13. Optical and Spectroscopic Techniques

Spectroscopy is the most important method for gaining detailed information on the structure and dynamics of atoms and molecules. The essential criteria of any spectroscopic technique are the attainable spectral resolution and the sensitivity.

Since lasers have been introduced as coherent narrow-band, intense radiation sources, spectroscopy has seen impressive progress. With single-mode lasers the spectral resolution can be greatly increased and finer details, generally hidden within the Doppler width of spectral lines, can be resolved. The available high intensity of lasers allows nonlinear spectroscopic techniques and the possibility of generating ultra-short light pulses has opened access to studies of very fast dynamical processes, such as the breaking of chemical bonds or the time-resolved redistribution of energy pumped into molecules by the absorption of photons.

In this first part we will concentrate on stationary methods of spectroscopy where the spectral resolution, the maximum achievable sensitivity and the development of optimum detectors are the main subjects.

13.1 Stationary Methods

Basic Principles of Spectroscopic Techniques

All spectroscopic techniques can be classified into those suitable for absorption spectroscopy and others adapted to emission spectroscopy. Emission spectroscopy demands the population of excited states that can emit the radiation. This excitation can be achieved by collisions (examples are gas discharges where electron impact excitation is the main excitation mechanism, or hot gases, such as the atmospheres of stars, where collisions between atoms or ions populate excited states) or by photon absorption (e.g. laser-excited fluorescence).

One important criterion for any spectroscopic technique is its sensitivity, which is defined as the minimum detectable number of photons absorbed or emitted on a transition. This is also a measure for the minimum number of atoms or molecules which can be monitored. In particular for analytical investigations the question of how few atoms or molecules can still be detected in the presence of other species and in a rough environment, is of crucial importance for the selection of the optimum technique. The ultimate sensitivity is reached when single atoms or molecules, for instance as pollutants in a gas, in a liquid or on surfaces can still be measured. One example, where this sensitivity is really needed, is the optical detection of rare isotopes in the presence of other species that are more abundant by many orders of magnitude.

Another essential feature of all spectroscopic techniques is the spectral resolving power R. It is defined

as

$$R = |\lambda/\Delta\lambda_{min}| = |\nu/\Delta\nu_{min}| \tag{13.1}$$

where $\Delta\lambda_{min}$ or $\Delta\nu_{min}$ is the minimum spectral interval (measured in wavelengths λ or in frequencies ν) that can still be resolved, i.e. two spectral lines separated by $\Delta\lambda > \Delta\lambda_{min}$ can be recognized as two separated lines. This minimal interval $\Delta\lambda_{min}$ depends on the profile of the spectral lines. A criterium postulated by Lord Rayleigh is the following Fig. 13.1.

Two spectral lines can be regarded as resolved, when the two partly overlapping line profiles have a dip between the two maxima with intensity I_{max}, which does not exceed $0.8\,I_{max}$.

The spectral resolving power R depends on

1. The spectroscopic instrument used for the separation of different wavelengths of absorbing or emitting transitions. These can be either spectrometers or interferometers.
2. On the line width of the absorption- or emission lines. For gaseous samples at low pressures this is generally the Doppler width, at higher pressures the pressure-broadened line profiles.

Absorption Techniques

Most spectroscopic applications are based on the absorption of radiation. Several techniques have been developed that either use the attenuation of the radiation passing through the absorbing sample, or that monitor various effects caused by the absorption of photons, such as a temperature increase in the sample, the change of electrical conductivity or light emission induced by the absorption [13.1].

We will start with classical absorption spectroscopy, in order to see which factors limit sensitivity.
Fig. 13.1 Rayleigh criterium for the resolution of two close spectral line profiles

Classical Absorption Spectroscopy. When a monochromatic electromagnetic wave with frequency ω and intensity I_0 passes through an absorbing sample with absorption path length L, the transmitted intensity is (Fig. 13.2)

$$I_t = I_0\,e^{-\alpha L} . \tag{13.2}$$

The spectral absorption coefficient $\alpha(\omega_{ik})$ of a transition $E_k \rightarrow E_i$ is determined by the absorption cross section σ_{ik} of the individual molecule on the transition $|i\rangle \rightarrow |k\rangle$, the difference $N_k - N_i$ of the populations densities and the ratio g_k/g_i of the statistical weights

$$L(\Omega_{ik}) = [N_k - (g_k/g_i)N_i]\sigma_{ik}(\Omega) , \tag{13.3}$$

where the statistical weights $g = (2J+1)$ give the number of possible orientations of the total angular momentum J of the levels involved.

For small absorptions the exponential function in (13.2) can be expanded into

$$I_t \approx I_0(1 - \alpha L) \Rightarrow \Delta I = I_0 - I_t \approx \alpha L I_0 \tag{13.4}$$

and we obtain from (13.3) for an absorption length L

$$\Delta I = [N_k - (g_k/g_i)N_i]\sigma_{ik}L I_0 . \tag{13.5}$$

For non-monochromatic radiation the total absorption depends on the relation between the spectral width of the absorbing transition and the bandwidth of the incident radiation.

For a spectral bandwidth $\Delta\omega_r$ of the radiation and an absorption half-width $\Delta\omega_a$ the relative total absorption is

$$\frac{\Delta I}{I_0} = \frac{L\int\alpha(\omega)I(\omega)\,d\omega}{\int I(\omega)\,d\omega} \approx \bar\alpha\frac{\Delta\omega_\alpha}{\Delta\omega_r} , \tag{13.6}$$
Fig. 13.2a,b Relative absorption by a transition with spectral half-width $\Delta\omega_a$ for different bandwidths $\Delta\omega_r$ of the incident radiation. **(a)** $\Delta\omega_r > \Delta\omega_a$, **(b)** for monochromatic radiation

where the integration extends over all frequencies, although only the interval $\Delta\omega_a$ within the absorption line profile contributes significantly to the absorption. This demonstrates that for $\Delta\omega_r > \Delta\omega_a$ the relative absorption increases with increasing ratio $\Delta\omega_a/\Delta\omega_r$ of absorption line width $\Delta\omega_a$ to radiation bandwidth $\Delta\omega_r$ Fig. 13.2. The use of narrow-band radiation sources is therefore not only advantageous for spectral resolution but also for increasing the sensitivity; this is often overlooked. Spectral profiles of absorption lines can only be measured if the bandwidth $\Delta\omega_r$ of the incident radiation is smaller than the absorption line width $\Delta\omega_a$.

The minimum detectable intensity change ΔI mainly depends on possible fluctuations of the incident intensity I_0 and on other noise sources such as detector noise. We summarize all noise contributions to a total noise ΔI_{noise}. Small absorptions $\Delta I = I_0\alpha L < \Delta I_{noise}$ need special electronic devices to be detectable. For the intensity change ΔI the detector gives an output signal $S \propto \Delta I$, while the noise contributes the amount $\delta S \propto \Delta I_{noise}$. A measure of the sensitivity is the achievable signal-to-noise ratio $S/\delta S$. From the condition

$$S \geq \delta S \Rightarrow \Delta I \geq \Delta I_{noise} , \tag{13.7}$$

we obtain with (13.6) the minimum detectable number density of absorbing molecules as

$$\Delta N = [N_k - (g_k/g_i)N_i] \geq \frac{1}{\sigma_{ik}L(S\delta S)} . \tag{13.8}$$

This shows that for a high sensitivity the absorption path length L should be as long as possible, the signal-to-noise ratio $S/\delta S$ as large as possible, and transitions with a large absorption cross section σ should be selected. We will see later how these requirements can be met experimentally.

Laser Absorption Spectroscopy. The aforementioned demands for high sensitivity and optimum spectral resolution can be best met when narrow-band lasers are used as the radiation sources. Absorption spectroscopy with monochromatic wavelength-tunable lasers resembles in many aspects microwave spectroscopy. The advantages of lasers are their wide tuning range and their possible applications in many spectral regions from the far infrared to the extreme ultraviolet.

A typical experimental set up is shown in Fig. 13.3. The output beam of a tunable laser is split by a 50% beam splitter BS2 into a reference beam and the signal beam that passes through the absorption cell. Another beam splitter BS1 directs a small fraction of the laser beam into a long Fabry–Pérot interferometer with mirror
Fig. 13.3a,b Comparison of absorption spectroscopy **(a)** with a broadband incoherent source, **(b)** with a tunable monochromatic laser

separation d which gives equidistant frequency markers separated by $\Delta\nu = c/2d$.

The advantages of this arrangement compared with conventional spectroscopy without lasers can be summarized as follows. (1) There is no need for a spectrometer for wavelength dispersion because the tunable laser is already monochromatic and the absorption lines appear as dips in the transmitted laser intensity I_t when the laser is scanned through the spectrum. (2) The spectral resolution is not limited by any instrument, but solely by the width of the absorption lines, which is generally given by their Doppler width. With Doppler-free techniques Sect. 13.1.4 even this limitation can be overcome. (3) Because of the good collimation of the parallel laser beam a long path length L through the absorption cell can be realized, for instance by multi-path arrangements with spherical mirrors. This enhances the sensitivity (since the absorption $\Delta I = I_0\alpha L$ is proportional to the absorption length L) and allows the detection of weak transitions or of tiny densities of absorbing molecules. (4) The small line width $\Delta\omega_L$ of the laser further increases the sensitivity (13.6). The latter advantage is often overlooked which is, however, not justified, as the following example illustrates:

Example. In conventional spectroscopy with a spectral continuum and a wavelength-selecting spectrometer the grating spectrometer may have a resolution of $\delta\nu = 0.5\,\text{cm}^{-1}$, while the Doppler width of the

absorption lines in the visible is typical about $\Delta \nu_a = 0.03\,\mathrm{cm}^{-1}$. This gives for the same absorption αL an intensity change ΔI that is 16 times smaller than for monochromatic radiation, resulting in a 16 times smaller sensitivity.

Modulated Absorption Spectroscopy. The sensitivity can be further enhanced by modulating the laser frequency ω_L at a modulation frequency f, similar to the situation in microwave spectroscopy [13.2]. The incident intensity can then be represented by

$$I(\omega, f) = I_0\{1 + \cos[\omega + a \sin(2\pi ft)t]\}\,. \quad (13.9)$$

This frequency modulation generates sidebands with the frequencies $\omega = \omega_L \pm n\Omega$ with $\Omega = 2\pi f$. The modulation amplitude may be smaller or larger than the line width $\Delta\omega_a$ of the absorption lines. We will first consider the case where it is larger than the line width of the absorbing transitions. In this case the sidebands lie outside the absorption profile if the frequency ω_L is tuned to the center ω_0 of the absorption line.

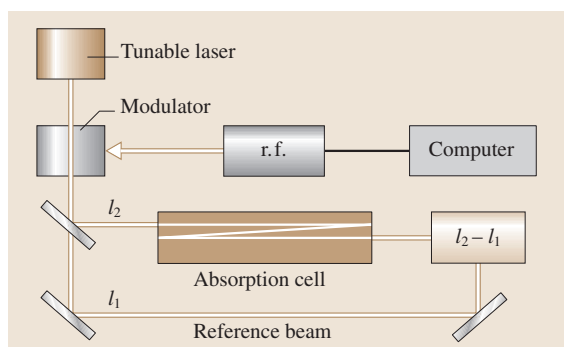
The experimental set up for modulation spectroscopy can be realized as follows Fig. 13.4. When


Fig. 13.4 Absorption spectroscopy with a frequency-modulated tunable laser, a reference beam and difference detection

Fig. 13.5 Principle of phase-modulated absorption spectroscopy, where the modulation amplitude is larger than the line width of the absorbing transitions

the laser beam from a tunable laser passes through an electro-optic modulator (a crystal which changes its refractive index proportional to the voltage applied to electrodes on opposite sides of the crystal) the optical path length is periodically changed and with it the phase of the optical wave. This phase modulation results in a frequency modulation because the frequency $\omega = \mathrm{d}\phi/\mathrm{d}t$ is the derivative of the phase ϕ. In contrast to pure frequency modulation here the phases of the two sidebands are opposite Fig. 13.5. If the transmitted intensity (the sum of the intensities of carrier and sidebands) is detected by a phase-sensitive detector (lock-in) tuned to the modulation frequency Ω, the measured signal is zero if there in no absorption because the lock-in detector measures the two differences $I_c - I_+$ and $I_c - I_-$ of the intensities I_c of the carrier and $I_\pm$ of the two sidebands, which have equal amplitudes but opposite signs and therefore cancel each other.

If, however, one of the sidebands coincides with an absorption line this sideband is attenuated and the balance is perturbed. Fluctuations of the incident intensity appear in the carrier as well as in the sidebands and therefore cancel for the difference measurement.

This eliminates most of the noise and therefore increases the sensitivity. When the carrier frequency coincides with the center frequency of the absorption line, the signal is zero. Since the signal has a zero-crossing at the center frequency of the absorbing transition, this frequency can be determined very accurately.

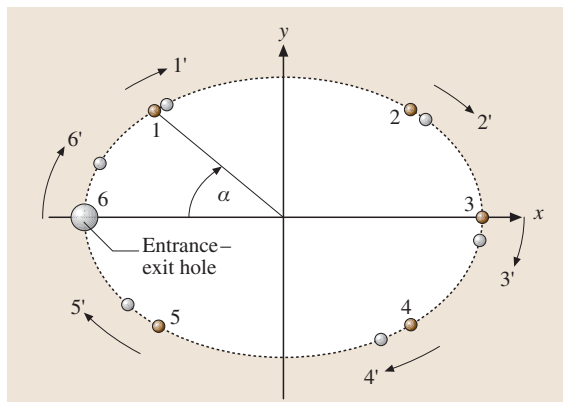
A further enhancement can be achieved, when the absorption path length L is increased. This can be realized by placing the sample inside an optical multipass configuration, which is shown in Fig. 13.6. It consists of two spherical mirrors with radius of curvature r and a separation of $d \approx r$. The incident laser beam enters through a small hole in one of the mirrors, is reflected by the opposite mirror and is focussed onto the first mirror. After many round trips the beam leaves through the same hole but at another angle, thus avoiding back-reflection into the source. The laser-beam spots on the
Fig. 13.6 Multipass absorption cell with spherical mirrors


Fig. 13.7 Laser beam spots on the mirror surfaces for successive reflections. *Brown circles* are on mirror M_2, *gray circles* on mirror M_1
Fig. 13.8a,b Absorption feature of a weak overtone transition in H_2O molecules. (**a**) measured with conventional unmodulated absorption spectroscopy, (**b**) with a phase-modulated (PM) laser and difference detection

in interference that would change with the wavelength λ. When the laser wavelength is tuned over the spectral region of interest, this would result in perturbing features overlapping the spectral lines. The maximum number of round trips is limited by the absorption of the sample and by the reflectivity r of the mirrors.

Example. For example, with a mirror reflectivity r of 98% the transmitted intensity has dropped after N round trips without absorption cell to

$$I_t = I_0 r^{-2N} = 0.01765 I_0 \text{ for } N = 100.$$

Assuming an absorption coefficient of $\alpha = 10^{-5} \text{ m}^{-1}$ and an absorption path length of $2NL$ the transmitted intensity becomes for $L = 1 \text{ m}$ is $I_t = I_0 r^{-2N} e^{-2N\alpha L} = 0.0176 e^{-0.002} \approx 0.01765 \times 0.998 \approx 0.01760$.

This illustrates that for weakly absorbing samples the mirror reflectivity rather than the sample absorption is the limiting factor for the number of passes. The enhanced sensitivity is illustrated in Fig. 13.8 where a conventional absorption measurement of a weak overtone absorption line of the H_2O molecule is compared with the signal obtained by the modulation technique. The enhancement of sensitivity amounts to two orders of magnitude.

If the modulation amplitude is smaller than the absorption line width we have the situation depicted in Fig. 13.9. A lock-in detector tuned to the modulation frequency measures the derivative of the absorption profile. From (13.4) we obtain for $\alpha L \ll 1$

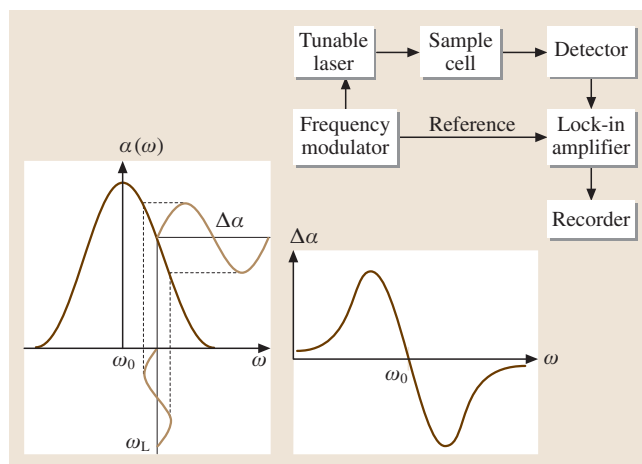
$$\frac{d\alpha}{d\omega} = -\frac{1}{LI_0} \frac{dI_t}{d\omega} . \tag{13.10}$$


Fig. 13.9 Principle of frequency-modulation spectroscopy with a modulation amplitude smaller than the absorption line width

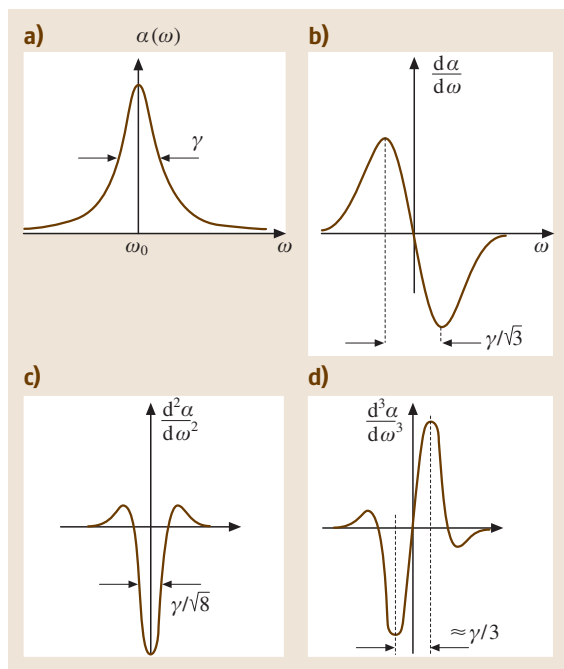
mirrors form a circle Fig. 13.7 with an angular distance that can be controlled by changing the mirror separation d. Due to the focusing by the spherical mirrors the spot size remains fairly constant even for many passes between the mirrors. This minimizes the overlap of spots from different reflections. Such an overlap would result


Fig. 13.10 Signal profiles of absorption lines when $\alpha(\omega)$ and its first three derivatives are measured

When inserting the modulated laser frequency

$$\Omega_L = \omega_0(1 + a\,\sin\Omega t) \tag{13.11}$$

this yields the Taylor expansion

$$I_t(\omega) = I_t(\omega_0) + \sum_n \frac{\alpha^n}{n!}\sin^n(\Omega t)\left(\frac{d^n I_t}{d\omega^n}\right)_{\omega_0}. \tag{13.12}$$

According to trigonometric relations the terms $\sin^n\Omega t$ can be replaced by a linear combination of $\sin(n\Omega t)$ and $\cos(n\Omega t)$. Ordering the different terms with respect to

Fig. 13.11 The principle of optoacoustic spectroscopy

their harmonic frequencies $n\Omega$ one obtains

$$\begin{aligned}
\frac{\Delta I}{I_0} \approx -aL\Bigg[&C + \left(\frac{d\alpha}{d\omega}\right)_{\omega_0}\sin(\Omega t)\\
&- \frac{a}{4}\left(\frac{d^2\alpha}{d\omega^2}\right)_{\omega_0}\cos(2\Omega t)\\
&- \frac{d^2}{24}\left(\frac{d^3\alpha}{d\omega^3}\right)_{\omega_0}\sin(3\Omega t) + \cdots\Bigg].
\end{aligned} \tag{13.13}$$

This means that the n-th derivative of the absorption profile is obtained if the lock-in detector is tuned to the harmonics $n\Omega$ of the modulation frequency Ω.

In Fig. 13.10 the measured profiles for the first three harmonics are illustrated. Since the technical noise generally decreases with increasing frequency, measurements at higher harmonics often yield a higher signal-to-noise ratio [13.3].

Optoacoustic and Optothermal Spectroscopy. With the techniques of absorption spectroscopy discussed so far absorption is detected as the difference between the transmitted and incident intensities. For small absorptions one has to measure a small difference of two large quantities, which has, of course, a larger noise than if the absorbed radiation power could be directly measured. This can be achieved by several techniques, which shall now be discussed. These are based on energy transfer from the absorbed photons to heat, and they monitor various effects caused by the temperature rise of the absorbing sample. We start with optoacoustic spectroscopy [13.4].

An absorption cell with volume V may contain $N = nV$ absorbing molecules, which can be excited into the energy level $E_i = E_k + h\nu$ by absorption of a photon $h\nu$ (Fig. 13.11). If the excited molecule collides with other atoms or molecules in the cell, it can transfer its excitation energy into translational or internal energy of the collision partners. If N_1 molecules are excited and transfer their excitation energy to the N molecules in the cell with f degrees of freedom, the energy $E = (f/2)kT$ of each particle is increased and the temperature of the gas rises by

$$\Delta T = \frac{N_1}{N}h\nu/(fk). \tag{13.14}$$

For a closed cell the total number N of molecules is constant. A temperature rise therefore increases the gas pressure $p = nkT$ by

$$\Delta p = nk\Delta T = \frac{N_1}{V}\frac{h\nu}{k}. \tag{13.15}$$
The energy of the absorbed photons is converted into kinetic energy, resulting in a pressure rise of Δp.

Until now we have neglected the radiative decay of the excited level. If the emitted fluorescence photons are not absorbed within the cell, their energy is not converted into a pressure increase. With the radiative transition rate R_{rad} and the nonradiative rate R_{nr}, which is caused by collisions, the quantum efficiency is

$$\eta = R_{rad}/(R_{rad} + R_{nr}) = 1/(1 + \tau_{all}/\tau_{nr}) \qquad (13.16)$$

and the transferred energy decreases to

$$\Delta E = N_1(1-\eta)h\nu = N_1 h\nu\tau_{rad}/(\tau_{rad} + \tau_{nr}) . \qquad (13.17)$$

The energy conversion increases with the ratio τ_{rad}/τ_{coll} of radiative lifetime to the collisional deactivation time of the excited level.

If the exciting laser beam is chopped at a frequency f that is smaller than the inverse transfer time $(1/\tau_{coll} + 1/\tau_{rad})$ the pressure in the cell is modulated at the frequency f. A sensitive microphone in the side wall of the cell detects these pressure changes which represent acoustic waves. When the chopping frequency is chosen to coincide with one of the acoustical eigen-resonances of the cell, standing acoustic waves are generated with amplitudes that are dependent on the acoustic quality factor Q of the cell and which are much higher than for the nonresonant case.

The technique is quite sensitive because the acoustic resonator acts as amplifier and stores the energy converted from the excited molecules into standing acoustic waves for a time $T_r \propto Q$. For illustration Fig. 13.12

Fig. 13.13 Optoacoustic spectroscopy in an acoustic resonance cell placed inside an optical multipass cell

shows the optoacoustic spectrum of a very weak overtone band in acetylene, with the different rotational lines. Since the absorbed optical photon energy is converted into acoustic energy the method is named *optoacoustic spectroscopy*.

The sensitivity can be further enhanced when the acoustic cell is placed inside an optical multipass cell Fig. 13.13. The laser beams inside this cell with spherical mirrors form a hyperboloid and excite acoustic standing waves on those locations in the acoustic cell where the standing acoustic waves have maximum amplitude, which optimizes the conversion efficiency for the energy transfer from the excited molecules into the acoustic mode.

The technique can also be applied to the investigation of thin films or of surfaces of solids and liquids. The absorbed incident radiation causes local heating, which results in a thermal deformation. This can be detected with a weak probe laser beam, which is incident on the surface at an angle α against the surface normal. For a flat surface the reflection angle is again α. However, if the surface is deformed by local heating, the local surface normal is inclined and therefore the reflection angle is changing Fig. 13.14 [13.6]. When the surface is heated by a pulsed laser, focussed onto the surface, the change of reflection angle of the continuous-wave (CW)

Fig. 13.12 Rotational lines in a vibration overtone transition of acetylene C_2H_2 measured with optoacoustic spectroscopy [13.5]
Fig. 13.14 Time-resolved measurements of surface deformations due to local heating induced by a laser pulse [13.6]
Fig. 13.15 Measurements of thermal waves in a thin metal sheet induced by absorption of a modulated laser beam [13.7]

Fig. 13.16 Schematic arrangement for optogalvanic spectroscopy in a hollow cathode discharge

probe laser can be monitored as a function of time. This gives a measure of the time constants of heat transfer from the local spot into the surrounding.

