. The linear thermal expansion coefficient is indicated for a temperature interval of $-30 - +70$ °C. The parameters of the polymers polymethylmethacrylate (PMMA), polycarbonate (PC), polystyrene (PS) and cyclic olefin copolymer (COC) with the reference wavelength 589 nm were taken from [8.30]. The parameters for cyclic olefin polymer (COP) are related to [8.31]. Due to their very low water absorption in comparison to conventional polymers, both COC and COP became attractive materials for molded polymer optics. The quantities of the infrared materials silicon and germanium were calculated after [8.25].

The optothermal expansion coefficients for refractive lenses cover a wide range of values, with both positive and negative sign, depending on the magnitude

of the thermal expansion coefficients and the variation of the refractive index with temperature. On the other hand, the optothermal expansion coefficients for diffractive lenses cover a smaller range and are dominated by the thermal expansion coefficients, which always assume positive quantities.

Comparable to the procedure to design achromatic lens doublets, it is also feasible to combine two optical elements to compensate the temperature dependencies of both. This method and the elements are called athermalization and athermats, respectively. In an all-refractive setup, it is necessary to use lens elements made of two different materials for athermalization. The alternative hybrid approach takes the advantage of the different values of optothermal coefficients for diffractive and refractive lenses made of the same material. This means that the realization of a hybrid athermat is possible, which offers advantages in reduced volume and weight compared to the all-refractive solution.

The total lens power of a hybrid athermat ϕ_{net} is the sum of the individual powers ϕ_{ref} and ϕ_{diff}

$$\phi_{\mathrm{net}} = \phi_{\mathrm{ref}} + \phi_{\mathrm{diff}} \ . \tag{8.33}$$

The optothermal expansion coefficient for the doublet $x_{f,\mathrm{net}}$ is given by

$$x_{f,\mathrm{net}} = x_{f,\mathrm{ref}} \frac{\phi_{\mathrm{ref}}}{\phi_{\mathrm{net}}} + x_{f,\mathrm{diff}} \frac{\phi_{\mathrm{diff}}}{\phi_{\mathrm{net}}} \ . \tag{8.34}$$

These equations allow one to calculate the contributions of the diffractive and the refractive parts of a lens

system when the total optical power is given. In order to realize a hybrid athermat with exclusively positive values for x_{ref} and x_{diff}, it is necessary to combine a positive and a negative lens element which partly compensate for each other in the optical power. Choosing a lens material with an opposite sign for x_{ref} and x_{diff} it is possible to combine lens elements with both positive or negative contributions so that their optical power is added and a more compact design can be realized.

8.1.2 Subwavelength Structured Elements

When light is incident on a surface-relief grating with period Λ the angles of the transmitted diffraction waves $\theta_{\mathrm{t},m}$ in the m-th diffraction order are given by the grating equation:

$$\sin\theta_{\mathrm{t},m} = \frac{m\lambda}{\Lambda n_2} + \frac{n_1}{n_2}\sin\theta_{\mathrm{i}} \ . \tag{8.35}$$

Here n_1 and n_2 are the refraction indices of the incident and the transmitting medium, respectively, θ_{i} is the incidence angle as measured from the grating's surface normal, and λ is the incident free-space wavelength.

If the period of the diffraction grating becomes much smaller than the optical wavelength λ, we find that only the zeroth order is allowed to propagate and all the other orders are evanescent

$$\Lambda \ll \lambda \rightarrow m = 0 \ . \tag{8.36}$$
Fig. 8.9 Illustration of different diffractive subwavelength structures and their thin-film equivalents from effective medium theory

The subwavelength-structured interface is optically equivalent to an unstructured film whose optical properties vary with profile depth. The substitution of an effective material for a high-frequency grating allows its description by effective medium theory (EMT). The effective index of refraction can be tailored to a chosen quantity by adjusting the fill factor of the grating structure. Figure 8.9 shows selected geometries of subwavelength structures and the corresponding index of refraction profiles resulting from EMT. A simple binary subwavelength grating translates into a single layer with a refractive index n_{eff} between n_1 and n_2 which is dependent on the fill factor. In the case of a multilevel surface relief profile the effective medium is a film stack where each layer corresponds to a distinct level of the surface relief profile. A triangular subwavelength grating is equivalent to a graded index-modulated surface in which the refractive index is converted from the incident medium to the substrate.

These effective media are also discussed in terms of artificial dielectrics because the subwavelength structures allow access to material properties that normally do not exist in inorganic glasses or optical polymers. The characteristics of the effective media offer a wide variety of applications and the realization of different components such as wave plates [8.32–34], antireflection surfaces [8.35–39], polarization sensitive elements [8.40–44] or blazed gratings and lenses [8.45–49].

Wave Plates

Wave plates are optical components to control the polarization of the electric field vector. For example a $\lambda/4$ wave plate is often used to convert linearly polarized light into circularly polarized light or vice versa and a $\lambda/2$ wave plate is commonly introduced to cause a rotation of linearly polarized light by 90°. The control mechanism of the wave plates is based on the different phase velocities for corresponding polarization directions in an anisotropic medium. Conventional wave plates are made of anisotropic birefringent materials such as calcite, quartz or mica.

An alternative type of wave plate can be realized by the form birefringence of subwavelength structures [8.50]. Here different indices of refraction for orthogonal polarization directions are correlated to the variation of the fill factors with the direction. In the following the basic principal of that kind of form birefringence will be discussed by analyzing the binary and lamellar relief structure of Fig. 8.9. Let ε_1 be the dielectric constant of the covering medium (spaces) and ε_2 the dielectric constant of the lamella material (lines). Further, consider a plane monochromatic wave which is incident on the zeroth-order grating and assume an electric field vector which is perpendicular to the lamellas. Following the boundary conditions of Maxwell's equations the normal component of the electric displacement D must be continuous across the interface between the lines and spaces so that for the corresponding electric fields E_1 and E_2 follows

$$E_1 = \frac{D}{\varepsilon_1}, \quad E_2 = \frac{D}{\varepsilon_2}. \tag{8.37}$$

A volume averaging of the electric field E leads to the effective dielectric constant $\varepsilon_\perp^{(0)}(= D/E)$

$$\varepsilon_\perp^{(0)} = \frac{\varepsilon_1\varepsilon_2}{\varepsilon_1 f + \varepsilon_2(1-f)}, \tag{8.38}$$

where the ratio $f = W/\Lambda$ represents the volume fraction or fill factor of the grating (W is the width of a single grating bar).

On the other hand, when the incident field has its electric field vector parallel to the lamellas then the tan-

gential component of the electric vector is continuous across the discontinuity and for the electric displacements in the two regions it follows that

$$\boldsymbol{D}_1 = \boldsymbol{E}\,\varepsilon_1, \quad \boldsymbol{D}_2 = \boldsymbol{E}\,\varepsilon_2 . \tag{8.39}$$

The averaging of the electric displacement $\boldsymbol{D}$ now leads to an effective dielectric constant $\varepsilon_{\parallel}^{(0)}$

$$\varepsilon_{\parallel}^{(0)} = \varepsilon_2 f + \varepsilon_1 (1 - f) . \tag{8.40}$$

With the refractive index $n = \sqrt{\varepsilon}$ we find a form birefringence of the subwavelength grating

$$\Delta n = \sqrt{\varepsilon_{\parallel}^{(0)}} - \sqrt{\varepsilon_{\perp}^{(0)}} . \tag{8.41}$$

For an incident wave normal to the grating and polarized at 45° with respect to the grating orientation, the phase retardation ϕ caused by a grating with relief depth h is

$$\phi = \frac{2\pi}{\lambda} \Delta n h . \tag{8.42}$$

The subscript (0) in the presented formulas for $\varepsilon_{\perp}^{(0)}$ and $\varepsilon_{\parallel}^{(0)}$ indicates a zeroth-order approximation with respect to the profile period-to-wavelength ratio Λ/λ. To obtain higher-order approximations in Λ/λ for the effective optical properties, it is necessary to analyze the field distributions in a nonstatic manner [8.51]. Following this approach the second-order expression in terms of the ratio Λ/λ for the effective dielectric constants are represented for both polarization directions by

$$\varepsilon_{\parallel}^{(2)} = \varepsilon_{\parallel}^{(0)} \left[1 + \frac{\pi^2}{3} \left(\frac{\Lambda}{\lambda} \right)^2 f^2 (1-f)^2 \frac{(\varepsilon_2 - \varepsilon_1)^2}{\varepsilon_0 \varepsilon_{\parallel}^{(0)}} \right] , \tag{8.43}$$

$$\varepsilon_{\perp}^{(2)} = \varepsilon_{\perp}^{(0)} \left[1 + \frac{\pi^2}{3} \left(\frac{\Lambda}{\lambda} \right)^2 f^2 (1-f)^2 \right.$$
$$\left. \times (\varepsilon_2 - \varepsilon_1)^2 \frac{\varepsilon_{\parallel}^{(0)}}{\varepsilon_0} \left(\frac{\varepsilon_{\perp}^{(0)}}{\varepsilon_1 \varepsilon_2} \right)^2 \right] . \tag{8.44}$$

Figure 8.10 shows the effective index of refraction as a function of the fill factor for different polarization directions calculated with both the zeroth- and second-order approach. Additionally, as an exact but time-consuming benchmark, the fully vector electro-
Fig. 8.10 Effective index of refraction as a function of the fill factor for different polarization directions calculated with the zero- and second-order EMT. Additionally RCWA was applied

magnetic method of rigorous coupled wave analysis (RCWA) has also been applied to investigate the accuracy of both approaches. For this diagram the incident medium was taken to be air ($n_1 = 1$), the substrate medium has a refractive index of $n_2 = 1.49$ and the period-to-wavelength ratio was set to be $\Lambda/\lambda = 1/3$.

In all three cases the deviation between the orthogonal polarization directions becomes significant in the central region where the dimensions of lines and spaces are similar. In the peripheral regions, where either the lamellas or the spaces become small compared to the grating period, the effective refractive indices reach the limiting values of the homogeneous substrate or air. Within the three methods, the second-order approximation and the RCWA results are broadly correspondent, while the values calculated with the zeroth-order ap-
Fig. 8.11 Schematic view of a binary 2-D effective medium

proximation are too small and therefore less suitable for accurate predictions.

Subwavelength structures which are periodic in two dimensions (2-D) show a polarization sensitivity that is dependent on the fill factor (L_x/Λ_x, L_y/Λ_y) and periodicity (Λ_x, Λ_y) in the orthogonal directions. A schematic view of such a 2-D structure is depicted in Fig. 8.11. It consists of an array of dielectric homogeneous pillars with a rectangular cross section periodically immersed in a second dielectric medium. In the totally symmetric case the periods and the widths of the pillars are identical in both dimensions which results in polarization insensitivity and a symmetry in the effective permittivity.

Instead of a corresponding EMT for the 2-D structures, several different approximations have been developed and compared to RCWA calculations [8.38, 39, 52]. The various approximations are based on different averaging procedures assuming that the effective permittivity of a 2-D structure is somewhere between the values for the orthogonal one-dimensional (1-D) structures. It has to be mentioned that a simple volume averaging is insufficient, but to get a more accurate result a complex consideration has to be carried out. In an exemplary extended averaging procedure the periodic binary rectangular structure is replaced by two different orthogonal one-dimensional structures. Here the permittivities of the two corresponding one-dimensional grating bars are set to be $\varepsilon_\perp$ and $\varepsilon_\parallel$, as calculated from the permittivity of the pillars [8.39].

Although 2-D effective-medium approximations show an acceptable validity especially in the long-wavelength limit, today increasingly rigorous design methods are applied. Here the further development in computing hardware and software reduces time and storage issues.

Antireflection Gratings

The reduction of Fresnel reflections at optical interfaces is an issue of enormous interest in a wide range of optical applications. Today antireflection (AR) coatings are most frequently based on multilayer interference structures with alternating high and low refractive indices. An alternative to the multilayer films are subwavelength structured antireflection surfaces, which provide a graded transition between the refractive indices of the two interfacing media. Such antireflective structures are also found in nature on the corneal surfaces of night-active insects [8.35, 53]. For example Fig. 8.12 shows scanning electron microscope images of a typical moth eye. In the upper image the hexagonal array of the facets of the compound eye is clearly visible. With increasing magnification (lower part) an area covered with conical and uniform protuberances is observable. The diameter of each protuberance is about 100 nm and the spatial periodicity is approximately 170 nm, well below the wavelength of the visible spectrum.

Different characteristics of subwavelength AR structures are advantageous compared to stacks of thin dielectric films, e.g., thin-film coatings may suffer from adhesion problems especially when the thermal expansion coefficients of substrate and layer material are different and the optical devices are used over a broad thermal range. Additionally, due to the restrictions in thin-film coating materials, the available number of discrete refractive indices is also limited. A further aspect concerns the sensitivity of the reflectance to incident angle or wavelength. Here, in general, a subwavelength AR structure tolerates more variations compared to simple layer configurations.

A binary pillar subwavelength structure (Fig. 8.9 top) shows an antireflection performance comparable to that achieved by an elementary single-layer dielectric coating. Following thin-film theory a single layer will exhibit minimum reflectivity at normal incidence when the reflectance from the air–film interface interferes destruc-
Fig. 8.12 Scanning electron microscopy images of a night-active insect. The upper part shows the hexagonal structure of the compound eye. With increased magnification (*bottom*) a subwavelength periodic surface corrugation becomes visible (courtesy of Prof. J. Spatz)

tively with the reflection at the film–substrate interface. This phase condition is fulfilled when the depth of the profile h satisfies

$$h = \frac{\lambda_0}{4n_{\mathrm{Layer}}} . \tag{8.45}$$

Additionally, complete destruction will only occur if the amplitudes of both reflecting waves are identical, which implies an amplitude condition for the refractive index of the layer n_{Layer}

$$n_{\mathrm{Layer}} = \sqrt{n_1 \cdot n_2} . \tag{8.46}$$

Exemplary, to fulfill the last equation for the interface between air ($n_{\mathrm{air}} = 1$) and a typical inorganic glass (assumption $n_{\mathrm{g}} = 1.5$) the refractive index of the layer has to be $n_{\mathrm{Layer}} \approx 1.22$ which is not available for thin-film materials. On the other hand, subwavelength structured effective media have the ability to control the effective index of refraction by simply adjusting the fill factor so that in principal each value is possible.

An extension to the single-layer equivalent binary subwavelength grating with improved optical performance is offered by the introduction of a multilevel stair-step surface relief (Fig. 8.9 center). A stair-step multilevel grating consisting of N steps shows similar optical characteristics compared to a traditional thin-film coating of N homogeneous layers. The optical properties of each individual layer are mainly dependent on the particular fill factor. In comparison to simple binary subwavelength gratings, the multilevel stair-step grating permits a large wavelength bandpass and is more tolerant against variations in the angle of incidence [8.54]. For triangular structured surface profiles (Fig. 8.9 bottom) the effective medium has gradient optical properties. By proper design of such surfaces extremely low reflectances can result [8.55].

Different techniques such as e-beam writing and mask-lithography [8.56] have been applied to realize master structures of subwavelength gratings. Among them, interference lithography (IL) has the advantage of allowing the realization of the complete array in a single exposure step over a large area. In the IL process, a photoresist-coated substrate is exposed with an interference fringe pattern generated by coherent beams [8.36, 57], where the grating period Λ is given by

$$\Lambda = \frac{\lambda}{2n \sin \theta} . \tag{8.47}$$

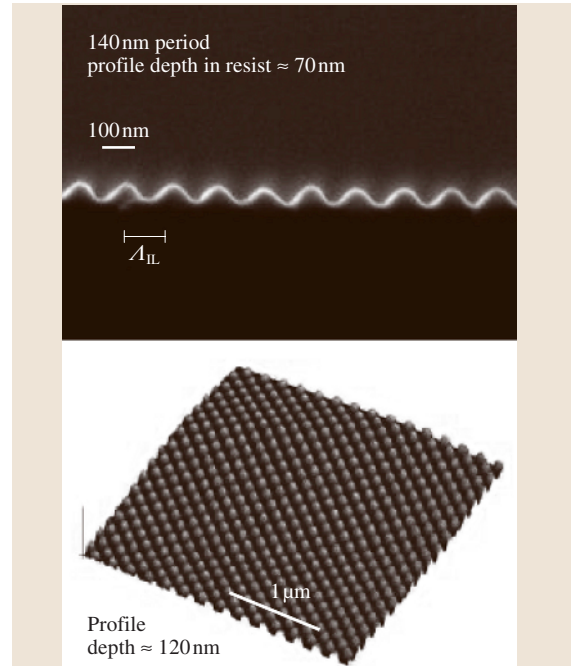
Here λ is the exposure wavelength, n is the refractive index, and θ is the half-angle between the interfering


Fig. 8.13 *Moth eye* surfaces generated by interference lithography (IL)

light waves under the condition of symmetric incidence. In air, the minimal obtainable grating period using counter-propagating waves ($\theta = 90°$) is therefore $\lambda/2$. To realize a periodic 2-D structure double- or multiple-exposure techniques are necessary with a defined rotation of the sample between the single exposure steps. During the recording process, a latent structure is created in the resist, which is transformed into a continuous surface phase profile in the subsequent development process. After the development process a stabilization of the pattern structure and an adjustment of the profile depth can be realized by selective reactive ion beam etching.

At the top of Fig. 8.13 a scanning electron microscope image of a linear photoresist grating is presented in side view. The sinusoidal corrugation shows a period of 140 nm and a depth of 70 nm. The identical spatial period in a two-dimensional pattern is obtained by double exposure and rotation of the sample by 90° [atomic force microscope (AFM) scan at the bottom of Fig. 8.13].

The structures were realized by the use of a frequency-quadrupled Nd-YAG laser with 266 nm wavelength. Deep-UV interference lithography requires additional process steps including pre- or soft-bake and post-exposure bake. Soft bake is necessary for solvent removal, stress reduction and resist planarization. The
Fig. 8.14 Measured transmission in dependence on the wavelength for three samples of subwavelength crossed gratings in fused silica. The depth of the structure is 300 nm and the diameter of the pillars is about 85 nm. In comparison to an unstructured surface, the transmission is increased significantly across a broad spectral range in the VIS

process of post-exposure bake is an essential, critical and indispensable step to guarantee solubility of the optical exposed areas of these chemical amplified photoresists. These technological procedures have to be performed very carefully to ensure constant conditions and to obtain reproducible and defined profile parameters.

Figure 8.14 shows the measured transmission as a function of the wavelength of three samples of subwavelength crossed gratings. The profile was transferred into fused silica by a reactive-ion etching process. Here the depth of the etched structure is 300 nm and the diameter of the pillars is about 85 nm. In comparison to an unstructured surface, the transmission is increased significantly across a broad spectral range in the visible spectrum.

Using immersion configurations in the IL process allows a further reduction of feature sizes. In the accom-
Fig. 8.15 Scanning electron microscope images of gratings with periods of 93 nm (10 800 1/mm). The gratings were obtained by single (*left*) and double (*right*) exposure technique using 266 nm immersion lithography

panying exposure setup the photoresist-coated substrate is typically sandwiched between UV-transparent prisms using an immersion liquid with a matched refractive index. The minimal period is decreased by a factor given by the refractive index of the immersion medium. The scanning electron microscope images presented in Fig. 8.15 show patterns with a grating period of 93 nm (10 800 lines/mm) which were obtained by single (left) or double (right) exposure using 266 nm immersion lithography. This structures are developed to serve as AR coatings for deep-UV applications.

Polarization–Sensitive Elements

Historically, the wire-grid polarizer (WGP) was perhaps the first component to make use of the properties of subwavelength structured gratings as it was applied by Heinrich Hertz to investigate the properties of the newly discovered radio waves at the end of the 19-th century. Meanwhile, with constant progress in manufacturing technologies, the wire-grid polarizer is also available for the infrared and the optical wavelength region as well.

The classical WGP consists of a subwavelength periodic grid of parallel, self-supporting and perfectly conducting wires. This structure is characterized by a high reflectivity of transverse electric (TE) polarization and simultaneously a high transmittance of the transverse magnetic (TM) polarization of the incident electromagnetic radiation.

For applications in the visible spectral range WGPs are realized as subwavelength-period metal gratings deposited on a dielectric substrate. The introduction of additional dielectric layers sandwiched between the metal grid and the supporting substrate allows the adjustment of the spectral operation bandwidth and to relax the tolerances of the acceptance angle [8.58]. A further extension to control the polarization properties of the WGP is possible when the subwavelength-period grating is already formed in the dielectric medium and the metal stripes are supported on the dielectric bars.

Due to their specific optical characteristics and the compactness, WGPs became of particular interest in projection display applications especially when combined with liquid crystal on silicon (LCoS) imager systems [8.59, 60]. In these setups, the WGP acts as a beam splitter, separating the incoming illumination radiation and the back-reflected and polarization-rotated light coming from the LCoS panel.

Commonly the working principal of the WGP is explained by the dissimilar electron mobility parallel and perpendicular to the metal wires. If the incident wave is polarized along the wire direction, a corresponding elec-
Fig. 8.16a–c Illustration of (**a**) blazed sawtooth profile, (**b**) blazed index and (**c**) blazed binary gratings

Fig. 8.17a,b Schematic comparison of diffractive lenses: (**a**) surface relief profile; (**b**) blazed binary approach

tron oscillation is induced. The reradiated wave cancels the incident wave in the forward direction, so that the wave is totally reflected. In contrast, if the incident wave is polarized perpendicular to the wire grid, and if the wire spacing is wider than the wavelength, then the oscillation of the electrons is restricted and the incident wave transmits the structure.

The approach of effective-medium theory (EMT) to describe the characteristics of subwavelength structured devices is also applicable to WGPs [8.61]. Hereby, the transmission and reflection properties of the wire grid polarizers can be estimated by inserting a complex value for the refractive index n_1 of the metal.

$$n_1 = n + i\kappa . \tag{8.48}$$

For a highly conducting metal $\kappa \gg n$ and spacers made of perfect insulators (n_2) the refractive indices for both polarization directions become:

$$n_\parallel = i\kappa\sqrt{f} , \tag{8.49}$$
$$n_\perp = n_2/\sqrt{1-f} . \tag{8.50}$$

In the case when the wire grids are made of perfect conductors and the dielectric spacers are made of perfect insulators, the incident radiation with a polarization parallel to the wire grids interacts with the medium equivalent to a metallic layer and is reflected. In contrast, for incident radiation polarized perpendicular to the wire grids, the element behaves as a perfect dielectric layer and the radiation is mainly transmitted.

In more-realistic scenarios the assumption of perfect conductivity is not suitable and therefore rigorous calculations become necessary to calculate the polarizing properties of the structures.

A different type of polarization-sensitive elements that provides a high polarization extinction ratio is based on a subwavelength structured multilayer system of alternating layers of dielectric materials with high and low refraction indices [8.40, 41]. In this approach the properties of anisotropic spectral reflectivity is realized by combining the effects of form birefringence of a high-spatial-frequency grating with the resonant reflectivity of a multilayer structure.

Subwavelength Blazed Gratings and Lenses

In the previous discussions on wave plates, antireflection coatings and polarizers based on subwavelength structures the properties of this artificial effective media were treated similarly to homogeneous thin films. Additionally, high-spatial-frequency structures can also be used to realize high-efficiency diffractive elements such as gratings and diffractive lenses.

The basic idea is a lateral tailoring of the local effective index of refraction by controlling the feature size of the subwavelength structures. Each individual period of a diffractive element which is larger than the wavelength is composed of a sublattice with variable width of lines and spaces forming a subwavelength binary surface profile.

The principal concept is illustrated in Fig. 8.16. A classic sawtooth blazed profile guarantees a continuous linear phase shift along each individual period by varying the depth of the structure in a material of constant refractive index and shows a phase step of 2π at

the end of each period (Fig. 8.16 top). The analog phase distribution can be modeled by a gradient index material with constant height (Fig. 8.16 center). In this so-called blazed index grating, the refractive index is varying linearly and continuously from 1 to a maximum value within the period. In a blazed binary grating (Fig. 8.16 bottom), the continuous gradient material is approximated by the variation of the structural dimensions of the binary subwavelength features.

For the first time the physical principle of this artificial distributed-index media was verified by the use of water waves [8.45, 62]. The concept was transferred to the infrared spectral range at 10.6 μm [8.63] and

was also applied to near-infrared and optical wavelengths [8.64, 65].

Blazed binary gratings allow a highly efficient coupling of light into the first diffraction order [8.46] which may even exceed the properties of a conventional blazed grating [8.48]. This enhanced performance has been interpreted as a pillar waveguiding effect responsible for a drastic reduction of the shadowing zone [8.66].

As an illustration, Fig. 8.17 shows a schematic comparison of a conventional diffractive lens based on a sawtooth surface profile and a subwavelength diffractive lens.

8.2 Electro-Optic Modulators

An electrooptic modulator (EOM) can be used to control the amplitude, phase, frequency, polarization or propagation direction of a light wave electrically. EOMs are typically used for external modulation of light sources, thus avoiding amplitude, frequency and linewidth stability issues associated with direct modulation.

EOMs in general consist of an electrooptic material embedded between a pair of plated electrodes. A voltage applied to these electrodes generates an electric field oriented mostly perpendicularly to the electrode surfaces. The field induces changes in the material structure or orientation and thus the refractive index or birefringence of the material is modulated by the electric field.

Two fundamental setups of EOMs can be differentiated: the *longitudinal-oriented modulation* where

the light wave propagates parallel (Fig. 8.18a) to the electric field direction and *transverse-oriented modulation* with the light wave propagating perpendicularly (Fig. 8.18b) to the electric field. In the case of the longitudinal configuration the electrodes must be transparent to the light to be modulated or a small aperture in each electrode must allow the light to propagate through the modulator.

EOM devices can be constructed as bulk or as integrated optical devices (Fig. 8.18c). *Bulk modulators* are made out of discrete pieces of electrooptical materials such as lithium niobate $LiNbO_3$, and lithium tantalate $LiTaO_3$. These materials have high electrooptical coefficients and can be used over a wide range of wavelengths.
Fig. 8.18 (a) A longitudinal-oriented EOM has the *E* field applied parallel to the light-propagation direction, **(b)** whereas in the transverse oriented EOM the light wave is propagating perpendicularly to the *E* field. **(c)** An integrated optical modulator of transverse type

Integrated optical modulators are wavelength-specific due to the waveguide technology used. They are used in transverse modulation schemes that allow the width of the waveguide to be much smaller than its length. Thus, the half-wave voltage (8.56) is very small (typically a few volts) compared to the high voltage requirements of bulk modulators (up to tens of kV). In [8.67] a $BaTiO_3$-based modulator is reported with broadband modulation up to 40 GHz and a half-wave voltage of 3.9 V.

Some applications of electrooptic modulators are Q-switching, all optical switching, active mode locking and laser-disk recording.

Pockels and Kerr Effects

Electrooptic material change their optical properties when affected by an external electric field due to the altered position, orientation or shape of the material's structure. When an electric field E is applied the refractive index as a function of E (Fig. 8.19) can be expressed as

$$n(E) = n - \frac{1}{2}k_{Pockels}n^3 E - \frac{1}{2}k_{Kerr}n^3 E^2 . \qquad (8.51)$$

If the change in refractive index is mostly linearly proportional to the applied field strength then the effect is known as the linear electrooptic effect or Pockels effect, with

$$n(E) = n - \frac{1}{2}r_{Pockels}n^3 E , \qquad (8.52)$$

where $r_{Pockels}$ is the linear electrooptic coefficient or Pockels coefficient.

The value of the electrooptic coefficient r depends on the directions of the light and the orientation of the applied electric field since the crystal is anisotropic.

In isotropic materials such as gases, liquids or centrosymmetric crystals the linear coefficient is zero and the change in the index of refraction depends on the square of the applied electric field. This is known as the quadratic electrooptic effect or Kerr effect, with

$$n(E) = n - \frac{1}{2}r_{Kerr}n^3 E^2 , \qquad (8.53)$$

where r_{Kerr} is the quadratic electrooptic coefficient or Kerr coefficient.

Considering an average value for $r_{Pockels} = 10$ pm/V and a modulation voltage of $V = 10$ kV (which results in an electrical field strength of $E = 10^6$ V/m in a 1 cm-thick medium), the electrically induced change in refraction index is approximately 10^{-5}. The same
Fig. 8.19 The refraction index as a function of the applied electrical field strength E: (*solid line*) Pockels medium; (*dashed line*) Kerr medium

range is achieved when using the Kerr effect with an average value of $r_{Kerr} = 10$ am^2/V^2 . Although this change in refractive index is very small it will result in a significant phase shift for a wave propagation distance that is much greater than a wavelength of the light. For the given example the phase shift will be approximately $\pi/2$ for a wavelength of 600 nm.

An anisotropic electrooptical crystal with Pockels characteristic (with the electrooptic coefficient $k_{Pockels}$) will be considered in the following compilation of modulation techniques.

8.2.1 Phase Modulation

In analogy to the definition of the electric field strength between the electrodes of a parallel-plate capacitor, the field strength in a Pockels modulator can be expressed as

$$E = \frac{V}{d} , \qquad (8.54)$$

where V is the applied quasistatic voltage on the electrodes of the modulator, and d is the distance between them (in the case of the longitudinal modulator it is equal to the length L).

In a *transversal Pockels modulator* (Fig. 8.18b) the phase shift is a function of the electric field strength E

$$\varphi = \varphi_0 - \pi\frac{n^3 L}{\lambda_0}k_{Pockels}E , \qquad (8.55)$$

where $\varphi_0 = 2\pi\, n_{(V=0)}L/\lambda_0$ is the natural phase shift and λ_0 is the free-space wavelength.

By reducing the electrode distance d the voltage necessary for a given phase shift will be also reduced. This applies particularly in integrated optical devices.

The required voltage to achieve a phase shift $\varphi = \pi$ is called the *half-wave voltage* and can be expressed as

$$V_\pi = \frac{\lambda_0 d}{n^3 k_{\text{Pockels}} L} . \tag{8.56}$$

It is convenient to express the phase shift by using V_π as

$$\varphi = \varphi_0 - \pi \frac{V}{V_\pi} . \tag{8.57}$$

In a longitutional Pockels modulator (Fig. 8.18a) the distance between the electrodes is equal to the distance of light modulation $d = L$ and thus φ is independent of d and L:

$$\varphi = \varphi_0 - \pi \frac{n^3}{\lambda_0} k_{\text{Pockels}} V \tag{8.58}$$

and the corresponding half-wave voltage is

$$V_\pi = \frac{\lambda_0}{n^3 k_{\text{Pockels}}} . \tag{8.59}$$

Frequency modulation can be achieved by applying a sinusoidal phase modulation. This is due to the fundamental interrelation between these two kinds of modulation, where the frequency modulation can be seen as phase modulation with integrated modulation signal [8.68]. Thus sinusoidal phase modulation results in sinusoidal frequency modulation [8.69].

Another approach is to apply a circular electric modulation field of frequency ω_m to cause the principle axes to rotate with angular velocity $\omega_\text{m}/2$. A setup is used where two circular polarizers (inverted with respect to each other) at both ends of the modulator convert linearly polarized light to circularly polarized and vice versa.

The circularly polarized optical wave with frequency ω at the input will be shifted to $\omega \pm \omega_\text{m}$ at the output, depending on the direction of rotation and field strength of the applied electric field [8.70].

8.2.2 Polarization Modulation

A polarization state converter or dynamic wave plate allows the controlled change of an input polarization at the output of the modulator. This is achieved by coherent addition of two orthogonal waves (portions of the input wave) within the modulator.

The orientation of the electrooptic medium and the direction of the electric field are configured to have control of the fast and slow axis in the cross section normal to the light path. The corresponding refractive indices

for this axis are

$$n_{x'} \approx n_x - \tfrac{1}{2} n_x^3 k_{x\text{ Pockels}} E , \tag{8.60}$$

$$n_{y'} \approx n_y - \tfrac{1}{2} n_y^3 k_{y\text{ Pockels}} E , \tag{8.61}$$

where n_x and n_y are the refractive indices in the absence of an electric field, and k_x and k_y are the appropriate electrooptic coefficients under the specific spatial and electric field conditions (for a detailed description see to [8.71] Chap. 18.2).

Light portions (the ordinary and extraordinary wave) propagate at different speeds through the system resulting in a relative phase difference Γ between them. This phase difference depends on the length of the system L and is also known as the retardation

$$\Gamma = \Gamma_0 + \frac{2\pi}{\lambda_0} (n_{x'} - n_{y'}) L , \tag{8.62}$$

where Γ_0 is the natural phase retardation with no voltage applied.

In the absence of natural birefringence $(n_x - n_y = 0)$ the induced retardation in a transverse modulator is

$$\Gamma_i = \frac{\pi}{\lambda_0} \left(k_{\text{Pockels }y} n_y^3 - k_{\text{Pockels }x} n_x^3 \right) \frac{VL}{d} . \tag{8.63}$$

The voltage required to achieve a retardation of $\Gamma_i = \pi$, which shifts a vertical polarized input wave to a horizontal polarized output wave, is the half-wave voltage V_π for the polarization modulator

$$V_\pi = \frac{\lambda_0}{k_{\text{Pockels }y} n_y^3 - k_{\text{Pockels }x} n_x^3} \frac{d}{L} . \tag{8.64}$$

The corresponding formulas for a longitudional modulator are equal to (8.61) without the d/L term due to the modulator's independence of d and L.

8.2.3 Intensity Modulation

Intensity modulation is achieved by altering the transmission of light, which is the ratio of output to input intensity, $T = I_\text{o}/I_\text{i}$. As phase or retardation modulation does not affect the intensity of the output light an additional element or setup is needed.

One approach is to add a polarizing analyzer to a dynamic wave plate as described in [8.70] in such a way that the analyzer's axis is orthogonal to the input polarization (crossed polarizer setup). With no voltage applied the output intensity is zero (point A in Fig. 8.20b) and with $V = V_\pi$ (point C in Fig. 8.20b) the output intensity reaches the level of the input intensity. The

transmittance T is a periodic function of V

$$T(V) = \sin^2\left(\frac{\Gamma_0}{2} - \frac{\pi}{2}\frac{V}{V_\pi}\right). \tag{8.65}$$

By operating the modulation voltage near $V_\pi/2$ (point B in Fig. 8.20b) the output intensity is nearly linearly related to the voltage.

Figure 8.21a shows a typical setup. The light entering the modulator after passing the input polarizer is linearly polarized. Its polarization direction is tilted 45° with respect to the direction of the electric field. With a voltage applied the light will be split into two orthogonal components that will have a relative phase difference Γ_i between them after passing through the modulator. The superposition of these two components results in elliptically polarized light that will be analyzed by the output polarizer. With $V = V_\pi$ the superposition again

results in linearly polarized light oriented at 90° with respect to the incoming light's polarization, and thus it will be fully transmitted by the analyzer.

It is also possible to use parallel polarizers, in which case the transmission behavior is inverted: full transmission at $V = 0$ and no transmission with $V = V_\pi$.

Another approach to modulate the intensity of light is to superpose the waves of the two branches of a Mach–Zehnder interferometer in which at least one branch contains a phase modulator (Fig. 8.22a). Assuming that the beam splitters divide the optical intensity equally, the intensity at the output I_o depends on the phase difference φ in the two branches:

$$I_o = \tfrac{1}{2}I_i + \tfrac{1}{2}I_i\cos\varphi = I_i\cos^2\frac{\varphi}{2}. \tag{8.66}$$

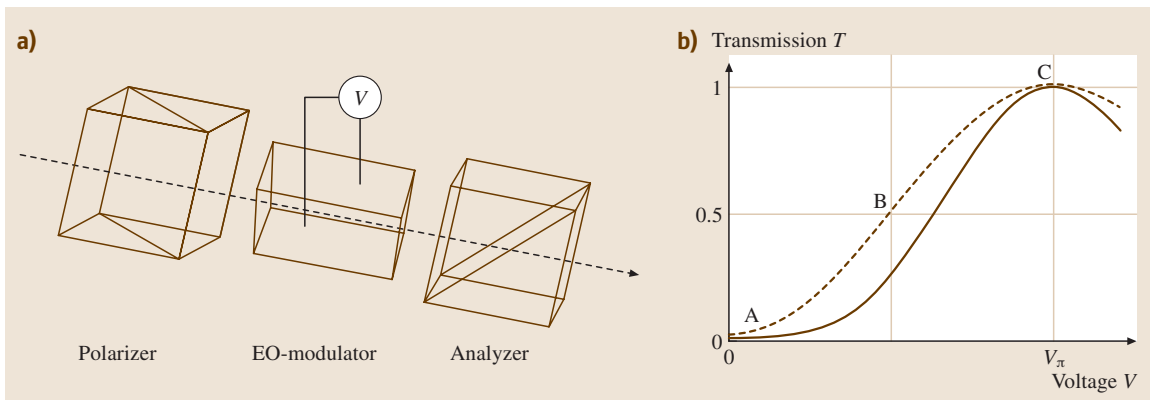
Considering the half-wave voltage expression for the phase shift (8.56), the transmittance $T = I_o/I_i$ is again
Fig. 8.20 (a) When linearly polarized light (parallel to the x-axis) enters the crystal, the output polarization state is in general elliptical. For $V = V_\pi$ the polarization is again linear, but turned 90° with respect to the input polarization. (b) The phase retardation is linearly related to the applied voltage. In the absence of an applied voltage only Γ_0 is present


Fig. 8.21 (a) An intensity modulator setup implementing a dynamic wave plate between two crossed polarizers, placed at 45° with respect to the retarder's axes. (b) The transmittance T varies with the applied voltage V, following the *dashed* line for a Pockels characteristic modulator and the *solid* line for Kerr characteristic, both for $\Gamma_0 = 0$
Fig. 8.22 (a) Mach–Zehnder interferometer where one branch contains a phase modulator. The transmittance of the interferometer T varies with the applied voltage V. The same setup can be used in an integrated optical device **(b)** where the input light is split into the two branches by a waveguide. With an additional electrode a push–pull configuration can be constructed **(c)** where the light in the two branches are modulated by the same voltage

a periodic function of V

$$T(V) = \cos^2\left(\frac{\varphi_0}{2} - \frac{\pi}{2}\frac{V}{V_\pi}\right). \tag{8.67}$$

Here the value of φ_0 depends on the optical path difference when no voltage is applied. A value of $\pi/2$ is used to operate the modulator in the nearly linear region around $T = 1/2$ (point B in Fig. 8.21b). If the modulator is switched between full transmission and total extinction, φ_0 can be used to select whether $V = 0$ or $V = V_\pi$ corresponds to $T = 0$ and $T = 1$ (points A and C in Fig. 8.21b).

A Mach–Zehnder-based modulator can also be constructed as an integrated optical device. The input optical waveguide is split into the two branches of the interfer-

ometer and recombined at the output (Fig. 8.22b). In addition to the setup where a phase modulator is added to one of the branches there is a configuration called push–pull, which adds an additional modulator to the second branch (Fig. 8.22c). Full transmission occurs at 0° net phase difference while total extinction occurs at 180°. This configuration requires lower drive voltages to achieve a required phase shift.

Due to the small electrically induced changes in the refractive index, thermal influences and stress-induced double refraction as well as birefringence can be rather disturbing. Therefore, electrooptic modulators often contain two equal Pockels cells in a configuration where the temperature dependence of the relative phase shift is largely canceled [8.72].

8.3 Acoustooptic Modulator

Devices that apply an acoustic wave to a medium guiding optical waves are called acoustooptic modulators (AOM). They consist of at least one acoustic wave generator (usually a piezoelectric transducer) attached to an optical material such as tellurium dioxide, crystalline quartz or fused silica. The applied acoustic wave influences the spatial density distribution of the optical material (by compression and rarefaction) and thus a corresponding change in the index of refraction is generated. Due to the periodic structure of the acoustic wave the variation in the index of refraction is also periodic and acts as a diffraction grating for an optical wave present in the medium (Fig. 8.23).

The distance of the periodically repeated planes of equal density is given by

$$\Lambda = \frac{v_s}{f_s}, \tag{8.68}$$

where v_s is the velocity of sound in the medium and f_s is the frequency of sound. In analogy to the formula for Bragg diffraction, the angles θ can be calculated for light diffracted from this periodic structure as (Fig. 8.20):

$$\sin\theta = \pm\frac{\lambda}{2\Lambda}, \tag{8.69}$$

where λ is the wavelength of light in the medium. For these angles the criteria for constructive interference is satisfied; θ represents both the angle of reflection as well as the angle of incidence. The intensity drops sharply for angles that differ slightly from θ.

Depending on the application there are many criteria for the choice of the material, including the transparency range, the optical damage threshold, and required size.

The characteristics of AOMs are given in Table 8.2.

Table 8.2 Characteristics of acoustooptic modulators [8.73]

Material	Bandwidth (MHz)	Rise time (ns)	Acoustic input power (W) saturation	Material wavelength range (µm)	Efficiency at maximum bandwidth (633 nm)
Glass	5–10	50	1–6	0.4–25	> 70%
PbMoO$_4$	> 80	4–6	0.5–1.5	0.42–5.5	> 70%
TeO$_2$	> 80	4–6	0.5–1.5	0.35–5	> 70%
Ge	10	70	20–30	2–20	> 50% at 10.6 µm
GaP	100–1500	0.7–10	0.02–2	0.6–1	> 80%
GaAs	50–200	5–20	0.02–2	1–1.6	> 30% at 1.5 µm
Fig. 8.23 AOM controlled by the sound intensity with a proportional modulated output intensity of the light

8.3.1 Intensity Modulator

The intensity of the reflected light is proportional to the intensity of the modulating sound wave for sufficiently weak sound intensity. At higher sound intensities nonlinear effects have a negative impact on the modulator.

The achievable bandwidth, B, is limited either by the size of the light beam waist (with the transit time $T = D/v_s$ of sound across the waist width D) to $B = 1/T$ (as shown in [8.71] Chap. 20.2) or by the transducer impedance mismatch, which can be overcome by inserting a quarter-wave plate.

8.3.2 Frequency Shifter

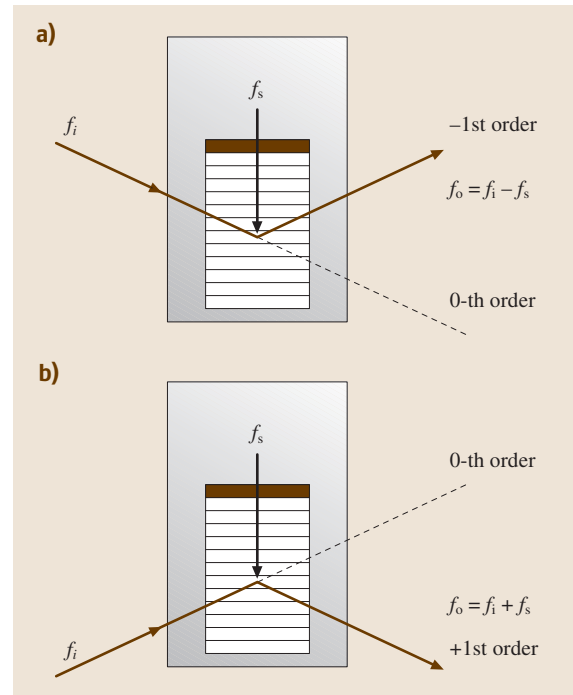
Partially reflected optical waves are Doppler-shifted by the refractive-index variations created by an acoustic plane wave that moves with a velocity v_s. While the angular frequency of the incident optical wave is $\omega = 2\pi f$ the reflected light is upshifted to an angular frequency $\omega + \Omega$ with $\Omega = 2\pi f_s$. This is achieved using a setup such as that shown in Fig. 8.24b where the acoustic wave propagates in the opposite direction to the in-


Fig. 8.24a,b Frequency shifter for (**a**) downshift and (**b**) upshift of the input light frequency

coming optical wave. In a geometry where light and sound waves travel in the same direction (Fig. 8.24a) the frequency of the reflected light is downshifted to $\omega - \Omega$.

Frequency shift over a range wider than the modulators range can be achieved by placing two modulators in series. When the first modulator applies an upshift and the second a downshift then the resulting output frequency will be shifted by the difference of the two frequencies. The sum of both frequencies will be achieved if both modulators apply an upshift. The overall efficiency is given by the combined diffraction efficiencies.

8.3.3 Deflector

By applying a wide acoustic frequency range with bandwidth Δf to an AOM the deflection (separation) angle 2θ can be made to vary proportionally to f_s. As θ is not only the reflected but also the required incidence angle a setup is needed where the incidence angle can be decoupled. This can be achieved by varying the direction of the acoustic wave corresponding to the applied acoustic frequency, for example by using multi-electrode transducers.

As the optical wave has a limited angular width the number of resolvable spots is limited to the ratio of the maximum scan angle variation $\Delta\theta = (\lambda/\nu_s)B$ to the angular width λ/D of the beam

$$N = \frac{D}{\nu_s} B . \tag{8.70}$$

Here, D/ν_s is the transit time of sound through the light beam's width and B is the bandwidth of the sound wave.

Some applications of AOMs applying the modulation technics described above are:

- cavity dumping in a laser resonator (deflection),
- active mode locking,
- laser printing, where the AOM modulates the power of the laser beam,
- high-frequency (HF) spectrum analyzer, where the AOM deflects the length depending on the (to analyze) modulation signal to a charge-coupled device (CCD) line detector,
- laser projector, where AOMs modulate the intensity of the RGB components of light according to the video signal to be displayed,
- laser scanning microscopy.

8.4 Gradient Index Optical Components

The local variation of the refractive index $n(x, y, z)$ in the optical material of an optical component involves several additional possibilities to generate new functions of the component. In contrast to conventional refractive optics where light is refracted at the abrupt transition from one homogeneous medium with index n_1 to a second one with index n_2, the direction of the propagating light changes continuously in gradient index (GRIN) media, depending on the distribution of the refractive index $n(x, y, z)$. The propagation in terms of geometrical optics is governed by the rules of Fermat's principle. This is described in more detail in Sect. 8.4.1.

Usually, four gradient index types are distinguished. For axial gradients the index varies only in the direction of the optical axis z, while in planes perpendicular to the optical axis the index is constant. For radial gradients, nowadays the most important type, the index is solely a function of the radial coordinate r, which is perpendicular to the optical axis z. In one-dimensional or lateral GRIN media, the index depends only on one coordinate, y, which is perpendicular to the optical axis. Spherical gradients exhibit a variation of the index with a spherical radius R,

$$
\begin{array}{lr}
n = n(z) & \text{axial gradient} \\
n = n(r = x^2 + y^2) & \text{radial gradient} \\
n = n(y) & \text{one-dimensional gradient} \\
n = n(R = x^2 + y^2 + z^2) & \text{spherical gradient}
\end{array}
\tag{8.71}
$$

For all the types of gradients described in (8.71), defined index profile functions exist that generate effects on incoming light beams similar to those of conventional optical components as, e.g., lenses. A radial (or one-dimensional) gradient with a nearly parabolic secant-hyperbolic index profile,

$$n(r) = n_0 \,\text{sech}(gr) , \tag{8.72}$$

with a maximum index n_0 on the optical axis creates a focusing lens (Fig. 8.25) with a periodic sinusoidal ray trace [8.74, 75] for meridional rays. Period P solely depends on the gradient parameter g,

$$P = 2\pi/g . \tag{8.73}$$

A radial gradient with a parabolic index profile bending outwards

$$n^2(r) = n_0^2[1 + (gr)^2] \tag{8.74}$$

acts as a diverging lens [8.76] (Fig. 8.25). Both types (8.72) and (8.74) result in a lens function with plane optical surfaces, which is a tremendous advantage for the production and application of miniaturized gradient index lenses.

A unique spherical gradient is Maxwell's fish-eye [8.77]

$$n(r) = \frac{n_0}{1 + (R/R_0)^2} , \tag{8.75}$$

which images all points on the surface ($R = R_0$) of a sphere in the surface on its opposite side; n_0 is the index at the center of the sphere. A modified version of the spherical or semi-spherical gradients is used in planar microlens arrays [8.78].

A so-called Luneburg lens [8.79] uses a spherical gradient

$$n(r) = n_0\sqrt{2 - (R/R_0)^2} \tag{8.76}$$

to collimate light from a point source at the surface of the sphere. A generalized type of similar profiles is employed for producing fiber-based cylindrical collimating lenses with small focal lengths [8.80].

Axial gradients are most commonly used to correct the spherical aberration of lenses made with a homogeneous medium with spherical surfaces. An axial index profile that eliminates the spherical aberration of parallel light rays striking the spherical surface of a plano-convex lens on the gradient side (Fig. 8.25) was derived analytically by Murty [8.81],

$$n(z) = \frac{n_0}{\sqrt{1 + 2n_0(n_0 - 1)z/r_c}}, \tag{8.77}$$

where n_0 is the index at the vertex ($z = 0$) of the spherical surface with a radius of curvature r_c.

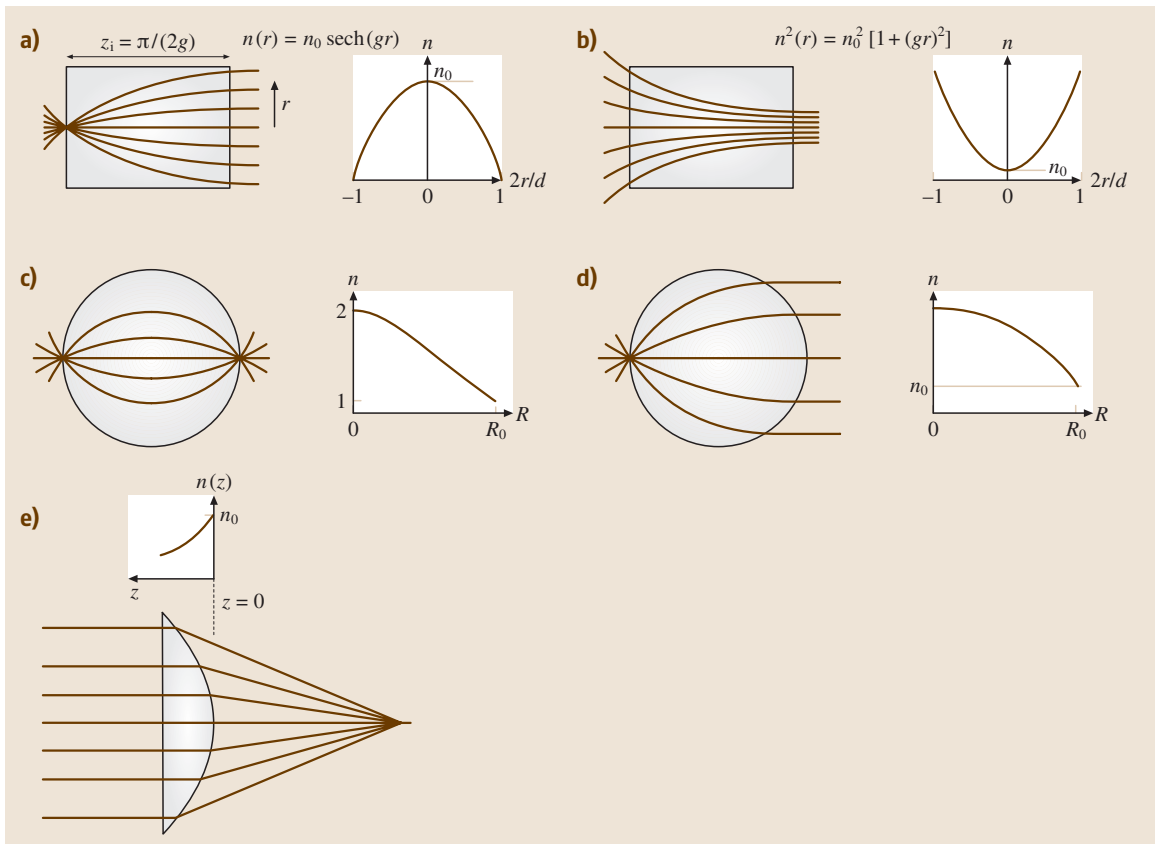
Most of these gradient examples represent analytical solutions of the ray equations (Sect. 8.4.1) but are difficult to fabricate in practice because of their exotic index value ranges. Gradient index materials used for the fabrication of optical components for the visible and near-infrared domain are most often silicate glasses and sometimes plastics, with indices between 1.4 and 1.9, allowing a limited index variation because of the chemistry, and mechanical and optical properties of the materials. Furthermore, applications often require the


Fig. 8.25a–e Different types of gradient-index components with lens performance (**a**) radial focusing lens, (**b**) radial diverging lens, (**c**) spherical lens – Maxwell's fisheye ($n_0 = 2$) and (**d**) Luneburg lens, (**e**) plano–convex lens with axial gradient

integration of GRIN components in a configuration that deviates from the ideal and analytical examples presented in this chapter. Hence, the index profiles are formulated in model functions, normally as a polynomial expression, introducing an appropriate number of design parameters. Numerical ray tracing is then performed to determine optimum index profile parameters for a specific configuration or application, also considering the technological feasibility. Section 8.4.1 will outline some fundamentals of ray tracing in gradient index media. A more-detailed introduction to the fundamentals of gradient index optics is given in [8.74, 79, 82–84].

8.4.1 Ray Tracing in Gradient Index Media

Light propagation in gradient index media can be described by different physical models, i. e., by ray tracing in the sense of geometrical optics, by scalar wave propagation [8.85], or by solving the vector wave equations [8.84]. The suitability of the models depends on the size of the gradients with respect to the wavelength and the effects under investigation. Besides gradient index waveguide optics, where wave propagation is appropriate [8.86], ray tracing is the most common method to describe, simulate and optimize gradient index components, because its calculations are comparably fast and compatible with the principles of optical design software. Hence, this method will be introduced in more detail in this section.

In the geometrical optical sense, ray propagation in media with a nonuniform index distribution $n(x, y, z)$ is described with the vector ray equation, which is derived from Fermat's principle [8.87]

$$\frac{\mathrm{d}}{\mathrm{d}s}\left[n(x, y, z)\frac{\mathrm{d}\boldsymbol{r}}{\mathrm{d}s}\right] = \nabla n(x, y, z), \qquad (8.78)$$

where $\boldsymbol{r}$ is the position vector and $\mathrm{d}s$ is the path element along the ray trace (Fig. 8.26).

The vector equation (8.78) can also be represented as a system of differential equations of second order for the coordinates x, y and z,

$$\frac{\mathrm{d}^2 x}{\mathrm{d}\tau^2} = \frac{\partial}{\partial x}\left(\frac{1}{2}n^2\right); \quad \frac{\mathrm{d}^2 y}{\mathrm{d}\tau^2} = \frac{\partial}{\partial y}\left(\frac{1}{2}n^2\right);$$

$$\frac{\mathrm{d}^2 z}{\mathrm{d}\tau^2} = \frac{\partial}{\partial z}\left(\frac{1}{2}n^2\right). \qquad (8.79)$$

The element $\mathrm{d}\tau$ results from the path element $\mathrm{d}s = n\,\mathrm{d}\tau$.

Analytical solutions of equation (8.79) exist for many index distributions, some well-known ones are presented before. Detailed descriptions are given in [8.74, 75, 79, 83].
Fig. 8.26 Ray trace in a inhomogeneous medium

In routine cases, where the index distributions have to be adapted and optimized to a specific design configuration of an optical system and to profile shapes that can be fabricated by applying an appropriate technology, the ray equations (8.79) are solved numerically by the Runge–Kutta method [8.88]. This procedure is mostly used in commercially available optical design software. The index profiles are usually formulated as polynomial expansions in r, R, x, y, and z. The computation of wavefront aberrations and point-spread functions (PSF) considering the diffraction furthermore requires the calculation of the optical path length OPL of rays tracing in gradient index media,

$$OPL = \int n(x, y, z)\,\mathrm{d}s\,;$$

$$\mathrm{d}s = \sqrt{\mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2}\,, \qquad (8.80)$$

where $\mathrm{d}s$ is the geometrical path element. The described Runge–Kutta method uses $\mathrm{d}\tau$ as the numerical step parameter. Hence, the calculation of the optical path length (OPL) can easily be included in the numerical procedure [8.89] by

$$OPL = \int n^2(x, y, z)\,\mathrm{d}\tau\,. \qquad (8.81)$$

8.4.2 Fabrication Techniques

Gradient index materials for visible light and near-infrared applications are usually based on transparent silicate glasses and sometimes on organic polymer materials. The refractive index can be changed by locally varying the chemical composition and structure and related optical and mechanical properties. Early models [8.90] relate the optical properties of homogeneous silicate glasses to their composition. More-recent studies [8.91, 92] also involve aspects of the index gradient fabrication and chromatic properties of the gradient glasses. The appropriateness of a GRIN fabrication technology depends on the following optical aspects:

- the desired index change Δn
- the profile shape and symmetry

- the depth of the gradient, which determines the size of the GRIN element
- the chromatic variation of the index profile.