When the heating laser is pulsed or modulated, thermal waves are generated, which transfer the heat away from the local heat source at the focus of the laser. At a distance x from the heat source the temperature reaches its maximum a time

$$\Delta t = (\rho c/2k)x^2 \tag{13.18}$$

after the heating pulse, where ρ is the density, C is the specific heat, and k is the thermal conductivity of the sample material. After the thermal diffusion length

$$x = D = (k/\pi c\rho f)^{1/2} \tag{13.19}$$

the amplitude of the thermal wave generated by a heat source modulated at a frequency f, has decreased to $A_0 e^{-2\pi} \approx 2\times10^{-3} A_0$.

Measurements of such thermal waves allow the determination of the thermal conductivity of the sample. A possible experimental arrangement is shown in Fig. 13.15. The temperature wave transmitted through the sample can be monitored with an infrared detector. The time constant of this detector limits the time resolution. In the case of a sinusoidally modulated heat source the detected signal is also modulated but shows a phase lag, which is a measure for the time delay between the generation and the arrival of the thermal wave.

Optogalvanic Spectroscopy. For the spectroscopy of high-lying atomic, molecular or ionic levels, gas discharges are convenient because many of these levels are populated by electron impact, in particular metastable

levels with long lifetimes. The discharge impedance depends on the number of electrically charged carriers, i. e., electrons and ions, which are created by electron impact ionization from excited levels of the neutral species. If the population of these excited levels is changed, for instance by absorption of photons, the electron density will change and therefore the impedance of the discharge. If the discharge is fed through a ballast resistor R by a power supply with constant voltage, the impedance change causes a corresponding change of the discharge current and of the voltage drop across the resistor R. This forms the basis for optogalvanic spectroscopy [13.8].

The experimental arrangement is shown in Fig. 13.16. The discharge tube (which might be a hollow cathode discharge or a discharge through a capillary, such as that used for the He–Ne laser or the argon-ion laser) is irradiated by the chopped output beam of a tunable laser (dye or semiconductor laser). This causes a modulation Δi of the discharge current at the chopping frequency f and a corresponding voltage modulation $\Delta U = R\Delta i$ across the ballast resistor R, which is coupled through a capacitance C into a lock-in amplifier and recorded by a computer. If the laser wavelength is tuned to a transition $E_i \rightarrow E_k$ the population of the two levels changes due to laser-induced transitions by

$$\Delta n_i = n_{i0} - n_{iL} \; ; \; \Delta n_k = n_{k0} - n_{kL} \; . \tag{13.20}$$

The corresponding voltage change is then

$$\Delta V = R\Delta i = a[\Delta n_i IP(E_i) - \Delta n_k IP(E_k)] \; , \tag{13.21}$$

where $IP(E_i)$ is the ionization probability of level E_i. The optogalvanic signals might be positive or negative, depending on the different ionization probabilities of the levels E_i and E_k.
Fig. 13.17 Optogalvanic spectrum of a neon discharge in a hollow cathode covered with a mixture of different metals [13.9]

Most gas discharge tubes are filled with noble gases. However, if the noble gas is mixed with other volatile components their spectra can also be measured by this technique.

Even molecules can be inserted into the discharge. Since some of the molecules might be fragmentized by electron impact the spectra of the mother molecules and their fragments overlap and assignment might be difficult [13.10].

In a hollow cathode discharge the ions that impinge onto the inner walls of the hollow cathode release atoms and ions of the wall material by sputtering processes. With higher discharge currents the spectra of these sputtered materials become increasingly prominent. This is illustrated in Fig. 13.17 where the optogalvanic spectrum of aluminium, copper and iron measured in a hollow cathode discharge is shown.

Investigations of the intensity and time behavior of optogalvanic signals give information on the radiative decay constants of highly excited levels and on collision cross sections for electron impact excitation and ionization. These parameters are important for understanding plasma characteristics.

Ionization Spectroscopy. The most sensitive detection technique is ionization spectroscopy. Here a laser is tuned through the spectrum of interest and excites a selected upper level for each absorbing transition. This excited level is ionized by a second laser Fig. 13.18. If the second laser is sufficiently intense, the ionizing transition can be saturated, which means that every excited molecule is ionized before it can emit a fluorescence photon or is deactivated by collisions. The ions can be collected by an electric field, accelerated and imaged

onto the cathode of an open ion multiplier. This is a device that is quite similar to a photomultiplier, except the photocathode is replaced by a metal cathode, where the ions, impinging with energies of a few keV produce electrons by ion bombardment. These electrons are further accelerated and multiplied as in a photomultiplier.

With an optimum design of the ion-collecting system each ion produced through photoionization by the second laser can be imaged onto the ion multiplier and produces a voltage pulse at the multiplier output, which can be counted.

If the first laser with wavelength λ_1 is tuned through the spectral region of interest and the second laser has a fixed wavelength λ_2, the measured ion rate $N_{ion}(\lambda_1)$ essentially gives the absorption spectrum $\alpha(\lambda_1)$ of transitions from the absorbing levels to the levels excited by laser L1. The sensitivity of this method is, however by several orders of magnitude higher than in absorption
Fig. 13.18a–c Level scheme for multiphoton ionization (**a**) resonant two-photon ionization, (**b**) excitation of auto-ionizing Rydberg states, (**c**) nonresonant two-photon ionization of molecules in a level excited by a third photon

spectroscopy, where the attenuation of the transmitted laser intensity is monitored. In favorable cases single atoms or molecules can be detected [13.11].

With a photon flux N_{L2} of the ionizing laser, the number of ions produced per second is

$$\dot{N}_{ion} = n_k V \Sigma_{kI} \dot{N}_{L2} , \tag{13.22}$$

where $P_{kI} = \sigma_{kI} \dot{N}_{L2}$ is the ionization probability by laser L$_1$, and n_k is the stationary population density of the excited level $\langle k|$ in the volume V inside the ionizing laser beam, from which ions can be extracted.

The stationary density n_k of molecules in level $|k\rangle$ is determined by the balance between excitation by laser L$_1$ and depopulation processes. If $R_k + P_{kI}$ is the total relaxation probability of the excited level $|k\rangle$, we obtain

$$\dot{n}_k = 0 = n_i \dot{N}_{L1} \Sigma_{ik} - n_k(P_{kI} + R_k) \Rightarrow$$

$$n_k = n_i \frac{\dot{N}_{L1} \Sigma_{ik}}{P_{ki} + R_k} . \tag{13.23}$$

With the ion yield efficiency $\eta = P_{kI}/(P_{kI} + R_k)$ this gives for the measured ion rate

$$S = \delta \dot{N}_{ion} = n_i \dot{N}_{L1} \dot{N}_{L2} V \frac{\Sigma_{ik} \Sigma_{kI}}{P_{kI} + Rk} , \tag{13.24}$$

where δ is the collection efficiency for the ions onto the detector.

Excitation Spectroscopy with Fluorescence Detection.

The total fluorescence intensity emitted from an excited level can be measured (without dispersion by a spectrometer) as a function of the wavelength λ of the exciting laser Fig. 13.19. Each absorbed photon creates a fluorescence photon if other deactivation processes of the excited level (for instance collision-induced radiationless transitions) can be neglected. This excitation
Fig. 13.19 Level scheme and experimental set up for excitation spectroscopy, where the undispersed laser-induced fluorescence is measured as a function of the excitation wavelength (PM = photomultiplier)

spectroscopy is a very sensitive version of absorption spectroscopy, as can be seen from the following estimation.

The fluorescence photons, imaged onto the cathode of a photomultiplier, create n_{pe} photoelectrons per second. With the quantum efficiency of the photocathode $\eta_{ph} = N_{pe}/N_{fl}$, the rate of absorbed laser photons N_a, the fluorescence quantum yield $\eta_{fl} = N_{fl}/N_a$, the geometrical collection efficiency δ of the fluorescence photons onto the photocathode, the measured rate of photoelectrons is given by

$$S = N_{pe} = N_a \eta_{fl} \eta_{ph} \delta . \tag{13.25}$$

The absorption rate

$$N_a = n_i \sigma_{ik} N_L A \Delta x \tag{13.26}$$

depends on the number density n_i of molecules in the absorbing level $\langle i|$ within the excitation volume $V = A\Delta x$, the absorption cross section σ_{ik}, the number N_L of laser photons incident per second and cm^2 in a laser beam with cross section A onto the sample with absorption path length Δx.

The collection efficiency δ for fluorescence photons can be enlarged by an elliptical mirror arrangement Fig. 13.20. When the intersection volume V of the laser and molecular beams is placed around one focal point A of the ellipsoid, the fluorescence is imaged at the second focal point B where an optical-fiber bundle transmits
Fig. 13.20 Optical set up with elliptical mirror and fibre bundle for effective collection of fluorescence photons

it either directly to the photomultiplier or to the entrance slit of the spectrometer.

Example. For example with a quantum efficiency $\eta_{\mathrm{ph}} = 0.2$ of the multiplier photocathode, a collection efficiency of $\delta = 0.1$, which demands collection optics for the fluorescence, which covers a solid angle of 0.4π, a fluorescence yield $\eta_k = 1$ for the excited level $\langle k|$ and a laser photon flux of $N_{\mathrm{L}} = 3 \times 10^{18}$ /s, which corresponds to a laser power of $1\,\mathrm{W}$ at $\lambda = 500\,\mathrm{nm}$, an absorption rate $N_{\mathrm{a}} = 10^4$ /s (which means a relative laser absorption of $\Delta I_{\mathrm{L}}/I_{\mathrm{L}} = 3 \times 10^{-15}$) gives a photoelectron rate $N_{\mathrm{pe}} = 200$ /s. If the dark current of the photomultiplier is $N_{\mathrm{pe}}(0) = 50$ /s, this gives a signal-to-background ratio of 4, which demonstrates that relative absorptions of less than 10^{-15} can still be detected. This represents a much higher sensitivity than any direct absorption measurement.

Intracavity Absorption. A large enhancement in sensitivity can be achieved when the absorbing sample is placed inside the cavity of the laser [13.12]. This increase of sensitivity has several causes:

1. When the resonator mirrors have transmission $T_1 = 0$ and $T_2 > 0$, the radiation intensity inside the cavity is larger by a factor $q = 1/T_2$ than outside and therefore the number of absorbed photons is multiplied by q. This advantage is quite similar to that of a multipass cell. Observing the laser-induced fluorescence emitted from excited atoms or molecules inside the resonator Fig. 13.21 therefore gives a larger signal proportional to the number of absorbed photons.
2. The output power of the laser depends on the gain of the active medium and the losses inside the laser cavity. Therefore additional losses by absorbing species

decrease the output power. This effect is particularly strong if the laser operates close above the lasing threshold Fig. 13.22. Under stationary conditions the population inversion saturates such that the saturated gain

$$g_s = \frac{g_0}{1 + I/I_s} = \frac{g_0}{1 + P/P_s} = \gamma \qquad (13.27)$$

just equals the total losses. Here g_0 is the unsaturated gain and I_s is the saturation intensity Sect. 13.3.1, which decreases the population inversion to one half of its unsaturated value.

This gives for the laser output power

$$P = P_s \frac{g_0 - \gamma}{\gamma} \ . \qquad (13.28)$$

If additional losses $\Delta\gamma$ are introduced by the absorbing sample the laser power drops to

$$P_a = P - \Delta P = P_s \frac{g_0 - \gamma - \Delta\gamma}{\gamma + \Delta\gamma} \ . \qquad (13.29)$$

The relative change of the output power is then

$$\frac{\Delta P}{P} = \frac{P - P_a}{P} = \frac{g_0 \Delta\gamma}{(g_0 - \gamma)(\gamma + \Delta\gamma)}$$
$$\approx \frac{g_0}{\gamma} \frac{\Delta\gamma}{g_0 - \gamma} fVN\Delta\gamma \ll \gamma \ . \qquad (13.30)$$

Compared with the single-pass absorption $\Delta P = P\alpha L$ for an absorption cell with length L outside the laser resonator the sensitivity enhancement is, with $\Delta\gamma = \alpha L$,

$$Q = \frac{g_0}{\gamma(g_0 - \gamma)} \ . \qquad (13.31)$$

Just above threshold g_0 is only slightly larger than γ and Q becomes very large. However, the laser output power becomes increasingly unstable as the threshold is approached. Therefore there is an upper limit on the attainable signal-to-noise ratio.

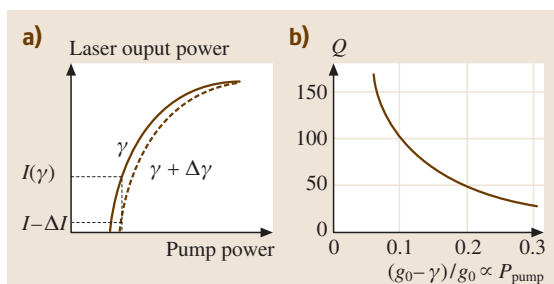
Fig. 13.21 Set up for intracavity absorption, monitored either by the laser-induced fluorescence (13.1) or by the laser output power (13.2)


Fig. 13.22 Laser output power as a function of pump power with and without an absorbing sample inside the laser cavity

3. The most sensitive technique for intracavity absorption is based on multimode lasers, where the coupling between different modes is essential for the high sensitivity. This can be understood as follows. Assume that one of the oscillating laser modes coincides with an absorption line of the intracavity sample. The power in this mode is then decreased and this mode causes less saturation of the gain medium. Neighboring laser modes that are closer to the absorbed mode than the saturation line width can take advantage of this decrease in the population inversion and gain intensity. This in turn decreases the gain for the weaker absorbed mode and weakens its power further. This mode coupling can therefore lead to a complete extinction of the absorbing mode. This means that a tiny absorption can cause a drastic change in the intensity of the absorbed mode.

More-detailed calculations show that the relative change of the output power is now

$$\frac{\Delta P}{P} = \frac{g_0 \Delta \gamma}{\gamma(g_0 - \gamma)}(1 + KM) , \qquad (13.32)$$

where M is the number of coupled laser modes and K ($0 \leq K \leq 1$) is a measure of the coupling strength. For $K = 0$ we obtain the same result as for a single-mode laser, while for $K = 1$ and a large number M of coupled modes the increase in sensitivity is remarkable.

In real lasers the mode coupling and the mode frequencies fluctuate with time due to thermal instabilities or fluctuations in the refractive index of the liquid gain medium of dye lasers. This introduces additional noise and decreases the sensitivity. It is therefore better to pump the laser with a pump laser whose output power follows a step function that starts at time $t = 0$ and then remains constant. The intracavity absorption is measured at times t with $0 \leq t \leq t_m$ that are shorter than
the mean mode lifetime t_m. The experimental set up is shown in Fig. 13.23 [13.13]. The CW broadband dye laser is pumped by an argon laser, whose output can be switched by the acoustooptical modulator AOM1. The laser output through mirror M_0 is gated by AOM2, dispersed by a spectrograph with a charge-coupled device (CCD) array and monitored by a computer.

In the course of time the spectral absorption profiles become deeper and narrower until they reach the spectral resolution of the spectrograph.

The maximum effective absorption length achieved with this technique is

$$L_{\text{eff}} = ct_{\text{max}} , \qquad (13.33)$$

where c is the velocity of light and t_{max} is the maximum observation time.

Example. With a typical delay time $t_{\text{max}} = 100\,\mu s$ the effective absorption length becomes $L_{\text{eff}} = 3 \times 10^8 10^{-4}$ m = 30 km. If an absorption dip in the dispersed output power of 1% can still be detected, this gives a sensitivity limit for the absorption coefficient of $\alpha_{\text{min}} = 3 \times 10^{-9}$ cm^{-1} [13.14].

13.1.1 Absorption and Emission Spectroscopy, Laser−Induced Fluorescence

Until now we have mainly discussed different techniques of absorption spectroscopy. The spectroscopy of radiation emitted from the excited levels of atoms or molecules plays an important role in plasma physics and in particular in astrophysics where the radiation emitted from stars or reflected by planets is the main source of information about extraterrestrial objects.

Emission spectroscopy requires a sufficient population of excited states and needs dispersive instruments to measure the spectrum, i. e. the wavelengths, intensities, line profiles and the degree of polarization of the emission lines.

The excited levels can be populated by thermal collisions if the temperature is sufficiently high (e.g. in the atmospheres of stars), or by electron impact in gas discharges. These mechanisms generally populate many levels and the emission spectrum is accordingly complex. The spectral resolution is limited by the dispersing instrument and reaches about 0.1−0.01 nm for grating spectrometers, while with interferometers the Doppler width of the emission lines can be seen.

The spectrum becomes much simpler if a single upper level can be selectively excited. This is possible in

Fig. 13.23 Experimental arrangement for intracavity laser spectroscopy with a step-function pump power and a variable delay for detecting the transmitted dye-laser output

many cases, when a single-mode laser is used for excitation and the fluorescence spectrum emitted by this single level is measured. A typical experimental set up is shown in Fig. 13.24. The fluorescence spectrum emitted by this excited level is dispersed by a spectrometer and the fluorescence lines are recorded by a photomultiplier or a charge-coupled device (CCD) array. If the fluorescence is, for instance, emitted from a single upper rotational–vibrational level (v, J) of a diatomic molecule, the allowed transitions represent a relatively simple vibrational progression with only one or two rotational lines in each vibrational band Fig. 13.23. The relative intensities of these vibrational bands allow the determination of the Franck–Condon factors. Such a laser-induced fluorescence spectrum is indeed much simpler than the emission spectrum from a gas discharge where many upper levels are populated and the total fluorescence is the superposition of all fluorescence series emitted by the different upper levels.

The wave numbers of the fluorescence lines are equal to the differences between the term values of the upper level and the terminating lower levels. If the upper level is the same for all lines the separations of the fluorescence lines just give the energy differences between the levels in the lower state Fig. 13.25. The vibrational spacings yield the vibrational constants of the lower electronic state and the rotational spacings the rotational constants and their dependence on the vibrational level. If the Franck–Condon factors for transitions into high vibrational levels of the electronic ground state are sufficiently large (this depends on the excited upper vibrational level), the vibrational levels in the electronic ground state can be measured up to the dissociation energy. This allows a very accurate determination of the potential curve [13.15].

The selective excitation of a single upper level is only possible if there is no overlap of absorptions lines within their line width. For excitation in a gas cell the spectral width is generally limited by the Doppler width. At higher temperatures many levels in the electronic ground state are thermally populated, which results in a higher density of absorption lines, and the mean distance between different lines is often smaller than the Doppler width. In such cases several upper levels are excited even with a single-mode laser. However, even then the resulting fluorescence spectrum is still simpler than the emission spectrum from a gas discharge.

This problem can be overcome by laser excitation in a cold and collimated molecular beam, where the Doppler width is greatly reduced and the temperature is
Fig. 13.24 Measurement of dispersed laser-induced fluorescence spectrum with wavelength calibration

decreased due to adiabatic cooling during the expansion of the beam from the reservoir through a nozzle into the vacuum chamber.

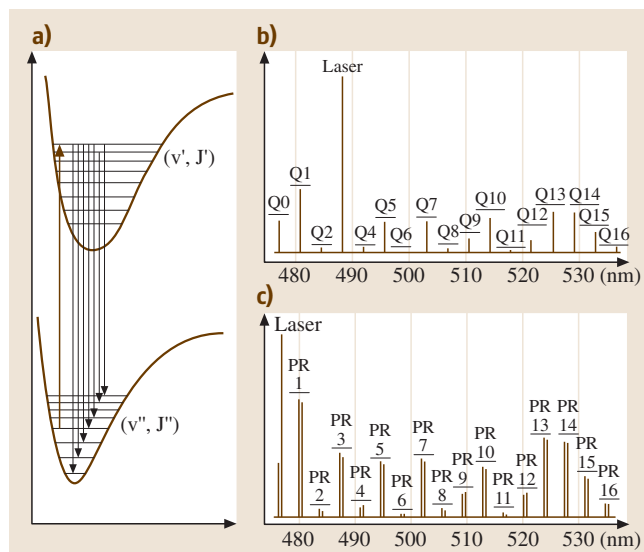
The laser-induced fluorescence spectroscopy has proved very useful for the investigation of inelastic collisions in excited states. These collisions transfer the initial population from the selectively excited level $|k\rangle$ into neighboring rotational–vibration levels $|j\rangle$. The fluorescence emitted from these levels is a direct measure of the transfer probability. The ratio $I_{fl}(j)/I_{fl}(k)$ yields the collision cross section for individual transitions if the densities of the collision partners is known. For such measurements the fluorescence must be dispersed by a spectrometer to separate the contributions emitted from the different levels.


Fig. 13.25a–c Laser-induced fluorescence spectra of the Na_2 molecule for two different selectively excited upper levels: **(b)** $v' = 3$, $J' = 43$, **(c)** $v' = 6$, $J' = 27$ in the $B^1\pi_u$ state

13.1.2 Laser Spectroscopy in Molecular Beams

The combination of laser spectroscopy with molecular-beam techniques has brought about a wealth of new information [13.16]. First of all there is the possible reduction of the Doppler width in collimated molecular beams, when a laser beam is crossed perpendicularly with the molecular beam. Due to the collimation the velocity components of the molecules parallel to the laser beam are greatly reduced. This line-width reduction allows the resolution of finer details in atomic or molecular spectra.

The second advantage is the drastic reduction of the temperature in a supersonic beam, where adiabatic cooling during the expansion of the molecules from their reservoir at high pressure through a narrow nozzle into the vacuum chamber converts the gas at thermal equilibrium at a temperature T_0 into a directed flow of molecules with a narrow spread of parallel velocities around the flow velocity ϑ. Through collisions during the expansion this drop of the *translational temperature* is partly transferred to the rotational and vibrational degrees of freedom and the population distribution is compressed into the lowest vibrational–rotational states. Although this might not be a strict thermal equilibrium, the rotational as well as the vibrational distribution can be approximated by a Maxwell–Boltzmann distribution and a temperature can be attributed. Typical values are $T_{\mathrm{trans}} = 0.1-1\,\mathrm{K}$, $T_{\mathrm{rot}} = 1-10\,\mathrm{K}$ and $T_{\mathrm{vib}} = 10-100\,\mathrm{K}$, depending on the pressure in the reservoir, the nozzle diameter and the specific molecules. This reduction of the population distribution onto the lowest levels results in a drastic simplification of the absorption spectrum and facilitates the assignment considerably [13.17].

The third advantage is the possible application of laser spectroscopy in the investigation of collision processes in crossed molecular beams. In particular for experiments on state-to-state inelastic or reactive collisions the laser can prepare the initial state of the collision partners and detect their final states. Therefore maximum information can be obtained about the interaction potential and its dependence on the distance between the collision partners and on their relative orientation.

Reduction of Doppler Width

In many cases spectral resolution is limited by the Doppler width of the absorption lines. This limitation often prevents the recognition of finer details in the spectrum, such as hyperfine splittings, Zeeman splittings in weak external fields or the rotational structure in molecular spectra. *Doppler-free* techniques that can overcome the limitations set by the Doppler width are then required to get full information from the atomic or molecular spectra.

An elegant way to reduce the Doppler width is the reduction of the velocity distribution of atoms or molecules in collimated molecular beams Fig. 13.26. Molecules, effusing from a reservoir through a small hole A into a vacuum chamber have to pass through a narrow slit with width b, at a distance d downstream of the molecular beam in order to reach the interaction region with the laser beam. If we choose the molecular-beam axis as the z-axis and the slit along the y-direction, the v_x-component of the molecules passing through the slit is reduced by the geometrical factor

$$v_x \le (b/2d)v = v_z \tan \varepsilon \,, \tag{13.34}$$

where $\bar{v} = (8kT/\pi m)^{1/2}$ is the mean velocity of particles with mass m, when the temperature of the reservoir is T, v_z is the velocity component parallel to the beam axis and ε with $\tan\varepsilon = b/2d$ being the collimation angle.

If the beam of a tunable single-mode laser crosses the molecular beam in the x-direction (i. e., perpendicular to the molecular-beam axis) behind the slit, only molecules within the narrow interval $v_x \le (b/2d)v$ contribute to the absorption, which means that the width $\Delta\nu$ of the absorption line is reduced compared to its Doppler width in a gas at thermal equilibrium.