Although several techniques such as, the sol-gel [8.93] and the chemical vapor deposition (CVD) [8.94] processes are described in the literature, ion exchange or diffusion technology in glasses and plastics are of most practical importance for the production of gradient index lenses [8.95–98] and are described here in more detail. However, CVD processes are of great industrial relevance for the production of graded index fibers for optical data transmission as well as for the fabrication of Luneburg-type cylindrical lenses (Sect. 8.4.3). Sol-gel techniques have been investigated in more detail because of their potential to fabricate large radial-gradient lenses of diameters larger than 5 mm to open up new applications to camera lenses or eyepieces in optical instruments [8.99]. To produce even larger GRIN lens elements, organic or plastic materials have been investigated in detail [8.100]. A combination of the diffusion of different monomers with different refractive indices followed by copolymerization generates the final index gradient.

Ion Exchange and Diffusion Processes in Glass

Diffusion processes in glass are used to produce most of the commercially available GRIN lens types. Large axial gradients [8.101] and radial gradients [8.102] are fabricated by fusion–diffusion between different initially homogeneous glasses of distinguished refractive indices, which are combined into a plate stack for axial gradients or by inserting rods in tubes of different glasses. After combination, the compound is annealed at temperatures well above the transition temperature and the softening point of the glasses, causing the diffusion of many components of the glasses, with the initial step-like index distribution forming a continuous index
Table 8.3 Polarizability, ion radius and possible refractive index change of monovalent ions suitable for ion exchange

Ion	Electronic polarizability (A^3)	Ion radius (Å)	Δn
Na^+	0.41	0.95	–
Li^+	0.03	0.65	≤ 0.01
K^+	1.33	1.33	≤ 0.01
Ag^+	2.40	1.26	≤ 0.14
Cs^+	3.34	1.65	≤ 0.03
Tl^+	5.20	1.49	$0.1 \ldots 0.2$

gradient. In the case of one-dimensional axial gradient with index changes as large as 0.4, blanks are used to grind and polish spherical lenses with corrected spherical and chromatic aberration (Sect. 8.4.3). In the case of radial gradients, a larger preform with the appropriate index profile produced by the described diffusion is afterwards drawn out to the final lens diameter at lower temperatures.

For producing radial and lateral gradients in smaller diameters between 0.1 and 3.0 mm, the ion exchange of monovalent cations between molten salt baths and initially homogenous borosilicate glass rods or slabs is used [8.95, 96, 103] at temperatures between 300 and 600 °C. This is below or in the range of the transition temperature of the glass, where the network of the glass formers is still rigid, but monovalent ions have some mobility and the salts are liquid (Fig. 8.27). Numerous technological aspects affect the feasibility of producing a desired final refractive index profile. The ions to be exchanged determine the possible index change (Table 8.3) and the ion exchange depth after a certain exchange time, which results from different polarizabilities and ion radii. Table 8.3 compares the relevant properties of monovalent ions [8.104].

The fabrication time depends on the kinematic properties of the ion exchange, which is described as an interdiffusion process of the ions A and B in the glass and the salt melt,

$$A_{\text{Glass}}^+ + B_{\text{Salt}}^+ \leftrightarrow A_{\text{Salt}}^+ + B_{\text{Glass}}^+ . \tag{8.82}$$
It is modelled by Fick's diffusion equation

$$\frac{\partial c_A(\mathbf{r}, t)}{\partial t} = \nabla[D(c_A, T)\nabla c_A(\mathbf{r}, t)] , \tag{8.83}$$

where c_A is the normalized concentration of cation A, and D is the diffusion coefficient. It generally depends on the concentration and the temperature T and describes most of the process-relevant properties of the

base glass composition and the kinematic behavior of the ions exchanged at different temperatures. Several empirical and physical models have been developed to enable a realistic simulation of the ion-exchange fabrication processes [8.104–107]. A process temperature has to be chosen where the diffusion coefficients are high enough to enable an economic production time, but still below or in the range of the softening point of the glass to avoid deformation of the glass blanks. Besides the temperature and the ion exchange time, the configuration of the initial and boundary conditions for the diffusion process, which can be controlled by varying the salt-bath composition, is an important tool to optimize the index profiles.

High-numerical-aperture lenses with radial gradients are obtained by large index changes of > 0.1. To produce GRIN lenses, in most cases they are generated by thallium/sodium–potassium ion exchange [8.95] (Fig. 8.28) or by the silver–sodium exchange [8.96, 103]. In contrast to silver, thallium is a very toxic material, larger portions of which, however, can initially be included in the base glass composition of the GRIN glass, because thallium oxide does not tend to reduce to metallic thallium during the melting process of the glass.

Silver is almost nontoxic, but glasses with a high content of silver oxide larger than $15 \, \text{mol} \, \%$ cannot be molten directly, because silver salts and oxides tend to reduce to metallic silver at typical melting temperatures above $1000 \, ^\circ\text{C}$, which causes a dark color in the glass. The glass would then not be useful for GRIN-lens production. Hence, a two-step process is generally used for the production of focusing GRIN lenses [8.96, 103], where a sodium-containing base glass is initially immersed in a silver-containing salt melt. This step is carried out sufficiently long to form a nearly uniform refractive index increase Δn (ion stuffing) (Fig. 8.29). In a second *burying* step, silver ions in the glass are partially removed and replaced by index-lowering sodium ions, where the glass substrates are immersed in a sodium-containing salt melt, yielding the desired parabolic profile.

Many applications require longer ray periods P (8.73) connected with lower numerical apertures and minimized chromatic aberrations. Preferably, the lithium-sodium ion exchange in alumo-borosilicate glasses is used to produce these types of radial GRIN lenses with smaller index changes Δn [8.108–111].

It is not claimed that this chapter is a complete representation of all the available GRIN fabrication techniques; rather it reflects the author's experience.

8.4.3 Application

Radial and Lateral Gradient Lenses with Plane and Spherical Surfaces

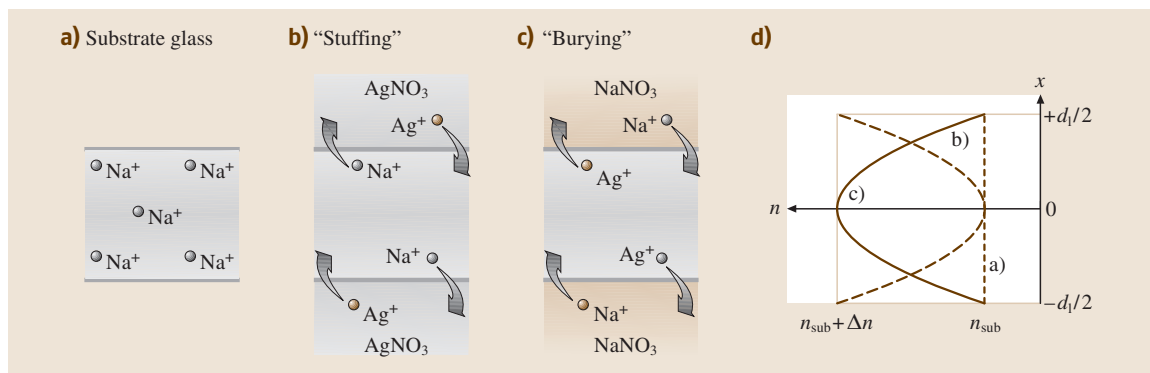
Micro GRIN lenses with almost parabolic radial or lateral index profiles are an interesting alternative to conventional homogeneous glass lenses since the lens performance depends on a continuous change of the refractive index within the lens material. Instead of


Fig. 8.29 Silver–sodium ion exchange for producing high-NA radial and one-dimensional GRIN lenses [8.103]
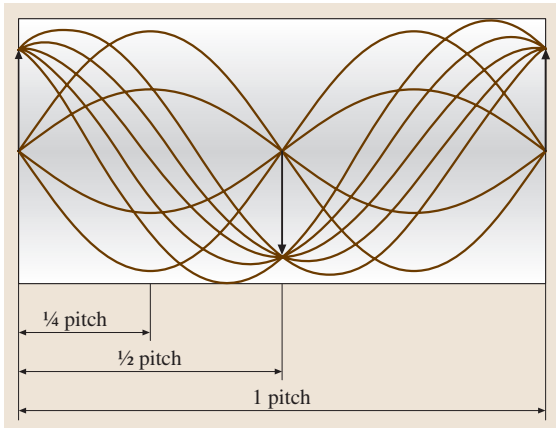

Fig. 8.30 Ray traces within a GRIN focusing lens of different pitch lengths

Fig. 8.31 GRIN endoscope without eyepiece function

complicated surface shapes, plane optical surfaces are used. The light rays are continuously bent within the lens until, finally, they are focussed on a spot. Miniaturized lenses are fabricated with thickness or diameter of 3 mm down to 0.2 mm. The simple geometry allows their cost-effective production in larger volumes and essentially simplifies the assembly of rather complex systems, including optical fibers, prisms and beam splitters, because these plane optical components can be attached directly to the GRIN lenses. Varying the lens length yields an enormous flexibility to fit the lens parameters, e.g., the focal length and working distance, to a specific requirement. Preferred ranges of application are optical telecommunication components, laser diode-to-fiber couplers, miniaturized endoscopes, and a variety of optical sensors. New emerging fields are endomicroscopic probes with high resolution requirements and miniaturized heads for optical coherence tomography (OCT). Before these applications are presented in more detail, some fundamental aspects will be considered.

An almost parabolic radial focusing refractive-index profile (8.72) realizes a continuous cosine ray trace within a GRIN focussing lens, the period or pitch length P of which (8.73) does not depend on the entrance height and the entrance angle of the light ray (Fig. 8.30).

Various imaging configurations can be designed using the same index profile by choosing different lens lengths.

- The quarter-pitch lens images a point source on the entrance surface of the lens into infinity, or colli-

mates it. This configuration is usually applied to the collimation of single-mode and multimode optical fibers and laser diodes, where the source can be attached directly to the lens. For high-power laser diodes, cylindrical GRIN lenses are used for fast-axis collimation. Together with other GRIN components they are easily integrated to form compact micro-optical systems.
- The half-pitch lens images an object on the entrance surface inverted on the exit surface of the lens (magnification $M = -1$).
- The 1 (2, 3, or more, respectively)-pitch lens images an object on the entrance surface of the lens identical to the exit surface (magnification $M = +1$). In endoscopes, those lenses are used as relay lenses, which transmit the image from the front part of the endoscope to the eyepiece (Fig. 8.31).
- Endoscope objective lenses are somewhat longer than a quarter-pitch lens. They image the object field to be viewed at a working distance on the exit surface of the lens on a reduced scale (Fig. 8.31).

The geometrical gradient constant g of the radial index profile (8.72) characterizes the steepness of the index gradient and, with the lens length z_1, determines the focal length, f, and the working distance, s, of the
Fig. 8.32 Image formation by a GRIN focussing lens
Fig. 8.33 Ray traces in a GRIN diverging lens

lens,

$$f = \frac{1}{n_0 g \sin(gz_1)} , \qquad s = \frac{1}{n_0 g \tan(gz_1)} . \qquad (8.84)$$

Figure 8.32 illustrates the procedure of optically designing an imaging GRIN system using these parameters.
Fig. 8.34 Single-mode fiber coupling by a pair of GRIN lenses

Fig. 8.35a,b Dense wavelength division multiplexing (DWDM) using GRIN lenses and narrow-band interference filters. **(a)** Two-channel multiplexer, **(b)** multichannel multiplexer [8.112]

The distance between the principal planes P_1 and P_2 indicates that GRIN lenses have to be treated as *thick* lenses. However, this fact does not influence the image quality and isoplanatic property of GRIN lenses.

The maximum acceptance angle of a GRIN collimation lens or the maximum viewing angle of a GRIN objective lens, respectively, ϑ, is determined by the numerical aperture (NA). As in fiber optics, it is derived from the maximum index change of the GRIN profile,

$$\sin(\vartheta) = NA = \sqrt{n_0^2 - n_R^2}$$
$$= n_0 \sqrt{1 - \text{sech}^2(gd/2)} , \qquad (8.85)$$

where n_R is the refractive index at the margin of the profile, and d is the diameter or the thickness of the lens.

Diverging lenses with plane optical surfaces are obtained by parabolic-shaped refractive index profiles (8.74), with the minimum of the index, n_0, at the center of the profile.

A characteristic ray trace through a diverging lens is shown in Fig. 8.33. The comparably short focal length of the lens, f, is also determined by the lens length z_1,

$$f = -\frac{1}{n_0 g \sinh(gz_1)} , \qquad s = -\frac{1}{n_0 g \tanh(gz_1)} . \qquad (8.86)$$

However, a periodic path of the rays is not obtained in this case. Those lenses are applied to the production of microoptical telescopes and scanners.

Optical communication systems use various fiber-optical components, where radial GRIN lenses with plane optical surfaces are successfully used on a large-volume scale, because of their advantageously small size, light weight, easy assembly and adjustment, and short focal length. Very well-established basic functions of GRIN lenses with diameters between 1.0 and 1.8 mm are the collimation of a single-mode fiber in the 1310 nm spectral band and in those between 1500 and 1600 nm and the low-loss coupling of a collimated beam again in a single-mode fiber (Fig. 8.34). The insertion loss can be kept very low (less than 0.5 dB) for distances L between a pair of GRIN lenses up to 25 mm and more, but in general, it is a function of this separation and other alignment factors [8.113, 114].

Optical elements, the function of which is sensitive to the angular orientation of the light, such as filters, optical crystals, gratings and moveable switching prisms, are placed between the GRIN lenses to build up a fiber-optical device. Most important are dense wavelength division multiplexing (DWDM) devices [8.112], where
Fig. 8.36 Plano–convex radial GRIN lens with spherical surface for coupling laser diodes (LD) into fibers [8.115]

a multi-wavelength signal in an incoming single-mode fiber (SMF) needs to be separated into many wavelength channels (Fig. 8.35).

Fiber-optical attenuators and splitters can be built up similarly to Fig. 8.35 depending on the filter properties of the element between the GRIN lenses. Often, fibers and GRIN lenses with angled facets are used for optical interconnects to minimize back-reflections, which can disturb the performance of precisely wavelength-tuned devices and systems.

Radial GRIN lenses are also fabricated with spherical surfaces to enable the efficient coupling of laser diodes to optical fibers (Fig. 8.36). The spherical surface allows a working distance (WD) of a few hundred microns between the laser facet and the lens surface, while the NA of the lens is somewhat increased with respect to a similar lens with plane surfaces. The working distance is often necessary because of the can-type package of many laser diodes with a window. The lens matches the high NA of the laser diode to the lower NA of the fiber. The spherical aberration introduced by the spherical surface of the lens can be corrected by adapting the radial index profile [8.115].

A one-dimensional or cylindrical GRIN lens with plane surfaces is obtained by a parabolic-like one-dimensional index distribution, which is oriented perpendicular to and not varying along the optical axis (Fig. 8.37). It is produced by ion exchange in glass plates and can be applied to fast-axis collimation of laser diode bars [8.116], or to the anamorphic shaping of elliptically diverging and often astigmatic beams of laser
diodes into the circular focussed beams that are necessary for efficient coupling into fibers, or for the pumping of solid-state lasers [8.117, 118].

In the field of conventional endoscopy, where an object in a barely accessible hollow space needs to be imaged with a large viewing angle through a small opening, the GRIN lens technology is important when the diameter of the optics has to be smaller than 2.0 mm, especially below 1.0 mm, as conventional lenses are difficult to manufacture and to assemble in long imaging systems. The complete imaging system of an endoscope can be built up with only two GRIN lenses: an objective lens of high numerical aperture (NA > 0.5), which generates a demagnified intermediate image of the object with a large viewing angle, and a relay lens of low numerical aperture (NA ≈ 0.1), which relays the intermediate image of the objective to the outside of the body (Fig. 8.31). Several ray periods or pitches of the GRIN relay with additional intermediate images may be necessary to generate the required length of the endoscope. It is also possible to integrate the eyepiece or ocular function within the same relay lens [8.118] to avoid additional optical elements. These GRIN systems do not lead to any internal Fresnel reflection losses because of the absence of internal optical surfaces within the imaging tube. The aberrations have been analyzed in comparison with those of conventional optical systems in endoscopes, and the possibilities of preventing and correcting the aberrations have been studied in detail [8.109, 110]. Flexible endoscopes use coherent imaging fiber bundles for image transmission over tens of centimeters. If the diameter of the optical channel is less than 1.0 mm, GRIN objective lenses, which can be attached directly to the fiber bundle, are preferably used as they yield good image quality. They are available in diameters down to 0.20 mm [8.119].

A novel field of application of GRIN lens systems is endomicroscopy, where small optical probes are needed to image biological tissue and corresponding specific functional features with subcellular resolution in the

Fig. 8.37 Cylindrical GRIN lens with a one-dimensional lateral index profile
Fig. 8.38 Magnifying telecentric GRIN telescope connected to a coherent fiber bundle for endomicroscopic probes

micrometer range. GRIN lens systems have been developed which provide the required lateral and axial resolution below one micron and 10 microns, respectively. They generate magnified telecentric images of the object (Fig. 8.38), which can then be transferred by coherent fiber bundles [8.120], by rigid GRIN relay lenses [8.121], or by scanning an individual probe fiber [8.122]. These endomicroscopic probes are often operated in a confocal or laser scanning scheme, most recently also involving multiphoton excitation [8.122].

Optical coherence tomography (OCT) is another example of the preferred application of radial GRIN optics. The penetration depth of OCT is generally less than 2–3 mm and also requires miniaturized endoscopic probes for internal medical diagnostics [8.123]. GRIN lenses with plane optical surfaces are relatively easy to combine with the single-mode signal fiber and prisms for beam deflection to allow the scanning of the tissue by rotating the optical assembly or by some other scanning method (Fig. 8.39).

Many optical sensing applications are also based on GRIN focusing rod lenses with radial gradients. A variety of physical parameters such as displacement, pressure, temperature, or fluid flow have been measured by intensity-modulated fiber-optical sensors, where the coupling efficiency between two fibers is varied by lateral and axial displacements of the GRIN lens with respect to the fiber positions, by displacing mirror
Fig. 8.39 OCT probe design with fiber, GRIN lens and scanning prism
Fig. 8.40 Generalized non-full-aperture Luneburg lens [8.80]

coatings on membranes, or by changing the reflectivity performance of the coating [8.124]. The problem of a stable intensity reference is overcome by sensor solutions where the phase of coherent Gaussian light beams is analyzed by interferometric setups comparable to those used in optical coherence tomography (Fig. 8.39) [8.125].

Luneburg–Type Cylindrical Lenses
One type of radial index profiles in glass fibers is also successfully used for the fabrication of cylindrical lenses of a generalized non-full-aperture Luneburg type [8.80]. Earlier design studies investigated solutions of Luneburg-type lenses with index profiles where the required large index variation or the absolute index range was difficult to fabricate. However, it has been shown that radial index profiles with a peripheral cladding layer of a preform glass tube, which can be fabricated using chemical vapor deposition (CVD) technology, result in a cylindrical lens performance with well-corrected spherical aberration. Here, the rod is transversally radiated by a divergent line source of limited numerical aperture up to 0.5 (Fig. 8.40) [8.126].

By tuning the drawing process, diffraction-limited microlenses can be produced in the shape of fibers or rods with precise diameters and polished surface quality. The fused-silica cladding and the gradient index core of these lenses can withstand very high temperatures (the transition temperature is $\approx 1100\,°C$). The lenses can be used in the visible and near-infrared spectrum. The rods or fibers are cut to the desired lengths. These lenses are used either as fast-axis collimators for single laser diodes or for building cylindrical-lens arrays for laser diode bars. In order to accommodate a small emitter pitch, the edge of the lens may be ground to a desired width [8.127]. Typical rod diameters are 0.06–3.0 mm with correspondingly scaled focal widths.

Large GRIN Lenses with Axial Gradients
In an axial-gradient lens, a spherically curved surface usually imparts the basic focussing power, whereas the axial index gradient controls or corrects aberrations, especially spherical aberration introduced by the refraction at the spherical surface. Commercially available axial gradients are produced by a bulk glass diffusion process [8.128] in large glass blanks with diameters up to 330 mm. For designing lenses, the index profile is described by

$$n(z, \lambda_{\mathrm{ref}}) = \sum_{k=0}^{11} n_k \left(\frac{z}{z_{\max}} \right)^k , \qquad (8.87)$$

where z is the axial distance from the blank surface and z_{max} is the blank thickness. In contrast to the simple analytical solution (8.77), which is however, difficult to realize, plano-convex, biconvex and meniscus-type lenses are fabricated from specially designed Gradium® glass blanks of standard diameters between 5 mm and 80 mm. The correction of spherical and chromatic aberration by adapting the index profiles is possible, which allows one to reduce the number of surfaces in optical systems and related reflection losses and mounting complexity. Binocular eyepieces and focus heads for high-power industrial Nd-YAG welding and cutting laser systems have been developed in addition to other applications [8.130].

GRIN Rod Lens Arrays

GRIN lenses, especially with plane optical surfaces, can easily be arranged into lens arrays because of their simple geometry and the possibility to grind and polish the optical surfaces of the individual lenses in the array simultaneously. A commercially very successful application is the SELFOC® lens array [8.129] which generates a non-inverted 1:1 image (Fig. 8.41). Usually, the arrays are composed of one or more rows of lenses. The images from adjacent lenses overlap and form a continuous erect image. The short total conjugate between the object plane and the image plane, typically 9–80 mm, allows the compact integration of the optical system, even if large plane objects of up to 60 cm width have to be imaged.

The generation of erect images by single lenses, which can overlap to a uniform large image, is ascribed to the unique property of radial focussing GRIN lenses to form intermediate images inside the lens rod according to the pitch length of the lenses. In general, the pitch length of rod lens arrays is between 0.5 and 1.0 pitches, resulting in a reduced intermediate image in the middle of the rod (Fig. 8.42)

Fig. 8.41 Non-inverted 1:1 imaging by a GRIN rod lens array [8.129]
Fig. 8.42 Imaging ray traces of one array lens with reduced intermediate image

The resolution, transmission, and homogeneity of the image quality are determined by the rod lens diameter, by the numerical aperture of the lens and the related lens aperture angle (the image cone in Fig. 8.41), by the total conjugate and the working distance between the object and the lens surface, and finally also by adapting the index profile to the imaging conditions. The optimization of these parameters has been investigated in many studies [8.131–133]. Traditionally, these lens arrays have been widely applied to various photocopiers and scanning devices, to large printing machines, to medical imaging devices, and to many production lines requiring permanent control of surface quality and defect detection.

8.5 Variable Optical Components

Single-lens optical systems are only used for the least-demanding applications. They suffer, among other things, from severe chromatic and spherical aberration. To solve these problems, corrective lenses have to be inserted into the light path. If, additionally the focus needs to be changed, then the lens elements need to be moved relative to one another. This also requires additional lens elements. Therefore, high-quality optical systems with

focusing ability need to have many elements, making them complex, heavy, and bulky.

Lenses are not the only optical components with the potential to change from fixed to variable optical properties. Other optical components that can do this include optical filters, polarizers, and attenuators.

Glass is a nearly perfect optical material, but it is static; after grinding and polishing it is fixed in
Fig. 8.43 Drop of water on CD acting as lens with the potential of a variable shape. The optical refractive power and the aberrations of it are obvious. The challenge here is the control of the surface shape of the lens and the encapsulation of such device to avoid influences from the environment such as evaporation or gravity effects

a particular shape, and a change in focal power is impossible. To make an optical zoom system with glass lenses, these fixed elements must be moved back and forth along the optical axis. Glass zoom lenses are big, heavy, and expensive, and suffer from a limited field of view. The whole zoom system also has to incorporate mechanical components, such as stepping motors or piezoelectric drivers and some kind of gearing mechanism.
Fig. 8.44a–c Schematic cross section of bi- and plano–concave **(a)**, convex **(b,c)** water lenses. The shape of the air–liquid interface depends on the inner pressure p_i and the capillary forces (after [8.134])

Variable optical components try to offer ways around these limitations. Different approaches, such as materials with internal microstructures that can be altered to change their shape and/or refractive index, have been studied. Micro-fluidic systems can produce such changes of optical interfaces by varying their internal pressure or actively changing liquids. The familiar technology of liquid crystals offers a way to modulate the refractive index. Liquid-crystal-based lenses and other devices are discussed in Sect. 5.9.1.

The goal of developing variable optical components has to be the integration of new (intrinsic) variable optical properties in such components, to make them cheaper, less prone to fail because of mechanical wear, and with a form factor as small as possible for a given purpose.

The focus of this section is on the setup, production, and function of such variable optical components and concepts discussed in research and academia in this field. In spite of the great potential of replacing more-complicated optical systems more work has to be done to develop the components to a higher level to make these components part of the standard catalogue of optical components.

8.5.1 Variable Lenses

The easiest device with the potential to work as a variable lens is a drop of optical transparent liquid, as shown in Fig. 8.43. There it is obvious that liquids can work as lenses.

A major challenge is the control of the shape of the drop and therefore its optical power as well as avoiding environmental influences such as gravity, vibration, evaporation, and centering the drop on the optical axis.

Water Lens
As early as the 17th century, the English scientist Stephen Gray built microscopes using water drops as lenses with a diameter of about 0.3 mm so that their curvature was not strongly influenced by gravity [8.135]. Due to the smooth surface of the drop, Gray found that the images these lenses created were quite good. The drops were kept from moving around by placing them in tiny holes drilled in a plate. Different hole diameters led to different lenses with different drop curvatures, and therefore different magnification factors.

Using the same idea of the refractive power of the interface between air and an optical liquid a variable-focus lens is easily realized. To control the shape of

such a liquid interface, pressure can applied. For this purpose the liquid interface of water contained in small wells is used. A schematic sketch of the lens housing and possible lens types is shown in Fig. 8.44.

A capillary barrier develops at the exit of the well due to the abrupt area expansion. The shape of the air–liquid interface is described by the Young–Laplace equation of capillarity.

That such a lens is an open system is an obvious disadvantage. Environmental conditions will easily influence the shape of the air interface and the optical liquid used will most likely evaporate and therefore the lens will not have the same characteristic over a longer period of time.

A way to overcome a couple of the drawbacks mentioned above is the introduction of another liquid that is immiscible with the optical liquid. Ideally it should have the same density and a different refractive index. By using a second liquid, evaporation can be minimized since the whole system of both liquids can be encapsulated very tightly. Such an approach is shown in Fig. 8.45. An active optical surface develops at the interface between the water and silicon oil and changes its shape depending on the pressure of the water.

Using liquids with an equal density minimizes the influence of gravity and the optical interface between both liquids will therefore only be minimal disturbed. This approach is also used in electrowetting-based liquid lenses.

Electrowetting–Based Lenses

Electrowetting Phenomenon. Electrowetting describes the phenomenon of spreading liquid drops on solid surfaces due to an applied voltage across the liquid and a counter-electrode underneath the solid surface.

Lippman [8.136] started the study of this effect by observing the influence of an electrostatic charge distribution on the capillary forces and tension at an interface. The relation between the contact angle of a liquid drop on a solid surface and the interfacial tension at the three-phase point were formulated by *Young* [8.137]. Combining the results of both studies leads to the Young–Lippman equation, which describes the change of the contact angle of a liquid drop on top of a solid surface induced by electrostatic forces when a voltage is applied between the drop and the underlying counter-electrode. In earlier research on electrowetting phenomenon the electrolytic decomposition of water upon applying voltages beyond a few hundred millivolts was a problem.
Fig. 8.45 Images of radius of curvature variation with pressure for liquid–liquid interface based lenses. The lens was made of water contained in a glass aperture (1 mm diameter) and immersed in low-viscosity silicon oil (after [8.134])

In the early 1990s *Berge* [8.138] introduced the idea of using a thin insulating layer to separate the conductive liquid from the metallic electrode in order to eliminate the problem of electrolysis. This new concept has become known as electrowetting on dielectrics (EWOD).

A detailed theoretical description of the electrowetting effect can be found in [8.139]. Only the basic idea is briefly discussed here. The phenomenon of electrowetting on dielectrics is shown in Fig. 8.46.

An electrically conducting fluid drop on an insulating surface usually forms a drop with a resulting contact angle θ_0 to the surface. The shape of the drop is determined by the minimization of the interfacial energies between the insulator and the droplet, the droplet and the surrounding gaseous phase, and the surrounding gaseous phase and the insulator.

If a voltage is applied between the droplet acting as one electrode and a (counter)electrode underneath the insulating film, the droplet spread over a wider area and the contact angle θ decreases. Additionally, the minimization of the interfacial energies leads to a change of the shape of the droplet. Depending on the applied voltage a wide variety of different shapes of the droplet are possible.