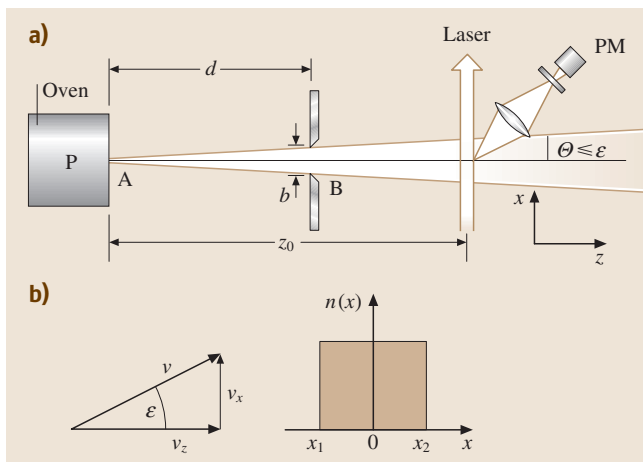
Example. With $b = 1\,\mathrm{mm}$, $d = 100\,\mathrm{mm} \Rightarrow \tan\varepsilon = 5 \times 10^{-3}$. instead of a typical Doppler width of $\Delta\nu_D = 1\,\mathrm{GHz}$ in the optical range, the line width is now


Fig. 13.26 Laser spectroscopy in a collimated molecular beam with reduction of the Doppler width (PM = photomultiplier)

reduced by a factor of 200 to $\Delta\nu_D^{red} = 5\,\text{MHz}$. This is already in the range of the natural line width. The quantitative treatment starts with the density of molecules in the beam with velocities v within the interval dv

$$n(V,r,\Theta)\,dV = \varphi_i \frac{\cos\Theta}{r^2} nv^2 e^{-(v|v_p)^2}\,dv\,, \quad (13.35)$$

where the normalization factor $C = (4/\sqrt{\pi})/v_p^3$ assures that the total density n of the molecules is

$$n = \int n(v)\,dv \quad (13.36)$$

and $v_p = (2\,kT/m)^{1/2}$ is the most probable velocity. The spectral profile of the absorption coefficient is

$$\alpha(\omega,x) = \int n(v_x,x)\Sigma(\omega,v_x)\,dv_x\,, \quad (13.37)$$

with $v_x = (x/r)v \Rightarrow dv_x = (x/r)\,dv$ and $\cos\Theta = z/r$ (Fig. 13.26b). We derive from (13.35) for the molecular density

$$n(v_x,x)\,dv_x = \varphi n \frac{z}{x^3} v_x^2 \exp[-(rv_x/xv_p)^2]\,dv_x\,. \quad (13.38)$$

The absorption cross section $\sigma(\omega,v_x)$ is a Lorentzian profile, Doppler-shifted by kv_x,

$$\sigma(\omega,v_x) = \Sigma_0 \frac{(\gamma/2)^2}{(\omega-\omega_0-kv_x)^2+(\gamma/2)^2}\,. \quad (13.39)$$

Inserting (13.38) and (13.39) into (13.37) gives (with $dv_x = d\omega/k$) the spectral profile of the absorption coefficient

$$\alpha(\omega) = \varphi \int_{-\infty}^{+\infty} \frac{e^{-\left(\frac{\omega-\omega_0'}{\omega_0' v_p \sin(\varepsilon/c)}\right)^2}}{(\omega-\omega_0')^2+(\gamma/2)^2}\,d\omega_0'$$

with $\omega_0' = \omega_0(1+v_x/c)$ (13.40)

which is called a Voigt profile. The Gaussian profile has a width of $\Delta\omega_D \sin\varepsilon$, reduced by a factor $\sin\varepsilon$ compared to the Doppler width in a gas at thermal equilibrium.

High-resolution absorption spectra can be measured by monitoring the total fluorescence $I_{fl}(\lambda_L)$ as a function of the laser wavelength (excitation spectroscopy), or by resonant two-photon ionization, where the ions are extracted by an electric field from the intersection volume of molecular and laser beams onto the
Fig. 13.27 Molecular-beam apparatus with different crossing points with laser beams for measuring the undispersed and the dispersed laser-induced fluorescence, and the ions produced by resonant two-photon ionization with subsequent mass selection by a quadrupole spectrometer (QMS)
Fig. 13.28 Resolved hyperfine structure (HFS) of a rotational transition in the Na$_2$ molecule, measured in a collimated molecular beam [13.18]

ion multiplier. A typical experimental arrangement is shown in Fig. 13.27. Here the molecular beam is crossed by several laser beams. In the first crossing point the laser-induced fluorescence is collected on both sides. The photomultiplier PM1 measures the total fluorescence while PM2 behind a monochromator monitors the dispersed fluorescence for a fixed excitation laser wavelength.

The second crossing point between the molecular beam and two superimposed laser beams is located in the ion source of a mass spectrometer. The first laser excites the molecules into an intermediate level $|i\rangle$ and the second CW argon laser brings them from the state $|i\rangle$ into an energy state just above the ionization threshold. This resonant two-photon ionization is very efficient in producing isotope-selective ions, or in the case of cluster beams to select specific cluster sizes for ionization. This is very helpful for the assignment of the spectra, if many different masses (e.g. isotopes or different cluster sizes in a cluster beam) are present.

For illustration of the attainable spectral resolution Fig. 13.28 shows the hyperfine structure (HFS) of a rotational transition ($J' \leftarrow J''$) in the electronic transition of Na_2 molecules from the $X^1\Sigma_g$ ground state into the mixed $A^1\Sigma_u - a^3\Pi_u$ upper state, where the two states are coupled by spin–orbit coupling [13.18].

Optothermal Spectroscopy in Molecular Beams

The temperature increase caused by the transfer of excitation energy can also be monitored by the change of electrical conductivity with temperature. This is used in the bolometer, which is a detector made of a material with a high temperature coefficient α of electrical conductivity $\sigma = \sigma_0[1 + \alpha(T)]$. Generally doped semiconductor materials are used. The coefficient α decreases with decreasing temperature. Therefore a bolometer is generally operated at low temperatures, e.g., at $T = 1.5\,\mathrm{K}$, which can be reached by evaporating ^{4}He in a helium cryostat. Even lower temperatures down into the milliKelvin range can be obtained by a ^{3}He^{4}He dilution refrigerator.

The temperature increase can be caused by the absorption of photons (in this case the bolometer acts as a radiation detector) or by the adsorption of excited

atoms or molecules at the surface of the bolometer. Here they transfer their excitation energy to the bolometer.

A typical arrangement for molecular spectroscopy in molecular beams is shown in Fig. 13.29 [13.19].

The molecular beam is crossed perpendicular by the beam of a single-mode laser, which excites the molecules into long-lived higher states (for example excited vibrational levels in the electronic ground state or Rydberg states with a long radiative lifetime).

The heat transfer rate from N molecules per sec with excitation energy $\Delta E = h\nu$ is

$$dQ/dt = N\Delta E = Nh\nu . \tag{13.41}$$

This results in a temperature increase $\Delta T = T - T_0$ of a bolometer with heat capacity C and heat conduction $G(T - T_0)$ to the surroundings at temperature T_0 without molecules impinging on the bolometer at the temperature T, which can be determined from energy conservation

$$P = Nh\nu = C(dT/dt) + G(T - T_0) , \tag{13.42}$$

where the incident power equals the thermal energy increase per sec of the bolometer and the power conducted to the surrounding. Under stationary conditions ($dT/dt = 0$) the temperature rise is obtained from (13.42) as

$$\Delta T = T - T_0 = Nh\nu/G . \tag{13.43}$$

In order to increase the sensitivity of a bolometer, heat conductivity to the surrounding should be as small as possible, i. e. the bolometer has to be thermally well isolated.

In order to subtract the background signal caused by the adsorption of molecules in their ground state, the excitation laser is chopped at a frequency f and the optothermal signal is detected through a lock-in amplifier. Now the energy transferred to the bolometer is time-dependent. The time constant of the bolometer should be shorter than the chopping period.

The time constant depends on the heat capacity C and the heat conductivity G. This can be seen as follows. Assume the transferred power is

$$P = P_0(1 + a\cos\Omega t)$$
$$\text{with}\quad a \leq 1\quad\text{and}\quad \Omega = 2\pi f . \tag{13.44}$$

Inserting (13.44) into (13.42) gives

$$T(\Omega) = T_0 + \Delta T[1 + \cos(\Omega t + \phi)] . \tag{13.45}$$
Fig. 13.29 Optothermal spectroscopy in a molecular beam with laser excitation and detection by a cooled bolometer

The temperature T is modulated at the same frequency Ω but shows a phase lag ϕ with

$$\tan\phi = \Omega C/G \tag{13.46}$$

against the modulated incident power, which depends on the heat capacity C, the heat conductivity G and the frequency Ω. The amplitude ΔT of the temperature modulation is

$$\Delta T = \frac{\bar{a}P_0\Sigma}{\sqrt{\Sigma^2 + \Omega^2 P^2}} \ . \tag{13.47}$$

At the frequency $\Omega_c = G/C$ the amplitude ΔT decreases by a factor of $\sqrt{2}$ against its DC value.

We see that the sensitivity is proportional to $1/G$ but the time constant $\tau \sim G/C$. A sufficiently fast and sensitive detector should have a minimum heat capacity. Since C decreases with temperature, this is again an argument for operating the bolometer at low temperatures [13.20].

In Sect. 13.2 it was shown that the absorption path length should be as large as possible in order to reach a higher sensitivity. Since a single pass through the collimated molecular beam is only about 1 mm, optical arrangements for increasing this absorption length have been designed. In Fig. 13.30 several solutions are illustrated. They consist either of two parallel mirrors, where the incoming laser beam is reflected back and forth between the mirrors, or of a pair of cat-eyes that are shifted against each other by a small amount δ. In the former arrangement the laser beam passes the molecular beam at an angle $90° - \varepsilon$ and the absorption lines are therefore Doppler-shifted by an amount $\Delta\nu = (\nu/c)\sin\varepsilon$, where ν is the velocity of the molecules. The largest advantage can be reached when the crossing point is placed in the beam waist of an external nearly confocal enhancement resonator with highly reflecting mirrors. The incoming laser beam has to be mode-matched to the fundamental mode of the resonator by an appropriate optical design, consisting of two lenses Fig. 13.28c. With such a design an enhancement by a factor 200 of the optical power in the crossing point can be achieved.

13.1.3 Nonlinear Laser Spectroscopy

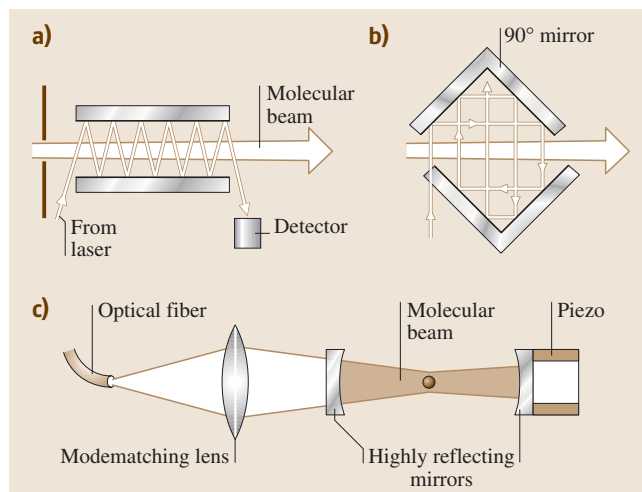
Several spectroscopic techniques that achieve sub-Doppler resolution are based on the nonlinear interaction of molecules with laser radiation. When a plane electromagnetic wave passes in the x-direction through an absorbing gas. We have seen above, that the attenuation dI of the intensity is related to the absorption coefficient


Fig. 13.30a–c Optical arrangements for generating many crossings of the laser beam with the molecular beam. (a) two plane-parallel mirrors, (b) two cat eyes arrangement, (c) crossing point inside a high Q enhancement resonator, where the laser beam is mode-matched to the fundamental mode of the resonator

α by

$$dI = -\alpha I \, dx \ . \tag{13.48}$$

The absorption coefficient

$$\alpha = \Delta N \Sigma_{ik}$$
$$\text{with } \Delta N = [N_k - (g_k/g_i)N_i]$$

is determined by the population difference ΔN and the absorption cross section σ. This gives for (13.48) the relation

$$dI = -[N_k - (g_k/g_i)N_i]\Sigma_{ik}I \, dx \ . \tag{13.49}$$

For sufficiently small intensities I the population densities N_i and N_k are not much affected, because relaxation processes can refill the population N_k of the absorbing level Fig. 13.31a. In this case the absorption coefficient α is independent of the intensity I and integration of (13.48) yields *Beer*'s law of linear absorption

$$I = I \, e^{-\delta N \Sigma x} \ . \tag{13.50}$$

For higher intensities the absorption rate can exceed the relaxation rates refilling the absorbing level $\langle k|$. This means that the population N_k decreases with increasing intensity I and the absorption coefficient therefore also decreases. Instead of (13.51) we have to write

$$dI = -\Delta N(I)I\sigma \, dx \ . \tag{13.51}$$
Fig. 13.31a,b Saturation of a transition (**a**) fluorescence intensity and population difference as a function of the excitation intensity, (**b**) level scheme

The change dI of the intensity and therefore also the absorbed power depends in a nonlinear way on the incident intensity. We can write the intensity-dependent population of the absorbing level $|k\rangle|$ as a power series

$$N_k = N_{k0}(1 - aI - bI^2 - \cdots) \qquad (13.52a)$$

with $b \ll a \ll 1$ and a corresponding relation for the upper level $|i\rangle$

$$N_i = N_{i0}(1 + aI - bI^2 \cdots) . \qquad (13.52b)$$

For the population difference we obtain Fig. 13.31b:

$$\Delta N = \Delta N_0(1 - 2aI - 2bI^2 - \cdots) . \qquad (13.53)$$

Inserting this into (13.51) gives

$$dI = \Delta N_0 \Sigma \, dx(I - 2aI^2 - 2bI^3 - \cdots) . \qquad (13.54)$$

The first term describes the linear absorption, the second term is quadratically dependent on I and diminishes the absorption because $d(\Delta N)/dI < 0$.

The nonlinear absorption can be demonstrated by measuring the intensity of the laser-induced fluorescence $I_{fl}(I_L)$ as a function of the laser intensity Fig. 13.31c. One can see, that I_{fl} first increases linearly with I_L, but for higher laser intensities the increase is sublinear, because the population difference and therefore the absorption coefficient decreases, which causes a smaller relative absorption of the laser intensity dI_L/I_L. For high laser intensities the fluorescence intensity approaches a constant value (saturation) that is limited by the rate of the relaxation processes refilling the absorbing level $|k\rangle$.

This saturation of the absorption can be used for Doppler-free spectroscopy [13.21], as will be outlined in the next section.

Saturation Spectroscopy

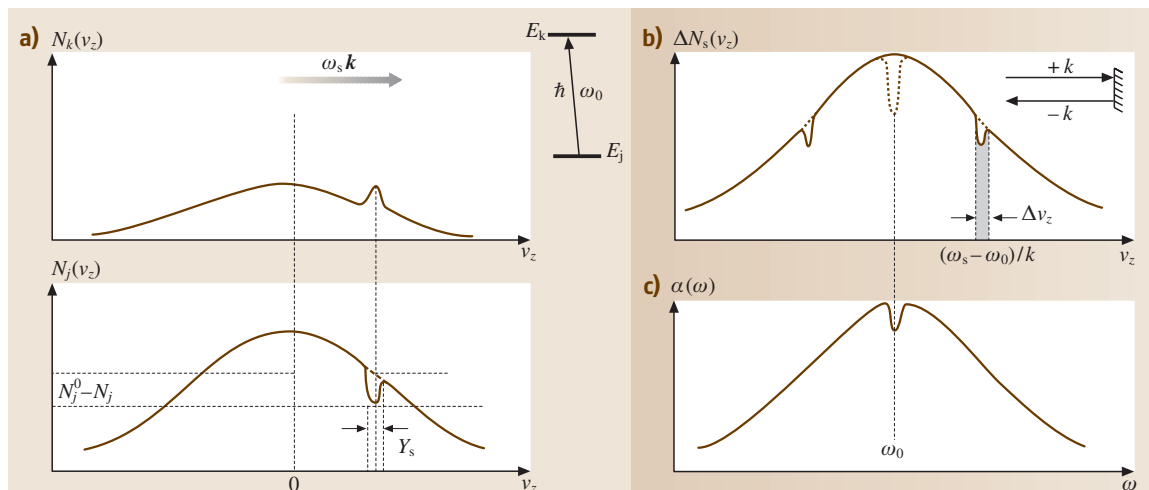
We consider a sample of atoms or molecules in the gas phase with a Doppler-broadened absorption profile around the center frequency ω_0. When a monochromatic laser beam with frequency ω passes in the x-direction through the sample, only those molecules can absorb the laser photons that are Doppler-shifted into resonance with the laser frequency. Since the Doppler shift is $\Delta\omega = kv_x$ these molecules must have velocity compo-


Fig. 13.32a–c Principle of saturation spectroscopy of Doppler-broadened transitions: (**a**) saturation hole and saturation peak in the velocity distribution of lower and upper level population, (**b**) situation for a standing wave, (**c**) Lamb dip in the Doppler-broadened absorption profile

nents v_{x}, that satisfy the relation

$$\omega = \omega_0(1 + kv_x) \pm \gamma , \tag{13.55}$$

where γ is the homogeneous line width of the transition. Because of saturation the population N_k in the absorbing level of these molecules decreases and N_i increases accordingly. In the velocity distribution $N_k(v_x)$ of all molecules a narrow dip is burnt with a spectral width γ, while a corresponding peak appears in the distribution $N_i(v_x)$ of molecules in the upper level Fig. 13.32a.

If the laser beam is reflected back into the sample by a mirror, its k vector is reversed and molecules with opposite velocity components interact with the reflected beam Fig. 13.32b. Now two holes, symmetric to $v_x = 0$ are burnt into the velocity distribution of the inversion $\Delta N(v_x)$, i.e., two different velocity classes $\pm(v_x \pm \gamma)$ interact with the two laser beams.

When the laser frequency ω_L is tuned over the Doppler-broadened absorption profile the two holes move towards each other as ω_L approaches the center frequency ω_0 of the molecular transition. For $\omega_L = \omega_0$ only one velocity class in the interval dv_x around $v_x = 0$ interacts with both laser beams. The molecules experience the double intensity and therefore the population inversion ΔN will more decrease for $\omega_L = \omega_0$ than for $\omega_L \neq \omega_0$. The absorption coefficient $\alpha(\omega)$ with a Doppler-broadened profile therefore has a dip around the center frequency ω_0 Fig. 13.32c. This dip, caused by the saturation of the population, is called the Lamb dip, named after Willis Lamb who explained this saturation effect quantitatively.

The width of the Lamb dip equals the natural line width of the molecular transition, broadened by saturation. It is about two orders of magnitude smaller than the Doppler width.

This narrow Lamb dip is used for Doppler-free spectroscopy (called saturation, or Lamb dip spectroscopy). Assume two transitions from a common level $\langle c|$ into two slightly split levels $\langle a|$ and $\langle b|$. If the splitting is smaller than the Doppler width the two Doppler-broadened spectral lines cannot be resolved. However, the two Lamb dips of these transitions are well separated Fig. 13.33.

A possible experimental arrangement is shown in Fig. 13.34. The beam of a wavelength-tunable laser is split by beam splitter (BS) into a strong pump beam and a weak probe beam, which pass in opposite directions through the sample cell. The detector measures the transmitted probe beam intensity as a function of the laser frequency ω_L. Each time the laser frequency coincides with the center frequency of a molecular transition, a Lamb peak appears in the transmitted intensity because the absorption exhibits a dip at this frequency.

The Doppler-broadened background can be eliminated when the pump beam is periodically chopped. Now a lock-in detector measures the difference of the transmitted probe intensity with the pump beam on and
Fig. 13.33 Resolution of the two Lamb dips of two close overlapping Doppler-broadened transitions with a common lower level
Fig. 13.34 Experimental arrangement for saturation spectroscopy with detection of the transmitted probe beam, resulting in Lamb dips on a Doppler-broadened background
Fig. 13.35 Saturation spectrum of the hyperfine-components of the $6^2S_{1/2} \to 7^2P$ transition at $\lambda = 459.3$ nm in a mixture of the isotopes ^{133}Cs, ^{135}Cs and ^{137}Cs [13.22]

off. The result is a Doppler-free spectrum Fig. 13.35 with a better signal-to-noise ratio.

Even with low-power lasers saturation spectroscopy can be performed when the sample is placed inside the laser resonator, where the intensity is much higher than outside Fig. 13.36. The standing wave inside the resonator can be composed of a back-and-forth traveling wave. Therefore the conditions for producing a Lamb dip are automatically fulfilled. Either the laser-induced fluorescence from the sample molecules can be monitored, which exhibits the Lamb dips, or the laser intensity transmitted through one of the resonator mirrors is measured, which shows corresponding narrow peaks in the laser output power at the center frequencies of the absorption lines of the sample molecules. If the resonator length is modulated while the laser wavelength is scanned, the first derivative of the Lamb dips or peaks is measured with a lock-in tuned to the modulation frequency f. Since the modulation of the absorption is not harmonic (even if the laser frequency is modulated sinusoidally), the modulated laser output also contains higher harmonics Sect. 13.1.2. When the lock-in is tuned to $3f$ the third derivative spectrum is obtained

Fig. 13.37. Here the Doppler-broadened background is essentially suppressed. Figure 13.36b shows such a third-derivative spectrum for the rotational transition $B^3\Pi_{mathrmu}(v' = 58, J' = 99) \leftarrow X^1\Sigma_g^+(v'' = 1, J'' = 98)$ in the I_2 molecule with its 21 hyperfine components.

Polarization Spectroscopy

While in saturation spectroscopy the selective decrease of absorption by the pump laser was monitored by the counter-propagating probe laser, in polarization spectroscopy it is the birefringence induced by the pump laser that is monitored by the probe laser [13.23]. The principle is shown in Fig. 13.38. The sample is placed between two crossed polarizers P_1 and P_2 that attenuate the linearly polarized probe laser by a factor of $10^5 - 10^7$, depending on the quality of the polarizers. A larger portion of the laser beam is split off by the beam splitter S and acts as a pump beam, which passes in the opposite direction through the sample cell. If the pump laser beam is circularly polarized (e.g., σ^+-polarization), it induces transitions with $\Delta M = +1$, where Mh is the projection of the angular momentum J of the sample molecules onto the direction of the pump beam. Due to saturation some of the M sublevels are partly depopulated (for our example in Fig. 13.38a these are the levels with $M = -2, -1, 0$). This leads to a partial orientation

of the molecules because their angular momentum J no longer has an isotropic orientational distribution but points more against the direction of the pump beam.

The linearly polarized probe beam can be composed of a σ^+ and a σ^- component. The two components experience different absorption and a different index of refraction when passing through the sample of orientated molecules. Adding the two components again after they have passed through the sample results in an elliptical polarization of the probe beam with the major axis rotated by a small angle α compared to the initial polarization direction, because of the different phase shifts of the σ^+ and the σ^- components. Now a small component of the electric vector parallel to the transmission axis of the second polarizer exists, which is transmitted to the detector. We will discuss this now more quantitatively.

The linearly polarized probe wave

$$E = E_0\, e^{i(\omega t - kz)} \text{with} \quad E_0 = \{E_0\,,0\,,0\} \qquad (13.56)$$

can be composed of a σ^+ and a σ^- component

$$E^+ = E_0^+\, e^{i(\omega t - k^+ z)}\,, \qquad E_0^+ = \frac{1}{2}E_0(\hat{x} + i\hat{y})\,,$$
$$E^- = 0E_0^+\, e^{i(\omega t - k^- z)} \qquad E_0^- = \frac{1}{2}E_0(\hat{x} - i\hat{y})\,,$$
$$(13.57)$$

where $\hat{x}$ and $\hat{y}$ are unit vectors.