The basic concept behind such a variable lens becomes obvious, by imaging the droplet being an optical
Fig. 8.46 Generic electrowetting setup. Conductive liquid droplet at zero voltage (*left*) and with applied voltage (*right*). See the text for details
Fig. 8.47 Schematic description of the device evolution from electrowetting on dielectrics to competitive electrowetting. The shape of the refractive interface is formed between the conducting liquid and the insulating liquid. Density matching makes the device insensitive to gravity forces. A conducting liquid is used as the electrode

transparent and conductive liquid with a refractive index n_l sitting on a thin insulating layer on top a transparent counter electrode. The refracting interface is formed between the optical liquid and the air.

Optical devices based on electrowetting can usually be separated into two subgroups. The first uses the electrowetting on dielectrics effect by moving liquid drops macroscopically on electrodes. A concept for an optical switch based on electrowetting on dielectrics [8.141] is discussed in Sect. 8.5.2. The second group of optical devices employs so-called competitive electrowetting. This is especially used to make lenses.

Competitive Electrowetting. The electrowetting described above has the disadvantage that it usually works best for tiny droplets where the influence of gravity is negligible. An optimization is most likely possible for special mounting positions and temperatures. For applications requiring larger diameters and which are not limited to one position of use the influence of gravity on the droplet surface has to taken into account. Additionally the influence of the electrode structures in the beam path is very often a disadvantage due to diffraction or the occurrence of stray light.

One way to avoid these disadvantages is to introduce another liquid into the system. The requirements for such a liquid are as follows. It has to be an insulating liquid, immiscible with the conducting liquid and should have the same density as the conducting liquid.

A schematic cross section through a device is shown in Fig. 8.47. The drop of insulating liquid is covered

with the conducting liquid. The device evolution is clearly visible. By applying a voltage between the conducting liquid and the counter-electrode the contact angles changes and therefore forces the liquid–liquid interface into different shapes. Due to the fact that the refractive indices for the two liquids are not equal a refracting surface is formed. This setup makes it possible to make a device insensitive to gravity forces due to the density match between the liquids. Because the packaging and the conducting liquid are used as electrodes, there will no electrodes disturb the optical path.

Components Based on Electrowetting.
Liquid Lenses. As mentioned competitive electrowetting allows the design of optical components with a refractive interface that can change its shape controlled by electrical voltage and that therefore have variable focal lengths. Such a lens was first described in [8.142]. The device is a closed cell filled with two immiscible liquids. A device with similar properties was presented in [8.143].

The first (insulating) liquid is a nonpolar oil while the other is a (conducting) aqueous salt solution. Both liquids were density-matched to within 10^{-3}. Due to this density matching of the two liquids the lens becomes insensitive to shocks and vibrations.
Fig. 8.48 Schematic representation of the liquid lens: two immiscible liquids (conducting salty liquid and insulating oily liquid) are trapped between two glass windows. The liquid–liquid interface moves from continuous ($V = 0$) to the *dashed line* when voltage is applied. The optical axis is shown as a *short line* made up of *long dashes* (after [8.140])
Fig. 8.49 Inverse focal length as a function of the applied voltage for an electrowetting-based lens. Two *curves* which correspond to increasing (*circle*) and decreasing (*square*) voltage are superimposed. The tiny hysteresis is most likely due to imperfect inner surfaces

Fig. 8.50 Schematic cross section of a membrane lens. The fluid is confined in the lens body between the glass window and the flexible membrane. The enclosed volume is changed by means of an external actuator. It is possible to obtain a converging lens (convex membrane) as well as a diverging lens (concave membrane)

The principal setup of such a liquid lens is shown in Fig. 8.48.

At low voltage, the water contact angle is high, i.e., the oil droplet has a low contact angle and vice versa. The optical power (or the inverse focal length) of a lens is shown as a function of the applied voltage in Fig. 8.49.

From 0 V to ≈ 36 V the lens has a concave and for higher voltages a convex shape. The focal length is therefore in the range −250 mm to infinity and from infinity to 40 mm.

Such electrowetting lenses seem to be very robust. It is reported that they can be switched more than 10^6 times without any sign of degradation. Switching speeds of the order of 10 ms have been achieved for a lens with a diameter of 2.5 mm [8.144]. To reach the maximal speed a precise adjustment of the liquids' viscosity is necessary, such that the drop motion is critically damped. Otherwise the droplet either oscillates several times or relaxes only slowly towards the new equilibrium shape.

Lenses with an aperture smaller 1 mm using competitive electrowetting can completely fabricated in MEMS technology [8.145]. To produce such lenses or lens arrays quadratic V-groove-defined holes are etched in a standard silicon wafer. These will later be used as cavities to hold the two liquids. Afterwards, all surfaces are passivated with an insulating layer consisting of silicon dioxide and a hydrophobic layer. For contacting the droplet, an ITO-structured Pyrex wafer is anodically bonded to the bottom of the wafer. The lens liquid is deposited in the middle of the V-groove, embedded in

the surrounding liquid, and another glass cover closes the system on top. A water-based inorganic salt solution with a refractive index of 1.51 and a density of 2.1 g/cm³ was used as lens liquid. As a surrounding liquid, a density-matched perfluorocarbon with a refractive index of 1.293 was used.

The lateral dimensions of prototype like system are 8 mm × 8 mm and the total thickness of the system is 1.525 mm. The lens aperture, which is equivalent to the size of the bottom of the V-groove, can be varied depending on application during lens production.

The back focal length of such a lens with an aperture of 300 μm can be varied between 2.3 mm and infinity using voltages between 0 V and 45 V.

Membrane Lenses

Variable lenses based on membranes have been discussed since the beginning of the 19-th century [8.146, 147]. More publications have been written and patents filed since then, but so far these devices have not made it to market, probably due to technical and material problems. They have mostly been discussed in the field of vision care in the form of spectacles with variable optical power.

Newer developments in the fields of material sciences, micromechanical technology, and optics make the successful development and production of such devices seem promising. The interest of companies and agencies looking for components for lightweight optical zoom systems [8.148] used, for example, in unmanned aerial vehicles, handheld optical devices (camera phones), and surveillance cameras is helpful in this area.

The general setup of such a lens is shown in Fig. 8.50. A cavity enclosing a transparent optical liquid with refractive index n_l has at least one variable and flexible side wall. For the optical liquids, water, salty solutions or index-matching liquids are used. The volume of the
Fig. 8.51 Dependence of effective focal length on fluidic pressure of the fluidic adaptive lens during lens-type transformation between biconvex and biconcave lens (after [8.148])

Fig. 8.52 Topography of a deflected membrane lens (aperture 400 μm) at different pressure values, measured with a surface profiler. The inflection points are seen on the outside of each graph (after [8.149])

liquid enclosed is varied by means of actuators and kept constant for a certain optical power of the optical device. It is easily seen that such a device can be used as a variable plano–convex/concave lens.

Lens diameters are 0.5–20 mm [8.149–151]. Microlens arrays can also be fabricated [8.149].

Polydimethylsiloxane (PDMS) is usually used as the membrane material [8.149, 151], although other materials such as polyvinylidene chloride, polyethylene, and polyvinyl chloride have also been discussed [8.152]; the membranes are usually 10–100 μm thick.

Setups with two flexible membranes on opposite sides of the device are als discussed in literature [8.153, 154] as well as devices with two separate cavities [8.155]. Such devices enlarge the possible choices of membrane-based variable lenses from plano–concave/convex to biconcave/convex and convex–concave and increase therefore the degrees of freedom in optical design setups.

Optical Performance of Membrane Lenses. The general optical performance of membrane lenses arises from the changes in the curvature of the membrane. Starting from a curvature with an infinite radius, where the lens acts as a parallel plate with no refractive power. With increasing pressure in the cavity, the liquid inside forms a convex lens, the lens radius decreases, and the refractive power becomes higher.

With decreasing cavity pressure the membrane forms a concave shape, and the radius decreases and

its diverging refractive power increases. Due to the more-experimental character of these devices and the wide variety of different lens parameters, such as the aperture, membrane material, membrane thickness, and optical liquids used, it is impossible to present an exact characterization of the optical performance of such lenses.

In a more-general approach an example of the optical performance of a membrane lens with two membranes taken from [8.148] is shown in Fig. 8.51.

The fluidic lens consists of a 4 mm-thick cylinder with a diameter of 20 mm, covered with two 60 μm-thick PDMS membranes on both sides of the cylinder. As the optical liquid a 63% sodium chromate solution with a refractive index of $n_l = 1.5$ was used. The pressure inside the chamber was controlled by a battery-powered fluidic control consisting of a miniaturized pump, pressure sensor, valves and an electronic control unit.

The transformation of the membrane shape from concave to convex is clearly seen, as well as the increase in optical power with decreasing radius of curvature of the membrane.

Aberrations in Membrane Lenses. The focal length of these variable membrane lenses is not the only interesting parameter. Other interesting parameters include the degree of sphericality and the apertures of the lenses that can actually be used optically.

The results of measurements of the curvature as a function of the applied pressure of a membrane lens with an aperture of 200 μm and a PDMS membrane

thickness of 50 μm [8.149], taken by using a mechanical profiler, are given in Fig. 8.52.

It is obvious that the lens profiles found are not ideally spherical. The first reason is the nonlinear deflection of the PDMS membrane. The nonlinearity of the elastic PDMS membrane, however, is an intrinsic effect of the material and is not alterable. Other, more-linear elastic materials have to be found. The other reason is the fixed edge of the membrane on a flat surface. This leads to an inflection line around the center of the lens at the lens edge. Outside this inflection line the lens curvature of a generally convex lens is concave. So the remaining convex usable aperture shrinks.

There are different ways to deal with these obstacles. The easiest is the development of such membrane lens for a special optical design, which means that the necessary change in focal length can be minimized and the mechanical setup, such as the aperture size, membrane thickness, and membrane fixtures of the lens can also be optimized.

The following countermeasures can be used in the special-purpose lens mentioned above, as well as in multipurpose lenses. To counteract the nonlinearity of the PDMS membrane a variation of thickness with the radius can be considered. This would probably increase the complexity of the manufacturing process and therefore raise the manufacturing costs. To counteract the observable inflection point a different fixture for the membrane on the lens edge may be possible. The fixture has to be formed in such a way that the membrane runs asymptotically smoothly onto the surrounding lens body. This change from a mostly 2-D approach to a more three-dimensional (3-D) approach unfortunately also probably means a change from a wafer-scale fabrication of multiple lens to a single-lens fabrication process. This leads to increased manufacturing costs for such devices.

The permeability of the membrane to gases and liquids is another issue that has to taken into account. A secondary experimental result observed while filling the lens mentioned in [8.149] is that any remaining bubbles quickly diffuse out of the system because the PDMS membrane is gas-permeable. On the other hand this means that gas is also able to permeate into the lens in the case of concave lenses, which makes this lens type more likely to fail during lifetime or makes the use of membrane lenses as concave lenses impossible.

For the thinnest membranes (thicknesses smaller than 10 μm) the membrane also becomes permeable to liquids. This leads to a loss of liquid over time and therefore to a slow change in the variable characteristic and a decay of the variable optical component in the long run.

More scientific research and development, i. e., the development of new membrane materials, the simulation of membranes in different fixtures, fabrication, optical, and environmental tests of membrane lenses are necessary to approach a perfect variable lens.

Production of Membrane Lenses. There are various ways to produce membrane lenses.

One method [8.151, 156] is it to produce the lens chamber and membrane separately using a soft lithography process. Afterwards the membrane and lens body are bonded together using an oxygen-plasma bonding technology. After the top of the lens has been formed, the bottom of the fluidic chamber is bonded to a thin glass slice for easy handling again using an oxygen-plasma-activated bonding technique.

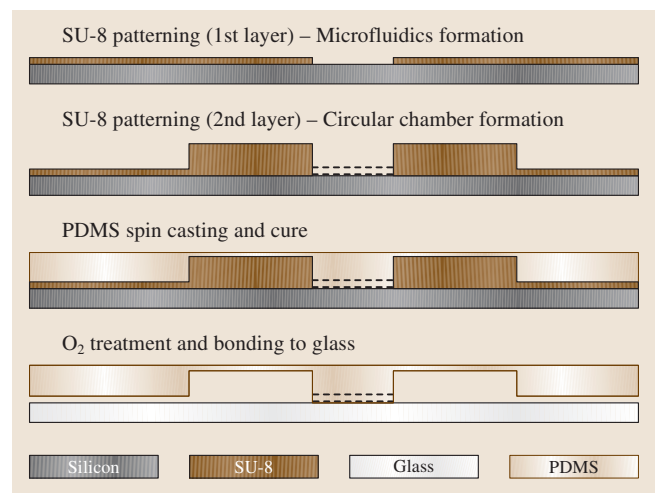
The detailed fabrication process of a membrane lens array is illustrated in Fig. 8.53. At first a ca. 10 μm-thick layer of photoresist is patterned onto a silicon wafer to form the mold for the microfluidic network. A second ca. 100 μm-thick layer of photoresist is patterned on top of the first layer to create circular chambers for the lenses. The PDMS prepolymer mixture is spincast over the mold and subsequently cured at 150 °C. The total thickness of the PDMS layer is approximately 140 μm. The thickness of the PDMS membrane in the lens area is ca. 40 μm. The cured PDMS is peeled off from the mold, treated with oxygen plasma and then irreversibly bonded to a glass substrate. Since the PDMS


Fig. 8.53 See for details (after [8.156])

layer contains both the microfluidic network and the circular chambers, no alignment is required during the bonding process.

Another way of producing membrane lenses as well as membrane lens arrays is the use of standard micro-electromechanical-systems (MEMS) processing techniques [8.149]. This has the advantage that no transfer process is necessary and therefore all process steps can take place on the same mechanical basis, which ensures similar quality for all optical elements. Using clean-room facilities ensures particle-free optical surfaces. Another advantage of using wafer-scale technology is that otherwise critical alignment steps during the assembly of various parts of the lens can be avoided. This technology seems to make the low-cost mass fabrication of such lenses possible.

A summary of the process is shown schematically in Fig. 8.54. Processing starts with photolithography on a silicon wafer polished on both sides in which the lens openings and the microfluidic channels are defined. A masking layer is deposited in wet oxidation and plasma-enhanced chemical-vapor deposition oxidation steps. The first oxide mask defines the contours of the circular lens openings with diameters of $300-600\,\mu m$, the fluidic channels, and the reservoir. This layer is structured by photolithography and subsequently opened by reactive-ion etching (RIE). In a second photolithography step, the photoresist layer is patterned. This second masking step defines the contours of the lens chambers and the reservoirs. These are then etched through half of the silicon wafer by an inductively coupled plasma (ICP) RIE process. The resist layer is removed afterwards. After coating the substrate with a primer to improve the adhesion of the PDMS to the silicon or silicon oxide, the PDMS film is spin-coated on top of the wafer. The PDMS film is cured and forms the pressure-actuated membrane, which encloses the working liquid and therefore defines the curvature of the lens.

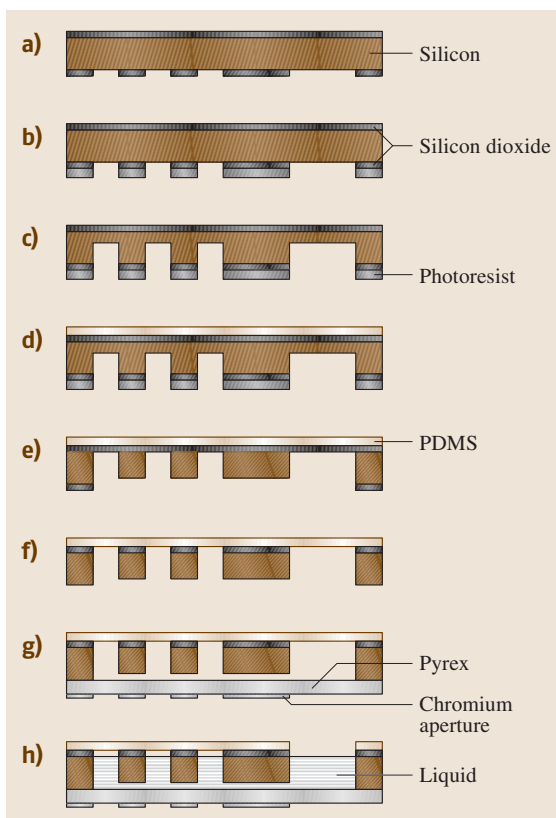
In a second ICP RIE etch step the lens chambers, the reservoirs, and the fluidic channels are etched simultaneously, passivated by the structured SiO_2 layer. The etching stops abruptly when the SiO_2 layer at the front side is reached due to the etch selectivity of SiO_2. The remaining front-side SiO_2 layer is removed in a final RIE step. This means that the PDMS membrane is now stretched freely over the silicon lens chamber. To cap the fluidic channels and chambers, a thin Pyrex wafer is being bonded to the back side of the silicon substrate with a UV-curable optical adhesive. To minimize scattered light and cross talk between the single


Fig. 8.54a–h Schematic process description: **(a)** Silicon wafer with both side SiO_2 layer and with back side opened by reactive-ion etching (RIE); **(b)** Photoresist, spin-coated and structured; **(c)** First inductively coupled plasma RIE etching; **(d)** Spin-coating of primer and PDMS; **(e)** Second ICP RIE etching; **(f)** SiO_2 removal; **(g)** Bonding of the Pyrex wafer and patterning of the back-side chromium layer; **(h)** Sawing and filling of the devices (after [8.149])

lenses of an array, an aperture stop made of a $100\,\mu m$-thick structured chrome layer on the Pyrex wafer is required.

The wafer stack is then separated into individual chips by sawing. To prepare the fluidic lenses for operation, the cavity is filled with a liquid optical medium.

A similar process to fabricate membrane lenses with two flexible membrane sides is described in [8.154].

Actuation Mechanism. A rudimentary activation mechanism, mostly used in laboratory setups, is the use of a syringe pump to inject fluid into the lens chamber. Other actuation mechanisms also employ external pressure. To get a higher degree of control over the lens,
Fig. 8.55 Schematic view in a magnetic actuator. The ferrofluid is confined between two flexible membranes; the lower membrane separates the ferrofluid from the working fluid (pressure connection). The attractive force between the electromagnetic field and the ferrofluid leads to a decreasing pressure in the pressure connection and therefore a change in the optical active surface of the membrane lens connected to the actuator (after [8.158])

the pressure is built up by, for example, piezoelectric elements, MEMS-based miniature pumps or ferrofluids. For advanced variable optical lens systems it is necessary to employ automatic control including a pressure sensor to ensure uniformity of the optical power of the lens over a given amount of time. Highly integrated pressure sensors are made, for example, by MEMS technology [8.157]. Such controls are still in development and have to be integrated with the variable optical parts to give the new variable optical components a chance on the market.

External Pressure. Variable focusing in liquid-filled lenses has been demonstrated by deflecting the lens membrane using pressure-driven mechanisms such as external pumps [8.150] or piezoelectric stack actuators [8.160].

Piezoelectric stack actuators are suitable actuators for driving variable optical lenses even though their working range is usually too short ($\approx 10\,\mu m$) to actuate the lens surface directly. There are two ways to solve this problem; both mechanically amplify the stroke of the piezoelectric actuator stack. The first is a mechanical lever that transforms the small stroke into a larger one, the other way makes use of the incompressibility of the liquid. The cross-sectional area of the cylinder pressed on with the piezoelectric aactuator stack is several tens of times larger than that of the lens surface, and therefore the distortion of the lens surface is a couple of times that of the cylinder.

Magnetic Actuation. Ferrofluids provide another method to actuate a given variable membrane lens by magnetic forces. Ferrofluids are liquids with paramagnetic properties that combine rheological characteristics with strong force action. They consist of magnetite particles (Fe_3O_4 with a diameter of $10\,nm$ dispersed in a liquid [8.161]. The possibility to fill any given or even changing geometry with ferrofluids and the easy integration into a system are the main advantages of this actuation method.

In Fig. 8.55 the actuator is shown as it generally functions [8.158]. A volume of ferrofluid is enclosed between two elastic membranes, which seal a chamber in a plastic housing. A magnetic field above the upper membrane attracts the ferrofluid and the upper membrane bulges upwards. The incompressible fluid causes the lower membrane to follow accordingly. Thereby, a negative pressure can be generated below the second membrane. This negative pressure can be used to pump a secondary fluid that fills the chamber below the double membrane and features a pressure connection to a membrane lens. The magnetic field can be produced by means of an electromagnet and thereby control the shape of the membrane lens by an electric voltage.

Due to the effect that ferrofluids can only be attracted by magnetic fields, this actuator is only able to decrease the optical power of a given membrane lens.

Stimuli-Responsive Hydrogels. Another way to change the optical power of a lens is the incorporation of stimuli-responsive hydrogels, as described in [8.159].
Fig. 8.56 Schematic view on a hydrogel lens setup. The interface between two immiscible optical liquids (water bottom, oil top) with different refractive indices forms an optical surface. The water is confined between the glass substrates, oil, and hydrogel ring. The outside of the hydrogel ring is accessible to various other liquids to change the volume of the hydrogel ring. Changes in the volume of the hydrogel ring lead to changes in the confined volume and therefore in the shape of the water–oil interface (after [8.159]).

The principal setup of such a lens system is shown in Fig. 8.56. There is a wide variety of hydrogels that react upon changing environmental conditions such as temperature or *p*H to incorporate or exclude water molecules in their structure, which results in a changing volume of the substances.

8.5.2 New Variable Optical Components

Electrooptical Switches Based on Electrowetting

A concept for a 1×2 optical switch based on total reflection and electrowetting [8.141] is outlined in Fig. 8.57.

The proposed sandwich structure consists of a top and bottom glass substrate each coated with an electrode structure and an insulating hydrophobic layer. One of the electrode structures is segmented and it is possible to switch the different electrodes in a timely manner to move the droplet in between the sandwiched structure using electrowetting forces.

A 45° prism is attached to both glass substrates to avoid total reflection at the air–glass surface and allows light to be coupled into and out of the device. The collimated light is guided through the prism into the electrowetting device. Placing the liquid droplet in the optical path, the gap between the two glass substrates is index-matched and the light is transmitted through the sandwich configuration to the output S2.

The liquid droplet can be driven out of the optical path by electrowetting forces due to the application of a voltage to the counter-electrodes in a timely manner. Now the gap between the top and bottom substrate is filled with air and not with index-matching liquids any-

more. Total reflection of the light beam takes place on the interface between the glass and air. Therefore the light will exit the device at the second output S1.

The concept has the potential to become highly integrated and applied in a matrix switch. In comparison to other concepts for optical switches it is important to note that this setup does not need precise movement and all optical parts that require precise alignment have fixed positions.

8.5.3 Outlook on Variable Optical Components

Variable optical components have great potential to replace conventional optical systems in a wide variety of applications [8.154]. Applications in high-volume and low-cost markets, for example cell phones and web cameras, are particularly appropriate for early use of components with intrinsic variable properties. The advantages of integrating these properties into the components will probably result in smaller form factors, more freedom in the design of such devices, easier and quicker assembly, and finally lower manufacturing costs and higher profit margins. The liquid lens from Varioptics (Lyon, France), which is based on electrowetting, is the component closest to serious production. Electronic controls are also ready and will probably be seen in prototype mobile-phone cameras in the next months [8.162]. Membrane lenses are not at this stage yet. More work has to be done to develop new membrane materials and to integrate actuation and control into the variable component.

Other developments, such as variable filters or polarizers based on liquid crystals will easily find special niche applications in which to succeed.

All technologies for variable optical components face strong competition from existing technologies. They have to find there way into optical designs and prove there advantages and abilities to potential users. Since existing technologies are already approved and in the market there have to be clear advantages of using the new technologies. In the end this will require lower manufacturing costs to replace existing operational solutions. The key to success will probably be an application that is made possible only through such a new technology.

The development of existing technologies is also progressing and continuing to give easier and cheaper solutions to the problems, and some technologies may become extinct due to changes in other areas.
Fig. 8.57a,b Schematic drawing of the concept for an optical switch based on electrowetting. **(a)** The liquid droplet with a refractive index close to the refractive index of the hydrophobic layers and glass is positioned in the beam path of the light by electrowetting. The light is transmitted nearly without any losses to S2. **(b)** The droplet is moved out of the beam direction. Total reflection occurs at the interface between the dielectric layer and air (after [8.141])

8.6 Periodically Poled Nonlinear Optical Components

Obtaining quasi-phase matching (QPM) by periodically alternating the sign of the second-order nonlinear coefficient $\chi^{(2)}$ was first proposed in 1962 in a landmark paper by *Armstrong* et al. [8.163]. It took, however, nearly 30 years until efficient generation of frequency-doubled laser light with QPM in a periodically poled nonlinear material was realized [8.164–166]. The final breakthrough of QPM occurred with the first tunable laser source in the infrared wavelength regime using a bulk periodically poled lithium niobate crystal (PPLN) in an optical parametric oscillator (OPO) setup [8.167, 168].

This section will briefly review the physics of quasi-phase matching (Sect. 8.6.1). Because it continues to be a challenge, a detailed description of the actually techniques used to fabricate periodically poled crystals will be given (Sect. 8.6.2) followed by the standard techniques for the visualization of the obtained structures (Sect. 8.6.3). Finally, the currently most prominent applications for periodically poled crystals are described (Sect. 8.6.4).

8.6.1 Fundamentals

Second-Harmonic Generation (SHG)

In second-harmonic generation (SHG, also called *frequency doubling*) photons interacting with a nonlinear medium are effectively combined to form photons with twice the energy, and therefore twice the frequency of the initial photons (Chap. 3).

For efficient SGH three features must mainly be fulfilled:

1. the pump intensity I must be sufficiently high over a certain propagation length since, at least for small conversion efficiencies, the SHG generation is proportional to I^2,
2. the nonlinear medium must have a high second-order nonlinear coefficient $\chi^{(2)}$, and
3. the light beams involved need to preserve their phase relationship over the propagation length.

Whereas (1) can be achieved by using high-power laser beams and for (2) a careful choice of the material is necessary, (3) requires additional measures since dispersion generally leads to a phase mismatch between the frequency of the pump laser beam (ω) and the frequency-doubled frequency (2ω).

This phase mismatch between ω and 2ω waves leads to destructive interference of the SHG light generated at
Fig. 8.58a,b Second-harmonic generation. **(a)** No phase matching: light generated at position 2 ($2\omega^{(2)}$) is out of phase with respect to the light generated at position 1 ($2\omega^{(1)}$). **(b)** Quasi-phase matching: by inversion of the sign of $\chi^{(2)}$, $2\omega^{(2)}$ is in phase with $2\omega^{(1)}$

the very beginning of the nonlinear crystal with that generated further inside the medium, thereby limiting the maximum output power (Fig. 8.58a). This problem can be overcome in birefringent crystals by choosing a particular orientation and keeping the crystal at a certain temperature such that both waves, ω and 2ω, propagate in the same direction and experience the same refractive index, so-called *noncritical phase matching* (NCPM). In general, these conditions are difficult to achieve, and because the value of $\chi^{(2)}$ also depends strongly on the orientation of the crystal, NCPM often results in an unsatisfying tradeoff.

There is, however, a very successful approach to preserving the phase relationship between ω and 2ω waves, so-called quasi-phase matching, which will be described in the following.

Quasi-Phase Matching (QPM)

For quasi-phase matching, the nonlinear susceptibility $\chi^{(2)}$ is modulated periodically to compensate for disper-
Fig. 8.59 **(a)** Efficiency of second-harmonic generation in a nonlinear crystal without phase matching, with quasi-phase matching (**b**), and with perfect phase matching (**c**). There Λ denotes the period length of the periodically poled nonlinear crystal

Table 8.4 Selected properties of frequently used nonlinear crystal materials utilized in periodically poled devices [8.169–171]. d_{im}: nonlinear optical coefficient; T: transparency range; opt. dam.: optical damage threshold for a given pulse duration

Crystal	d_{im} (pm/V)	T (μm)	Opt. dam. (GW/cm^2)
Lithium niobate (LiNbO$_3$)	$d_{33} = -27$	0.36–5.8	0.5 (10 ns)
Lithium tantalate (LiTaO$_3$)	$d_{33} = -21$	0.32–5.5	
Potassium titanyl phosphate (KTP, KTiOPO$_4$)	$d_{33} = 8.3$	0.34–3.2	4.4 (1.3 ns)
Beta barium borate (BBO, β-BaB$_2$O$_4$)	$d_{22} = 2.3$	0.2–2.6	9.9 (1.3 ns)
Cadmium selenide (CdSe)	$d_{33} = 36$	0.75–25	0.06 (10 ns)
Gallium arsenide (GaAs)	$d_{14} = 94$	0.9–17	

sion, i.e., in a nonlinear crystal, the orientation of the optical axis is periodically inverted. In ferroelectric materials this can be achieved by periodic inversion of the spontaneous polarization, i.e., of the ferroelectric domains (Fig. 8.58b). The period length Λ determines the wavelengths for which the specific nonlinear process is quasi-phase-matched. This Λ can be determined by an empirical relationship called the Sellmeier equation between the refractive indices n_i and wavelengths λ_i for a particular medium. Figure 8.59 schematically depicts the effect of QPM on the efficiency of second-harmonic generation in a nonlinear crystal.

The phase-matching condition for QPM and for the splitting of a pump wave into signal and idler waves is

$$\Delta k = k_p - k_s - k_i = 2\pi/\Lambda , \tag{8.88}$$

where k_p, k_s, and k_i are the wave vectors of the pump, signal, and idler waves, respectively, and Δk is the so-called phase mismatch, assuming that all wave vectors are collinear with the grating vector. Energy conservation requires $\omega_p = \omega_s + \omega_i$.

Frequently Used Materials
For practical applications plenty of different properties of nonlinear crystals are of importance, first of all of course the magnitude of the nonlinear coefficient $\chi^{(2)}$, particularly if the available optical intensities are low. However, the optical transparency for all the involved wavelengths is also of major importance, as well as the optical damage threshold. The latter is a measure of the maximum optical intensity for a given wavelength and pulse duration supported by the crystal without being destroyed. Although there has been substantial improvement in the past years, the optical damage resistance of nonlinear optical crystals is still a challenging research area [8.172–174]. Properties such as the material's potential to be periodically poled, the availability of crystals with consistently good quality, large size and a reasonable price and finally chemical durability may also influence the choice for a specific material. Table 8.4

lists the main properties of some relevant nonlinear crystals. A more-detailed list can be found in [8.169].

Very recently, a new type of materials, so called oriented-patterned (OP) materials have been developed, with gallium arsenide (GaAs) being the most promising example [8.175]. This is mainly due to its large nonlinear susceptibility, broad transparency range, low optical absorption, high thermal conductivity, high laser-damage threshold, and last but not least well-developed material technology.

8.6.2 Fabrication of Periodically Poled Structures

Depending on the application, periodically poled structures with period lengths of a few to some tens of microns are required. The necessary interaction length, i.e., the size of the periodically poled structure should reach several mm, over a thickness of some hundreds of microns to obtain reasonable output power. The latter specification can be circumvented by using waveguide techniques, thereby achieving a much higher interaction length for the confined light. Although advantageous because the required material length is shorter, and also because the periodically poled structures are necessary only at the surface layer, the crucial drawback of this approach lies in the optical damage threshold of the material, which is why higher output powers are generally achieved in bulk periodically poled crystals.

Electric Field Poling
Poling of domain patterns is usually achieved via ferroelectric domain engineering: applying electric fields of appropriate polarity and field strengths above the so-called coercive field E_c to cause domain reversal. The standard technique for the generation of periodic domain structures uses patterned electrodes generated using a photolithographic process (Fig. 8.60). This technique fails, however, for small poling periods ($\ll$ 5 μm) in thick crystals ($\geq$ 0.5 mm), because of an unavoidable

spreading of the poled region with respect to the electrode size due amongst others to the enhanced electric fields at the electrode edges.

Corona Poling. To overcome these limitations, miniaturization of the electrodes is required. A possible solution relies on corona poling, thereby applying the required electric fields through an ultra-sharp tip (e.g., from a scanning force microscope) to the positions of the crystal to be poled [8.176]. A drawback of this technique is the sequential writing of domain patterns, which is therefore relatively slow. It is therefore preferred only for the generation of domain structures for storage applications [8.177].

E-Beam Poling. A similar technique uses the electron beam from an electron-beam lithography system to deposit electrons on top of the crystal, thereby generating the high electric fields required for poling. Gratings with periods as small as $1.6\,\mu m$ across $500\,\mu m$-thick $LiNbO_3$ crystals have been obtained [8.178]. Even smaller structures of $< 200\,nm$ can be generated in thin ($< 10\,\mu m$) liquid-phase epitaxy (LPE) $LiNbO_3$ films [8.179]. As for corona poling, this technique is slow because it is sequential and lacks a precise long-range periodicity due to stepping misalignment.

Light-Assisted Poling

To overcome these limitations on the depth of domain growth, a very promising new technique has been developed: light-induced poling. Controlled domain reversal is obtained by applying a homogeneous electric field slightly smaller than E_c in addition to a modulated UV-light intensity pattern (ideally generated by two interfering laser beams) [8.180]. Because in certain crystals (namely Mg-doped $LiNbO_3$) UV light reduces the coercive field [8.181], the light pattern is transferred into a domain pattern. In recent experiments, all-optical switching of ferroelectric domains has also been achieved, thereby avoiding the application of any electric field to the crystal.

Poled Growth

In some materials, namely $LiNbO_3$, poling of domain patterns during crystal growth has been successfully demonstrated with period lengths smaller than $4\,\mu m$ [8.182, 183]. Although quite promising, the quality, namely the long-range periodicity of those periodically poled crystals, is not yet satisfactory, therefore this technique still needs improvement for wider application.

For the generation of orientation-patterned GaAs, all-epitaxial growth has been utilized. This process is based on photolithography and molecular-beam epitaxy to grow a thin-film template with the desired periodic crystal inversions. In a further step, a thick film is grown on this sample by hydride vapor-phase epitaxy to fabricate bulk orientation-patterned crystals [8.171].

8.6.3 Visualization of Ferroelectric Domain Structures

For the improvement of the quality of domain patterns a reliable, easy-to-use visualization technique is required. Freshly poled domain structures can be observed by means of optical microscopy due to stress-induced birefringence at the domain boundaries. The main drawbacks of this simple technique are its limited lateral resolution (a few microns) as well as the restriction to recently made domains. Among a multitude of visualization techniques [8.184], two standard methods are mostly applied, as discussed briefly below. Whereas the first is best suited for a large overview on the domain structures, the second enables an otherwise unreachable lateral resolution.

Domain-Selective Etching

This technique is based on the fact that the etch rate of a certain material depends on the orientation of the polar axis. As a consequence the domain configuration can be transferred into a topographical structure which can then be imaged by means of optical microscopy, or in the case of smaller domain patterns ($<$ micron-sized) as a topographical image by scanning force microscopy. Although it is destructive, this technique is still that most often used, mainly because of its ease of use [8.185].

Piezoresponse Force Microscopy (PFM)

This technique takes advantage of the fact that all crystals exhibiting ferroelectric domains are also piezoelectric. Furthermore, inverting the orientation of the spontaneous polarization also inverts the piezoelectric tensor element. This is why applying an electric field to a crystal reveals the domain structure as a topographical structure via the converse piezoelectric effect. In PFM, a standard scanning force microscope is modified to allow application of voltages to the tip, thereby generating an electric field inside the crystal at the position of the tip while it scans across the surface. Depending on the orientation of the ferroelectric domain, the crystal expands or contracts underneath the tip, thus allowing one to map the domain configuration with a lateral resolution of some $10\,nm$. The thickness changes to be measured are on the order of only some $10\,pm$ and hence a frequency-selective detection scheme is used, applying

an alternating voltage to the tip with subsequent lock-in detection [8.186].

8.6.4 Applications

In general periodically poled nonlinear materials are used to obtain quasi-phase-matching conditions for frequency conversion and therefore a higher output light power at the desired wavelength. Frequency conversion in nonlinear optical materials can be classified as follows:

- Second-harmonic generation (SHG):
  $\omega + \omega \rightarrow 2\omega$;
- Sum-frequency generation (SFG):
  $\omega_1 + \omega_2 \rightarrow \omega_3$;
- Difference-frequency generation (DFG):
  $\omega_3 - \omega_2 \rightarrow \omega_1$;
- Optical parametric generation (OPG):
  $\omega_3 \rightarrow \omega_1 + \omega_2$.

The current state of the art of the two main applications, frequency doubling via SHG and optical parametric generation as a source of infrared (IR), light will be presented in the following.

Second–Harmonic Generation (SHG)

Frequency doubling, thereby generating shorter wavelengths, is of special interest mainly because infrared light is relatively cheap, high-power IR laser diodes are available, howeven, laser light in the blue wavelength range is still difficult to obtain. For the experimental realization, there are several boundary conditions that need to be fulfilled. This is the reason why blue lasers based on frequency doubling in periodically poled nonlinear materials can only reach output powers of about 100 mW. Their main drawback currently lies in the optical damage threshold of the material. Note that the crystals need to have a high damage threshold for the pump as well as for the SHG light. Because the efficiency of SHG is proportional to I^2 of the IR pump light, a high power density inside the nonlinear medium is desired. From this point of view, waveguide techniques appear an ideal concept for efficient frequency doubling. However, optical damage of the crystals is still a crucial drawback. Currently, using MgO-doped periodically poled lithium niobate (PPLN), an output power of 25 mW (340 nm) out of 81 mW in the waveguide-based technique has been shown [8.187]. Typical values for an intracavity periodically poled potassium titanyl phosphate (PPKTP) frequency doubler, using a bulk crystal for frequency doubling, are 234 mW (461 nm) with 310 mW input
Fig. 8.60a,b Standard technique for the generation of periodically poled bulk nonlinear crystals. A single-domain crystal (spontaneous polarization P_s) is partially poled by applying a voltage through structured electrodes (**a**). In (**b**) the resulting domain pattern is shown
Fig. 8.61a–c Signal and idler output wavelengths of OPO operation for different grating periods Λ. The pump sources shown are (**a**): Nd:YAG (2ω) laser – 532 nm; (**b**): Nd:YAG laser – 1064 nm; (**c**): Er-doped fiber laser – 1550 nm

power [8.188] or even 500 mW (473 nm) with 800 mW input power [8.189].

Optical Parametric Generation

Many applications require laser sources in the mid-infrared wavelength between 2 μm and 20 μm, mainly for spectroscopic measurements of organic and inorganic molecules. A continuously tunable laser source with a narrow linewidth in this wavelength region is therefore highly desirable. A possible solution consists of using the OPG process, which allows the generation of the desired wavelength depending on the pump wavelength and the nonlinear material used. It can be tuned by choosing the phase-matching conditions, i. e., coarsely by the grating period Λ of the periodically poled nonlinear crystal and a fine adjustment by heating the crystal (Fig. 8.61). In order to make a powerful laser source, the nonlinear medium is brought into a cavity that is tuned on resonance for the non-desired wavelength. An overview of mid-IR frequency generation can be found in [8.169].

There are basically two different operation schemes for optical parametric oscillators (OPO). For continuous-wave operation a high pump-laser intensity is required to reach the threshold for frequency conversion. Another possibility consists of using an intracavity pumped setup, with the nonlinear medium placed inside the laser cavity.

Most OPOs, however, are pumped with nanosecond pulses from a Q-switched laser, thus easily reaching the required light intensities inside the nonlinear material. Typical emissions are nanosecond pulses in the near- or mid-infrared region with pulse energies up to a few millijoules.

8.7 Photonic Crystals

A photonic crystal (PC) is defined, in a narrow sense, as a crystal in which the dielectric constant (ε) periodically varies spatially in specific directions; for the reader's convenience we cite several textbooks and feature issues of journals for PCs [8.190–200]. In order to control the light field, the lattice constant (a) should be comparable to the wavelength λ of the relevant light. In the case where the variation is along one direction, it is called a 1-D PC. Similarly, we define 2-D and 3-D PCs, corresponding to the cases where ε varies along two and three independent directions, respectively.

Figure 8.62 shows schematics of representative examples. For a 1-D PC there is the well-known example of the multilayer dielectric film; in this review, however, there is little mention of 1-D PCs. In the case of 2-D PCs, shown in Fig. 8.62b, the intersection of air or dielectric rods with the plane perpendicular to the rod axis form a 2-D lattice; this plane is the 2-D PC plane. Let us consider the simple case of a 1-D PC. As is well known, states (or eigenmodes) of light in this PC with wave vector $\mathbf{k}$ parallel to this particular direction differ greatly from those in a uniform dielectric. Similarly, the respective eigenmodes of light with $\mathbf{k}$ in the 2-D plane for 2-D PC and with $\mathbf{k}$ in an arbitrary direction in the 3-D PC become unique compared to homogeneous 2-D and 3-D dielectrics. As for a 3-D PC, there are a variety of examples other than the two shown in Fig. 8.62c. An array of polystyrene spheres suspended in water, the first 3-D PC sample, was made as early as the 1960s and is the example shown on the right of Fig. 8.62c. Currently, a similar sample called an artificial opal crystal made of SiO_2 is also being intensively studied, together with so-called inverse opals.

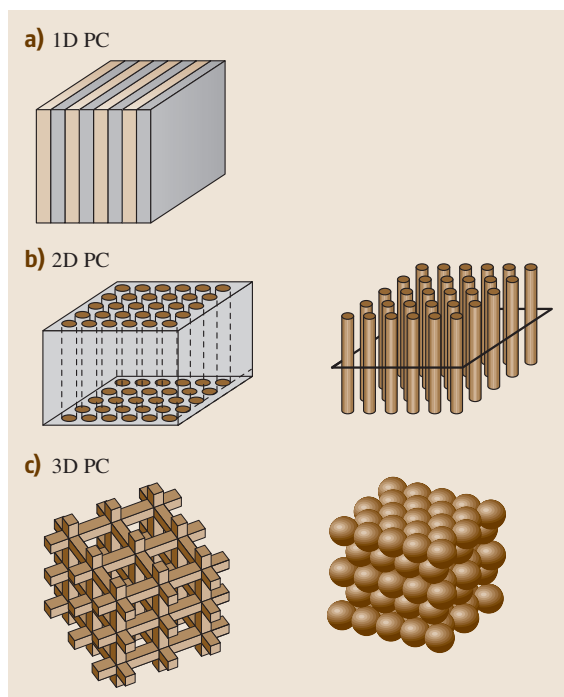
The situation for the PC slabs shown in Fig. 8.63a also greatly differs from those of the corresponding 1-D


Fig. 8.62 Schematics of representative 1-D, 2-D and 3-D photonic crystals
Fig. 8.63a,b Schematics of (**a**) photonic-crystal slabs and (**b**) photonic-crystal fiber

and 2-D PCs. Namely, if the thickness of the slab is of the same order as or smaller than the relevant wavelength of light, the situation is completely different from 1-D (2-D) PCs where the sample thickness is a priori assumed to be infinitely large. For the latter case, a plane wave propagating along one direction (1-D PC) or in the 2-D plane can be well defined, so that there is no need to treat a 2-D PC problem three-dimensionally. Figure 8.63b shows a schematic of a PC fiber, another important example of PCs where the plane perpendicular to the fiber forms a 2-D PC lattice except for the central portion along which light can propagate. There are two types of PC fibers: holey (index guiding) fibers, in which the central potion is made of a dielectric, and photonic band-gap fibers, in which it is filled with air.

Thus far we have classified PCs according to their dimensionality. However, there are related systems which are not covered by this classification based on the translational invariance. Quasi-crystal PCs having parallel rods arrayed on 2-D quasi-crystal lattice sites, and their relatives specified by well-controlled randomness of the rod sites are typical examples [8.201]. Since they are both characterized by the existence of a clear-cut photonic bandgap (PBG), we treat them as PCs in this article. Concerning fabrication methods of the representative samples in the optical region, see [8.200].

8.7.1 Photonic Band Structures

Light States in Photonic Crystal

In general the eigenstates (modes) of light are specified by a set $(\mathbf{k}, \hbar\omega, \mathbf{e})$, where $\mathbf{e}$ is the unit vector denoting polarization. The eigenstate in a PC where $\varepsilon(\mathbf{r})$ varies periodically with respect to $\mathbf{r}$ (position vector) differs greatly from that in a homogeneous medium. Suppose for simplicity that the dielectric (insulator) has the vacuum magnetic permeability μ_0. Assuming that the light is harmonic, i. e., $\mathbf{E}(\mathbf{r}, t) = \mathbf{E}(\mathbf{r}) \exp(-\mathrm{i}\omega t)$ and $\mathbf{H}(\mathbf{r}, t) = \mathbf{H}(\mathbf{r}) \exp(-\mathrm{i}\omega t)$, the equation, e.g., for $\mathbf{E}(\mathbf{r})$ can be derived from Maxwell's electromagnetic equations as

$$\operatorname{rot}\operatorname{rot}\mathbf{E}(\mathbf{r}) = [\omega^2 \varepsilon(\mathbf{r})]\mathbf{E}(\mathbf{r}) . \tag{8.89}$$

Namely, the problem is reduced to solving this equation, which was first done for a 3-D periodic array of dielectric spheres [8.202]. A similar equation can also be derived for $\mathbf{H}(\mathbf{r}, t)$, but $\mathbf{H}(\mathbf{r})$ is obtained from $\mathbf{E}(\mathbf{r})$ by using the relation, $\operatorname{rot}\mathbf{H}(\mathbf{r}) = -\mathrm{i}(\omega/c^2)\mu_0\varepsilon(\mathbf{r})\mathbf{E}(\mathbf{r})$.

The above equation can be solved by using, for example, the widely used plane-wave expansion method [8.197, 200]. Namely, the solution $\mathbf{E}_\mathbf{k}(\mathbf{r})$ is ex-

pressed as a superposition of Bloch-type plane waves,

$$\mathbf{E}_\mathbf{k}(\mathbf{r}) = \Sigma\mathbf{e}_\mathbf{k}(\mathbf{G}_i) \exp[\mathrm{i}(\mathbf{k} + \mathbf{G}_i)\cdot\mathbf{r}] , \tag{8.90}$$

where $\mathbf{G}_i$ is the i-th reciprocal lattice vector, and the vector amplitude $\mathbf{e}_\mathbf{k}(\mathbf{G}_i)$ is to be determined so as to satisfy the (8.89). Substituting (8.90) and the Fourier expansion version of $\varepsilon(\mathbf{r}) = \Sigma\varepsilon(\mathbf{G}_i) \exp(\mathrm{i}\mathbf{G}_i\cdot\mathbf{r})$ into (8.89) and setting the coefficients of each of the plane waves to zero, we get the eigenvalue equations for $\mathbf{e}_\mathbf{k}(\mathbf{G}_i)$. From this equation, the secular equation for the eigenvalues ω^2 can be derived; needless to say, for each eigenstate characteristic spatial patterns of the electric [$\mathbf{E}_\mathbf{k}(\mathbf{r})$] and magnetic [$\mathbf{H}_\mathbf{k}(\mathbf{r})$] field are specified. We note that, in a 3-D PC with a sufficiently large variation of ε, i. e., $\varepsilon = 10$ against 1 (air), we often need to include more than 1000 plane waves to obtain very accurate values of ω^2; this is because the coupling between light and matter is much stronger in the optical (visible) region than in the X-ray region, because of the much stronger Bragg diffraction.

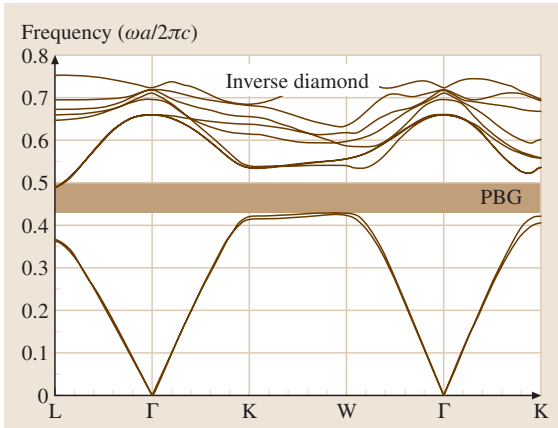
We plot the eigenfrequency (eigenenergy) $\omega(\mathbf{k})$ thus obtained as a function of $\mathbf{k}$ in the reduced Brillouin zone (BZ), which is called the *photonic band* (PB); The PB is split into many bands, which are numbered by the band index n in order of inverse energy. The photonic band structure (PBS) shown by $\omega_n(\mathbf{k})$ is unique and quite different from that in the homogeneous media in terms of the density of light states (DOS). A remarkable difference is that in a PBS a particular energy region often exists where no light states exist for any direction [8.203]
Fig. 8.64 Photonic band structure of a 2-D PC of cylinders arrayed in a square lattice: TM bands (*thick lines*) and TE bands (*thin lines*). The cylinders of $\varepsilon = 12$ are arrayed in a lattice in air. The ratio of the radius r of cylinders to a is 0.3. The frequency ω is shown in dimensionless units, i. e., by being normalized by $2\pi c/a$


Fig. 8.65 3-D photonic band structure with the diamond lattice (a sample of inverse diamond structure; for details, see the text)

Fig. 8.66 Guided modes in a 2-D air-rod PC slab below the air-light line. *Filled* and *open circles* denote even and odd modes, respectively. The parameters are such that $\varepsilon = 11.9$, $r = 0.44a$ and $d = 2a/3$ where r and d refer to the hole radius and the slab thickness, respectively [8.204]

or for a range of directions often appears. We call the former a full (PBG) and the latter an incomplete photonic band gap (or stop band). Hereafter we call both of them simply as PBG when there is no need to emphasize the difference.

Here a question arises as to whether a PBS obtained for an infinitely large system makes sense in a realistic finite sample. This question is reasonable because the true bound states do not exist in the case of photons, in contrast to electrons which have definite bound states in the negative energy region. If the escape from a finite PC to the exterior region is large, the PB picture valid for an infinite system would lose its practical meaning. A pioneering work examined this question as early as the 1980s [8.205], revealing that the PBS in the ideal case can be used for a finite structure if the (lossless) eigenstate is regarded as leaky. Several important examples of PBS are presented below.

2–D Band Structure

Figure 8.64 shows an example of a 2-D PBS for a 2-D PC of dielectric cylinders ($\varepsilon = 12$) arrayed in a square lattice in air. The eigenmodes can be specified by their polarization, and are classified as TM or TE modes for E or H parallel to the cylinders, respectively; in this case, three 2-D PBGs are seen to open only for TM modes. Each band belongs to the specific irreducible representation of the relevant point group, which depends not only on the polarization, but also on the k direction. As a result, for example, if the group of a wave-vector k contains a mirror operation, then any state of that k is classified into even or odd symmetry according to whether E is

symmetric or antisymmetric with respect to the mirror plane. This statement is important, for example, in coupling between external light and a PC state. Suppose an external light beam incident at normal incidence on a flat surface of a PC sample. Then, if the group of k with k the wave vector of incident light involves a mirror operation and the polarization is perpendicular to the mirror plane, the odd-parity (even-parity) modes cannot be coupled to even-parity (odd-parity) external light, and are called *uncoupled modes*. We note that the first and second bands are often called the dielectric and air band, respectively, since the electric field is localized to a considerable extent around the dielectric cylinders and the air background, respectively [8.193].

3–D Band Structure

Figure 8.65 shows an example of a PBS for an inverse diamond lattice structure, which is composed of tetrabonds consisting of air rods (diameter r) in a dielectric of $\varepsilon = 7$; $r/a = 0.1$. The shape of the first BZ is the face-centered cubic (FCC) lattice. It is seen that a full PBG opens in all directions; the fact that a full PBG opens in a 3-D PC with a diamond structure has been experimentally evidenced in the optical region [8.199]. This PBG corresponds to the well-known BG of electrons in a semiconductor such as GaAs, which also has the same BZ structure. The photonic and electronic structures resemble each other in many respects,

which arises from the resemblance of the two wave equations.

Band Structure of Slab-Type PCs

Air-hole semiconductor 2-D slab PCs have been studied intensively. In particular, two kinds of slab PCs are the most important: the air-bridge type, in which the core is suspended in air, and the clad type. A slab PC with the core made of AlGaAs or Si, and that of SiO_2/Si/SiO_2 are representative of the former and the latter, respectively. A typical PBS calculated for a triangular-lattice air-bridge PC is shown in Fig. 8.66.

The guided modes exist in the region below the so-called air light cone, where light can be confined due to total internal reflection [8.193]; light belonging to the modes inside this cone are leaky, i. e., light escapes from the slab region, just like the case for conventional slab waveguides (WGs). It is seen that for TE-like modes there is an energy region where no guided modes exist. Usually, in the case of slab PCs the term PBG is used for this situation. It is important to note that even in these 2-D PC slabs strong 3-D confinement of light is realized with a combined use of a 2-D PBG in the 2-D plane and total reflection in the direction perpendicular to the plane.

Band Structures of Other PCs

Metallic Photonic Crystal (MPC). In a MPC the plasmon modes of individual units can hop from one unit to another to form tight-binding plasmon bands. Due to the multipolar moments associated with the excited charge fluctuation, they can mix with light to become plasmon polariton bands. A large band gap, omnidirectional in favorable cases, originates from the large frequency difference between the different plasmon modes of individual units [8.206]. Thus, MPCs have potential applications in waveguiding and signal processing using their wide bandgaps. Furthermore, polariton bands in MPCs accompany a strong local field due to the charge fluctuation confined on the surfaces of the arrayed units. One can then obtain a strongly enhanced optical signal when a weak optical sign somehow excites plasmon polariton bands. Efficient biosensors or biomedical sensors can therefore be designed using MPCs. Another motivation for MPC research is provided by the strong transmission of light in an MPC. This is enabled by perforating a thick metal slab periodically with holes of subwavelength dimensions [8.207]. The use of a slab MPC with an array of holes has attracted renewed interest for the application of this extraordinary transmission

to negative refraction and the superlensing effect in imaging [8.208, 209].

Quasi-PCs. Quasiperiodic systems, which are not translationally invariant in a strict sense, but still have long-range order, can have a PBG. Arrayed units stacked in a Fibonnaci sequence in 1-D or arranged by Penrose tiling in 2-D or 3-D space are examples of quasicrystals (QC). In QCs electrons or photons have a character intermediate between localization and delocalization. Therefore by developing a well-controlled quasi-PC, we can use well-localized states on one hand, which yields a very large quality factor when used, e.g., in lasing. At the same time, diffraction is observed by exciting a delocalized PB state, whose diffraction pattern is understood in terms of the reciprocal lattice of quasi-PCs. Using a delocalized state in lasing, the coexistence of the localization and delocalization characters has been demonstrated experimentally recently [8.210]. Besides Fibonnaci and Penrose lattices, several other relaated systems have been analyzed theoretically to demonstrate the presence of PBGs and a butterfly diagram in the BG [8.206].

How to Examine the Band Structure Experimentally

A simple and reliable method to investigate a sample's PBS experimentally is to observe either the transmittance (T) or reflectance (R_e) spectrum, or both in general, by varying the wavelength as well as the direction of incident light. To do this we need several samples with different surface normals. For wavelengths corresponding to a stop band (PBG), T drops greatly, whereas R should be unity, since there exist no photon modes inside in a particular direction for the external light to couple to. However, the reverse is not necessarily true. That is, observation that the external light is completely or totally reflected over a wavelength range does not necessarily indicate that the range corresponds to a stop band [8.200]. This is because complete reflection or drastic attenuation of T occurs for a portion of the uncoupled band; the extent to which external light couples to an individual coupled band depends on the character of the band itself.

8.7.2 Unique Characteristics

We summarize the unique and outstanding features that 2-D and 3-D PCs generally exhibit. PCs are well suited for controlling light, both the radiation field and light propagation characteristics. This important

potential arises primarily from one or two of their features.

Photonic Band Gap

As seen in Fig. 8.64 there are three PBGs for TM modes, although a full 2-D PBG common to both polarized modes does not open in this case. It is known that a 2-D PBG common to TE and TM modes exists for a triangular lattice of air cylinders only if the ε difference between the background material and the air (cylinders or holes) is large enough [8.200]. For a 3-D PBG, the diamond structure is recognized to be the best for opening a full PBG with a large gap width, as shown in Fig. 8.65; an inverse diamond structure also belongs to the diamond structure. For other structures, it is rather difficult to realize a full 3-D PBG with a wide width. However, it is generally recognized that a variety of unique devices can be developed with a PC without using a 2-D or 3-D band gap, as will be shown below.

Defect Mode I. Classification

It is possible to introduce a defect or disorder at a particular lattice point or position, or thereby in an otherwise completely periodic PC lattice. Introducing this kind of defect creates a new eigenmode (eigenband) called a defect mode (defect band) in a PBG. An example of a zero-dimensional (0-D) or point defect in a 1-D or 2-D PC of air cylinders or dielectric pillars is to change the size (diameter) of the target cylinder/pillar compared to the host. One special case of this is to remove the cylinder or pillar completely. Another typical example of a 0-D defect in a 1-D PC is to alter the period at one lattice position, e.g. by changing the distance to the adjacent positions compared to that of the host. This kind of 0-D defect mode corresponds to an impurity state, analogous to a donor or acceptor state for electrons in a semiconductor; in the case of an air hole, increasing (decreasing) the hole size causes a decrease (increase) of the dielectric constant at that location, in good correspondence to the acceptor (donor) formation of electrons [8.193].