The two components experience different absorption coefficients α^+ and α^- and also different refractive indices n^+ and n^-. After a path length L through the sample region that has been orientated by the pump laser the two components are

$$E^+ = E_0^+\, e^{i(\omega t - k^+ L + i\alpha^+ L/2)}\,,$$
$$E^- = E_0^+\, e^{i(\omega t - k^- L + i\alpha^- L/2)}\,. \qquad (13.58)$$

Because of the difference $\Delta n = n^+ - n^-$ a phase difference

$$\Delta\Phi = (k^+ - k^-)L = (\omega L/c)(n^+ - n^-) \qquad (13.59)$$

has developed between the two components and because of the difference $\Delta\alpha = \alpha^+ - \alpha^-$ there is also a difference

$$\Delta E_0 = (E_0/2)[e^{-\alpha^+ L/2} - e^{-\alpha^- L/2}] \qquad (13.60)$$

in the two amplitudes.

The windows of the absorption cell are slightly bent because of external atmospheric pressure and they therefore show a birefringence which is different for the two circularly polarized components and causes an additional phase shift.
Fig. 13.38 Level scheme and experimental set up for Doppler-free polarization spectroscopy

Behind the exit window the electric field vector of the probe beam is obtained by adding the σ^+ and σ^- components. This gives a slightly elliptical polarized wave with a major axis that is tilted by the small angle θ against the x-axis. This increases the transmittance through the crossed analyzer. The transmitted amplitude becomes (Fig. 13.39)

$$E_t = E_x \sin\theta + E_y \cos\theta\,. \qquad (13.61)$$

The detector signal is proportional to the transmitted intensity. Besides the signal there is also a frequency-independent background due to the residual transmission ξ of the crossed polarizers.

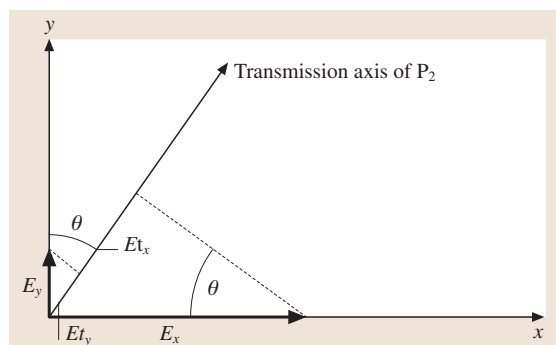
Similar to the case in saturation spectroscopy the line profile of the signals are Doppler-free and are determined by the homogeneous line width γ (natural line width plus collision broadening plus saturation broaden-


Fig. 13.39 Transmitted polarization components through the analyzer

ing), because only molecules with velocity components $v_x = 0 \pm \gamma k$ can interact with both counter-propagating laser beams.

The final result for the transmitted intensity, measured when the laser frequency is tuned over an absorption line of the sample molecules, is

$$I_t = I_0 \, e^{-\alpha L} \left(\Sigma^2 + \Theta'^2 + \tfrac{1}{4} \Delta \alpha_\omega^2 + \Theta' \, \Delta \alpha_0 L \frac{x}{1+x^2} \right)$$
$$+ \left[\tfrac{1}{4} \Delta \alpha_0 \Delta \alpha_\omega L + \left(\frac{\Delta \alpha_0 L}{4} \right)^2 \right] \frac{1}{1+x^2}$$

with

$$x = \frac{\omega_0 - \omega}{\gamma_s / 2} \, . \tag{13.62}$$

The advantages of polarization spectroscopy, compared to saturation spectroscopy are as follows:

1. The technique is essentially background-free. Besides the small residual terms $I_0 \xi$ with $\xi = 10^{-5}$–10^{-7} the detector only receives a signal when the pump beam is not blocked. In saturation spectroscopy the pump beam changes the absorption of the probe beam by a small amount and the small difference between two large signals is detected. The sensitivity of polarization spectroscopy is therefore much higher.
2. Uncrossing of the polarizers ($\theta > 0$) increases the dispersion term in (13.62). Such a dispersion signal is ideally suited to stabilize a laser frequency onto the zero-crossing of the signal, which occurs at the center of the Doppler-free absorption line. Choosing $\theta = 0$ yields Lorentzian line profiles, where the magnitude of the signals can be optimized by changing the birefringence of the windows (e.g., by squeezing them gently).
3. It turns out that the signal magnitude and profile depends on the specific molecular transition. For a circularly polarized pump beam the signals of Q-lines ($\Delta J = 0$) are suppressed, while for a linearly polarized pump beam the magnitude of the signals for P- and R-lines ($\Delta J = \pm 1$) decreases rapidly with increasing rotational quantum number J. The assignment of a complex molecular spectrum is therefore facilitated.

Doppler–Free Two–Photon Spectroscopy

For sufficiently strong laser intensities it can happen that an atom or molecule simultaneously absorbs two photons $\hbar \omega_1$ and $\hbar \omega_2$ from two lasers, or two photons $\hbar \omega_1$ from the same laser. Depending on the relative orienta-

tions of the two photon spins, transitions with $\Delta L = 0$ or $\Delta L = \pm 2$ are induced. Two-photon transitions are weaker by several orders of magnitude than allowed one-photon transitions. Therefore lasers with sufficient high intensities are demanded for their observation. The probability of two-photon absorption is greatly enhanced if a molecular level E_m is close to the energy $E_k + \hbar \omega_1$ or $E_k + \hbar \omega_2$.

For a two-photon transition from the initial lower level $\langle k|$ to the final level $\langle f|$ in a molecule at rest energy conservation demands

$$E_f - E_k = \hbar (\omega_1 + \omega_2) \, . \tag{13.63}$$

When the molecule moves with velocity v the frequency ω of the light wave is shifted in the molecular frame to $\omega' = \omega - kv$. The resonance condition (13.63) now becomes

$$E_f - E_k = \hbar (\omega_1 + \omega_2) - hv(k_1 + k_2) \, . \tag{13.64}$$

If the two photons come from two counter-propagating traveling beams from the same laser, we have the situation that $\omega_1 = \omega_2$ and $k_1 = -k_2$. This has the consequence that the last term in (13.64), which contains the velocity of the molecule, is zero. The two-photon absorption in this case becomes independent of the molecular velocity, which means that all molecules within the velocity distribution contribute to the two-photon absorption, which is now Doppler-free. The experimental arrangement is shown in Fig. 13.40. The sample is placed inside the resonator of a single-mode laser. The two-photon transition is monitored by the laser-induced fluorescence, emitted from the upper level E_f into intermediate levels E_m that are connected to $\langle f|$ by allowed one-photon transitions. A Faraday rotator acts as an optical diode and prevents the reflected beam from passing
Fig. 13.40 Doppler-free two-photon spectroscopy

back into the laser, because this could cause instabilities in the laser.

When the laser frequency ω is tuned over the two-photon resonance the signal consists of a narrow peak (produced by two photons with opposite k-vector) and a Doppler-broadened background, produced by two photons from the same beam with parallel k-vectors Fig. 13.41. The Doppler width is twice as large as that of a one-photon transition with frequency ω. The probability that the two photons come from opposite beams is twice as large as that for two photons from the same beam. This implies that twice as many molecules contribute to the narrow peak than to the broad background. The narrow peak is therefore $2\Delta\omega_D/\Delta\omega_n$ times as high than the background. Since the Doppler width $\Delta\omega_D$ is about two orders of magnitude larger than the natural line width $\Delta\omega_n$ the background can be neglected.

In Fig. 13.42 the Doppler-free spectrum of lead atoms on the transition $7p^3P_0 \leftarrow 6p^23P_0$ at $\lambda = 450.4\,\text{nm}$ illustrates the high spectral resolution allowing the measurement of the isotope shifts [13.24].

More extensive coverage of two-photon spectroscopy can be found in [13.25].

13.1.4 Polarimetry and Ellipsometry

Similar to the principle in polarization spectroscopy a technique called *polarimetry* uses the change of the polarization of a light wave which has passed through an anisotropic sample. However, in contrast to polarization spectroscopy the anisotropy is not induced by a polarized pump wave but is inherent to the sample, which consists of so-called *active molecules*. For example, all chiral molecules, such as butanol Fig. 13.43 or blood sugar, turn the polarization vector of a linearly polarized wave by an angle

$$\alpha = (n^+ - n^-)\pi d/\lambda , \qquad (13.65)$$

where n^+ and n^- are the refractive indices for σ^+ and σ^- light and d is the path length through the sample Fig. 13.44.

In solids optical anisotropy can be induced by internal or external stress. In such cases optical polarimetry can give a two-dimensional picture of the stress distribution. This is used by glass blowers to check whether glass after tempering is stress-free. For mechanical engineering models, Plexiglas can be used to test the stress distribution in frame constructions of buildings and bridges [13.26].

The *spectral ellipsometry* technique uses the polarization characteristics of an optical wave and their
Fig. 13.41 Narrow line profile of Doppler-free two-photon absorption with Doppler-broadened background

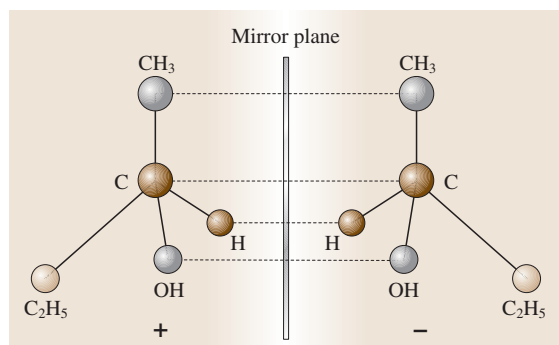

Fig. 13.43 The two mirror images of butanol as example of chiral molecules

changes when the wave is reflected by a surface or transmitted through a sample for sensitive detection of material parameters, such as absorption and birefringence. It is generally applied to solids and liquids, where
Fig. 13.44 Principle and experimental set up for polarimetry
Fig. 13.45 Schematic experimental arrangement for ellipsometry

there are no sharp absorption lines. Therefore the main emphasis is placed on the sensitivity rather than on the spectral resolution. Besides tunable lasers as radiation sources broadband incoherent light sources are also used in combination with a monochromator for wavelength selection.

The basic principle is illustrated in Fig. 13.45. The incident light passes through a polarizer P and is reflected at the surface of the sample. The polarization characteristics of the reflected light are analyzed by the analyzer A and the photomultiplier behind the spectrometer monitors the intensity of a selected spectral interval transmitted through the spectrometer.

Depending on the absorption coefficient $\alpha(\omega)$ light with intensity I_0 penetrates into the sample. After a penetration depth $d = 1/\alpha$ its intensity has decreased to I_0/e and the reflected light with intensity $I_r = rI_0$ gives information on the complex reflection coefficient r, which also depends on the absorption coefficient α. For linearly polarized incident light the reflected light is gen-
Fig. 13.46 Illustration of the Fresnel formulas for the components of the electric field vectors of the incident and reflected wave

erally elliptically polarized, which gives the name to the method [13.27].

For non-absorbing samples the refractive index n is real and the intensity and the polarization characteristics of the reflected light are governed by the Fresnel formulas. We can compose the electric vector of the incident linearly polarized light of a component $E_\parallel$ parallel and a component $E_\perp$ perpendicular to the plane of incidence Fig. 13.46. The amplitude reflection coefficient for the two components [13.28]

$$P_\parallel = \frac{E_{r\parallel}}{E_{i\parallel}} = \frac{n_2 \cos\alpha - n_1 \cos\beta}{n_2 \cos\alpha + n_2 \cos\beta} \,, \tag{13.66a}$$

$$P_\perp = \frac{E_{r\perp}}{E_{i\perp}} = \frac{n_1 \cos\alpha - n_2 \cos\beta}{n_1 \cos\alpha + n_2 \cos\beta} \,, \tag{13.66b}$$

is then determined by the refractive indices n_1 and n_2 of the two media and the angle α against the surface normal. Using the Snellius refraction law $\sin\alpha/\sin\beta = n_2/n_1$ we can replace the refractive indices by the refraction angle β and obtain

$$P_\parallel = \frac{\tan(\alpha - \beta)}{\tan(\alpha + \beta)} \,,$$
$$P_\perp = \frac{\sin(\alpha - \beta)}{\sin(\alpha + \beta)} \,. \tag{13.67}$$

The reflected intensity is then

$$I_{r\parallel} = I_{i\parallel} \frac{\tan^2(\alpha - \rho)}{\tan^2(\alpha + \rho)} \,,$$
$$I_{r\perp} = \frac{\sin^2(\alpha - \rho)}{\sin^2(\alpha + \rho)} \,.$$

Since the reflection coefficients for the two components are different, the plane of polarization of the reflected

wave is tilted against that of the incident wave. If γ_i is the angle of the electric vector E of the incident wave against the plane of incidence, the angle γ_r of the reflected wave becomes, according to the Fresnel formulas,

$$\tan \gamma_r = \frac{E_{r\perp}}{E_{r||}} = -\frac{\cos(\alpha - \beta)}{\cos(\alpha + \beta)} \tan \gamma_i . \qquad (13.68)$$

For absorbing materials the index of refraction

$$n = n - i\kappa \qquad (13.69)$$

becomes complex where both the real part n and the imaginary part κ depend on the wavelength. This introduces a phase shift, which is generally different for the two polarization components. The reflected light is elliptically polarized.

13.1.5 Optical Pumping and Double Resonance

We have discussed in Sect. 13.1.1 that emission spectra become much simpler when a single level is selectively populated. Such a selective population or depletion of a level by absorption of photons is called optical pumping, when a noticeable population change ΔN against the thermal population is achieved. The technique of optical pumping is, however, more general than just changing the population of a level. It can also create an alignment of atoms or molecules in the *labeled* level, as we have seen for the example of polarization spectroscopy. This changes the polarization characteristics of a wave transmitted through the sample.

Optical pumping forms the basis for various double-resonance techniques. Assume the pump laser is tuned to a selected transition $|i\rangle \rightarrow |k\rangle$ Fig. 13.47 and depletes the lower level $|i\rangle$. If a second radiation field [radiofrequency (RF), microwave, infrared or visible radiation]
with tunable frequency is simultaneously applied to the sample, the depleted level will be partly refilled, when the frequency of this second radiation field coincides with a transition $|i\rangle \rightarrow |m\rangle$ from the depleted level $|i\rangle$ to other levels $|m\rangle$. This can be monitored either by the increased absorption of a probe laser or by the increase of the fluorescence induced by the pump laser.

If, for example, the pump laser depletes a hyperfine component of an atomic state, the depleted level can be refilled by RF transitions $|ij\rangle \rightarrow |in\rangle$ from another HFS component, which is not depleted by the pump Fig. 13.47. When the laser-induced fluorescence is observed as a function of the radiofrequency, a peak is measured at the resonance frequency ω_{inj}, which gives the separation of the two HFS levels. In this case the RF–optical double resonance acts like an amplifier of the RF transitions, because

1. the optical pump increases the population difference ΔN between the two HFS levels and therefore the absorption of the radio frequency (RF).
2. The absorption of one RF photon is monitored by emission of a visible photon, which has an energy about 10^6 times larger than the RF photon and can be detected with a much higher efficiency.

The accuracy of measuring the separation of the levels using radio frequencies is much higher than through the difference of the frequencies of two optical transitions from the two HFS levels into a level in the upper excited state. The RF transition can occur in the lower as well as in the upper state of the optical transition. In the latter case one observes a dip in the fluorescence intensity from level $|k\rangle$ when the RF is tuned through resonance.

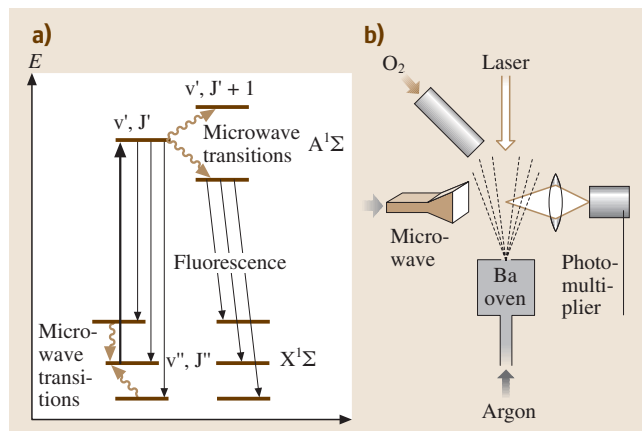
Fig. 13.47 Schematic level scheme for optical pumping and optical–microwave double resonance with fluorescence detection


Fig. 13.48 Example of optical–microwave double-resonance spectroscopy in the excited electronic state of BaO [13.29]
Fig. 13.49 Optical double resonance in a molecular beam as a substitute for the conventional Rabi technique

Optical–microwave double resonance can be applied to transitions between two rotational levels of molecules, where the optical pump depletes one of the levels in the ground state or populates one of the two levels in an excited state Fig. 13.48. Besides increasing the absorption of the microwave the double resonance in excited states transfers the accuracy of microwave spectroscopy to measurements of excited states that are thermally not populated and are therefore not accessible to conventional microwave spectroscopy.

An interesting application of this double-resonance spectroscopy is the modification of the Rabi technique for RF transitions in molecular beams [13.30]. The in-

homogeneous magnetic fields A and B are replaced by two beams of the pump laser Fig. 13.49. Radiofrequency or microwave transitions in a region between the two crossing points induce population changes that are detected by the corresponding changes in the laser-induced fluorescence in the second crossing point B. Since the fluorescence detection is very sensitive Sect. 13.1.2, this method is very useful for measuring small level splittings of free molecules or Zeeman or Stark splittings in a homogeneous magnetic or electric field in region C with high accuracy.

Similar to the simplification of the fluorescence spectrum by selective excitation of a single upper level, double-resonance methods are valuable tools for assigning complex absorption spectra. Assume the probe laser is tuned through the absorption spectrum and the absorption is monitored via the laser-induced fluorescence. When the pump laser, tuned to a specific optical transition, is chopped the population of the upper and the lower levels of the pump transition are modulated with opposite phases. Measuring the laser-induced fluorescence (LIF) induced by the probe laser with a lock-in amplifier while the probe-laser frequency is tuned yields only those transitions out of the whole spectrum that start or terminate in the modulated levels. Since one level of these probe transitions is already known, the assignment of the other level can be readily performed by applying the selection rules for the probe transitions [13.31].

13.2 Time-Resolved Methods

13.2.1 Basic Principles

The *high-resolution techniques* outlined in Sect. 13.1 of this chapter allow the very precise determination of energy levels in atoms and molecules from which the structure of atoms and molecules can be inferred. Their high sensitivity makes them useful for analytical applications where a tiny number of molecules can be detected. These CW techniques may be called static methods.

On the other hand the investigation of dynamical processes demands *time-resolved* methods, where the time resolution covers the large span from many seconds to attoseconds (10^{-18} s) [13.32–36]. Examples are the decay of excited atomic or molecular states populated by short pulses of light in the ultraviolet, optical or infrared spectral region. The excitations of valence

electrons generally decay within 10^{-3}–10^{-9} s, while high-energy atomic states populated by inner-shell excitation with subsequent X-ray emission might decay in times as short as 10^{-15} s. metastable states of atoms or molecules may persist for milliseconds to even many seconds, while the dissociation of molecules excited into states with repulsive potentials can occur within less than 10^{-12} s [13.37]. Relaxation of excited electrons in metals or semiconductors occurs within a time scale of 10^{-13}–10^{-15} s and excited states of atomic nuclei can even decay in times shorter than 10^{-18} s.

Another class of time-dependent processes are collision-induced transitions in atoms or molecules, where two partners A and B collide and the internal structure of A or B may be changed during the collision and energy may be exchanged between the collision partners. Examples are energy transfer between the internal

energies of A and B or deactivation of excited states in one of the collision partners. Such processes generally take place within the nano- to femtosecond time scales, depending on the density and the relative velocity of the collision partners [13.38].

The time resolution achieved in spectroscopy is determined by the light source and the detector. In the pre-laser period flash lamps with pulse durations between 10^{-3} to 10^{-6} s have been used and the available detectors were also limited in their time resolution to about 10^{-6} s. The invention of pulsed lasers has changed the situation dramatically. It is now possible to produce sub-femtosecond pulses down to about 10^{-16} s using high-harmonic generation by femtosecond lasers. Also the limit in time resolution of detectors can be overcome by new detection techniques, such as pump-and-probe experiments.

In this chapter different techniques of time-resolved spectroscopy, detection schemes and a selection of possible applications are presented and their advantages and limitations are discussed.

13.2.2 Wavelength–Tunable Short Pulses

The generation and detection of short laser pulses with fixed center frequencies has already been discussed in detail in Chap. 12 of this handbook. For many applications in time-resolved spectroscopy wavelength-tunable pulses are demanded. They can be produced in different ways.

1. A laser with a broad spectral gain profile is used as a light source and the wavelength is tuned across the gain profile by wavelength-selecting elements (such as prisms, gratings or interferometers) inside the laser cavity.
2. Optical parametric amplification in nonlinear optical crystals are used where a pump photon is split in a nonlinear crystal into two photons, called the signal and idler, and both the signal and the idler can be tuned over a wide range in the visible or infrared region, either by seeding the system with a wavelength-tunable laser, and/or by using an optical parametric oscillator and changing the phase-matching conditions of the crystal [13.40].
3. Optical frequency mixing in nonlinear crystals (sum or difference frequencies) can transfer the tuning range of visible lasers into the ultraviolet or infrared region [13.41].

For the generation of ultrashort pulses Ti:sapphire lasers are generally used. They can deliver high peak powers but have only moderate pulse energies. Their wavelength can be tuned over the gain profile of the laser. There are two ways of amplifying their pulse energies: conventional amplification in a gain medium with inverted population, which is pumped by a powerful pump laser, or parametric amplification. While the first method has only moderate gain in one amplifying stage and therefore needs several successive stages, the second method exhibits much larger gain in a single stage.

In particular for the production of coherent radiation in the vacuum ultraviolet (VUV), where either high harmonics of the fundamental laser wavelength are produced or several successive steps of frequency doubling or tripling in nonlinear crystals and gases are necessary [13.42], high peak powers and pulse energies of the laser output in the visible are needed. We therefore start with experimental techniques for the amplification of wavelength-tunable short pulses.
Fig. 13.50 Regenerative amplifier system for ultrafast chirped pulses [13.39]

Generation of Tunable Femtosecond Pulses with High Peak Powers

The output pulses from a femtosecond oscillator can be amplified in a regenerative amplifier. A schematic diagram of the set up for a high-power femtosecond laser system is depicted in Fig. 13.50 [13.39]. The laser oscillator consists of a Ti:sapphire crystal in a resonator formed by two spherical and a flat mirror. Two prisms serve as dispersion compensators. The crystal is pumped by a mode-locked argon laser. The femtosecond output pulses generally show a frequency chirp (i.e., the optical frequency varies from the leading to the trailing edge of the pulse). These chirped pulses are expanded in time by a grating pair, where the two gratings are not parallel as for pulse compression, but are arranged in such a way that the time profile of the chirped optical pulse becomes broader (pulse stretcher). This pulse stretching is necessary before the pulses are amplified in order to avoid excessively high peak powers in the amplifier, which would destroy the optics. The amplifier, generally a Ti:sapphire crystal pumped by a pulsed solid-state laser, is placed inside a multiple-reflection device that allows the laser pulse to travel many times through the amplifying medium. The energy of the pump pulse must be high enough to restore the inversion of the gain medium between two successive traversals of the amplified pulses (regenerative amplifier). The energy amplification of this multipass device might be as high as 10^6. The repetition rate of the amplified output pulses is limited by that of the pump laser for the regenerative amplifier and is generally not higher than 10 kHz while the mode-locked oscillator before amplification has a repetition frequency of about 100 MHz, which means that only every $10\,000^{th}$ pulse of the mode-locked train is amplified. These amplified pulses are selected by a Pockels cell (PC) and are then further amplified in a second amplifier stage before they are compressed by a parallel grating pair, resulting in ultrashort pulses with peak powers of up to 10 TW [13.43, 44].

Example. The oscillator may deliver output pulses with 50 fs pulse width and 30 nJ energy. This gives a peak power of 600 kW. With an energy amplification of 10^6 the peak power of the amplified and compressed pulse is then 600 GW. If a compression down to 10 fs can be reached the peak power may be as high as 3 TW.

Optical pulse compression can also be realized using nonlinear dispersion in optical transparent materials. By compressing the output pulses of a multistage Ti:sapphire laser amplifier system in a neon-gas-filled hollow fibre, optical pulses with duration of 5 fs and pulse energy of 1 mJ (peak power 0.2 TW) can be generated [13.45].