In addition to these 0-D defects, 1-D and 2-D types of defects, i.e., line and plane defects, can also be created and are important in controlling light. A 1-D defect in a 2-D PC of air cylinders or dielectric pillars can be created, for example, by leaving a single line of air cylinders imperforated, or removing a single line of pillars, i.e. introducing an empty (air) line, respectively. In a 3-D PC, e.g. made of air holes, a 1-D defect is such that a single line of holes are left unopened. A typical example of a 2-D defect is obtained, for example, by leav-

ing one lattice plane structureless (homogeneous) in a 3-D PC.

Defect Mode II. Function

Let us discuss the physical properties of the defect modes. By exciting this mode, light can be localized around the defect, or the region with disorder.

(i) Microcavity. As the 0-D defect mode is localized in a small special region, the mode does not have a definite wave vector $\boldsymbol{k}$. This feature is similar to that for impurity states of electrons in the band gap. This kind of defect serves as an optical microcavity, exhibiting outstanding characteristics. Recently, various kinds of microcavities have been intensively explored using a semiconductor-based slab PC. As a result, a microcavity with a Q-value as large as, say, 3×10^5 but with an extremely small volume of the order of 3×10^{-14} cm^3 has even been developed [8.211]. Another type of superior microcavity or nanocavity has also been developed on the basis of the line-defect PC waveguide described below. Importantly, those extremely small microcavities provide strong coupling between light and matter, so that they have the potential to be used in physics and in application [8.212].

(ii) PC Waveguide. Unlike the point-defect case, the line-defect mode shows a particular dispersion in a PBG [8.193]. Let us consider an important application,
Fig. 8.67 Dispersion curves of a line-defect 2-D PC slab waveguide calculated by using the 3-D finite-difference time-domain (FDTD) method (for details, see the text): both the frequency ω and wavenumber k are shown in dimensionless units

i. e. a line defect in an air-bridge slab PC with air holes. The line defect is introduced by filling a single line of air holes along the $\Gamma - K$-direction (adopted as the x-axis) in the triangular lattice; the z-axis is normal to the 2-D plane formed by the x- and y-axes. Figure 8.67 shows the dispersion curves of the TE-polarized line-defect modes, where the frequency is plotted as a function of k_x only in the relevant region; remember that a large band gap opens for TE guided modes (Fig. 8.66). The hatched area, which are called the slab bands, are obtained by projecting all the band $\omega_n(k_x, k_y)$ in the first BZ onto the $\omega - k_x$ plane; one of the two modes is an *even mode*, characterized by its field profile symmetric with respect to the mirror plane (xz-plane) and the other mode having an antisymmetric profile is called an *odd mode*.

This line defect operates as a new type of waveguide (WG), known as a PC WG. It is easy to fabricate a bend WG in a 2-D plane by combining two line defects in directions that differ by 60° among six equivalent $\Gamma - K$ ones. Importantly, light belonging to the line-defect-guided modes propagates through a sharp corner without any loss [8.193]. Similarly, it is possible to design a stereoscopic PC WG using a combination of line defects with different directions in a 3-D PC.

Double-Heterostructured Microcavities.
A line-defect slab PC WG can be designed as a heterostructure. This structure, e.g., in an air-hole PC WG, can easily be fabricated by introducing a somewhat larger lattice constant or slightly smaller air holes in a portion of the line defect. Double-heterostructured microcavities are such that the cavity position is sandwiched between two PC WGs. This serves as a microcavity because light with a frequency of $\omega_c^a > \omega > \omega_c^b$, where ω_c^a and ω_c^b are the cutoff frequency for the guided mode for the original and the sandwiched WGs, respectively, is localized in the particular portion [8.213].

Photonic–Crystal Fibers.
We have already described two kinds of PC fibers, both of which were pioneered by *Russel* et al. [8.214, 215]. Those fibers have periodic structures in the cross-sectional plane and uniform structures along the long axis. The central portion of the holey fiber is a dielectric, while that of the PBG fiber is an air hole whose size is larger than the others. Therefore, the central portion is regarded as a kind of line defect introduced in the 2-D PC. The guided mode is confined there. The confinement is due to total reflection and due to the presence of a band gap for the two fibers, respectively. Note that in the holey fibers the average refractive index

of the surrounding region is smaller than that of the core. Both fibers are known to exhibit superior characteristics.

Small Group Velocity
Both the group velocity v_g and the group-velocity dispersion (GVD) play an important role in light propagation. Theoretically, v_g is given by the slope $\nabla_k \omega_n(k)$ of a band. Generally speaking, there are many portions or positions in a PC where the band slope is flat, which makes v_g anomalous. At the band edge v_g should always become extremely small. A position with such a flat energy dispersion is also encountered at anti-crossed (upper and lower) bands; a photon at those points is sometimes called a heavy photon in analogy with the heavy electron [8.216]. A relatively flat band with a small v_g is also frequently encountered in 2-D and 3-D PCs. Moreover, there are many bands where v_g becomes negative.

A small v_g indicates that the electric field strength becomes very large, or equivalently, that the DOS is very large. This fact is very important, since the effective interaction length between light and matter becomes longer due to the smallness of v_g. More specifically, the enhanced light-matter interaction caused by the small v_g greatly intensifies, generally speaking, the radiation field involved in many optical processes in PCs. The examples are light absorption and emission, light scatterings such as Raman and Brillouin scattering, near-field phenomena near the PC surfaces, local field inducing an enhanced polarization and magnetization, and many nonlinear optical processes such as second-harmonic generation SHG). In all of them we can expect resonantly enhanced optical signals, often orders of magnitudes larger than those for a conventional sample of the same length. The small group velocity of light in PCs has indeed been one of the main stimulants of the PC research made until now. In the laser using PCs the threshold value of the electric current or fluence for pumping can be greatly reduced by this effect. However, the GVD is generally very large in a PC and this fact is disadvantageous for the propagation and processing of short light pulse.

Remarkable Polarization Dependence
In the case of 2-D PCs, and 2-D and 1-D PC slabs, the PBS is highly polarization dependent (see Figs. 8.64 and 8.66). Therefore, the propagation characteristics of light incident from outside differ remarkably for such a PC sample; in contrast, the polarization dependence is, generally speaking, less remarkable for 3-D PCs, in particular, with the diamond lattice. As a consequence, a unique polarizer can be developed by making use of a pair of specific bands for two different polarized light

beams with the same frequency. A simple example is the case when there exists a stop band due to a PBG (or an uncoupled band) for one polarized beam, while there is a coupled band for the other.

Peculiar Band I. Anomalous Refraction

There are a variety of peculiar PBs or band points where anomalous features manifest themselves from the viewpoint of crystal optics; here we describe the cases of 2-D and 3-D PCs. However, we note that, even in a simple 1-D PC based on a periodic layered medium with each layer being isotropic, the whole structure is known to become anisotropic, i.e., birefringent [8.217]. Theoretically, the property of light in a PC as well as a homogeneous system is determined by the group of k, i.e., the group of symmetry operations that leave the vector k in question at rest. The irreducible representations of the group of k thus entirely determine the anisotropic properties. From this group-theoretical analog, PCs naturally embody all the optical properties exploited in crystal optics to date, often on a much larger scale. Furthermore, the band-folding effect operates in PCs in that the magnitude $|k|$ also introduces remarkable optical diversity [8.216, 218].

In order to understand the propagation characteristics of light, we need to examine the equi-frequency (energy) surface (EFS) of frequency ω obtained by sweeping k over the entire BZ. The propagation characteristics of light at such a peculiar point are very complicated. The directions and magnitudes of the phase and group velocities are generally different from each other [8.216]. First of all, Snell's law of refraction does not hold in general in PCs. We list several other anomalies here.

1. Multi-refraction phenomena. This is because there exist several EFSs for a given ω in k space. As a result, if all of these are excited simultaneously by incident light of ω, refraction will be double, triple, quadruple, etc., according to the number of excited bands.
2. Conical refraction. There happens to be a singular point in k space where the group velocity, i.e., the vector normal to the EFS of the band, is not uniquely determined, e.g., at the intersections between two EFSs and at the point where an EFS shrinks to a point. In this phenomenon a light beam of that k propagates in the PC along the surface of a certain cone.
3. Superprism effects. Generally speaking, several bands participate simultaneously in constructing an

EFS; there the direction of v_g, which is normal to the EFS, does not coincides with that of k. A special case occurs such that the direction of v_g changes drastically when the direction of k is varied slightly. This is called the superprism effect [8.199].

Peculiar Band II. Negative Refraction and Left-Handed Properties

Left-handed (LH) material is usually defined to be the one having permeability μ and ε both negative [8.209]. When a LH system is homogeneous, a propagating plane-wave light of wave vector k has the LH property in the sense that the direction of the Poynting vector is reverse to that of k and, as a result, three vectors, i.e., electric field, magnetic field and k, compose in this order the left-handed system. The LH system is well-defined in this way, when only a single k is involved. In a homogeneous LH system, a negative refraction takes place by necessity, in which an incident light beam is refracted at the entrance surface in the wrong way with respect to the surface normal. In the case of PCs, any PB state is composed of many plane waves whose wave vectors are mutually different. Therefore, both of the concepts of negative refraction and LH property have to be referred to the average of these plane waves. In this context we should note that the group velocity of the (n, k) state, defined to be $\nabla_k \omega_n(k)$, is just a quantity referring to this average. The direction of the group velocity is often quite different from that of k by the superprism effect mentioned above and the case of $\nabla_k \omega_n(k) \cdot k < 0$ is very frequently encountered. Therefore, the phenomenon of the negative refraction indeed occurs very often in PCs, in which the beam direction of an incident plane-wave light bends at the PC surface in the wrong way, the direction of the inside beam being an average of many plane waves composing an excited PB state. It is important to note that the negative refraction in PCs takes place in ordinary PCs, which have μ and ε both positive and is demonstrated by examining the inside beam direction using numerical simulation and experiment [8.219, 220]. Negative refraction is important in achieving superlensing effects in PCs [8.208]. The precise LH nature in PCs, on the other hand, is hard to define, because the direction of the inside beam is an average of many Poynting vectors. Some of them may compose a LH system with the wave vector k, defined within the first Brillouin zone. But, as for the actual wave vector, taking an umklapp shift by a reciprocal lattice vector into account, that Poynting vector will certainly make up a normal right-handed system. In spite of this ambiguity, however, the negative refraction using PCs opens a way to pursue

negative refraction and LH propagation in the optical region.

8.7.3 Applications

Light–Source Devices

To date, a variety of PC lasers have been developed with different lasing mechanisms and PC structures [8.221]. Most of them are based on PC slabs, because they are relatively easy to fabricate. These may be categorized into:

(1) point-defect lasers
(2) band-edge lasers

The concept of the lasers of category (1) was first put forward by *Yablonovitch* [8.203]. By using an ultrasmall point-defect optical cavity in a PBG, which enables ideal control over spontaneous emission, an ultra-low-threshold or threshold-less laser should be, in principle, possible. In fact, lasers of the literally point-defect type, lasers based on the double-heterostructured cavities described above, and stick resonators have already been developed. Lasers using quasi-crystal PCs may be considered to be a variation of category (1) laser.

The band-edge laser, i. e., category (2) laser, makes use of the small v_g and feedback mechanism arising from the Bragg diffractions contributing to the band edge; this feedback is 2-D, and therefore, this type of PC laser may be regarded as a 2-D laser, in contrast with the 1-D laser based on distributed feedback (DBF). In this case, there is essentially no need for a PC to have a PBG; in other words, even a weakly modulated PC suffices for this purpose. However, category (2) lasers utilizing a PBG-related band edge, in which the feedback is strong, has also been studied. A unique feature of this type PC laser is that coherent operation is possible over a wide 2-D area. In the case of the Γ point lasers using higher bands, the laser emission comes out in the vertical direction as a result of diffraction. This novel type of vertically emitting laser emits within a narrow solid angle and has the advantage that single-frequency operation is realized at high powers. Category (2) lasers were also developed based on line-defect PC WGs [8.222, 223]

As for the laser material, quantum wells (QWs, typically GaInAsP/InP), quantum dots (QDs, GaAs/InAs) and organic materials are employed by being embedded in a 2-D PC slab. In most cases, optical pumping is adopted, but in some cases, electric pumping is also employed.

It is now expected that 2-D PC slabs will be used to improve the extraction efficiency of light-emitting diodes (LEDs) that are embedded in other materials; the efficiency of light emitted to free space is usually poor (less than 10%), being restricted by, e.g., internal total reflection. Theoretically, a considerable improvement is expected by making use of leaky modes in a 2-D PC slab, but experimentally, for various reasons, the improvements achieved so far have been disappointing [8.221].

Other Optical and Communication Devices

Based on the unique characteristics of 2-D and 3-D PBSs described in Sect. 8.7.2, a variety of PC-based devices have been proposed; some of them are commercially available. Those include polarization beam splitters or polarization filters, wavelength filters, optical resonators, dispersion compensators, superprisms and superlenses. Some do not require a full PBG (3-D) or a 2-D PBG, while others, such as resonant wavelength filters using defect cavities, dispersion compensators based on coupled-cavity waveguides or polarization filters, do require a PBG. For example, a polarization-selective filter based on a 2-D PC allows vertically polarized light to be transmitted, while horizontally polarized light cannot pass because of the BG. A high performance with an extinction ratio of $-50\,\text{dB}$ can be attained. For these devices, the autocloning technology developed for the industrialization of PCs is highly suitable for the fabrication of large, homogeneous 2-D and 3-D PC samples [8.205].

Photonic–Crystal Fibers

PC fibers are commercially available. The holey fiber has unique and superior features [8.221]. The single-mode condition is maintained over a very wide frequency range from the visible to the near-infrared. Applying this condition to a small core size, strong confinement of light is realized. Making use of this feature, a variety of nonlinear optical phenomena such as Raman amplification, four-wave mixing, and the generation of supercontinuum radiation have been observed. Another feature is that a very large absolute value of positive and negative dispersion and a zero-dispersion wavelength can be arbitrarily achieved by designing the lattice and/or the air-hole diameter. These features are very attractive for novel types of optical fiber and devices, and PC fibers have already been used in place of conventional fibers. The PBG fiber also has unique features different from the holey fiber; their single-mode propagation and small bend radius possible with a large air-core size make these promising for high-power light transmission.

Planar Integrated Optical Circuits

Semiconductor-based PC slab WGs as well as PC slabs described in Sect. 8.7.1 and Sect. 8.7.2, respectively, are suited for the development of ultrasmall and ultrafast optical planar integrated circuits, in particular all-optical switches and optical buffer memory for future use in sub-terabit communication [8.200]. There are two reasons for this. One is that the PC slab WGs show superior light-propagation characteristics, particularly for an abruptly bent PC WG. The other reason is that good-quality samples can be fabricated by making use of state-of-the-art nanotechnology; besides, the fabrication process is rather simple. Currently research on this subject is therefore very active all over the world. It is remarkable that propagation loss can become as small as $0.5-0.7$ dB/mm for straight PC WGs [8.224, 225]. To date, a variety of components including Y-splitters, WGs with intersections, directional couplers, dispersion compensators, and Mach–Zehnder-type switches have already been successfully developed [8.226].

Tunable Coherent Light Sources Based on the Smith–Purcel Effect

Electrons traveling along a straight trajectory are accompanied by a photon cloud, which decays exponentially away from the trajectory. The associated light can thus be observed only in the immediate neighborhood of the trajectory. If light scatterers are arrayed periodically within the decay range, the radiated photons suffers from umklapp scattering and become visible in the far field. The acquired momentum change shifts the phase-space point of the radiated photon from the outside to the inside of the light cone. This is called Smith–Purcell (SP) radiation. Usually SP radiation is observed using a metal grating. If a PC is used in place of a grating, the movement of the phase-space point is influenced by the presence of a band structure. In fact the SP spectrum, characterized by a series of sharp radiation signals, is observed by placing a PC near the high-energy electron beam and agrees satisfactorily with theoretical calculations [8.227, 228]. SP radiation is an interesting example of the use of PCs for electron–photon interactions.

8.7.4 Summary

The band structures of both bulk PCs and PCs with defects exhibit unique and marked features including the existence of PBGs, which are highly suitable for controlling the radiation field and light propagation characteristics. As a consequence, unique and novel devices are expected to be developed and currently, active research is being undertaken. This is particularly true for semiconductor-based PC slabs.

8.8 Optical Fibers

With the development of extremely low-loss optical fibers and their application to communication systems, a revolution has taken place during the last 35 years. In 2001, using glass fibers as the transmission medium and light waves as carrier waves, information was transmitted at a rate of more than 1 terabit per second (which is roughly equivalent to the transmission of about 15 million simultaneous telephone conversations) through one hair-thin optical fiber. Experimental demonstration of transmission at the rate of 14 terabits per second over a 160 km-long single fibers was demonstrated in 2006, which is equivalent to sending 140 digital high-definition movies in one second. This can be considered an extremely important technological achievement. In this section we will discuss the propagation characteristics of optical fibers with special applications to optical communication systems and also present some of their non-communication applications such as in sensing.

8.8.1 Historical Remarks

The idea of using light waves for communication can be traced as far back as 1880 when Alexander Graham Bell invented the photophone shortly after he invented the telephone in 1876. Actually according to reports (published in June 2002), an Italian immigrant, Antonio Meucci, was the inventor of the telephone; indeed Meucci demonstrated his *teletrfono* in New York in 1860. Alexander Graham Bell took out his patent 16 years later. This has apparently been recognized by the US Congress.

In the remarkable photophone experiment of Graham Bell, speech was transmitted by modulating a light beam, which traveled through air to the receiver. The transmitter consisted of a flexible reflecting diaphragm that could be activated by sound and was illuminated by sunlight. The reflected beam was received by a parabolic reflector placed at a distance. The parabolic reflector

concentrated the light onto a photoconducting selenium cell, which formed part of a circuit with a battery and a receiving earphone. Sound waves present in the vicinity of the diaphragm vibrated the diaphragm, which caused a consequent variation of the light reflected by the diaphragm. The variation of the light falling on the selenium cell changed the electrical conductivity of the cell, which in turn changes the current in the electrical circuit. This changing current reproduces the sound on the earphone. This was the first experiment on optical communication. To quote from [8.229]: "*In 1880 he* (Graham Bell) *produced his "photophone" which to the end of his life, he insisted was " . . . the greatest invention I have ever made, greater than the telephone . . . ". Unlike the telephone it had no commercial value.*"

After this beautiful experiment by Alexander Graham Bell, not much work was carried out in the field of optical communications. This is because there was no suitable light source available that could reliably be used as the information carrier. The advent of lasers in 1960 immediately triggered a great deal of investigation aimed at examining the possibility of building optical analogues of conventional communication systems. The first such modern optical communication experiments involved laser-beam transmission through the atmosphere. However, it was soon realized that laser beams could not be sent in the open atmosphere for reasonably long distances to carry signals unlike, for example, microwave or radio systems operating at longer wavelengths. This is due to the fact that a light beam (of wavelength about 1 μm) is severely attenuated and distorted owing to scattering and absorption by the atmosphere. Thus for reliable long-distance light-wave communication in terrestrial environments it would be necessary to provide a transmission medium that could protect the signal-carrying light beam from the vagaries of the terrestrial atmosphere. In 1966, *Kao* and *Hockham* [8.230] made an extremely important suggestion;

they noted that optical fibers based on silica glass could provide the necessary transmission medium if metallic and other impurities could be removed from the silica. In 1966, when the paper by Kao and Hockham was published, the most transparent glass available had extremely high losses (of more than about 1000 dB/km, implying a power loss by a factor of 100 in traversing only 20 m of the fiber); this high loss was primarily due to trace amounts of impurities present in the glass. Obviously this loss was too high even for short distances such as a few hundred meters. The 1966 paper of Kao and Hockham triggered the beginning of serious research into removing traces of impurities present in the glass, which resulted in the realization of low-loss optical fibers. In 1970, Kapron, Keck and Maurer (at Corning Glass, USA) were successful in producing silica fibers with a loss of about 17 dB/km at the helium–neon laser wavelength of 633 nm. Since then, technology has advanced with tremendous rapidity. By 1985 glass fibers were routinely being produced with extremely low losses: less than 0.25 dB/km, which corresponds to a transmission of more than 94% of the incident power after traversing 1 km of the optical fiber. Because of such low losses, the distance between two consecutive repeaters (used for amplifying and reshaping the attenuated signals) could be as large as 250 km.

8.8.2 The Optical Fiber

At the heart of an optical communication system is the optical fiber that acts as the transmission channel carrying the light beam loaded with information. The light beam is guided through the optical fiber due to the phenomenon of total internal reflection (often abbreviated to TIR). Figure 8.68 shows an optical fiber, which consists of a (cylindrical) central dielectric core (of refractive index n_1) cladded by a material of slightly lower refractive index n_2 ($< n_1$). One usually defines a parameter $\Delta = (n_1 - n_2)/n_2$, which represents the fractional difference in the refractive index between the core and cladding. The necessity of a cladded fiber (Fig. 8.68) rather than a bare fiber, i. e., without cladding, was felt because of the fact that, for the transmission of light from one place to another, the fiber must be supported, and supporting structures may considerably distort the fiber, thereby affecting the guidance of the light wave. This can be avoided by choosing a sufficiently thick cladding.

When a light pulse propagates through an optical fiber it suffers from attenuation due to various mechanisms; also the pulse broadens in time, leading to what
Fig. 8.68 Ray propagation through a step-index optical fiber
Fig. 8.69 Attenuation spectrum of a typical silica optical fiber (after [8.231])

Fig. 8.70 Loss spectrum of an optical fiber with ultimately low water content. Note that the low-loss window extends from 1250 nm to 1650 nm ($\approx$ 50 THz) and such fibers are now available commercially (after [8.232])

is termed pulse dispersion. Apart from this, due to the high intensity of light present in the fiber, nonlinear optical effects come into play. Attenuation, pulse dispersion and nonlinear effects represent three of the most important characteristics that determine the information-transmission capacity of optical fibers. Obviously, the lower the attenuation (and similarly, the lower the dispersion and the smaller the nonlinear effects) the greater will be the required repeater spacing and therefore the higher the information-carrying capacity and the lower the cost of the communication system.

8.8.3 Attenuation in Optical Fibers

Losses in optical fiber are specified in terms of the unit dB/km, defined as

$$\alpha[\text{dB/km}] = \frac{10}{L[\text{km}]} \, \log\left(\frac{P_{\text{in}}}{P_{\text{out}}}\right) . \tag{8.91}$$

Here P_{in} and P_{out} are the input and output powers corresponding to an optical fiber of length L (km). Figure 8.69 shows a typical dependence of fiber attenuation coefficient α as a function of wavelength of a typical silica optical fiber [8.231]. It may be seen that the loss is about 0.25 dB/km at a wavelength of around 1550 nm. Various methods such as the modified chemical vapor deposition (MCVD) process or the outside vapor deposition (OVD) process allows one to fabricate such fibers with very low losses. The losses are caused due to various mechanisms such as Rayleigh scattering, absorption due to metallic impurities and water in the fiber, and due to intrinsic absorption by the silica mol-

ecule itself. The Rayleigh scattering loss varies as $1/\lambda_0^4$, i.e., shorter wavelengths scatter more than longer wavelengths. Here λ_0 represents the free-space wavelength. This is the reason why the loss coefficient decreases up to about 1550 nm. The two absorption peaks around 1240 nm and 1380 nm are primarily due to traces of OH^- ions and traces of metallic ions. For example, even 1 ppm (part per million) of iron can cause a loss of about 0.68 dB/km at 1100 nm. Similarly a concentration of 1 ppm of OH^- ions can cause a loss of 4 dB/km at 1380 nm. This shows the level of purity that is required to achieve low-loss optical fibers. If these impurities are completely removed, the two absorption peaks disappear (Fig. 8.70) and we will have very low losses over the entire range of wavelength starting from 1250 nm to 1650 nm [8.232]. In a typical commercially available fiber the loss is about 0.29 dB/km, 0.19 dB/km and 0.21 dB/km at $\lambda_0 = 1310$ nm, 1550 nm and 1625 nm respectively. Such fibers open up a bandwidth of more than 50 THz for communication. For $\lambda_0 > 1600$ nm the increase in the loss coefficient is due to the absorption of infrared light by the silica molecules. This is an intrinsic property of silica and no amount of purification can remove this infrared absorption tail.

As can be seen, there are two windows at which the loss attains its minimum value in silica fibers. The first window is around 1300 nm (with a typical loss coefficient of less than 1 dB/km) where fortunately (as we will see later) the material dispersion is negligible. However, the loss attains its absolute minimum value of about 0.2 dB/km around 1550 nm. The latter window has be-

come extremely important in view of the availability of erbium-doped fiber amplifiers.

8.8.4 Modes of a Step–Index Fiber

The modal analysis of an optical fiber allows us to understand its propagation characteristics, which play an extremely important role in the design of a fiber optic communication system. The step-index fiber (Fig. 8.68) is characterized by the following refractive index distribution

$$n(r) = n_1, \qquad 0 < r < a \qquad \text{core},$$
$$= n_2, \qquad r > a \qquad \text{cladding}. \qquad (8.92)$$

In actual fibers $\Delta \ll 1$ and this allows the use of the so-called scalar wave approximation (also known as the weakly guiding approximation). In this approximation, the modal fields are assumed to be nearly transverse and can have an arbitrary state of polarization. Thus, the two independent sets of modes can be assumed to be x-polarized and y-polarized, and in the scalar approximation they have the same propagation constants. These linearly polarized modes are usually referred to as LP modes. In this approximation, the transverse component of the electric field (E_x or E_y) satisfies the scalar wave equation.

$$\nabla^2 \Psi = \frac{n^2}{c^2} \frac{\partial^2 \Psi}{\partial t^2}, \qquad (8.93)$$

where c ($\approx 3 \times 10^8$ m/s) is the speed of light in free space. In most practical fibers n^2 depends only on the cylindrical coordinate r and therefore it is convenient to use the cylindrical system of coordinates and write the solution of (8.93) in the form

$$\Psi(r, \phi, z, t) = \psi(r, \phi) \, e^{i(\omega t - \beta z)}, \qquad (8.94)$$

where ω is the angular frequency and β is known as the propagation constant. Equation (8.94) defines a propagating mode of the fiber. Since ψ depends only on r and ϕ, the modes represent transverse field configurations that do not change as they propagate through the optical fiber except for a phase change. From (8.94) we can define the phase velocity and group velocity of the mode as

$$v_p = \frac{\omega}{\beta} = \frac{c}{n_{\text{eff}}(\omega)} \quad \text{and} \quad v_g = \left(\frac{d\beta}{d\omega} \right)^{-1}, \qquad (8.95)$$

where

$$n_{\text{eff}} = \frac{\beta}{k_0} \qquad (8.96)$$
Fig. 8.71 Graded-index optical fiber with power-law profile

is referred to as the effective index of the mode and $k_0 = \omega/c$ represents the free-space propagation constant.

Substituting for Ψ in (8.93) we obtain

$$\frac{\partial^2 \psi}{\partial r^2} + \frac{1}{r} \frac{\partial \psi}{\partial r} + \frac{1}{r^2} \frac{\partial^2 \psi}{\partial \phi^2} + \left[k_0^2 n^2(r) - \beta^2 \right] \psi = 0. \qquad (8.97)$$

Equation (8.97) can be solved by using the method of separation of variables and because the medium has cylindrical symmetry, the ϕ dependence will be of the form $\cos l\phi$ or $\sin l\phi$ and for the function to be single-valued [i. e., $\Phi(\phi + 2\pi) = \Phi(\phi)$] we must have $l = 0, 1, 2, \ldots$ Thus the complete transverse modal field is given by

$$\Psi(r, \phi, z, t) = R(r) \, e^{i(\omega t - \beta z)} \begin{cases} \cos l\phi \\ \sin l\phi, \end{cases} \qquad (8.98)$$

where $R(r)$ satisfied the radial part of the equation

$$r^2 \frac{d^2 R}{dr^2} + r \frac{dR}{dr} + \left\{ \left[k_0^2 n^2(r) - \beta^2 \right] r^2 - l^2 \right\} R = 0. \qquad (8.99)$$

Before we write the solutions of this equation, we will make some general comments about the solutions of (8.99) for an arbitrary cylindrically symmetric profile having a refractive index that decreases monotonically from a value n_1 on the axis to a constant value n_2 beyond the core–cladding interface $r = a$ (Fig. 8.71). The solutions of (8.99) can be divided into two distinct classes: guided and radiation modes, which are described below.

Guided Modes
For β^2 satisfying

$$n_2^2 < \frac{\beta^2}{k_0^2} < n_1^2 \qquad (8.100)$$

the fields $R(r)$ are oscillatory in the core and decay in the cladding and β^2 assumes only discrete values; these are known as the *guided modes* of the system. For a given value of l, there will be several guided modes, which are designated LP_{lm} modes ($m = 1, 2, 3, \ldots$); LP stands for linearly polarized. If one solves the vector wave equation, the modes are classified as HE_{lm}, EH_{lm}, TE_{0m}, and TM_{0m} modes, the correspondence is $LP_{0m} = HE_{lm}$; $LP_{1m} = HE_{2m}$, TM_{0m}, and $LP_{lm} = HE_{l+1,m}$, $EH_{l-1,m}$ ($l \geq 2$) [8.233]. Further, since the modes are solutions of the scalar wave equation, they can be assumed to satisfy the orthonormality condition

$$\int\limits_{\sigma}^{\infty} \int\limits_{0}^{2\pi} \psi_{lm}^*(r, \phi)\, \psi_{l'm'}(r, \phi)\, r \; \mathrm{d}r \; \mathrm{d}\phi = \delta_{ll'}\delta_{mm'} \; .$$

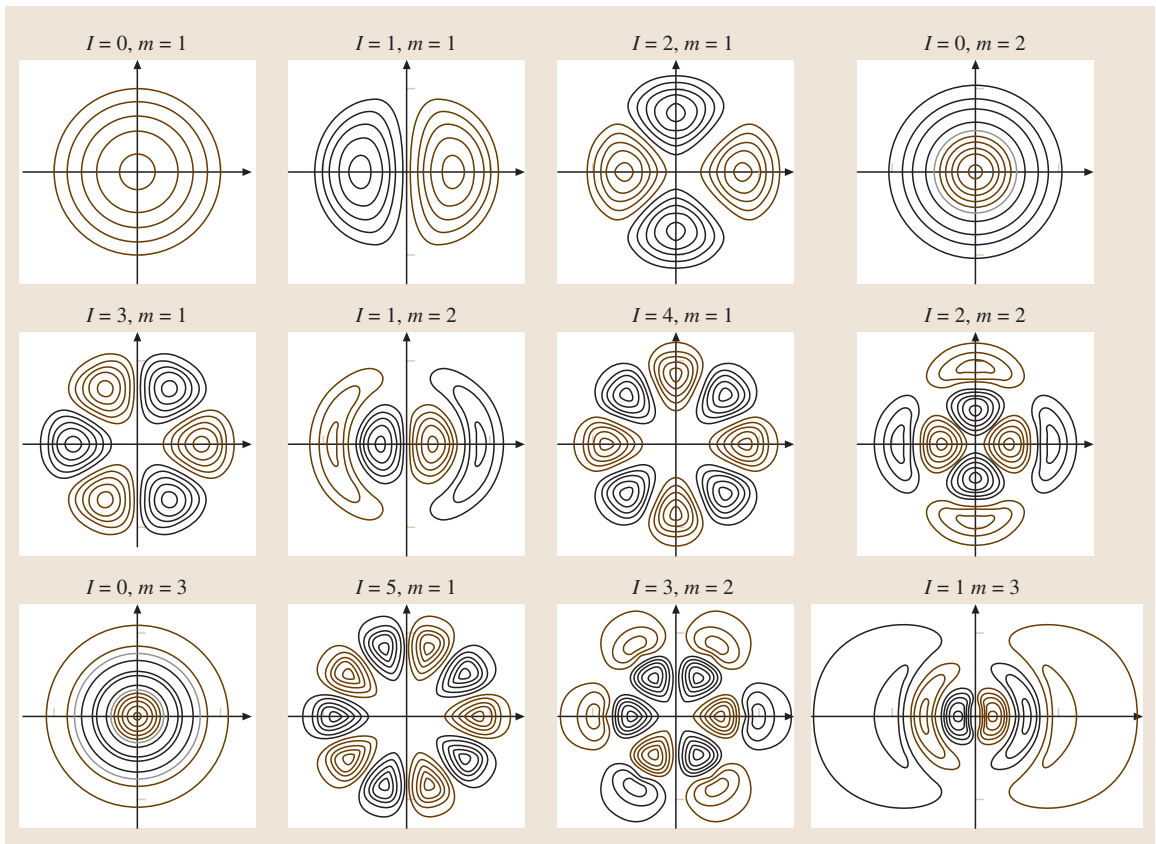
$$(8.101)$$
Fig. 8.72 Variation of effective index with V for a step-index fiber (after [8.234])


Fig. 8.73 Field patterns of some low-order guided modes (after http://www.rp-photonics.com/fibers.html, Rutger Paschotta, Date of last access: January 5, 2007)

Radiation Modes

For β values such that

$$0 < \frac{\beta^2}{k_0^2} < n_2^2 \tag{8.102}$$

the fields are oscillatory even in the cladding and β can assume a continuum of values. These are known as the *radiation modes*.

Now, for a step-index profile, the well-behaved solution of (8.99) can be written in terms of the Bessel functions J_l and K_l:

$$\psi(r, \phi) = \begin{cases} \dfrac{A}{J_l(U)} J_l \left(\dfrac{Ur}{a} \right) \begin{pmatrix} \cos l\phi \\ \sin l\phi \end{pmatrix}, & r < a, \\[3mm] \dfrac{A}{K_l(W)} K_l \left(\dfrac{Wr}{a} \right) \begin{pmatrix} \cos l\phi \\ \sin l\phi \end{pmatrix}, & r > a, \end{cases} \tag{8.103}$$

where A is a constant and we have assumed continuity of ψ at the core–cladding interface and

$$U \equiv a\sqrt{k_0^2 n_1^2 - \beta^2} \quad \text{and} \quad W \equiv a\sqrt{\beta^2 - k_0^2 n_2^2}. \tag{8.104}$$

The normalized waveguide parameter V is defined by

$$V = \sqrt{U^2 + W^2} = k_0 a \sqrt{n_1^2 - n_2^2}. \tag{8.105}$$

The waveguide parameter V (which also depends on the operating wavelength λ_0) is an extremely important quantity characterizing an optical fiber. For guided modes $n_2^2 k_0^2 < \beta^2 < n_1^2 k_0^2$ and therefore both U and W are real. It is convenient to define the normalized propagation constant

$$b = \frac{\beta^2/k_0^2 - n_2^2}{n_1^2 - n_2^2} = \frac{W^2}{V^2}. \tag{8.106}$$

Thus $W = V\sqrt{b}$ and $U = V\sqrt{1-b}$. Using (8.100) we see that guided modes are characterized by $0 < b < 1$. Continuity of $\partial\psi/\partial r$ at $r = a$ and use of identities involving Bessel functions give us the following transcendental equations, which determine the allowed discrete values of the normalized propagation constant b of the guided LP_{lm} modes [8.235]:

$$V(1-b)^{1/2} \frac{J_{l-1}\left[V(1-b)^{1/2}\right]}{J_l\left[V(1-b)^{1/2}\right]}$$
$$= -Vb^{1/2} \frac{K_{l-1}\left(Vb^{1/2}\right)}{K_l\left(Vb^{1/2}\right)}, \quad l \geq 1 \tag{8.107}$$

and

$$V(1-b)^{1/2} \frac{J_1\left[V(1-b)^{1/2}\right]}{J_0\left[V(1-b)^{1/2}\right]}$$
$$= Vb^{1/2} \frac{K_1\left(Vb^{1/2}\right)}{K_0\left(Vb^{1/2}\right)}, \quad l = 0 \tag{8.108}$$

The solution of these equations will give us universal curves describing the dependence of b (and therefore U and W) on V. For a given value of l, there will be a finite number of solutions and the m-th solution ($m = 1, 2, 3, \ldots$) is referred to as the LP_{lm} mode. The variation of b with V forms a set of universal curves, which are plotted in Fig. 8.72 [8.234]. As can be seen, at a particular V value the fiber can support only a finite number of modes. Figure 8.73 shows the typical field patterns of some of the low-order LP_{lm} modes of a step-index fiber.

Guided and radiation modes form a complete set of solutions in the sense that any arbitrary field distribution in the optical fiber can be expressed as a linear combination of the discrete guided modes $\psi_j(x, y)$ and the continuum radiation modes $\psi(x, y, \beta)$:

$$\Psi(x, y, z) = \sum a_j \psi_j(x, y) e^{-i\beta_j z}$$
$$+ \int a(\beta) \psi(x, y, \beta) e^{-i\beta z} \, d\beta \tag{8.109}$$

with $|a_j|^2$ proportional to the power carried by the j-th guided mode and $|a(\beta)|^2 \, d\beta$ proportional to the power carried by radiation modes with propagation constants lying between β and $\beta + d\beta$. The constants a_j and $a(\beta)$ can be determined from the incident field distribution at $z = 0$.

8.8.5 Single–Mode Fiber (SMF)

As is obvious from Fig. 8.72, for a step-index fiber with $0 < V < 2.4048$ we will have only one guided mode – namely, the LP_{01} mode also referred to as the fundamental mode. Such a fiber is referred to as a single-mode fiber and is of tremendous importance in optical fiber communication systems. As an example, we consider a step-index fiber with $n_2 = 1.447$, $\Delta = 0.003$ and $a = 4.2\,\mu\text{m}$, giving $V = 2.958/\lambda_0$, where λ_0 is measured in μm. Thus for $\lambda_0 > 1.23\,\mu\text{m}$, the fiber will be single-mode. The wavelength for which $V = 2.4045$ is known as the *cut-off wavelength* and is denoted by λ_c. In this example, $\lambda_c = 1.23\,\mu\text{m}$.

For a single-mode step-index fiber, a convenient empirical formula for $b(V)$ is given by

$$b(V) = \left(A - \frac{B}{V} \right)^2 , \quad 1.5 \lesssim V \lesssim 2.5 , \qquad (8.110)$$

where $A \approx 1.1428$ and $B \approx 0.996$.

Spot Size of the Fundamental Mode

The transverse field distribution associated with the fundamental mode of a single-mode fiber is an extremely important quantity and determines various important parameters such as splice loss at joints between fibers, launching efficiencies from sources, bending loss etc. For a step-index fiber one has analytical expression for the fundamental field distribution in terms of Bessel functions. For most single-mode fibers with a general transverse refractive-index profile, the fundamental mode field distributions can be well approximated by a Gaussian function, which may be written in the form

$$\psi(x, y) = A \, e^{-\frac{x^2+y^2}{w^2}} = A \, e^{-\frac{r^2}{w^2}} , \qquad (8.111)$$

where w is referred to as the spot size of the mode field pattern and $2w$ is called the mode field diameter (MFD). The MFD is a very important characteristic of a single-mode optical fiber. For a step-index fiber one has the following empirical expression for w [8.236]:

$$\frac{w}{a} \approx 0.65 + \frac{1.619}{V^{3/2}} + \frac{2.879}{V^6} , \quad 0.8 \leq V \leq 2.5 , \qquad (8.112)$$

where a is the core radius. As an example, for the step-index fiber considered earlier operating at 1300 nm we have $V \approx 2.28$ giving $w \approx 4.8 \, \mu m$. Note that the spot size is larger than the core radius of the fiber; this is due to the penetration of the modal field into the cladding of the fiber. The same fiber will have a V value of 1.908 at $\lambda_0 = 1550$ nm, giving a value of the spot size $\approx 5.5 \, \mu m$. *Thus, in general, the spot size increases with wavelength.* The standard single-mode fiber designated G.652 for operation at 1310 nm has an MFD of $(9.2 \pm 0.4) \, \mu m$ and an MFD of $(10.4 \pm 0.8) \, \mu m$ at 1550 nm.

For $V \geq 10$, the number of modes (for a step-index fiber) is approximately $1/2V^2$ and the fiber is said to be a multimoded fiber. Different modes (in a multimoded fiber) travel with different group velocities, leading to what is known as intermodal dispersion; in the language of ray optics, this is known as ray dispersion arising due to the fact that different rays take different amounts of time in propagating through the fiber. Indeed in a highly multimoded fiber, we can use ray optics to calculate pulse dispersion.

8.8.6 Pulse Dispersion in Optical Fibers

In digital communication systems, information to be sent is first coded in the form of pulses and then these pulses of light are transmitted from the transmitter to the receiver where the information is decoded. The larger the number of pulses that can be sent per unit time and still be resolvable at the receiver end, the larger will be the transmission capacity of the system. A pulse of light sent into a fiber broadens in time as it propagates through the fiber; this phenomenon is known as pulse dispersion and occurs primarily because of the following mechanisms.

1. In multimode fibers, dispersion is caused by different rays taking different times to propagate through a given length of the fiber. In the language of wave optics, this is known as *intermodal dispersion* because it arises due to different modes traveling with different group velocities.
2. Any given light source emits over a range of wavelengths and, because of the dependence of refractive index on wavelength, different wavelengths take different amounts of time to propagate along the same path. This is known as material dispersion and, obviously, it is present in both single-mode and multimode fibers.
3. In single-mode fibers, since there is only one mode, there is no intermodal dispersion. However, apart from material dispersion, we have what is known as waveguide dispersion. Physically, this arises due to the fact that the spot size (of the fundamental mode) depends explicitly on the wavelength.
4. A single-mode fiber can support two orthogonally polarized LP_{01} modes. In a perfectly circular core fiber laid along a perfectly straight path, the two polarizations propagate with the same velocity. However due to small random deviations from circularity of the core or due to random bends and twists present in the fiber, the orthogonal polarizations travel with slightly different velocities and get coupled randomly along the length of the fiber. This phenomenon leads to polarization mode dispersion (PMD) which becomes important for high-speed communication systems operating at 40 Gb/s and higher.

Obviously, waveguide dispersion and polarization mode dispersion are present in multimode fibers also – however, the effects are very small and can be neglected.

Dispersion in Multimode Fibers

A broad class of *multimoded* graded-index fibers can be described by the following refractive-index distribution:

$$n^2(r) = n_1^2 \left[1 - 2\Delta \left(\frac{r}{a}\right)^q\right], \qquad 0 < r < a,$$
$$= n_2^2 = n_1^2 (1 - 2\Delta), \qquad r > a, \qquad (8.113)$$

where r corresponds to a cylindrical radial coordinate, n_1 represents the value of the refractive index on the axis (i. e., at $r = 0$), and n_2 represents the refractive index of the cladding; $q = 1$, $q = 2$ and $q = \infty$ correspond to the linear, parabolic, and step-index profiles, respectively (Fig. 8.71). Equation (8.113) describes what is usually referred to as a power-law profile, which gives an accurate description of the refractive-index variation in most multimoded fibers. The total number of modes in a highly multimoded graded-index optical fiber characterized by (8.113) are approximately given by

$$N \approx \frac{q}{2(2+q)} V^2. \qquad (8.114)$$

Thus, a parabolic-index ($q = 2$) fiber with $V = 10$ will support approximately 25 modes. Similarly, a step-index ($q = \infty$) fiber with $V = 10$ will support approximately 50 modes. When the fiber supports such a large number of modes, then the continuum (ray) description gives very accurate results. For the power-law profile, it is possible to calculate the pulse broadening due to the fact that different rays take different amount of time in traversing a certain length of the fiber; details can be found in many text books; see for example [8.235]. The time taken to propagate through a length L of a multimode fiber described by a q-profile (8.113) is given by

$$\tau(L) = \left(A\tilde{\beta} + \frac{B}{\tilde{\beta}}\right) L, \qquad (8.115)$$

where

$$A = \frac{2}{c(2+q)}, \qquad B = \frac{qn_1^2}{c(2+q)} \qquad (8.116)$$

and for rays guided by the fiber $n_2 < \tilde{\beta} < n_1$. Using (8.115) we can estimate the intermodal dispersion in fibers with different q values. Thus, for $n_1 \simeq 1.46$ and $\Delta \simeq 0.01$, the dispersion would be 50 ns/km for a step-index fiber ($q = \infty$), 0.25 ns/km for a parabolic index fiber ($q = 2$) and for $q = 2 - 2\Delta$ (referred to as the optimum profile exhibiting minimum dispersion) it will be 0.0625 ns/km.

Thus we find that for a parabolic-index fiber the intermodal (or ray) dispersion is reduced by a factor of about 200 in comparison to the step-index fiber and for the optimum profile there is a further reduction by a factor of four. It is because of this reason that first- and second-generation optical communication systems used near-parabolic-index fibers. In order to further decrease the pulse dispersion, it is necessary to use single-mode fibers because there will be no intermodal dispersion. However, in all fiber optic systems we will have material dispersion, which is a characteristic of the material itself and not of the waveguide; we will discuss this in the following section.

Material Dispersion

Above we have considered the broadening of an optical pulse due to different rays taking different amounts of time to propagate through a certain length of the fiber. However, every source of light has a certain wavelength spread, which is often referred to as the *spectral width of the source*. An LED would have a spectral width of about 25 nm and a typical laser diode (LD) operating at 1300 nm would have a spectral width of about 2 nm or less. The pulse broadening (due to wavelength dependence of the refractive index) is given in terms of the material dispersion coefficient D_m (which is measured in ps/(km nm)) and is defined by

$$D_m = -\frac{10^4}{3\lambda_0} \left(\lambda_0^2 \frac{d^2 n}{d\lambda_0^2}\right) \text{ps/(km nm)}. \qquad (8.117)$$

λ_0 is measured in μm and the quantity inside the square brackets is dimensionless. Thus D_m represents the material dispersion in picoseconds per kilometer length of the fiber per nanometer spectral width of the source. At a particular wavelength, the value of D_m is a characteristic of the material and is (almost) the same for *all* silica fibers. When D_m is negative, it implies that the longer wavelengths travel faster; this is referred to as normal group velocity dispersion (GVD). Similarly, a positive value of D_m implies that shorter wavelengths travel faster; this is referred to as anomalous GVD.

The spectral width $\Delta\lambda_0$ of an LED operating around $\lambda_0 = 825$ nm is about 20 nm; at this wavelength for pure silica $D_m \approx 84.2$ ps/km nm. Thus a pulse will broaden by 1.7 ns per kilometer of fiber. It is interesting to note that, for operation around $\lambda_0 \approx 1300$ nm (where $D_m \approx 2.4$ ps/(km nm)), the resulting material dispersion is only 50 ps per kilometer of the fiber. The very small value of $\Delta\tau_m$ is due to the fact that the group velocity is approximately constant around $\lambda_0 = 1300$ nm. Indeed the wavelength $\lambda_0 \approx 1270$ nm is usually referred to as the zero-material-dispersion wavelength, and it is because of such low material dispersion that optical communication systems shifted their operation to around $\lambda_0 \approx 1300$ nm.

Optical communication systems in operation today use LDs with $\lambda_0 \approx 1550$ nm having a spectral width of about 2 nm. At this wavelength the material dispersion coefficient is 21.5 ps/(km nm) and the material dispersion $\Delta\tau_m$ would be 43 ps/km.

Dispersion in Multimode Fibers

In multimode fibers the total dispersion consists of intermodal dispersion ($\Delta\tau_i$) and material dispersion ($\Delta\tau_m$) and is given by

$$\Delta\tau = \sqrt{(\Delta\tau_i)^2 + (\Delta\tau_m)^2} \tag{8.118}$$

In one type of extensively used coding referred to as non-return to zero (NRZ) the maximum permissible bit rate is approximately given by

$$B_{max} \approx \frac{0.7}{\Delta\tau} \tag{8.119}$$

Operation around 1310 nm minimizes $\Delta\tau_m$ and hence almost all multimode fiber systems operate in this wavelength region with optimum refractive-index profiles having small values of $\Delta\tau_i$.

Dispersion in Single–Mode Fibers

In the case of a single-mode optical fiber, the effective index $n_{eff} = \beta/k_0$ of the mode depends on the core and cladding refractive indices as well as the waveguide parameters (refractive-index profile shape and radii of various regions). Hence n_{eff} would vary with wavelength even if the core and cladding media were assumed to be dispersion-less (i.e., the refractive indices of core and cladding are assumed to be independent of wavelength). This dependence of effective index on wavelength is due to the wave-guiding mechanism and is referred to as *waveguide dispersion*. Waveguide dispersion can be understood from the fact that the effective index of the mode depends on the fraction of power in the core and the cladding at a particular wavelength. As the wavelength changes, this fraction also changes. Thus, even if the refractive indices of the core and the cladding are assumed to be independent of wavelength, the effective index will change with wavelength. It is this dependence of $n_{eff}(\lambda_0)$ that leads to waveguide dispersion.

Thus the total dispersion in the case of a single-mode optical fiber can be attributed to two types of dispersion, namely material dispersion and waveguide dispersion. Indeed it can be shown that the total dispersion coefficient D is given to a good accuracy by the sum of material (D_m) and waveguide (D_w) dispersion coefficients [8.237]. The material contribution is given by (8.117) while the waveguide contribution for

a step-index fiber is given by

$$D_w = -\frac{n_2\Delta}{c\lambda_0}\left(V\frac{d^2(bV)}{dV^2}\right) \tag{8.120}$$

A simple empirical expression for waveguide dispersion for step-index fibers is

$$D_w = -\frac{n_2\Delta}{3\lambda_0} \times 10^7$$
$$\times \left[0.080 + 0.549(2.834 - V)^2\right] \text{ps/(km nm)}, \tag{8.121}$$

where λ_0 is measured in nanometers.

In the single-mode regime, the quantity within the bracket in (8.120) is usually positive; hence the waveguide dispersion is negative. Since the sign of material
Fig. 8.74 Variation of material, waveguide and total dispersion with wavelength for a standard single-mode fiber
Fig. 8.75 Variation of total dispersion for three types of single-mode fibers

Table 8.5 Values of dispersion and dispersion slope for some standard fibers at 1550 nm (after [8.238])

Fiber type	D (ps/(km nm))	S (ps/(km nm²))
Standard SMF (G.652)	17	0.058
LEAF (Corning)	4.2	0.085
Truewave-reduced slope (OFS)	4.5	0.045
TeraLight (Alcatel)	8.0	0.057

dispersion depends on the operating wavelength region, it is possible that the two effects namely, material and waveguide dispersions, cancel each other at a certain wavelength. Such a wavelength, which is a very important parameter of single-mode fibers, is referred to as the zero-dispersion wavelength (λ_{ZD}). For typical step-index fibers the zero-dispersion wavelength falls in the 1310 nm wavelength window. Since the lowest loss in an optical fiber occurs at a wavelength of 1550 nm and optical amplifiers are available in the 1550 nm window, fiber designs can be modified to shift the zero-dispersion wavelength to the 1550 nm wavelength window. Such fibers are referred to as dispersion-shifted fibers (with zero dispersion around 1550 nm) or nonzero-dispersion-shifted fibers (with finite but small dispersion around 1550 nm). With proper fiber refractive-index profile design it is also possible to have a flat dispersion spectrum, leading to dispersion flattened designs. Figure 8.74 gives the spectral variations of a standard SMF (with zero dispersion close to 1310 nm) while Fig. 8.75 shows the total dispersion in three standard types of fibers namely G.652, G.653 and G.655 fibers. The G.655 fibers have a small but finite dispersion around the 1550 nm wavelength. The small dispersion is required to avoid four-wave mixing.

It appears that when an optical fiber is operated at the zero-dispersion wavelength, the pulses will not suffer any dispersion at all. In fact zero dispersion only signifies that the second-order dispersive effects are absent. In this case the next-higher-order dispersion namely third-order dispersion characterized by $d^3\beta/d\omega^3$ will become the dominant term in determining the dispersion. Thus in the absence of second-order dispersion, we can write for dispersion suffered by a pulse as

$$\Delta\tau = \frac{L\,(\Delta\lambda_0)^2}{2}\frac{dD}{d\lambda_0}\,, \tag{8.122}$$

where $S = dD/d\lambda_0$ represents the dispersion slope at the zero-dispersion wavelength and is measured in units of ps/km nm². Third-order dispersion becomes important

when operating close to the zero-dispersion wavelength. In the presence of only third-order dispersion, the pulse does not remain symmetric. Table 8.5 lists values of D and S for some standard fibers at 1550 nm.

Dispersion and Maximum Bit Rate in Single–Mode Fibers

In a digital communication system employing light pulses, pulse broadening would result in an overlap of adjacent pulses, resulting in inter-symbol interference leading to errors in detection. Apart from this, since the energy in the pulse gets reduced within the time slot, the corresponding signal-to-noise ratio (SNR) will decrease. One can offset this by increasing the power in the pulses. This additional power requirement is termed the *dispersion power penalty*. Increased dispersion would imply an increased power penalty.

In order to keep the interference between adjacent bits below a specified level, the root-mean-square width of the dispersed pulse needs to be kept below a certain fraction ε of the bit period. For a 2 dB power penalty, $\varepsilon \approx 0.491$ [8.239]. Using this condition we can estimate the maximum bit rate B for a given link length L and dispersion coefficient D operating at 1550 nm as

$$B^2 DL < 1.9 \times 10^5 \,\text{Gb}^2\text{ps/nm}\,, \tag{8.123}$$

where B is measured in Gbps, D in ps/(km nm) and L in km. Thus for a bit rate of 2.5 Gb/s the maximum allowed dispersion (DL) is approximately 30 400 ps/nm while for a bit rate of 10 Gb/s the maximum allowed dispersion is 1900 ps/nm.

Dispersion–Compensating Fibers

There already exist millions of kilometers of conventional single-mode fibers in underground ducts operating at 1310 nm and these fibers have very low dispersion at the operating wavelength. One could significantly increase the transmission capacity of these system by operating these fibers at 1550 nm (where the loss is extremely small) and we can have the added advantage of using erbium-doped fiber amplifiers (EDFAs) for optical amplification in this wavelength range. However, if we operate conventional single-mode fibers at 1550 nm, we will have a significant residual dispersion of about 17 ps/(km nm). Such a large dispersion would result in a significant decrease in the information-carrying capacity of the communication system. On the other hand, replacing the existing conventional single-mode fibers by lower-dispersion fibers would involve huge costs. As such, in recent years there has been considerable amount of work in upgrading of the installed 1310 nm

optimized optical fiber links for operation at 1550 nm. This is achieved by developing fibers with very large negative dispersion coefficients, a few hundred meters to a kilometer of which can be used to compensate for dispersion accumulated over tens of kilometers of the fiber in the link.

By changing the refractive-index profile, one can alter the waveguide dispersion and hence the total dispersion. Indeed, it is possible to have specially designed fibers whose dispersion coefficient (D) is large and negative at 1550 nm. These types of fibers are known as dispersion-compensating fibers (DCFs). A short length of a DCF can be used in conjunction with the 1310 nm optimized fiber link so as to have small total dispersion value at the end of the link. There are a number of different fiber designs with optimized refractive-index profiles which have extremely large negative dispersion coefficient and a small length of which can compensate for the accumulated dispersion of a link. Some of the important ones include depressed clad designs, W-type fiber designs and dual-core coaxial designs [8.240–243].

If $D_T(\lambda_n)$ and L_T represent the dispersion coefficient and length of the transmission fiber and $D_C(\lambda_n)$ and L_C represent the corresponding quantities of the DCF, then to achieve zero net dispersion at a chosen wavelength λ_n we must have

$$D_T(\lambda_n)L_T + D_C(\lambda_n)L_C = 0 \qquad (8.124)$$

Hence for given values of $D_T(\lambda_n)$, L_T and $D_C(\lambda_n)$, the length of the DCF required is given by (8.124) showing that $D_C(\lambda_n)$ and $D_T(\lambda_n)$ should have opposite signs. Also the larger the value of $D_C(\lambda_n)$ the smaller the length of the required DCF. Since the wavelength dependence of dispersion of the link fiber and the dispersion-compensating fiber are in general different, in general the DCF would compensate for dispersion only at the design wavelength. However in a wavelength division multiplexed system it is necessary to compensate for the accumulated dispersion of all the wavelength channels simultaneously. For this to happen the relative dispersion slope (RDS), which is the ratio of the dispersion slope (S) and the dispersion coefficient (D) of the two fibers evaluated at the wavelength λ_n, must be equal. Typically the RDS of a G.652 fiber is about $0.0034 \, \text{nm}^{-1}$ while that of large-effective-area (LEAF) fiber from Corning is about $0.0202 \, \text{nm}^{-1}$. DCFs with similar RDS values are commercially available.