Optical Parametric Systems

Optical parametric devices, delivering femtosecond pulses with widely tunable wavelengths from the ultraviolet into the near-infrared spectral region, are very useful tools for spectroscopy [13.40, 46–48]. Their basic principle can be described as follows (Fig. 13.51):

A pump photon with energy $\hbar\omega_p$ and wave vector $\boldsymbol{k}_p$ is split by parametric interaction in a nonlinear optical crystal (e.g. β-Barium-Borate BBO) into a signal photon $\hbar\omega_1$ and an idler photon $\hbar\omega_2$, such that energy conservation

$$\omega_p = \omega_1 + \omega_2 \tag{13.70a}$$

and momentum conservation

$$\boldsymbol{k}_p = \boldsymbol{k}_1 + \boldsymbol{k}_2 \tag{13.70b}$$

for the frequencies ω_i and the wave vectors $\boldsymbol{k}_i$ are fulfilled. The phase velocities of the pump, signal and idler waves are matched by proper orientation of the birefringent crystal. Since the extraordinary index of refraction depends on the angle between the beam propagation and the optical axis of the nonlinear crystal, tilting the crystal allows continuous wavelength tuning of the signal and idler waves. If besides the pump wave, a weak signal wave (seed beam) is sent into the nonlinear crystal the signal wave will be enhanced much more than the idler wave. For the generation of high-power ultrashort pulses a non-collinear optical parametric amplifier (NOPA) has proved to be efficient [13.48]. Its basic principle is shown in Fig. 13.52. It consists of three main functional blocks:

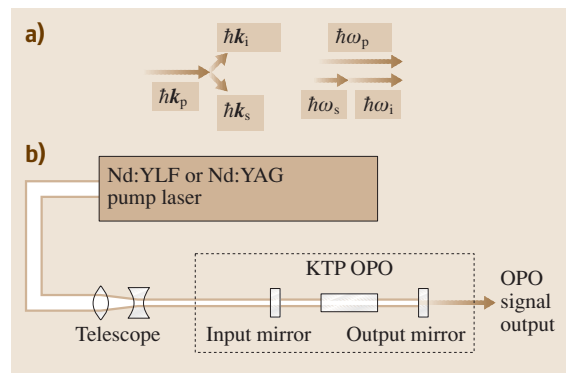
1. Continuum generation by focussing a small fraction of the near-infrared (NIR) pump beam onto a sapphire disk


Fig. 13.51 Principle of optical parametric processes
Fig. 13.52 Schematic Illustration of a non-collinear parametric amplifier (NOPA)

2. Parametric amplification of the seed light in a β-barium-borate (BBO) crystal pumped by the frequency-doubled pump light
3. The compression of the broadband output pulses

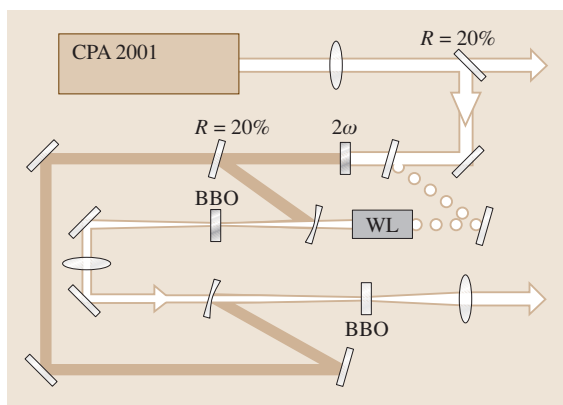
The difference of this system, compared to amplification by an inverted gain medium is the following: while for conventional amplification the inversion can be stored for a time depending on the relaxation rates of the active medium, in parametric amplification there is only gain during the time of the pump pulse. It is therefore necessary that the seed and pump pulses overlap in time. This can be achieved by using the same laser source for the seed and pump. If for instance, the pump beam is provided by the frequency-doubled output of a Ti:sapphire femtosecond laser and the seed beam comes from the spectral continuum (generated by focussing the output beam of the Ti:sapphire laser at $\lambda = 800$ nm onto a sapphire plate) both beams are generated by the same laser and the time overlap is guaranteed (Fig. 13.53). The phase-matching condition ((13.70a) and (13.70b)) selects from the continuum of difference frequencies


Fig. 13.53 Schematic set up for a widely tunable optical parametric amplifier [13.49]
Fig. 13.54 (a) Schematic diagram for multipass non-collinear optical parametric chirped pulse amplifier (DG = diffraction grating, PC = Pockels cell) (b) beam alignment in the amplifier. The pump beam (not shown) aims at the center of the circle [13.50]

$\omega = \omega_p - \omega_s$ the desired wavelength for amplification (Fig. 13.52b). If the output of the OPA is mixed with the pump beam in a second BBO crystal, sum or difference frequencies can be generated and this widely tunable intense coherent source proves very useful for spectroscopy across a broad spectral range [13.49].

In Fig. 13.54 a possible experimental set up for multipass non-collinear parametric chirped-pulse amplification is shown [13.50]. The seed source is a Kerr-lens mode-locked Ti:sapphire laser, which delivers a 78 MHz train of pulses with 30 nm spectral width. After passing a pulse stretcher the prolonged pulses enter the multipass parametric amplifier with a BBO crystal, which is pumped by the frequency-doubled output of a Nd:YAG laser with a pulse width of 8 ns. The pump and seed beams cross each other in the BBO crystal at an angle of $2.4°$. The amplified pulses are compressed by a grating pair. With such an arrangement terawatt femtosecond pulses can be realized [13.51].

Ultraviolet pulses with duration of 7 fs are efficiently generated by frequency doubling the output of a non-collinear optical parametric amplifier [13.52]. The ultraviolet pulses are tunable between 275 to 335 nm. The acceptance bandwidth of the doubling crystal is increased by a factor of 80 through high-order achromatic phase-matching. The chirp of the visible pulses and the

dispersion introduced along the beam path are compensated partially before and partially after the doubling crystal [13.53].

Measuring Spectral and Time Profiles of Ultrashort Optical Pulses

Often ultrashort laser pulses show a time-dependent frequency profile, where the optical frequency of the pulse changes during the pulse width ΔT (chirp). Furthermore, its time and frequency profile may change on its way from the point of generation to the point where the measurement takes place because of dispersion in the air and in any optical elements through which the pulse passes. There are several detection techniques that can measure the time and frequency profile of the pulses. One of them is the frequency-resolved optical gating (FROG) method, which has already been discussed in Chap. 12 of this handbook. Recently, a new technique for direct electric field reconstruction [13.53], which is capable of measuring not only the temporal shape but also the phase of ultrashort pulses directly at the interaction point of a spectroscopic measurement, has been developed. It is called spectral phase interferometry for direct electric field reconstruction (SPIDER) and is a modification of spectral shearing interferometry, which relies on the measurement of interference between two replicas of the wavefront one wants to characterize, displaced by a small amount X along the spatial x-axis (Fig. 13.55). For an electric field

$$E(x) = \sqrt{I(x)}\,e^{i\varphi(x)} \tag{13.71a}$$

which interferes with a spatially shifted replica of itself

$$E(x+X) = \sqrt{I(x+X)}\,e^{i\varphi(x+X)} . \tag{13.71b}$$

The interference pattern is recorded by a square-law detector as

$$S(x) = I(x) + I(x+X) \\ + 2\sqrt{I(x)}\sqrt{I(x+X)}\cos\left[\varphi(x)-\varphi(x+X)\right] . \tag{13.71c}$$

Fig. 13.55 Experimental set up for the SPIDER detection technique [13.54]

The measurement of the intensity at a point x is directly related to the phase difference

$$\Delta\varphi(x) = \varphi(x) - \varphi(x+X) \tag{13.71d}$$

between the phase of the initial wavefront at point x and at point $x+X$. This phase difference can be extracted for the interference pattern by Fourier-transform techniques [13.54].

Now a third pulse that is obtained from the initial pulse by a beam splitter is sent through a dispersive medium where the pulse gets a frequency chirp and becomes much broader. This is superimposed in a non-linear crystal with the two replicas of the short unknown pulses. During the short pulse the chirped pulse can be regarded as monochromatic but during the delay time $\tau = X/c$ between the two replica pulses the frequency of the chirped pulse changes from ω_c to $\omega_c + \Omega$. Therefore, the sum frequency is accordingly changed. The total signal measured by the square-law detector after sum-frequency generation is given by

$$S(\omega_s) = I(\omega+\omega_c) + I(\omega+\omega_c+\Omega) \\ + 2\sqrt{I(\omega+\omega_c)}\sqrt{I(\omega+\omega_c+\Omega)} \\ \times \cos\left[\varphi(\omega+\omega_c)-\varphi(\omega+\omega_c+\Omega)\right] . \tag{13.71e}$$

This signal contains all the information on the phase and spectral profile of the unknown pulse, which can be obtained by a Fourier transform from the measured signal as a function of the delay time τ, which is related to the phase difference $\Delta\varphi = \Omega/\tau$.

The advantages of the SPIDER technique can be summarized as:

1. The experimental set up is simple and does not involve any moving parts,
2. The interferogram is measured with a one-dimensional spectrometer,
3. The acquisition of the experimental trace is done in a single shot,
4. The reconstruction of the pulse shape from the experimental data is quick and shows low sensitivity to the noise background.

One disadvantage is that this technique does not characterize the pulses at the position of the experiment because they split the beam before the actual characterization, thus introducing additional phase through the material dispersion. Therefore a modification of the SPIDER technique has been developed [13.55, 56], called zero-additional-phase SPIDER (ZAP-SPIDER).

Its basic principle is based on interference between a pair of temporally delayed pulses that are spectrally
shifted against each other (Fig. 13.56). The unknown pulse to be characterized is sent into a nonlinear crystal where it overlaps with two strongly chirped auxiliary pulses coming from different directions, which are replicas of the same parent pulse. The nonlinear interaction between the three pulses results in two approximately monochromatic pulses at the sum and difference frequencies, which overlap in the BBO crystal with the pulses to be characterized. For visible pulses the crystal is adjusted for sum-frequency mixing and for UV pulses for difference-frequency mixing. Changing the time delay between the unknown pulse and the auxiliary pulses results in mixing of the unknown pulse with different frequencies (because of the strong chirp) of the auxiliary pulses. One thus obtains two spectrally sheared replicas with center frequencies at ω_0 and $\omega_0 + \Omega$, which propagate in two different directions because of the phase-matching condition in the nonlinear crystal. The two pulses are recombined with a small delay τ in a spectrograph. The resulting interferogram encodes the phase difference between pairs of sheared frequencies. The complete spectral phase of the unknown pulse is then obtained from a Fourier transform and a special filtering technique [13.56]. A good comparison between different techniques for measuring ultrashort optical pulses can be found in [13.57].

13.2.3 Time-Resolved Spectroscopy

In this section some techniques that allow the study of dynamical problems with a time resolution ranging from microseconds to femtoseconds are described. We will first discuss a sensitive method for absorption spectroscopy transferred to measurements in the time domain. Then an old problem will be presented, namely the determination of the lifetimes of excited states of atoms and molecules. These lifetime measurements yield very accurate values for transition probabilities and give, together with measurements of line intensities, information about the abundance of different elements in the atmospheres of stars.

Cavity-Ring-Down Spectroscopy

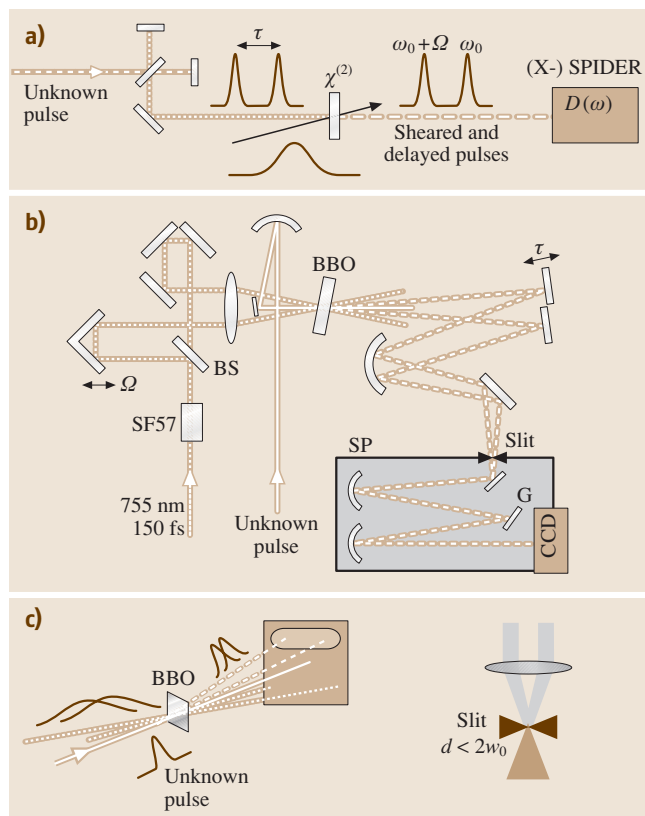
During recent years a new very sensitive absorption spectroscopy technique has been developed, named *cavity-ring-down spectroscopy* (CRDS). It measures the absorption of a sample placed inside an optical cavity by monitoring the time decay of the radiation power stored in the cavity [13.58]. Instead of measuring the small difference between the incident and transmitted radiation power in conventional absorption spectroscopy,


Fig. 13.56 (a) Set up for the ZAP-SPIDER method. **(b)** Experimental set up. SF57 = dispersive glass, BS = beam splitter, Ω = delay for adjusting the spectral shear, τ = delay to adjust mean fringe spacing. **(c)** Interference of two spatially separated beams focussed into a thin slit [13.56]

this technique measures the number of cavity round-trip times after which the power has dropped to $1/e$ of its initial value. Its basic principle can be understood as follows.

When a laser pulse with input power P_0 is sent into an optical cavity with two highly reflecting mirrors the pulse will be reflected back and forth between the two mirrors (Fig. 13.57a). For each round trip a small fraction will be transmitted through the end mirror M_2 to the detector. With a mirror reflectivity $R_1 = R_2 = R$, and transmission $T = 1 - R - A$, where A includes all losses of the cavity (absorption, diffraction, scattering except those losses introduced by the absorbing sample) the transmitted power of the first output pulse is

$$P_1 = T^2 \, e^{-\alpha L} P_0 \, , \tag{13.72a}$$
Fig. 13.57 (a) Set up for cavity-ring-down spectroscopy. **(b)** Coupling of incident laser beam into the ring-down cavity with mode-matching optics

where α is the absorption coefficient of the absorbing sample with absorption length L inside the optical cavity with mirror separation d. If the sample fills the whole cavity we obtain $L = d$. For each additional round trip the pulse power decreases by the factor $R^2 \exp(-2\alpha L)$: After n round trips the output power of the $(n+1)$-th pulse has decreased to

$$P_{n+1} = (R e^{-\alpha L})^{2n} P_1 . \tag{13.72b}$$

With $R = 1 - (T + A)$ and $A + T \ll 1 \to \ln(1 - A - T) \approx -(A + T) = 1 - R$ this can be written as

$$P_{n+1} = P_1 e^{-2n(1 - R + \alpha L)} . \tag{13.72c}$$

The time interval between two successive pulses equals the round-trip time $T = 2d/c$. The envelope of the discrete pulse sequence is the continuously decaying function of the output power from the resonator with the absorbing sample

$$P(t) = P_1 e^{-t/\tau_1} \tag{13.72d}$$

with the time constant (Fig. 13.57b)

$$\tau_1 = (d/c)/(1 - R + \alpha L) . \tag{13.73a}$$

The empty cavity $(\alpha = 0)$ has the longer decay time

$$\tau_2 = (d/c)/(1 - R) . \tag{13.73b}$$

The difference between the reciprocal decay times

$$1/\tau_1 - 1/\tau_2 = (c/d)\alpha L \tag{13.74}$$

directly yields the absorption αL.

Example. $R = 0.999$, $d = L = 1$ m, $\alpha = 10^{-6}\,\text{cm}^{-1} = 10^{-4}\,\text{m}^{-1} \to \tau_1 = 3.03\,\mu\text{s}$, $\tau_2 = 3.33\,\mu\text{s}$. The difference is small. However, with $R = 0.9999$ we obtain $\tau_1 = 16.5\,\mu\text{s}$ and $\tau_2 = 33\,\mu\text{s}$. This shows how important a high reflectivity of the cavity mirrors is.

A more detailed treatment of CRDS has to take into account the mode structure of the cavity, because the high Q-value of the cavity can only be obtained for those frequencies that match the optical modes of the cavity. For all those wavelengths λ_i contained in a laser pulse, for which $v_i = c/\lambda_i \neq m\, c/2d$, the cavity Q, and with it the sensitivity, will be small. Therefore, small absorption lines at those wavelengths may just escape detection. There are several solutions to this problem.

1. The laser pulse is sent into the high-Q cavity without mode-matching optics. It then excites not only longitudinal modes but also many transverse modes. In a non-confocal cavity the frequencies of these transverse modes are closely spaced and fill the frequency distance $\Delta v = c/2d$ between the longitudinal modes. Their frequency separation is smaller than the Doppler width of the absorption lines, insuring that all absorption lines are detected. The advantage of this method is the simple experimental set up without mode-matching optics. Its disadvantage is the smaller sensitivity, because the average over all transversal and longitudinal modes yields a smaller Q-value, than for a single longitudinal mode.

2. The phase fronts of the incoming pulses are imaged by a suitable optical system into the cavity in such a way that they coincide exactly with those of the fundamental modes of the cavity (Fig. 13.57b). This gives the highest possible Q-value. However, now the cavity length has to be stabilized onto the laser frequency and has to be synchronously tuned when the laser frequency is tuned through the absorption spectrum, insuring that the cavity mode is always in resonance with the laser frequency. With this mode-matching set up the spectral resolution is limited either by the Doppler width of the absorption lines or by the pulse length ΔT, which gives a Fourier-limited resolution of $\Delta v = 1/(2\pi\Delta T)$.

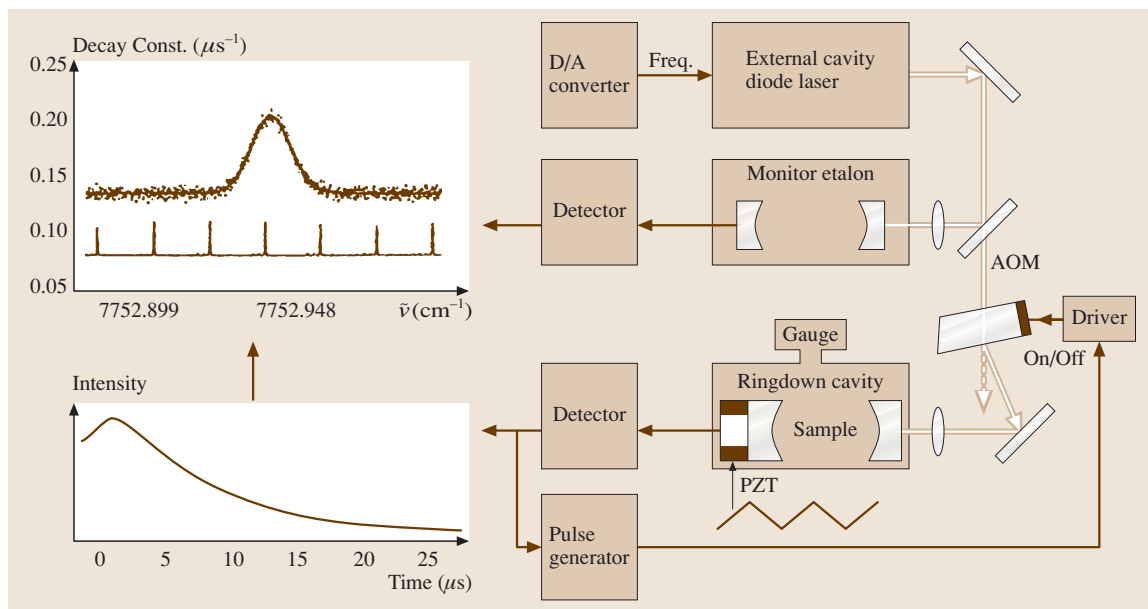
The highest Q-value and therefore the highest sensitivity is achieved with CW lasers where the output beam of the laser is sent through a modulator that forms pulses of the desired length ΔT and a spectral bandwidth that is adapted to the width of the cavity modes. Since this width Δv is smaller than the Doppler width, one can measure the line profiles and can investigate the


Fig. 13.58 Experimental arrangement for cavity-ring-down spectroscopy with a CW external cavity diode laser [13.58]
Fig. 13.59 Heterodyne detection of ring-down signals [13.59]

influence of pressure broadening. In Fig. 13.58 a possible set up for cavity-ring-down spectroscopy with an external cavity CW diode laser is shown [13.58]. The output beam is pulsed by an acousto-optical modulator and the length of the ring-down cavity is slowly changed by a sawtooth voltage to the piezo, on which one of the mirrors is mounted.

The achievable sensitivity is limited by the accuracy of measuring the decay times τ_1 and τ_2. This accuracy in turn is limited by the noise of the decay curve. The main sources of noise are the intensity fluctuations of the laser and fluctuations and drifts of the cavity length.

A particularly sensitive technique that can eliminate at least part of this noise is based on heterodyne measurements (Fig. 13.59). The output beam of a CW laser is split into two partial beams. One of these is sent directly through mode-matching optics into the cavity, which is stabilized onto the laser frequency. The output signal of the cavity serves as a local oscillator.

The optical frequency of the second beam is shifted by an acoustooptic modulator by exactly the mode separation $\Delta\nu = c/2d$, thus matching the neighboring mode. The amplitude of this *signal beam* is modulated at a frequency of $40\,\text{kHz}$. Both partial beams are again superimposed before they enter the cavity and are in resonance with two adjacent longitudinal cavity modes. The transmitted power

$$
\begin{aligned}
P_t &\approx |E_s(t) + E_{LO}\, e^{i(2\pi t \Delta\nu + \varphi)}|^2 \\
&= |E_s(t)|^2 + |E_{LO}|^2 + 2E_s E_{LO} \cos(2\pi \Delta\nu t + \varphi)
\end{aligned}
\tag{13.75}
$$

is measured by the detector. While the second beam consists of pulses with $25\,\mu\text{s}$ pulse width and results in an exponential decay of the transmitted signal, the power of the fist beam is constant and can therefore be used to stabilize the cavity.

The interference term in (13.75) is the product of the large amplitude of the local oscillator (note that the transmitted amplitude of the CW beam $A_t = (1-A)^2\, e^{-\alpha L}$ is for $A \ll 1$ and $\alpha L \ll 1$ nearly that of the incident

amplitude) and the much smaller amplitude E_s of the modulated signal beam. Measuring the decay of this interference term at the frequency $\Delta\nu = c/2d$ yields a much larger signal as obtained with the conventional cavity ring-down technique, which now decay with the time constant 2τ, but has a much better signal-to-noise ratio.

More information on CRDS can be obtained from the reviews [13.60–62].

Lifetime Measurements

The population N_i of an excited state $|i\rangle$ of a free atom decays exponentially from the value $N_i(0)$ at time $t = 0$, to the value

$$N_i(t) = N_i(0)\,e^{-t/\tau} \tag{13.76}$$

at time $t > 0$. The quantity τ is the mean spontaneous lifetime of state $|i\rangle$, which is related to the total transition probability A_i by $A_i = 1/\tau_i$. Typical values of the lifetime of excited valence electrons lie in the nanosecond range.

If the excited atom A collides with other atoms or molecules B, its population can additionally decrease by inelastic collisions. The rate of such deactivating collisions

$$R_i = N_B \sigma_{inel} \langle v_r \rangle \tag{13.77a}$$

depends on the number density N_B of the collision partners B, the collision cross section σ and the relative velocity v_r. The total transition probability for deactivating the excited state $|i\rangle$ is then increased to

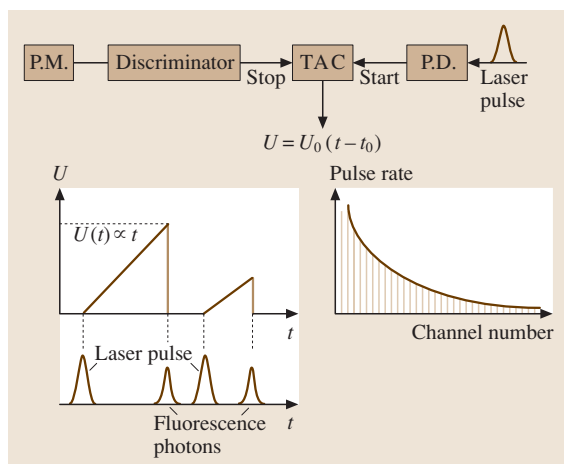
$$A_i^{eff} = A_i^{spont} + R_i \tag{13.77b}$$


Fig. 13.60 Single-photon delayed coincidence technique

and the effective lifetime of the excited state is reduced according to

$$1/\tau_i^{eff} = 1/\tau_i^{spont} + R_i \ . \tag{13.78}$$

The experimental technique for measuring lifetimes depends on the order of magnitude for τ. For lifetimes in the micro- to nanosecond range, the atoms can be excited by a short laser pulse (e.g., a nanosecond pulse) and the decay of the laser-induced fluorescence is monitored with a fast oscilloscope. Digital transient recorders can measure decay curves with a time resolution in the picosecond range.