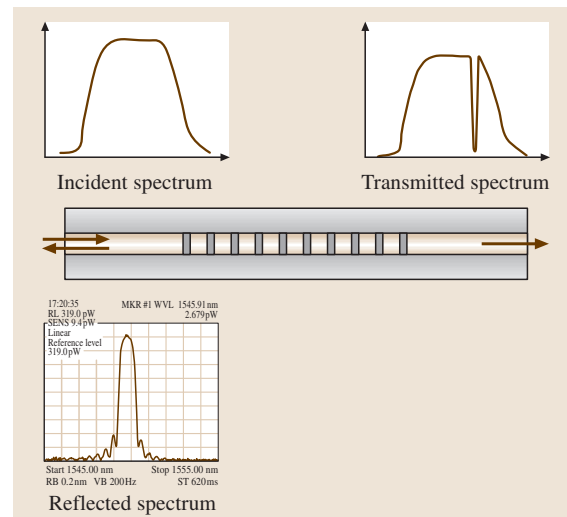
Polarization Mode Dispersion (PMD)
A perfectly circular single-mode fiber actually supports two orthogonally polarized modes with equal propagation constant. When such a fiber is laid along a perfect straight path, the two orthogonally polarized fundamental modes of the fiber have identical group velocities and any pulse launched into the fiber undergoes dispersion only due to material dispersion and waveguide dispersion effects. However in actual fibers, there is always a very small ellipticity of the fiber cores or there are non-symmetric strains in the fiber or the fibers have bends and twists when laid in the link; this causes a difference of velocities between the two orthogonal polarized modes. This difference leads to the phenomenon of polarization mode dispersion. The effect of PMD is as if the fiber supported two modes with two different velocities; thus a pulse launched with some arbitrary polarization state would split into two pulses due to the two different velocities. Locally PMD is due to differential velocities of the two polarizations while globally it is combined with random polarization coupling along the fiber length. Since the fiber property as well as the external perturbation is random along the length of the fiber, this effect is a random phenomenon. Due to the random nature, the PMD effect increases as the square root of length rather than as length. PMD is usually measured in terms of the differential group delay (DGD) between the two polarizations. In order that PMD does not cause increased bit error rates, the differential group delay should be less than 10% of the bit period. Thus for a 2.5 Gb/s system, which consists of pulses of duration 400 ps, the max-


Fig. 8.76 The transmitted and reflected spectrum from an FBG. The reflected spectrum is an actual measured spectrum

imum allowed PMD is 40 ps and for a 40 Gb/s system the maximum allowed PMD is only 2.5 ps. If the PMD of the fiber is 0.5 ps/km$^{0.5}$, then for a 40 Gb/s link the maximum length due to PMD effects will be 25 km. Thus PMD effects become extremely important for systems operating at high bit rates, typically 40 Gb/s and higher. Commercially available single-mode fibers have typically PMD of less than 0.2 ps/km$^{0.5}$. In an actual system, a contribution to PMD also comes from other components used in the link, such as optical amplifiers, dispersion-compensating elements.

8.8.7 Fiber Bragg Gratings

When a germanium-doped silica-core fiber is exposed to ultraviolet radiation (with wavelength around 0.24 μm), the refractive index of the germanium-doped region increases; this is due to the phenomenon known as *photosensitivity* which was discovered by Kenneth Hill in 1974. The refractive index increase can be as large as 0.001 in the core of the fiber. If the fiber is exposed to a pair of interfering UV beams, then in regions of constructive interference, the refractive index increases while it does not change in regions of destructive interference. This results in a periodic variation of refractive index within the core of the fiber and this is referred to as a fiber Bragg grating (FBG). The period of the grating can be controlled by appropriately choosing the angle between the interfering beams. If we consider a polychromatic beam incident on the fiber, as shown in Fig. 8.76, then the reflection from the periodic structure will add up in phase when the following Bragg condition is satisfied:

$$\Lambda = \frac{\lambda_B}{2 n_{\text{eff}}} , \tag{8.125}$$

where λ_B is referred to as the Bragg wavelength. The corresponding peak reflectivity R_p and bandwidth $\Delta\lambda$ are given by [8.233]

$$R_p = \tanh^2 \left(\frac{\pi \Delta n \, L I}{\lambda_B} \right) \tag{8.126}$$

and

$$\frac{\Delta\lambda}{\lambda_B} \approx \frac{\lambda_B}{n_{\text{eff}} L} \left[1 + \left(\frac{(\Delta n) L I}{\lambda_B} \right)^2 \right] . \tag{8.127}$$

Here Δn is the peak refractive-index change in the grating and L is the grating length. The quantity I represents the transverse overlap integral of the modal distribution with the region where the grating is formed. It accounts for the fact that only a fraction of the mode interacts

with the grating. If the modal distribution is assumed to be described by a Gaussian with a spot size of w_0 and if the grating is assumed to exist only within the core of radius a, then $I = (1 - e^{-2a^2/w_0^2})$. For a typical single-mode fiber operating at 1550 nm, $n_{\text{eff}} \approx 1.4475$ and the required grating period is about 0.54 μm. Figure 8.76 also shows a typical measured reflection spectrum of an FBG. For a grating with $\Delta n = 4 \times 10^{-4}$ and $L = 2$ mm, the peak reflectivity would be 0.86 and the bandwidth would be about 1 nm.

Some Applications of FBGs

Fiber Bragg gratings find many applications in telecommunication and sensing [8.244, 245]. These include applications in fiber grating sensors, add/drop multiplexers, to provide external feedback for laser-diode wavelength locking, and dispersion compensation. Here we discuss two applications.

FBG-Based Sensors. FBGs have a great potential for applications as sensors for sensing mechanical strain, temperature, acceleration etc. Since the Bragg wavelength depends on both the refractive index of the fiber as well as on the period of the grating, any external parameter that changes any of these would result in a change in the reflected wavelength. Thus by measuring the *changes in the reflected wavelength*, the external perturbations affecting the grating can be sensed. This is the basic principle of their application in sensing. The typical strain sensitivity of an FBG is about 1.3 pm/με at 1550 nm. Since the refractive index as well as the period of the grating change with change in temperature, the temperature change of an FBG would also result in a change in the peak reflected wavelength. The temperature sensitivity of FBGs is typically about 6 pm/°C. One of the important attributes of FBG sensors is that they can be multiplexed into a single fiber. FBGs with different Bragg wavelengths are fabricated at different points along the length of a single-mode fiber. Light from a broadband source is coupled into the fiber and light at different wavelengths get reflected from the individual gratings and are analyzed by the detection circuit. The wavelengths of the FBGs are so chosen that they do not overlap with each other and fall within the band of the source. By measuring the changes in the Bragg wavelength of individual FBGs, the strains or temperature changes at each of the location of the FBG can be independently measured. Among the various issues in connection with FBG sensors, is the problem of separating the changes brought about by temperature and strain. Fiber optic sensing technology is rapidly advancing and

FBGs are now being tested for structural monitoring. In the future it may be possible to multiplex perhaps 100 sensors on a single fiber, which gives enormous capability for structural monitoring.

Dispersion Compensation. Fiber Bragg gratings can also be used for dispersion compensation. In a uniform FBG, the period of the refractive-index modulation is constant along the length of the grating. If the period of the grating varies along its length, this is referred to as a *chirped fiber Bragg grating*. In such chirped FBGs since the period of the grating varies along the length, the Bragg wavelength also varies along the position in the grating (Fig. 8.77). When light propagates through such a grating, different wavelength components present in the incident wave will get reflected at different positions along the grating; this will lead to different wavelength components having different time delays to return to the input end. By using an appropriately chirped FBG one can indeed compensate for the differential delay of different wavelengths accumulated while propagating through an optical fiber link. Let us consider propagation of a pulse of light through an optical fiber operating at a wavelength longer than the zero-dispersion wavelength of the fiber. This would correspond to say operating a G.652 fiber (having a zero dispersion at 1310 nm) at a wavelength of 1550 nm. Thus if we consider three wavelength components such that $\lambda_1 > \lambda_2 > \lambda_3$ contained within the pulse, then, we can see that, due to dispersion in the fiber, wavelength λ_1 would suffer a larger delay than wavelength λ_2, which in turn will suffer a delay longer than λ_3 while propagating through the fiber. In order to compensate for this dispersion, we need to delay the wavelength component λ_3 more than the component λ_2, which in turn should suffer a delay more than at λ_1. In order to achieve this, the chirped grating is designed so that wavelength λ_1 re-

flects from the near end of the grating, λ_2 reflects from a portion farther away while λ_3 reflects from the far end so as to compensate for the differential delay between all the wavelength components and thus lead to dispersion compensation.

As an example a chirped grating of length 11 cm would have a dispersion of about 1380 ps/nm operating over a bandwidth of 0.61 nm. This grating can compensate for dispersion accumulated over a fiber with a dispersion coefficient of 17 ps/(km nm) and of length 81 km over a bandwidth of 0.61 nm, which approximately corresponds to 76 GHz of frequency bandwidth. It is interesting to note that the difference in period between the front and back end of the 11 cm-long grating is only about 0.25 nm while the average period of the grating is about 0.534 μm.

Chirped dispersion compensating gratings are commercially available for compensation of accumulated dispersion of up to 80 km of G.652 fiber for up to 32 wavelength channels. Unlike dispersion-compensating fibers, chirped FBGs provide the possibility of tweaking the required dispersion compensation, especially for 40 Gbps systems where the margin of dispersion available is rather small. Also by using nonlinearly chirped FBGs it has been shown that delay variation from −200 ps to −1200 ps is possible.

8.8.8 Erbium−Doped Fiber Amplifiers (EDFAs)

In traditional long-distance optical fiber communication systems, compensation of loss and dispersion is usually accomplished by using electronic regenerators in which the optical signals are first converted into electrical signals, then processed in the electrical domain and then reconverted into optical signals. Whenever the system limitation is due to insufficient optical power rather than dispersion, what is needed is just amplification of the signal and optical amplifiers can indeed perform this job. Optical amplifiers are devices that amplify the incoming optical signals in the optical domain itself without any conversion to the electrical domain, and have truly revolutionized long-distance fiber optic communications. Compared to electronic regenerators, optical amplifiers do not need any high-speed electronic circuitry, are transparent to bit rate and format, and most importantly can amplify multiple optical signals at different wavelengths simultaneously. Thus their development has ushered in the tremendous growth of communication capacity using wavelength division multiplexing (WDM) in which multiple wavelengths
Fig. 8.77 Dispersion compensation using a chirped FBG

carrying independent signals are propagated through the same single-mode fiber, thus multiplying the capacity of the link. Of course compared to electronic regenerators, they have some drawbacks too; they do not compensate for dispersion accumulated in the link and they also add noise to the optical signal. As we will see later, this noise leads to a maximum number of amplifiers that can be cascaded so that the received signal-to-noise ratio is within the limits.

Optical amplifiers can be used at many points in a communication link. A booster amplifier is used to boost the power of the transmitter before launching into the fiber link. The increased transmitter power can be used to go farther in the link. The preamplifier placed just before the receiver is used to increase the receiver sensitivity. Inline amplifiers are used at intermediate points in the link to overcome fiber transmission and other losses. Optical amplifiers can also be used to overcome splitter losses, for example for the distribution of cable television (CATV).

The three main types of optical amplifiers are the erbium-doped fiber amplifier (EDFA), the Raman fiber amplifier (RFA) and the semiconductor optical amplifier (SOA). Today most optical fiber communication systems use EDFAs due to their advantages in terms of bandwidth, high power output and noise characteristics. Detailed discussions on EDFAs can be found in many texts, e.g., [8.247, 248].

Optical amplification by EDFA is based on the process of stimulated emission, which is the basic principle behind laser operation. Figure 8.78 shows the three lowest-lying energy levels of the erbium ion in a silica matrix. A pump laser at 980 nm excites the erbium ions from the ground state to the level marked E_3. The level E_3 is a short-lived level and the ions jump down to the level marked E_2 after a time lasting less than a microsecond. The lifetime of level E_2 is much larger and is about 12 ms. Hence ions brought to the level E_2 stay there for a long time. Thus by pumping hard enough, the population of ions in the level E_2 can be made larger than the population of level E_1 and thus achieve population inversion between the levels E_1 and E_2. In such a situation, if a light beam at a frequency $\nu_0 = (E_2 - E_1)/h$ falls on the collection of erbium ions, it will get amplified. For erbium ions, the frequency ν_0 falls in the 1550 nm band and thus it is an ideal amplifier for signals in the 1550 nm window, the lowest-loss window of silica-based optical fibers. In the case of erbium ions in silica matrix, the energy levels are not sharp but are broadened due to interaction with other ions in the silica matrix. Hence the system is capable of amplifying optical signals over a band of wavelengths.

Let N_1 and N_2 represent the number of erbium ions per unit volume in the ground level and the excited level, respectively, and let $I_p(z)$ and $I_s(z)$ represent the variation of intensity of the pump at frequency ν_p (assumed to be at 980 nm) and the signal at frequency ν_s, assumed to be in the region of 1550 nm. As the beams propagate through the fiber, the pump would induce absorption from E_1 to E_3 while the signal would induce absorption and stimulated emissions between levels E_2 and E_1. Under the assumption that the lifetime of level E_3 is very small, $N_3 \approx 0$, and we can write for the rate of change of population of level E_2 as [8.235]

$$\frac{dN_2}{dt}\left(=-\frac{dN_1}{dt}\right) = -\frac{N_2}{t_{sp}} + \frac{\sigma_{pa}I_p}{h\nu_p}N_1$$
$$- (\sigma_{se}N_2 - \sigma_{sa}N_1)\frac{I_s}{h\nu_s}\,.$$

(8.128)

Here $\sigma_{pa}(\sigma_{sa})$ and $\sigma_{pe}(\sigma_{se})$ are the absorption and emission cross sections at the pump (signal) wavelengths, respectively; t_{sp} is the spontaneous lifetime of the level

Fig. 8.78 The three lowest-lying energy levels of erbium in a silica matrix
Fig. 8.79 Absorption and emission cross section of erbium ions in silica matrix (after [8.246])

E_2. Subscripts p and s correspond to the pump and signal, respectively. The absorption and emission cross sections depend on the frequency, the specific ion as well as on the pair of levels for a given ion. Figure 8.79 gives the typical absorption and emission cross section of erbium ions in silica glass fiber [8.246].

In (8.128) the first term on the right-hand side corresponds to spontaneous emission, the second term to pump absorption while the third term corresponds to signal transitions. The pump and signal intensity variation with z are caused due to absorption and stimulated emission and can be described by the following equations:

$$\frac{dI_p}{dz} = -\sigma_{pa} N_1 I_p \, , \quad \frac{dI_s}{dz} = -(\sigma_{sa} N_1 - \sigma_{se} N_2) \, I_s \, .$$

$$(8.129)$$

In the case of optical fibers since the pump and signal beams propagate in the form of modes, we should describe amplification in terms of powers rather than in terms of intensities. For a given doped fiber and input pump and signal powers, the above equations can be solved to obtain the gain of the amplifier.

A typical EDFA consists of a short piece (≈ 20 m in length) of erbium-doped fiber (EDF) and which is pumped by a 980 nm pump laser through a wavelength division multiplexing (WDM) coupler. The WDM coupler multiplexes light of wavelength 980 nm and 1550 nm from two different input arms to a single output arm. The 980 nm pump light is absorbed by the erbium ions to create population inversion between levels E_2 and E_1. Thus, incoming signals in the 1550 nm wavelength region get amplified as they propagate through the population-inverted doped fiber.

Figure 8.80 shows typical measured gain spectra of an EDFA for various input signal powers. As can be seen in the figure, an EDFA can provide amplifications of greater than 20 dB over the entire band of 40 nm from 1525 nm to about 1565 nm. This wavelength band is referred to as the C band (conventional band) and is the most common wavelength band of operation. We also note that the gain decreases and the spectrum flattens as the input signal power increases, showing signal saturation. With proper amplifier optimization, EDFAs can also amplify signals in the wavelength range of 1570–1610 nm; this band of wavelengths is referred to as the L band (long-wavelength band). With novel doped-fiber profiles it is possible to achieve amplification in the short-wavelength band of 1480–1520 nm by using EDFAs [8.249, 250]. In these designs, the emission in the C band needs to be continuously filtered out
Fig. 8.80 Gain spectrum of an EDFA at different input signal power levels

so that the wavelengths in the S band can use the population inversion for amplification. The C-band and L-band amplifiers together can be used to simultaneously amplify 160 wavelength channels. Such systems are indeed commercially available now.

It can be seen from Fig. 8.80 that although EDFAs can provide gains over an entire band of 40 nm, for low input signal powers the gain is not flat, i.e., the gain depends on the signal wavelength. Thus if multiple-wavelength signals with the same power are input into the amplifier, then their output powers will be different. In a communication system employing a chain of amplifiers, a differential signal gain among the various signal wavelengths (channels) from each amplifier will result in a significant difference in signal power levels and hence in the signal-to-noise ratio (SNR) among the various channels. In fact, signals for which the gain in the amplifier is greater than the loss suffered in the link, will keep on increasing in power level while those channels for which the amplifier gain is less than the loss suffered will keep on reducing in power. The former channels will finally saturate the amplifiers and will also lead to increased nonlinear effects in the link while the latter will have reduced SNR, leading to increased errors in detection. Thus such a differential amplifier gain is not desirable in a communication system and it is very important to have gain-flattened amplifiers. Wavelength filters with appropriate filter characteristics compensating for the gain variation can be designed to flatten the gain of the amplifier. Such filters are usually

placed within the amplifier between two gain units to optimize in terms of gain efficiency and noise characteristics. Filters based on fiber Bragg gratings, long-period gratings or thin-film filters are used. Typical gain flatness of better than 0.5 dB can be achieved and commercially available EDFAs are all gain-flattened. Other techniques involving modification of the refractive index profile to flatten the gain have also been demonstrated.

Noise in EDFA

In an EDFA population inversion between two energy levels of erbium ion leads to optical amplification by the process of stimulated emission. Erbium ions occupying the upper energy level can also make spontaneous transitions to the ground level and emit radiation. This radiation appears over the entire fluorescent band of emission of erbium ions and travels both in the forward as well as in the backward direction along the fiber. Part of the spontaneous emission generated at any point along the fiber gets coupled into the propagating mode of the fiber and can also get amplified just like the signal as it propagates through the population-inverted fiber. The resulting radiation is called amplified spontaneous emission (ASE). This ASE is the basic mechanism leading to noise in the optical amplifier [8.248]. ASE appearing in a wavelength region not coincident with the signal can be filtered using an optical filter. On the other hand, the ASE that appears in the signal wavelength region cannot be separated and constitutes the minimum added noise from the amplifier.

If P_{in} represents the signal input power (at frequency ν) into the amplifier and G represents the gain of the amplifier then the output signal power is given by $G P_{in}$. Along with this amplified signal, there is also ASE power which can be shown to be given by [8.248]

$$P_{ASE} = 2n_{sp}(G-1)h\nu B_o , \qquad (8.130)$$

where B_o is the optical bandwidth over which the ASE power is being measured (which must be at least equal to the optical bandwidth of the signal), and $n_{sp} = N_2/(N_2 - N_1)$. Here N_2 and N_1 represent the population densities in the upper and lower amplifier energy levels of erbium in the fiber. The minimum value for n_{sp} corresponds to a completely inverted amplifier for which $N_1 = 0$ and thus $n_{sp} = 1$. For a gain of 20 dB, typical ASE powers within a band of 0.1 nm is about $0.6\,\mu W (= -32\,dB\,m)$ which corresponds to an ASE noise spectral density of $-22\,dBm/nm$. We can define the optical signal-to-noise ratio (OSNR) as the ratio of

the output optical signal power to the ASE power

$$OSNR = \frac{P_{out}}{P_{ASE}} = \frac{G P_{in}}{2n_{sp}(G-1)h\nu B_o} , \qquad (8.131)$$

where P_{in} is the average power input into the amplifier (which is about half of the peak power in the bit stream, assuming equal probability of ones and zeroes).

Each amplifier in a chain adds noise and thus in a fiber optic communication system consisting of multiple spans of optical fiber links with amplifiers, OSNR will keep falling and, at some point in the link when the OSNR falls below a certain value, the signal would need to be regenerated. Hence there is a maximum number of amplifiers that can be placed in a link beyond which the signal needs to be regenerated. For a link consisting of multiple spans of transmission fiber and EDFAs compensating the loss of each span, the OSNR is given by

$$OSNR(dB) \approx P_{out}(dBm) - 10\log(n) + 58$$
$$- F(dB) - 10\log(N+1) - L_{sp}(dB) , \qquad (8.132)$$

where P_{out} is the total output power from the amplifier in dBm, n represents the number of wavelength channels in the link, F represents the noise figure of each EDFA (assumed to be the same), N represents the number of amplifiers, and L_{sp} the loss of each span. As a typical example we consider a link consisting of EDFAs with the following specifications: $P_{out} = 17\,dBm$, $n = 32$, $F = 5\,dB$, $L_{sp} = 20\,dB$. If we require an OSNR of 22 dB at the end of the link, then using (8.132) the maximum number of amplifiers that can be used in the link comes out to be about 18. If more than this number of amplifiers are employed then the OSNR will fall below the required value of 22 dB. Thus for proceeding further along the length, the signal needs to be regenerated. It is also interesting to note from (8.132) that, to achieve the same OSNR at the output of the link, the number of amplifiers in the chain can be increased by reducing the noise figure of each amplifier or by increasing the output power of the amplifiers or by decreasing the span loss. Indeed by choosing smaller span loss, the number of amplifiers can be increased significantly so that the distance for regeneration can be made very large. Thus reducing each span loss by 3 dB would result in a doubling of the maximum allowed number of amplifiers (all other parameters being the same). Of course in this case, we would have to employ a larger number of amplifiers.

This discussion was based on the optical signal-to-noise ratio of the amplifier. When the amplified output

is received by a detector, then the detector converts the optical signal into an electric current and the noise characteristics of the generated electrical signal are of importance. Apart from the optical signal, the amplified spontaneous emission within the bandwidth of the signal also falls on the photodetector. However, the ASE noise is completely random and contains no information. The photodetector would convert the total optical power received into electrical current and in the current there would be beating between the signal and noise fields and between noise fields at different frequencies. These lead respectively to signal–spontaneous beat noise and spontaneous–spontaneous beat noise. Under normal circumstances, the signal–spontaneous noise term and the signal shot-noise terms are the important noise terms and assuming the input to the amplifier to be shot noise limited we can calculate the output SNR from the noise terms. The amplifier noise figure defined as the ratio of input electrical signal-to-noise ratio to output electrical signal-to-noise ratio is given by

$$F = \frac{1 + 2n_{sp}(G-1)}{G} \ . \tag{8.133}$$

Thus the noise figure depends on the inversion through n_{sp} and on the amplifier gain through G. For large gains $G \gg 1$, the noise figure is approximately given by $2n_{sp}$. Since the smallest value of n_{sp} is unity, the smallest noise figure is given by 2, or in decibel units as 3 dB.

Fig. 8.81 Spontaneous Raman scattering from 25 km of a standard single-mode fiber

Noise figure is a very important characteristic of an amplifier and determines the overall performance of any amplified link. Noise figures of typical commercially available EDFAs are about 5 dB.

8.8.9 Raman Fiber Amplifier (RFA)

Another very important fiber based amplifier is the Raman fiber amplifier (RFA), which is based on the phenomenon of stimulated Raman scattering. The attractive feature of RFAs are that they can be made to work in any wavelength band by simply choosing appropriate pump wavelengths, they also have a large bandwidth and have lower noise figures compared to EDFAs. Apart from this, the link fiber can itself be used as the amplifier and thus the signal gets amplified as it covers the distance along the communication link itself; such amplifiers are referred to as distributed amplifiers.

When we send a strong light beam at a wavelength of 1450 nm through a long (≈ 10 km) optical fiber, the light beam undergoes Raman scattering from the molecules of the glass fiber and this gives rise to scattered light at higher wavelengths. Figure 8.81 shows a typical spontaneous Raman spectrum from an optical fiber pumped by radiation at 1450 nm. As can be seen the scattered radiation occupies a large band and the peak of the scattered radiation lies at about 100 nm away from the pump wavelength. Indeed Raman scattering in silica leads to a Raman shift of between 13 and 14 THz, which corresponds to about 100 nm at the wavelength of 1550 nm.

If in addition to the strong pump light we also launch a weak light beam (referred to as the signal beam) with its wavelength lying within the band of spontaneous Raman scattering, then it leads to what is referred to as stimulated Raman scattering. In this case, the pump and signal wavelengths are coherently coupled by the Raman scattering process and the scattered radiation is coherent with the incident signal radiation much like

stimulated emission that occurs in the case of a laser. It is this process that is used to build Raman fiber amplifiers (Fig. 8.82). Since the spontaneous Raman scattering spectrum is broad, the corresponding gain spectrum of the Raman amplifier is also very broad. The other interesting feature is that, no matter what the wavelength of the pump light is, the fiber can act like an amplifier in the wavelength range corresponding to the spontaneous Raman scattering spectrum.

The propagation equations describing the variation of signal power (P_s) and pump power (P_p) along the length of the fiber for a counter-pumped Raman amplifier are given by [8.251]

$$\frac{dP_s}{dz} = \gamma_R P_p P_s - \alpha_s P_s \; ;$$
$$\frac{dP_p}{dz} = \frac{\nu_p}{\nu_s} \gamma_R P_p P_s + \alpha_p P_p \; , \qquad (8.134)$$

where ν_p and ν_s are the pump and signal frequencies, γ_R is the Raman gain efficiency defined by

$$\gamma_R = \frac{\iint g_R(\nu, r) \psi_p^2 \psi_s^2 r \, dr}{2\pi \iint \psi_p^2 r \, dr \iint \psi_s^2 r \, dr} \approx \frac{g_R(\nu)}{A_{eff}} \; , \qquad (8.135)$$

where ψ_p and ψ_s are the transverse variation of pump and signal modal fields and g_R represents the material Raman gain coefficient and A_{eff} is the effective area defined by

$$A_{eff} = \frac{2\pi \iint \psi_p^2 r \, dr \iint \psi_s^2 r \, dr}{\iint \psi_p^2 \psi_s^2 r \, dr} \; . \qquad (8.136)$$

Since the modal field profiles depend on the fiber refractive-index profile, the value of γ_R can be very different for various fibers. For example for standard SMFs, γ_R is $0.5-1 \, W^{-1}km^{-1}$, for dispersion-compensating fibers it is $2.5-3 \, W^{-1}km^{-1}$ and for highly nonlinear fibers it is about $6.5 \, W^{-1}km^{-1}$. Photonic-crystal fibers and holey fibers can have extremely small mode effective areas and hence can provide extremely large Raman gains. The larger value of γ_R, the larger is the stimulated Raman scattering and the larger the corresponding gains that are achievable. Figure 8.83 shows a typical length variation of pump and signal power of a counter pumped Raman amplifier.

Like any amplifier, in the case of Raman amplifiers also the amplified signal is accompanied by noise generated due to amplification of spontaneous Raman scattering that takes place within the fiber. Since amplification is taking place over a long length of the fiber, additional noise due to the phenomenon of double Rayleigh scattering (DRS) is also generated. Signals propagating in the forward direction suffer Rayleigh scattering and generate power in the backward direction. The backward propagating signals can undergo further Rayleigh scattering (double Rayleigh scattering, DRS) and generate power in the forward direction. These signals also use the same pump power to get amplified and constitute DRS noise. This noise becomes important for reasonably large pump powers and long interaction lengths when the gain becomes large. Apart from this, the amplified spontaneous Raman scattered light in the backward direction can get Rayleigh scattered to the forward direction which would also add to noise.

One can obtain approximate expressions for the Raman gain and spontaneously emitted noise power,
Fig. 8.83 Signal and pump power variation along the length of a Raman amplifier
Fig. 8.84 Typical gain spectrum of a Raman amplifier

which are given by

$$G(\text{dB}) = 10 \log \left(\frac{P_s(L)}{P_s(0)\mathrm{e}^{-\alpha_s L}} \right) \approx 4.34 \frac{\gamma_R}{\alpha_p} P_p(L) \,,$$

(8.137)

where the last approximation is valid for $\alpha_p L \gg 1$ and

$$P_{sp}(L) = 2h\nu\Delta\nu$$
$$\times \left[\frac{4.34}{G} \exp\left(\frac{G}{4.34} \right) - \left(1 + \frac{4.34}{G} \right) \right] .$$

(8.138)

Here G defines the on–off gain, which is the ratio of output power with the Raman pump on to that of the output power when the Raman pump is switched off.

In Raman amplifiers the pump beam can propagate in the same direction as the signal or in the reverse direction. The former case is referred to as co-propagating (forward pumping) and the latter one as contra-propagating (backward pumping). Raman scattering phenomenon is an extremely fast process with time scales in the femtosecond (10^{-15} s) regime. This can lead to the transfer of power fluctuations from the pump to the signal. One way to avoid this is to have backward pumping (Fig. 8.82) wherein the pump fluctuations induced gain fluctuations get averaged out and thus the noise in the signal due to pump fluctuations is much lower.

Figure 8.84 shows a measured on–off gain spectrum of a backward-pumped Raman fiber amplifier corresponding to an input pump power of 750 mW at a wavelength of 1453 nm and an input signal power of 0.14 mW over a 25 km long span of single-mode fiber. On–off gains of greater than 12 dB are easily achievable.