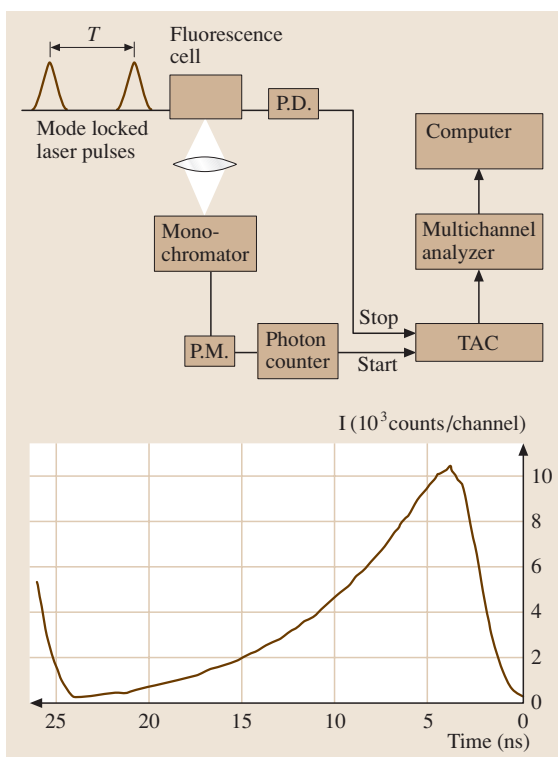
For small intensities another method is more suitable. It is based on time-correlation spectroscopy of single fluorescence photons [13.63]. Its principle is depicted in Fig. 13.60. The sample atoms or molecules are irradiated by a regular time sequence of short pulses delivered from a mode-locked cavity-dumped CW laser. The cavity-dumping frequency is chosen such that the time interval between two successive pulses is at least three times the expected lifetime of the excited


Fig. 13.61 Experimental arrangement for lifetime measurements and decay curve of the excited $B^1\Pi_u$ state of the Na$_2$ molecule. The time scale runs from *right to left*

molecules. A fraction of each laser pulse is sent to a fast photodiode, which delivers the trigger signal to define the starting time $t = 0$ of a time-to-amplitude converter (TAC). This TAC delivers a ramp voltage $U = at$. The first fluorescence photon detected at time t_1 after the excitation pulse stops the ramp. The output voltage $U = at_1$ is stored in a multichannel analyzer or in a computer. Measuring many events yields the probability distribution of decay times, which gives the exponential decay of (13.76). The detected fluorescence rate should be smaller than the repetition rate $f = 1/T$ of the laser pulses in order to insure that at most one fluorescence photon is detected during the time T between two excitation pulses. With a ramp time of 50 ns and 1000 channels the time resolution is 50 ps. In order to reduce the dead time of the TAC, the time sequence is often inverted: the TAC is started by the fluorescence photon emitted at time t_1 after the excitation pulse and is stopped by the next excitation pulse. Since the repetition rate of the pulses from a mode-locked laser is very stable, the true delay time t_1 can be directly inferred from the measured time difference $T - t_1$. In Fig. 13.61 the whole set up for this method is depicted and a decay curve of an excited level of the Na_2 molecule with the inverted time scale is shown for illustration [13.64].

Pump-and-Probe Techniques

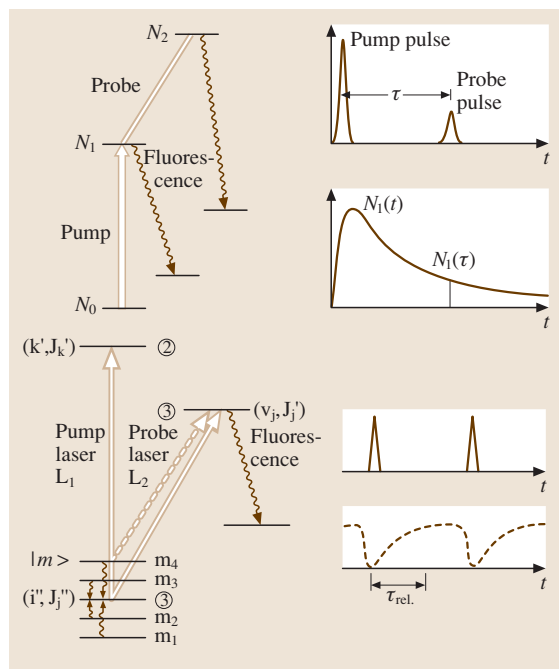
If time resolution in the pico- to femtosecond range is required, direct detection by electronic devices is not fast enough. Here a new technique has been developed, which uses a fast pump pulse that excites or depletes a specific level in atoms or molecules, and a delayed fast probe pulse, that probes the effect of the pump pulse at a controlled time delay (Fig. 13.62). Generally both pulses come from the same laser. The output pulse of the laser is split by a beam splitter into two parts, which
Fig. 13.62 Pump-and-probe technique


Fig. 13.63 Possible level schemes for the pump-and-probe technique

travel through different path lengths before they are recombined by a second beam splitter. The pump pulse depletes the lower level of the pump transition in a molecule and populates the upper level. The probe pulse can either probe the depletion of the lower level, or can further excite the excited molecules. The intensity of the fluorescence from the excited levels can serve as a monitor (Fig. 13.63a). The intensity of the probe-laser-induced fluorescence from level $|2\rangle$ is measured as a function of the delay time between pump and probe. If the sum of the photon energies is above the ionization limit, the probe laser can even ionize the excited molecules. The measured ion rate $N_{ion}(t)$ as a function of the delay time t of the probe pulse then gives the time-dependent population of the upper level $|1\rangle$.

The depleted lower level can be refilled by fluorescence from the upper level or by inelastic collisions. The weak probe pulse monitors this refilling process by measuring the fluorescence intensity induced by the probe pulse as a function of the delay time (Fig. 13.63b) because the fluorescence intensity is proportional to the population of the lower level. With this technique a time resolution of a few femtoseconds can be achieved. Note, that the time resolution of the detector can be much worse.
Fig. 13.64 Schematic level scheme for pump-and-probe experiments with a Raman-shifted probe beam

Fig. 13.65 Pump-and-probe technique with a white-light continuum and a non-collinear optical amplifier, allowing measurements of the dynamical processes over a broad spectral range

Often it is desirable that the pump and probe lasers have different wavelengths. When two different lasers are used for the pump and the probe pulses even good time synchronization between the two pulses shows a jitter, which might be as large as a few nanoseconds. Therefore time resolution in the femtosecond range cannot be achieved. There are, however, ways to get around this problem. If a tunable laser is pumped by a short laser pulse, a fraction of the pump pulse energy can be used as the pump for the experiment and the tunable laser pulse as the probe. Another method uses the Raman shift of a fixed-frequency laser. By selecting different molecules in the Raman shifter the wavelength of the probe pulse can be shifted against that of the pump pulse into resonance with another transition of the sample molecule. With this technique the time-dependent population of other vibrational or rotational levels than those connected with the pump transition can be monitored.

An even more general technique uses a white-light source as a pump and an NOPA as the probe (Fig. 13.64). If the output of the NOPA is superimposed in the sample with the spectral continuum from the white-light source, generated by the same Ti:sapphire laser that pumps the NOPA, the whole spectrum of the sample within the bandwidth of the white-light source and the dynamics of the sample molecules can be measured with the pump-and-probe technique, where the delay between the pump and probe can be mechanically adjusted by an appropriate optical delay line.

Examples

Examples for applications of this pump-and-probe technique are measurements of the fast relaxation processes of excited vibrational levels of molecules in liquids, induced by collisions [13.65], which play an important role in chemical reactions. The enhancement of the reaction rate by vibrational excitation of the reac-

tants can select specific reactions. For the investigation of such processes infrared pico- to femtosecond laser pulses are used as the pump and probe. With frequency-doubled visible laser photons excited electronic states of molecules can be populated and may either dissociate, or transfer their excitation energy in collisions to their collision partner. The pump-and-probe technique can measure the energy transfer times.
If polyatomic molecules are photo-ionized by two or more photons in a short laser pulse, the excited molecular ions can be into excited states which either radiate or dissociate into different neutral or ionized fragments (Fig. 13.65). The ionized fragments can be detected by a time-of-flight mass spectrometer. The detection of the neutral fragments, which are much more abundant at low excitation energies of the molecular parent ion, can be measured by ionizing them with a second laser pulse (probe pulse). It is interesting to follow the reaction paths in the excited parent molecules that lead to the measured fragmentation, which often involves energy conversion from electronic to vibration energy of the excited species. This can be achieved by varying the time delay between the pump and probe pulses and observing the fragment mass spectrum as a function of the delay time [13.66].

13.2.4 Coherent Time–Resolved Spectroscopy

While in the foregoing sections mainly the intensity profiles of the short pulses were utilized for spectroscopic measurements, for many experiments the information about the phase of the optical oscillation is important. If definite correlations between the phases of optical pulses can be established, the phases of molecular wave functions in excited states can be controlled if these levels are excited by such phase-controlled pulses. In these

cases new interference effects are observed that can give more-detailed information on these states and their time evolution. We will illustrate this by several examples.

Quantum Beat Spectroscopy

Quantum beat spectroscopy is based on the coherent simultaneous excitation of two or more molecular levels from a common lower level by a short optical pulse (Fig. 13.66).

The wave function of these levels at time $t = 0$ of the exciting pulse is the coherent superposition

$$\Psi(t = 0) = \Sigma c_k \psi_k(0) \tag{13.79}$$

of the wave functions of the different excited states. If the level $|k\rangle$ decays with decay constant $\gamma_k = 1/\tau_k$ into a lower level $|m\rangle$, the wave function $\Psi(t)$ becomes

$$\Psi(t) = \Sigma c_k \psi_k(0) e^{-i\omega + \gamma/2)t} \tag{13.80}$$

with $\omega_{km} = (E_k - E_m)/\hbar$. If this decay is due to population decay the fluorescence power emitted by the excited levels is proportional to the square of the transition-matrix element and we obtain the signal

$$S(t) \approx I_{Fl}(t) = C \left| \langle \psi_m | \boldsymbol{\varepsilon} \cdot \boldsymbol{\mu} | \Psi(t) \rangle \right|^2 , \tag{13.81}$$

where C is a constant factor that depends on the experimental conditions, $\boldsymbol{\varepsilon}$ is the polarization unit vector of the emitted light, and $\boldsymbol{\mu} = e \cdot \boldsymbol{r}$ is the electric dipole operator.

If we insert (13.80) into (13.81) we obtain, for the example of two excited levels $|1\rangle$ and $|2\rangle$ with equal decay constants $\gamma_1 = \gamma_2 = \gamma$, the result:

$$I(t) = C e^{-\gamma t}(A + B \cos \omega_{12} t) \tag{13.82}$$

with $A = c_1^2 \left| \langle \psi_m | \boldsymbol{\varepsilon}\boldsymbol{\mu} | \psi_1 \rangle \right|^2 + c_2^2 \left| \langle \psi_m | \boldsymbol{\varepsilon}\boldsymbol{\mu} | \psi_2 \rangle \right|^2$ and $B = 2c_1 c_2 \left| \langle \psi_m | \boldsymbol{\varepsilon}\boldsymbol{\mu} | \psi_1 \rangle \right| \cdot \left| \langle \psi_m | \boldsymbol{\varepsilon}\boldsymbol{\mu} | \psi_2 \rangle \right|$.

The intensity $I(t)$ shows an exponential decay superimposed with a modulation at the frequency $\omega_{12} = (E_1 - E_2)/\hbar$, which directly yields the level separation $\Delta E = (E_1 - E_2)$.

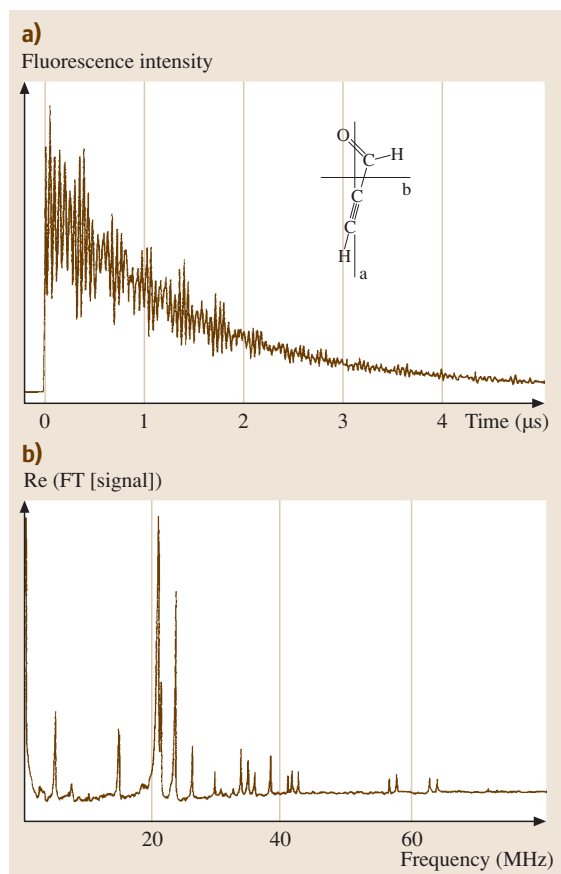
If the levels are separated by an external electric or magnetic field, the measured splittings yield the electric or magnetic dipole moments in these states. Since the dipole moments depend on the coupling of angular momenta, the specific coupling scheme for the investigated states can be inferred. Often the total angular momentum of a molecular level results from coupling of this level with other levels in different electronic states, e.g. spin–orbit couplings between singlet and triplet states. In such cases quantum beat spectroscopy can give valuable information about these couplings, because it measures the lifetimes and the energy separation simultaneously. Figure 13.67 illustrates the Zeeman quantum beats of ex-


Fig. 13.67 Zeeman quantum beat fluorescence signal of excited propynal molecules where at least seven levels were coherently excited [13.67]

Fig. 13.66a,b Quantum-beat spectroscopy (**a**) level scheme, (**b**) quantum beats observed in the fluorescence of two coherently excited levels and the Fourier transform of the beat signal

cited levels in the propynal molecule [13.67], where the Fourier transform of the complex measured beat signal yields the energy levels involved.

Molecular Wave–Packet Dynamics

Another example for time-resolved coherent spectroscopy is the investigation of wave packet dynamics of electronically excited molecules. The femtosecond pump laser with optical frequency $\nu = E/h$, time duration Δt and Fourier-limited energy width $\Delta E = \hbar/\Delta t$ coherently excites a group of vibrational levels within the energy range $E \pm \Delta E$. The superposition of their wave functions represents a wave packet that moves with the average vibrational frequency between the inner and outer turning points of the potential. For the example of the Na_2 molecule shown in Fig. 13.68, the wave packet is excited by two-photon absorption from the electronic ground state into the $2\,^1\Pi_g$ state. The further excitation of the excited molecule by the probe laser depends on the delay between the pump and probe pulses. If the molecule is excited at that time, when the wave packet is at the inner turning point, molecular Na_2^+ ions are formed, while excitation at the outer turning point leads to dissociation into $Na + Na^+$ and produces atomic Na^+

Fig. 13.68 Wave-packet dynamics and coherent control for the dissociation and selective ionization of the Na_2 molecule [13.68]

ions [13.68]. This is an example how a specific product channel can be selected just by choosing the proper time delay between the pump and probe pulses.

Photon Echoes

The time-resolved coherent excitation of molecules can also be used to obtain information not only about the population decay but also about the phase decay. This is realized with the technique of photon echoes which can be understood as follows.

Assume N molecules have been simultaneously excited by a short laser pulse from a lower level $|1\rangle$ into the upper level $|2\rangle$. The total fluorescence power emitted by the transition $|2\rangle \to |1\rangle$ is given by

$$P_{Fl} = \Sigma\hbar\omega D_{21} \,, \tag{13.83}$$

where D_{21} is the dipole matrix element for the transition $|2\rangle \to |1\rangle$ and g_1 and g_2 are the statistical weight factors of levels $|1\rangle$ and $|2\rangle$. The sum extends over all N molecules.

With coherent excitation at time $t = 0$ a definite phase relation is established between the wave functions of the N molecules in level $|2\rangle$. We therefore obtain:

$$|\Sigma D_{12}|^2 = |N\,D_{12}|^2 = N^2|D_{12}|^2 \,, \tag{13.84}$$

whereas for incoherent excitation the phases of the N molecules are random and the result would be $N|D_{12}|^2$. This shows that the total fluorescence power at a time t just after the excitation pulse, where the molecules are still in phase, is N times larger than that for incoherent excitation.

In order to produce photon echoes the molecules are excited at time $t_1 = 0$ by a $\pi/2$ pulse (Fig. 13.69). This is a pulse with a controlled energy that changes the phase of the wave functions of both levels by $\pi/2$ and creates equal populations in levels $|1\rangle$ and $|2\rangle$. Such a system represents an oscillating dipole with oscillation frequency $\omega_{12} = E/\hbar$.

Because of the finite line width $\Delta\omega$ of the absorbing transition $|1\rangle \to |2\rangle$ (for example the Doppler width) the frequencies ω_{12} of the N molecules are not all equal but are distributed within the interval $\Delta\omega$. This causes the phases of the N oscillating dipoles to develop in time at different rates after the end of the $\pi/2$ pulse. At a time $t_2 < T_1$ smaller than the population decay time T_1 but larger than the phase relaxation time T_2 the phases of the N dipoles are randomly distributed.

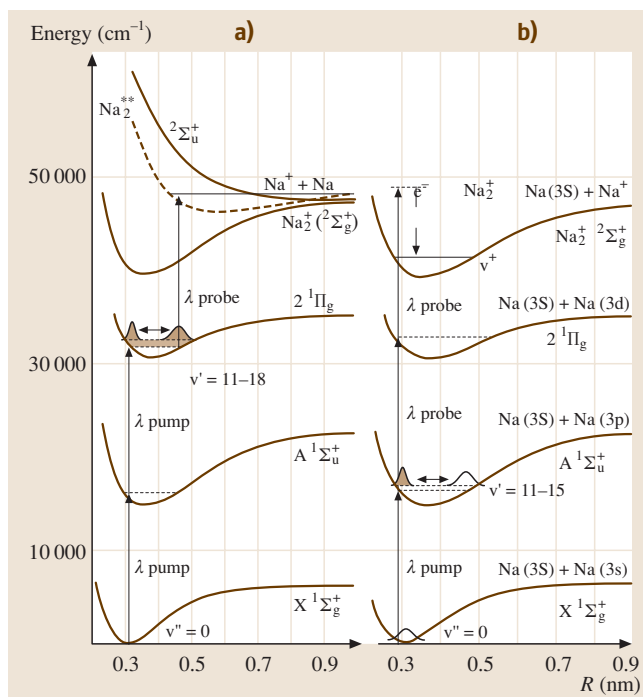
The molecules are now irradiated at time $t = t_2$ by a second pulse with twice the energy of the first excitation pulse. This pulse inverts the phase of the induced


Fig. 13.69 Pulse sequence for the generation of photon echoes and the time evolution of the pseudo-polarization vector, where the photon echo is emitted at $t = 2\tau$

polarization and is therefore called a π pulse. It causes a reversal of the phase development for each dipole. After the time $t_3 = 2t_2$ all molecules are again in phase and they emit a signal which is proportional to N_2^2, where

$$N_2(2t_2) = N_2(0)\,\mathrm{e}^{-2t_2/T_1} \tag{13.85}$$

is the population of molecules in the excited state $|2\rangle$, that have survived the time $2t_2$ after excitation by the first pulse. This signal is called the *photon echo* and is much stronger than the incoherent fluorescence that is emitted at all times $t > 0$ but is only proportional to $N_2(t)$.

The amplitude of the photon echo decreases with increasing time delay due to the population relaxation with the *longitudinal relaxation time* T_1.

A second, generally faster relaxation process is the phase relaxation with the *transverse relaxation time* T_2. This can have several causes:

1. Phase-perturbing collisions change the phase of the oscillating dipoles and therefore prevent them from all being in phase at $t = 2t_2$. Since such collisions give rise to homogeneous line broadening, this contribution to the echo decay is the homogeneous part.
2. The different velocities of the molecules within their Doppler width also cause different phase shifts (the inhomogeneous part).

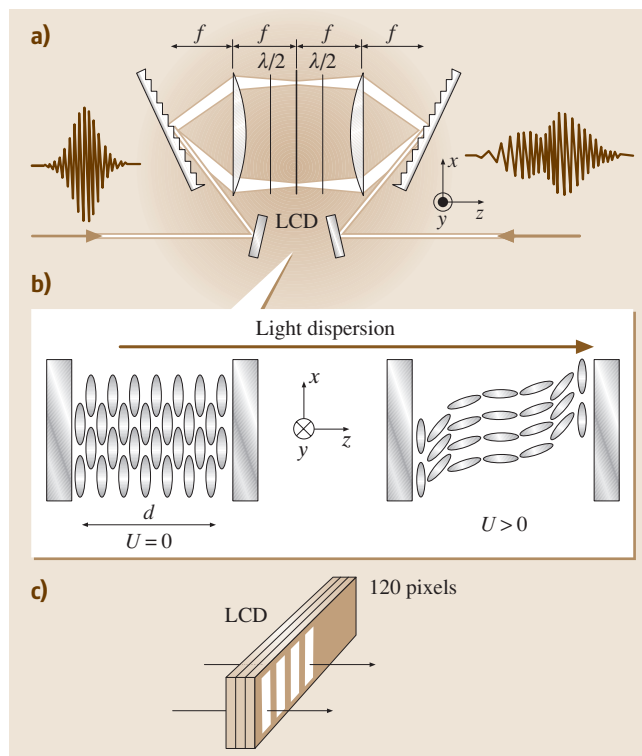
This second contribution, however, does not prevent the dipoles from restoring their phase at the echo time $t = 2t_2$ and therefore does not diminish the amplitude of the photon echo. The Fourier transform of the decay


Fig. 13.70 Pulse shaping for coherent control by controlling the refractive index of transparent pixels in a liquid-crystal mask

times of the photon echo therefore gives Doppler-free line widths.

The time evolution of the system can be best described by the *pseudo-polarization vector*, which is defined as $P = \{P_x, P_y, P_z\}$, where P_x and P_y describe the components of the atomic polarization by the optical wave traveling in the z-direction, and $P_z = D_{12}\Delta N$ is the product of the transition dipole moment D_{12} and the population difference $\Delta N = N_1 - N_2$ between the two levels. The time development of P describes the time-dependent polarization of the molecular system. This is depicted schematically in Fig. 13.70, where relaxation processes have been neglected.

More-detailed information about photon echoes and their applications can be found in [13.70, 71].

13.2.5 Applications of Short Laser Pulses

In this section some selected applications of short laser pulses will be presented, in order to give a feeling for the large variety of possible applications of light pulses in different time domains.

Generation of High Harmonics and X–Ray Spectroscopy

When an intense visible laser pulse is focussed into a noble gas high harmonics of the fundamental wavelength are generated. This can be understood as follows: due to the strong electric field of the light pulse rapid multiphoton ionization of the gas atoms takes place within a fraction of the cycle of the light. The free photoelectrons are accelerated back and forth through the atomic core by the alternating electric field, which changes its

direction so fast that the electrons cannot leave the atom. During this acceleration period they emit radiation from the visible down to the X-ray region. Although the period of the electron movement is that of the fundamental light wave, high harmonics are generated due to the nonlinear interaction with the atomic force field and the electric field of the light wave (Fig. 13.71). Coherent X-ray radiation up to photon energies of 700 eV has been observed when a 10 fs pulse of several mJ energy (peak power 10^9 W) is focussed onto a xenon sample, where an intensity of 10^{19} W/m^2 was reached at a focus diameter of $10\,\mu$m. The photon yield was nearly constant over several hundred eV [13.69, 72]. This system represents an intense source of soft X-ray radiation that can compete well with synchrotron radiation in terms of spectral intensity, but is much cheaper than an electron accelerator and storage ring.

Applications in Chemistry and Molecular Dynamics

The dream of chemists is to control chemical reactions by excitation with properly formed laser pulses. This dream has meanwhile become true at least for some favorable cases by a method called coherent control. Its implementation demands very short laser pulses for the following reason: in order to enhance a specific reaction one has to excite specific molecular levels, which decay into the wanted reaction channel. The density of states in electronically excited molecules increases strongly with excitation energy and with the number of atoms in a molecule and the interaction between different states also increases. Even if a single selected level has been excited by photon absorption the excitation energy is spread among many interacting states within a short time, thus washing out the desired selectivity. Therefore the wanted reaction has to start before this energy redistribution takes place. The method of coherent control can overcome these difficulties because it uses femtosecond pulses and prepares a favourable excited state that leads to the optimization of the wanted reaction. Its basic principle is as follows.

The reaction path of an excited polyatomic molecule often depends on the spatial distribution of the molecular wave function in this state, which can be controlled by the shape and frequency distribution of the excitation pulse. When the molecules under investigation are excited by femtosecond pulses the rate of the desired reaction is monitored and serves as the input signal for an optimization procedure where the time profile of the pulse is modified until the optimum reaction rate has been achieved. This optimization can be reached even
Fig. 13.71 Generation of high harmonics of focussed intense femtosecond pulses [13.69]

if the detailed nature of the excited-state wave function is not known. Since the spatial and time distribution of the molecular wave packet is created by the coherent excitation of ultrashort laser pulses with controlled time, frequency and phase profiles, the technique is called *coherent control*. The pulse shaping (Fig. 13.70) can be performed as follows.

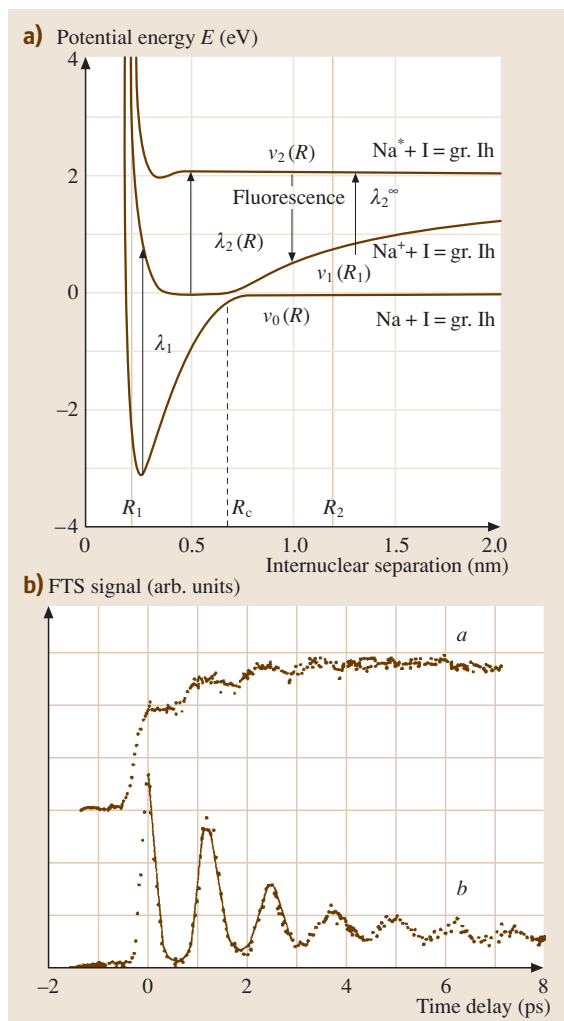
The incoming beam is diffracted by an optical grating in the focal plane of a lens. Since the diffraction


Fig. 13.72a,b Time-resolved spectroscopy of the dissociation of NaI [13.73]. **(a)** Potential diagram with the pump transition at λ_1 and the probe transition at $\lambda_2(R)$. **(b)** Atomic Na fluorescence $I_{Fl}(\Delta t)$ as a function of the delay time Δt with λ_2 tuned to the atomic Na transition (*curve a*) and to $\lambda_2(R)$ with $R < R_c$ (*curve b*)

angle depends on the wavelength, the different spectral components in the pulse are spatially separated and pass through a mask consisting of many liquid-crystal pixels. The refractive index of these pixels can be controlled by an appropriate applied voltage, thus introducing a controlled phase shift of the light passing through them. These phase shifts can be independently changed for the various spectral components. After passing through a second lens a second grating recombines the spatially separated spectral components. Their superposition gives a pulse shape that depends on the amplitudes and the phases of these components and can therefore be changed by the voltages applied to the pixels, which are in turn controlled by the optimization signal. A learning algorithm changes the different voltages in small steps until an overall optimum for the reaction rate has been reached [13.74, 75].

This technique has been successfully applied to a number of molecules [13.76], even including large biological molecules such as the carotenoid molecules, which play an important role in photosynthetic light-harvesting [13.77].

In many cases excitation of higher vibration levels in the electronic ground state can itself enhance a chemical reaction considerably, in particular if local bonds can be excited. For instance the excitation of a local vibration involving the double bond in ethylene $CH_2=CH_2$ will lead to fragmentation into two CH_2 radicals, while excitation of a single bond will split off a hydrogen atom. Here pulse shaping in the infrared spectral region is required in order to excited the desired vibrational mode. Unfortunately there are no liquid masks available for the mid-infrared. It is, however, possible to transfer the pulse shape of a visible pulse by difference-frequency mixing in a nonlinear crystal to a pulse with the difference frequency in the infrared [13.78].

The application of femtosecond spectroscopy to fast molecular processes allows one for the first time to observe in real time the breaking and formation of chemical bonds. We will illustrate this by some examples. The first is the photodissociation of NaI [13.37, 73]. The adiabatic potential diagram of NaI (Fig. 13.72) shows an avoided crossing between the repulsive potential of the two interacting neutral atom Na+I and attractive Coulomb potential of the ions $Na^+ + I^-$, which is mainly responsible for the strong binding of NaI at small internuclear distances R. If the molecule NaI is excited by a short laser pulse with wavelength λ_1 the excited molecule with reduced mass μ starts to move towards larger distances R with a velocity $v(R) = [(2/\mu)(E - E_{pot}(R))]^{1/2}$. When it reaches the avoided crossing at $R = R_c$ it may

either stay on the potential curve $V_1(R)$ and oscillate back and forth between R_1 and R_2, or it may tunnel to the potential curve $V_0(R)$, where it separates into Na+I.

This can be measured with a probe pulse with a wavelength λ_2 tuned into resonance with the transition from $V_1(R)$ into the excited-state potential $V_2(R)$ that dissociates into Na*+I. Since the dissociation time (a few picoseconds) is very short compared with the lifetime of the excited Na*(3p) atom, the dissociation NaI* molecule nearly exclusively emits at the atomic resonance fluorescence of $\lambda = 589$ nm. Monitoring the intensity of the atomic fluorescence as a function of the delay time yields the time behavior of the dissociation process. If the probe laser wavelength λ_2 is tuned to to a transition at $R < R_c$ one obtains the lower curve in Fig. 13.72b, showing the oscillation of the system between R_1 and R_2, while for $R > R_c$ the upper curve is obtained, giving the number of molecules in the potential $V_0(R > R_c)$.

The second example is the isomerization of Stilbene, i. e. the photoinduced structural change of excited stilbene form trans- to cis-stilbene (Fig. 13.73). Since the structural change also causes a corresponding change of the rotational constants, a pump-and-probe experiment of the rotating molecule can measure the rotational period and with it the rotational constants [13.79].

Often the molecular structure in excited electronic states is not known and in many cases it might even change with time, due to isomerization processes. Here a very elegant technique has been developed based on time-resolved Laue diagrams of excited molecules. The molecules are excited by a femtosecond pulse. Part of the same laser pulse is focussed onto a target, where a very hot plasma that emits short X-ray pulses in the femto- to attosecond range is produced. These are used to take a Laue diagram of the excited molecule. Varying the time delay between the excitation and the X-ray pulses can follow the structural change of the excited molecule [13.80–82].
Fig. 13.73 Isomerization of stilbene

Ultrafast Processes in Biology

Many primary processes of biological reactions proceed on a femtosecond time scale. Examples are the visual process in the retina cells of the eye after photon excitation, or the photosynthesis of green plants. The investigation of the different steps in these complex processes demands a combination of spectroscopic techniques with high time resolution and spectral selectivity [13.83].

The first steps in the visual process after the excitation of retinal molecules in the protein rhodopsin in the retina of the eye are isomerization processes where the structure of the molecules in the excited states is changing in such a way that the energy decreases. This can be studied by time-resolved Raman spectroscopy, which gives information on the vibrational frequencies [13.84].

In the photosynthesis of green plants the light-harvesting molecules are carotenoids, which absorb in the blue–green spectral range and transfer their excitation energy to chlorophyll molecules. These transfer processes are in competition with radiationless deactivation. Both kinds of processes proceed on a femtosecond time scale. The final outcome of such transfer processes is proton transfer in chlorophyll, which has been found to be the most important process in the photosynthesis of green plants. It consists of many steps that can be followed by femtosecond spectroscopy. With coherent control, the intermediate processes that decrease the efficiency of proton transfer can be suppressed, thus increasing the yield [13.85].

Applications in Medicine

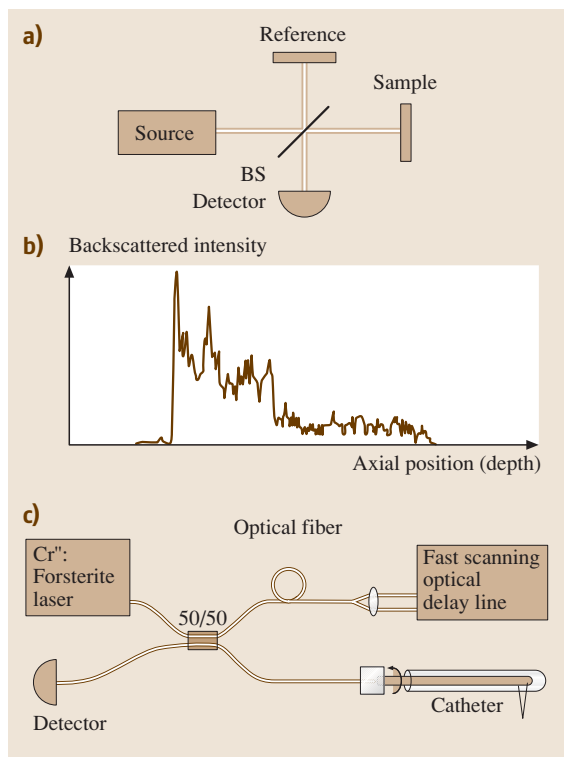
Although for many medical applications ultrashort lasers do not play an essential role, there are some examples where femtosecond pulses are superior to longer laser pulses [13.86] for the following reasons. Femtosecond lasers allow the application of high peak powers but low energy to human tissues. Because of the low energy, damaging high temperatures are avoided but the resultant nonlinear effects cause absorption in regions of the body which are transparent for linear absorption. By sending the laser pulses through a microscope with a large numerical aperture, small focal spots can be realized and microsurgery is possible. This is, for instance, used for intraocular and intrastromal refractive surgery. The high peak power may result in microplasma formation with subsequent stress waves into the surrounding tissue and chemical reactions. If the limits of unwanted destruction are precisely known, this can be used to create surgical effects. Therefore femtosecond


Fig. 13.74 Optical coherence tomography

lasers enable the creation of extremely spatially confined chemical, thermal and mechanical effects in biological media.

Another area where the high time resolution is essential is optical tomography; here the output beam of the laser is split into a reference beam and a part that is sent into selected parts of the body (Fig. 13.74), for instance into the brain. The interference between the reference beam and the radiation backscattered from a thin region of the sample is measured as a function of the delay time between the reference and backscattered signal pulses. Any change in the composition of the tissue changes the interference pattern. The spatial localization becomes better with increasing spectral width of the radiation source. Therefore light-emitting diodes or broadband pulsed lasers are often used. Examples where this technique has been successfully applied are tumors in the brain or in the female breast or plaques in arteries that might cause heart attack [13.87].

A modern device based on an interferometer for optical tomography using optical fibres and a fibre beam splitter is shown in Fig. 13.74b.

Applications in Geodesy and Environmental Research

Short laser pulses are well suited for accurate distance measurements. When a pulse is emitted at time $t = 0$ and is reflected by a target at time $t = t_1$ the backscattered light, collected by a telescope, is received at $t = t_2 = 2t_1$. The distance between the receiver and target is then $d = t_1/c$, where c is the speed of light. With intense picosecond laser pulses the distance between the retro-reflector, placed by astronauts on the moon, and the receiver could be measured within a few centimeters [13.88]. In order to decrease the divergence of the beam caused by diffraction, the laser beam has to be enlarged by a telescope.

For many applications in distance measurements this method has become the standard technique. For shorter distances pulsed diode lasers have sufficient intensity to give a good signal-to-noise ratio and accuracies with uncertainties within the mm–cm range.

For environmental studies of our atmosphere different techniques have been developed (Sect. 13.3). The light detection and ranging (LIDAR) method is based on Mie backscattering by aerosols in the atmosphere. Pollutant molecules in the atmosphere lead to specific absorption of the beam if the laser wavelength is tuned to an absorption line of these molecules, thus decreasing the intensity of the backscattered pulse. For LIDAR measurements the backscattered intensity is alternately measured at an absorption wavelength λ_1 and a wavelength λ_2 where the molecules do not absorb. The ratio of the two backscattered intensities measured at time t

$$I_b(\lambda_1, t) = A \exp(-2\alpha_1 L) \text{ and}$$
$$I_b(\lambda_2, t) = A \exp(-2\alpha_2 L) \qquad (13.86)$$

gives the absorption $L(\alpha_2 - \alpha_1)$. Here $L = t/c$ is the distance to the backscattering target and $\alpha = N\sigma$ is the absorption coefficient, which depends on the density N of the absorbing molecules and the absorption cross section σ. The scattering cross section does not differ much for two close wavelengths λ_1 and λ_2.

If this intensity-ratio signal is measured at two different times t_1 and t_2, the ratio of the two signals just gives the absorption which takes place within the spatial range $\Delta L = L_1 - L_2$ (differential LIDAR) [13.89].

With femtosecond terawatt lasers a long plasma channel can be produced along the laser beam. Due to self-focussing caused by the nonlinear part of the refractive index, in atmospheric air the laser beam shows a series of plasma regions along the beam (like sausages on a string), which emit brilliant white light. These bright plasma spots can be used as spatially well-defined and

spectrally broad light source in the atmosphere. If the telescope is directed towards one of these plasma regions the received radiation has passed through the atmospheric layer between the telescope and the light source. The resulting absorption lines of this layer can be spectrally resolved and give for a single laser shot the whole spectrum of absorbing molecules in this layer [13.90]. The advantage of this method is the simultaneous detection of the whole spectrum of all absorbing constituents. Its disadvantage is that it only measures the total absorption integrated over the path length from the radiation source to the detector without giving information about the local variation of the density of absorbing molecules. This disadvantage can be partly compensated by viewing different parts of the plasma channel, which extends over several hundred meters.

Applications of Femtosecond Lasers in Material Science and Processing

The ultimate switching time in semiconductor chips is limited by the relaxation and diffusion times of excited electrons. With the decreasing size of electronic devices the electronic properties of metals are changing with the size of the nanostructures. Here femtosecond spectroscopy can obtain information about the different processes. One example is the investigation of the electron–lattice interaction in single silver nanoparticles [13.91].

Short-pulse lasers are also playing an increasing role in material processing. Although there are many applications of CW lasers and laser pulses with pulse widths in the milli- to nanosecond range for welding or cutting of materials or for drilling holes into specific hard materials, such as diamonds, ceramics, where mechanical drills are hard to use, femtosecond pulses have specific characteristics that make them superior to longer laser pulses in many cases. For example for drilling holes with diameters below $100\,\mu m$ but a larger depth, femtosecond pulses give cleaner and better-defined holes. This is due to the fact that the material is just evaporated without forming liquid drops that deteriorate the crater edge [13.92, 93].

Generation and Applications of Attosecond Pulses

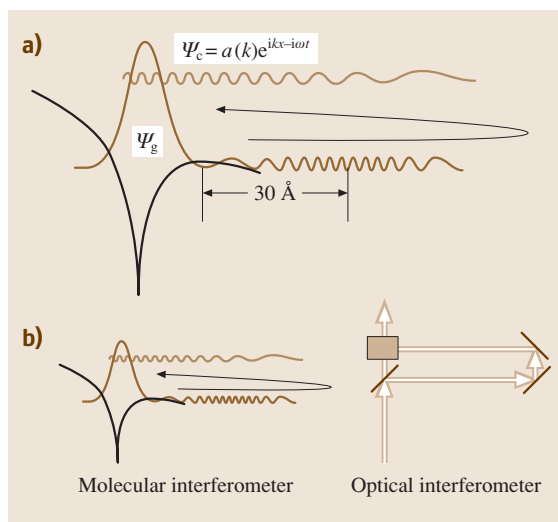
Although the realization of attosecond pulses is only a few years old, there are already numerous applications. Attosecond pulses are produced by focussing high-intensity femtosecond laser pulses into a sample of noble gas atoms in an atomic beam. The extremely high electric field of the pulse, which might even exceed the Coulomb field of the atom core, generates a highly nonlinear field where the atomic electrons are accelerated and emit high harmonics of the fundamental wavelength of the femtosecond pulse. Since the intensity of the n-th harmonics is proportional to the n-th power of the fundamental intensity, the higher harmonics are preferentially produced during the peak of the femtosecond pulse and their time profile is therefore much narrower than that of the fundamental pulse. From this process ultrashort X-ray pulses are available, which can be used for X-ray diagnostics of ultrafast processes. One example is the production of Laue- iagrams of excited vibrating molecules [13.37, 73]. Since for ordinary Laue diagrams the molecular vibrations wash out the exact geometry of the molecule, pulses with a pulse width short compared to the vibration period can give sharp Laue diagrams for the molecular structure at a specific moment of the vibration. Therefore direct information can be gained about the change of the molecular geometry when the molecule is excited. For biomolecules such a change might be essential for the biological function of the molecule. The experimental technique uses the femtosecond pulse at the fundamental frequency or at its second harmonic for excitation of the molecule and the X-ray attosecond pulse, generated


Fig. 13.75 (a) One-dimensional cut through an atomic potential in the strong field of a high-power femtosecond laser, showing the paths of the wave packets of the photodetached and returning electron, **(b)** comparison between molecular and optical interferometers [13.87]

as high harmonics by the same femtosecond pulse for diagnostics [13.94].

Another interesting application is the diagnostics of laser-produced high-temperature plasmas and inertially confined fusion. The fast ignition process can occur within attoseconds and the detailed diagnostics of these processes and their time sequence may result in a better understanding and optimization of laser-induced fusion processes [13.95].

The high peak powers attainable with femto- and attosecond pulses can generate electron bunches with high energies reaching beyond 1 MeV. There are serious estimations that even GeV electron pulses can be produced by wake-field acceleration in laser-produced plasmas. This new kind of particle accelerators has found wide interest, since it might also be used for proton acceleration. Although practical realization might still be far away, many laser laboratories and theoretical groups are working on this subject with increasing success [13.96].

A very interesting field is the study of electron dynamics during photo-ionization of atoms or molecules. The ejected electron might be forced by the strong laser field to return to the ion core before it can escape (Fig. 13.75a). The resulting interference between the wave functions of the outgoing and the returning electron give information on the structure of the electronic wavefunction of the orbital from which the electron was released [13.97]. As illustrated in Fig. 13.75b this techniques may be regarded as molecular interferometry, in analogy to optical interferometry. Depending on the phase of the optical field, angular asymmetries of the ejected photoelectrons are observed, which can be utilized to measure the absolute phase of optical fields [13.98].

13.3 LIDAR

13.3.1 Introduction

LIDAR stands for light detection and ranging and is the optical counterpart to radio detection and ranging (RADAR). As the name suggests these are range-resolved mapping techniques, where a microwave transmitter is replaced with a pulsed laser system. Photons backscattered from solid targets or from aerosol particles or molecules in the atmosphere are recorded using an optical telescope and an appropriate detection system. Range information is obtained through the time delay of the backscattered photons. Solid or liquid targets give rise to a sharp echo in the backscattered radiation at a time delay

$$T = \frac{2R}{c} , \qquad (13.87)$$

where R is the distance and c is the velocity of light. This means that a time delay of $1\,\mu\text{s}$ corresponds to a distance of $150\,\text{m}$. We thus see that for laser pulses of a typical length of $10\,\text{ns}$, resulting in an echo width of $1.5\,\text{m}$ (light travels $30\,\text{cm}$ in a ns), quite good range resolution can be obtained. This is the basis for normal pulsed laser range-finders. For laser light with a sharp emitted wavelength the elastically scattered echo is detected at the same wavelength. However, weak inelastically scattered Raman components, specific to the molecules irradiated, can also be detected offset from the laser frequency by the molecular vibrational frequency. More prominently, laser-induced fluorescence (LIF) from the target molecules is also observed on the long-wavelength side, in particular if the laser emits at ultraviolet (UV) wavelengths. The LIF signal is frequently spectrally broad, but certain information about the target molecules can still be obtained. In contrast, if a sufficiently powerful laser beam is focused onto a target, the pulses may induce optical breakdown and laser-induced breakdown spectroscopy (LIBS) signals from the free atoms and ions in the hot plasma can be recorded, providing elemental information.

It may be more unexpected to find that a signal from the free atmosphere itself is obtained when the laser pulse traverses it. This is due to elastic Mie and Rayleigh scattering from particles and molecules, respectively. Raman and fluorescence signals can also occur. Fluorescence from atoms or molecules in the atmosphere is normally quenched due to collisional de-excitation, but is prominent if the pressure is low, such as in the Earth's mesosphere. With reference to Fig. 13.76 [13.99], which shows a LIDAR measurement scenario, the intensity of the backscattered radiation, $P(\lambda, R)$, as a function of range R, is given by

$$P(\lambda, R) = CWn_{\text{b}}(R)\sigma_{\text{b}}\frac{\Delta R}{R^2}$$
$$\times \exp(-2\int_0^R [\sigma(\lambda)N(r) + K_{\text{ext}}(r)]\,\text{d}r ,$$

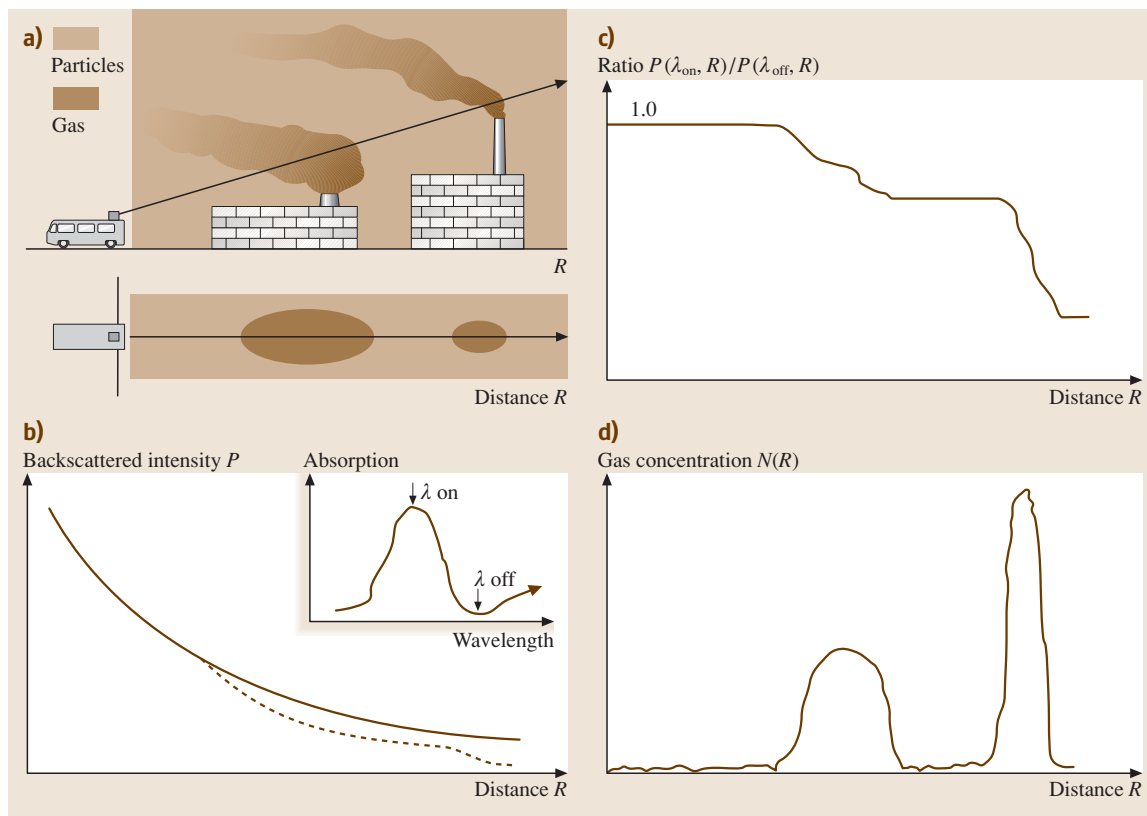
$$(13.88)$$


Fig. 13.76a–d The principles of LIDAR (**a**) scenario of LIDAR measurement at an industrial plant, with the atmosphere also seen from above (**b**) LIDAR curves for on- and off-resonant wavelengths (**c**) divided DIAL curve, on/off (**d**) evaluated gas concentrations for the chosen direction (After [13.99])

where C is a system constant, W is the transmitted pulse energy, and $n_b(R)$ is the number density of scattering objects with backscattering coefficient σ_b. Generally, the signal is for realistic atmospheres dominated by the elastic Mie scattering from particles. A main, and expected, observation from (13.88) is that the signal falls off with a $1/R^2$ dependence, basically reflecting the normal illumination law. Further, exponential light attenuation due to absorbing molecules or atoms of a concentration $N(r)$ and with wavelength-dependent absorption cross section $\sigma(\lambda)$ occurs, integrated over the range R, which is traversed twice. There is also an attenuation K_{ext} due to scattering particles with negligible wavelength dependence for small frequency excursions. In the differential absorption LIDAR (DIAL) approach, which is used for the monitoring of minor species such as air pollutants, a tuneable laser is intermittently fired at a wavelength λ_{on} for which a gas of interest absorbs, and at a reference, non-absorbed wavelength λ_{off}, which

is located so close that the scattering properties are the same. All on-resonance LIDAR transients are averaged in one computer memory, and all off-resonance (reference) transients are averaged in a second one. By then dividing the two signals, as indicated in (13.89), and in Fig. 13.76, it is possible to eliminate almost all unknown system and atmospheric parameters, leaving a ratio signal that only depends on the differential absorption coefficient for the gas (ideally the off-resonance cross section is zero, but this is not always the case)

$$\frac{P(\lambda_{on}, R)}{P(\lambda_{off}, R)} = \exp\left[-2(\sigma_{on} - \sigma_{off})\int_0^R N(r)\,\mathrm{d}r\right].$$
(13.89)

We note, that the $1/R^2$ dependence is now eliminated, and in particular that the ratio is independent of the range-dependent number of scattering particles. Thus

the method works without knowledge of this otherwise very crucial parameter. The range-resolved concentration of gas molecules can be obtained from the slope of the ratio curve, as evaluated in (13.90)) and indicated in Fig. 13.76. Clearly the range of useful measurements is limited by the signal-to-noise ratio, and for very long ranges basically zero is divided by zero. Measurement in different directions allows a three-dimensional picture of the gas distribution to be determined.

$$N(R, R + \Delta R) = \frac{1}{2\Delta R(\sigma_{\text{on}} - \sigma_{\text{off}})}$$
$$\times \ln \frac{P(\lambda_{\text{off}}, R + \Delta R)P(\lambda_{\text{on}}, R)}{P(\lambda_{\text{on}}, R + \Delta R)P(\lambda_{\text{off}}, R)} .$$
$$(13.90)$$

LIDAR work was pioneered by *Fiocco* and *Smullin* [13.100]. R. M. Shotland performed initial DIAL work on water vapor [13.101], while early DIAL experiments on an air pollutant (NO_2) were demonstrated by Rothe et al. [13.102] and Grant et al. [13.103]. Our own LIDAR work started in 1975.

LIDAR techniques are extensively discussed in a number of monographs; [13.104–106] and [13.107, 108] represent recent additions. LIDAR achievements are reported in the biennial International Laser Radar Conferences (ILRC), arranged by the International Coordination Group for Laser Atmospheric Studies (ICLAS). The most recent conference was arranged in Nara, Japan, in 2006 [13.109]. This literature provides comprehensive coverage of the field. In the present account, the field will mainly be illustrated by examples from the laboratory of the present author; further information on this work can be found, e.g., in the reviews [13.110–112].

The next section discusses the basic instrumentation used in LIDAR measurements. Then atmospheric applications including meteorology, pollution monitoring and space experiments will be presented. Section 13.3.4 deals with LIDAR experiments on fixed targets, including altimeter, LIF and LIBS LIDAR applications. Unconventional LIDAR-like applications in other fields of science, such as medicine and materials sciences, will then be exemplified. Finally, some conclusions are drawn.

13.3.2 Instrumentation

A LIDAR system consists of a transmitting laser, a receiving telescope, a detector, signal-handling electronics and a computer for capturing the signals and evaluating the data. The system can be placed fixed or be installed in a truck, an airborne platform or a satellite. Means for scanning the laser beam for interrogating a certain area are also frequently provided. The laser transmitter should be pulsed to provide adequate range resolution. For studying particles in the atmosphere, i. e. aerosols, a fixed frequency laser, such as a Q-switched Nd:YAG laser operating at 1064 nm can be used. Flashlamp pumping is now increasingly being replaced by pumping by powerful diode lasers that provide higher efficiency, lower heat dissipation and longer lifetime. It is also common to use harmonics of the emission at 532, 355 and 266 nm, generated with high efficiency in nonlinear optical crystals. By using a number of such frequencies, information on the size of the scattering particles can be obtained due to the wavelength dependence of the Mie scattering. Clearly, particles both backscatter through σ_b and attenuate through K_{ext}. For evaluation of the particle concentrations and properties a relation between these two quantities must be established, which is a key aspect in inversion algorithms being developed for this purpose. To use the DIAL method a narrowband tuneable laser must be used, and here dye lasers or titanium-doped sapphire lasers can be employed with the second or third harmonic of the Nd:YAG laser normally used as the pump. Such pump radiation can also be frequency converted over wide wavelength ranges using an optical parametric oscillator (OPO). By nonlinear harmonic generation, or mixing with fixed-frequency radiation, tuneable radiation over a wide range from the deep UV to the mid-IR spectral regions can be obtained. Excimer lasers, crudely tuneable by stimulated Raman scattering in hydrogen or deuterium gas, are sometimes used in the UV region, mostly for ozone monitoring.

The laser radiation is normally sent with a controlled divergence into the atmosphere by using a beam expander. A folding and beam-directing mirror is frequently used, also for directing backscattered radiation into the receiving telescope, which is normally of a Newtonian or Cassegrainian type and with a typical diameter of 10–100 cm. The laser beam typically has a divergence of 1 mrad and the telescope field of view is selected to match this value using an appropriate aperture. Backscattered light is detected by a photomultiplier tube or an avalanche photodiode placed behind a narrow-band filter matching the detection wavelength and blocking out sunlight. Gain-switching is frequently employed to handle the large signal dynamic range otherwise obtained. The signal is digitized with a transient recorder and signal averaging is performed until an adequate signal-to-noise ratio is obtained at the longest

ranges of interest. In order to ascertain the validity of (13.90) in DIAL measurements (i. e., that particle scattering did not change between on- and off-resonance measurements) the laser wavelength has to be switched back and forth between adjacent shots.

In the IR region, where photomultiplier tubes having high efficiency and amplification are not available, it can be advantages to use *heterodyne* or *coherent* detection of the LIDAR signal. Then the LIDAR signal is mixed at the detector with a frequency-offset laser frequency and the beat note is detected at an intermediate frequency. This technique is best achieved if the system is equipped with a CW seeding laser which is pulse-amplified in the LIDAR transmitter. The seeding laser is then also a suitable local oscillator for the heterodyne detection. Clearly, Doppler shifts due to moving atmospheric particles occur, and this is a basis for LIDAR detection of wind speed.

When LIF or LIBS signals from solid targets are to be detected the detector is replaced with an optical multichannel analyzer, i. e., a spectrometer followed by a gated and image-intensified CCD. The spectrometer can be fibre-coupled to the focal plane of the telescope, and by properly gating the system, the full LIF or LIBS signal can be captured for each laser shot, with suppression of the ambient light, which can be made negligible during the short gate when the desired signal is present.

An example of a mobile laser radar system is shown in Fig. 13.77 [13.113]. The system, currently used by the Lund University group, has a Nd:YAG-pumped OPO as a transmitter, which covers the spectral range 220–3500 nm by nonlinear optical wavelength extensions. A vertically directed 40 cm-diameter Newtonian telescope is used in conjunction with a rooftop computer-controlled scanning mirror that selects the measurement direction for the aligned transmission and
Fig. 13.77 Lund University mobile LIDAR system configured for vertical traverses or free scanning atmospheric measurements, and for water sounding downwards. (After [13.113])

detection lobes. A gated spectrometer is also shown for solid-target applications. Equipped with a motor generator, towed by the truck and providing electricity, a fully autonomous LIDAR system is obtained for land-based and ship-borne applications. The examples of LIDAR experiments shown in the figures of the present paper were all obtained using this system. Clearly, an airborne or satellite-installed LIDAR system must fulfill stringent requirements with regards to weight, efficiency and reliability. We will discuss this further below.

13.3.3 Atmospheric LIDAR Applications

Mesosphere

There are numerous applications of LIDAR techniques for atmospheric sounding. A specialized application is to investigate the low-density layers of atoms, such as sodium, potassium and iron in the mesosphere at heights of about 100 km, where meteorites impinging on the Earth's upper atmosphere are vaporized. The pressure is so low that collisional de-excitation of the laser-excited species (at about 589, 765 and 372 nm, respectively) is negligible and bright atomic fluorescence can be observed. These layers exhibit gravitational-wave patterns and, by probing the line shapes with a narrow-band excitation laser, temperature as well as velocities can be derived from line widths and shifts. A recent utilization of the bright emission is for *laser guide star* applications [13.114], where the localized emission is used for active control of astronomical telescopes to compensate for atmospheric turbulence using *adaptive optics*.

Meteorology

Accurate weather forecasting requires powerful prediction models and equally important, accurate input data. Traditionally, synoptic observations from a global network of observational sites have been used. With the availability of meteorological satellites in geostationary orbits global coverage of many important parameters has been achieved. However, to increase predictive accuracy global wind fields and vertical water-vapor profiles are much needed. Such information can be obtained with LIDAR techniques. Actually, we have already discussed above how Doppler heterodyne techniques can be used to measure range-resolved wind speed. The Doppler shift in the line profile of the scattering molecules and particles can also be observed in direct intensity measurements where a narrow-band transmitter is used to induce the scattering and the so called double-edge technique [13.115, 116] is used to observe wind-induced frequency shifts. By using a Fabry–Pérot interferometer

or optically thick atomic or molecular gas cells in the path of the detected light this can be partially blocked out. When the profile is moved in frequency due to the wind, more or less of the light is *scraped off* by the sharp edge filter, and the data can be converted into velocity. After extensive fixed-system and airborne tests the technique is now ready for satellite global coverage within the European Space Agency's (ESA) AEOLUS project, where a frequency-tripled Nd:YAG laser at 355 nm is used.

Water vapor can be measured by DIAL but also more simply using Raman scattering of this high-concentration molecule. By blocking the elastically scattered laser radiation at, e.g., 355 nm and by only monitoring the intensity of the Raman–Stokes shifted water-vapor line at 408 nm through a narrow-band interference filter, vertical profiles for many kilometers are readily obtained.

We have already discussed that, while aerosols and cloud particles yield a strong elastic Mie scattering signal, its interpretation is complex due to the interplay of backscattering and extinction. Accurate measurements of the aerosol influence on the Earth's radiation budget are very important in assessing global change and warming. The uncertainty in the aerosol load is presently the single most important uncertainty in modeling climate forcing [13.117]. By using strong Raman scattering from the uniformly mixed major species nitrogen, in the case for 355 nm excitation centered at 387 nm, it is possible to measure particle extinction independently, since the Raman signal can only be reduced by the particles. In contrast, the elastic signal due to particles is increased by an increasing load of particles but reduced by attenuation. By studying the detected depolarization of primary linearly polarized laser light it is possible to determine the shape of the scattering particles. Spherical particles (such as water droplets) keep the initial polarization, while elongated particles, such as ice needles and snow crystals, exhibit depolarization. A complication is that multiple scattering in spherical particles is also depolarizing. After many years of extensive studies in fixed and airborne LIDAR installations, a dedicated satellite system, (CALIPSO), was launched in 2006, and is now providing global coverage of particle scattering and depolarization using 1064 and 532 nm radiation from a Nd:YAG laser, designed to operate for few years at 20 Hz.

The backscattered signal due to particles and molecules can further be separated by using a Fabry–Pérot interferometer or a gas filter to block the spectrally

sharp Mie signal (the particles only move due to the wind), while the wings of the Doppler-broadened Rayleigh scattering is passed (as molecules move at thermal velocities, typically a few hundred meters per second). This technique obviously then also leads to the possibility of measuring range-resolved atmospheric temperature. A further method to measure temperature by LIDAR is to use the rotational Raman signal from nitrogen, which maps out the Boltzmann thermal population distribution on the different rotational levels of the ground-state molecule.

Global warming is a great concern, and is primarily believed to be induced by carbon dioxide emissions due to increasing burning of fossil fuels. Thus, detailed mapping of the sources and sinks of this gas is important, and many projects aimed at DIAL monitoring of CO_2 around $2\,\mu$m using Tm,Ho:YLF lasers are now under way.

Minor Species and Pollution

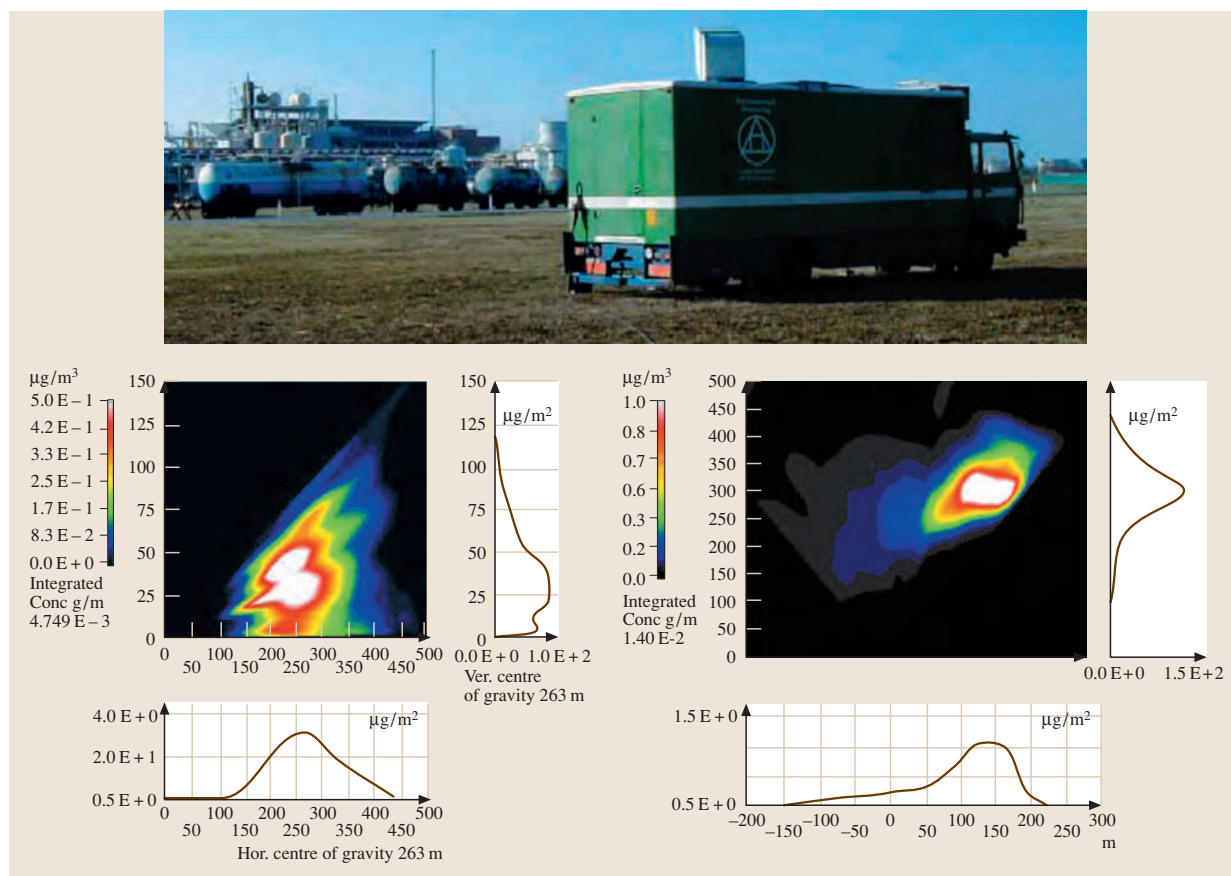
Minor species and pollutant gases in the troposphere can be mapped using the DIAL technique. Raman LIDAR does not have the required sensitivity and fluorescence does not work because of the quenching at atmospheric pressures. As a first illustration we will discuss a very special pollutant, mercury, actually the only one present in the atmosphere as a free atom, rather than as a molecular compound. Disregarding isotopic shifts and the hyperfine structure, mercury atoms have a single transition rather then a multitude of vibrational–rotational transitions over which the molecules are distributed. Thus we automatically gain a sensitivity increase of a factor of about 1000 for mercury, which is needed, since the background levels of this gas is on the ppt $(1:10^{12})$ level. Mercury, atmospherically present in atomic form to about 90%, is emitted from chlor-alkali plants producing sodium hy-


Fig. 13.78 DIAL measurements of atomic mercury. Top, mobile LIDAR system seen at the Rosignano Solvay chlor-alkali plant, Bottom left, vertical scan, and bottom right, horizontal scan. (From [13.118, 119])

droxide (the cathode in the cells for electrolysis of brine is liquid mercury, into which the sodium ions move, forming amalgam, which on washing yields the natron lye). Furthermore, coal-fired power plants and incineration plants including crematories emit mercury. It is also an interesting geophysical tracer gas related to ore deposits, geothermal reservoirs and volcanic activities. DIAL measurements are performed using the 254 nm mercury transition, which can be induced using a frequency-doubled dye laser or OPO. An illustration of atomic mercury DIAL at a chlor-alkali plant is shown in Fig. 13.78 [13.118, 119], where individual LIDAR returns taken fan-like and perpendicularly through the plume downwind from the plant, have been used to generate a plume cross section showing spatially resolved concentration. The area-integrated concentration times the perpendicular wind speed yields the flux, which is the environmentally important parameter. This reasoning can convincingly be supported by a consideration of units:

$$\frac{[g]}{[m^3]}[m][m]\frac{[m]}{[s]} = \frac{[g]}{[s]} \qquad (13.91)$$

yielding the proper flux unit g/s. Typical fluxes for plants of this kind can be tens of g/h. Atomic mercury monitoring is considered as a special case study in [13.110] and is also discussed in [13.111] regarding geophysical emissions. We performed LIDAR measurements of mercury at the three largest mercury mines in the world: Almaden (Spain), Abbadia S. Salvatore (Italy) and Idrija (Slovenia).

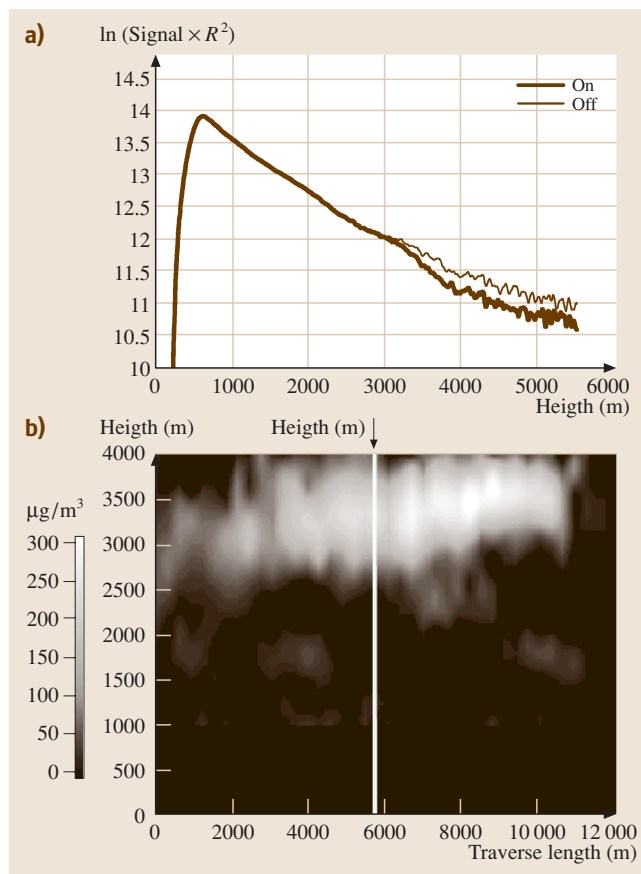
Another pollutant of even more concern is sulphur dioxide SO_2, which contributes heavily to the acidification of lakes and to atmospheric loading with sulphate particles. Sulphur dioxide is emitted from volcanoes, but the main sources are anthropogenic and are due to the combustion of sulphur-containing fuels. We illustrate SO_2 monitoring with the case of volcanic emission. Figure 13.79 shows data from ship-borne measurements of the Italian volcano Mt. Etna, where the Swedish mobile LIDAR system is placed on the aft deck of the Italian research vessel *Urania*, making a 12 km-long underpass of the volcanic plume, which is encountered at about 3 km height [13.120]. Individual *on* and *off* LIDAR returns are also shown at a particular location to illustrate how the plume cross section is built up. It can be noted that the curves are identical until the height of the plume, where they run apart. Both curves also show extended backscattering due to volcanic aerosols above the smooth background. It is interesting to note that the aerosol plume is


Fig. 13.79 DIAL monitoring of SO_2 from Mt. Etna. The measurements were performed in a 12 km scan with the system firing vertically from the aft deck of the research vessel *Urania*, making a traverse under the volcanic plume off the city of Catania. On- and off-resonance LIDAR curves are shown in the upper part of the figure for one particular location. (After [13.120])

slightly below the SO_2 plume due to gravitational separation. This recording yielded a flux of about 50 t/h as the background emission for this active volcano. LIDAR measurements of geophysical gases are discussed in [13.111].

As a third example of LIDAR measurements we will discuss the monitoring of hydrocarbons, which poses special challenges. The primary C−H stretch vibrational transition in hydrocarbons is around 3.4 μm with small variations between different species. The individual rotational structures also lead to heavy spectral overlap between different hydrocarbons. Thus, in the presence of several hydrocarbons it is not possible to use the basic DIAL concept with an *on* and an *off* wavelength,
a) Lidar curve
b) Methane
c) Ethane
d) Propane
e) 0-Diff.
Fig. 13.80 Illustration of simultaneous measurements of methane, ethane and propane as evaluated from measurements on a calibrated gas mixture release. Seven different probing wavelengths are indicated and differential absorption in the gases is observed. (After [13.113])◀

but rather several, carefully selected wavelengths allowing the different overlapping species to be measured together. We have developed a swiftly tuneable OPO for LIDAR applications, where switching to up to 60 wavelengths can be accurately performed between adjacent laser shots, and where LIDAR transients can be averaged for each selected wavelength [13.113, 121]. We illustrate the monitoring of a controlled release of a mixture of methane, ethane and propane with selected DIAL curves showing differential absorption for each gas at the location of gas release 60 m away from the LIDAR system. The wavelength pairs chosen are shown in the spectral inset; in particular the absence of a DIAL signal when two off-resonance curves are divided is also illustrated. In the case of methane monitoring we note that the DIAL curve has a continuous slope, apart from the step at the release. This is due to the ambient presence of methane in the atmosphere at a level of a few ppm. It is difficult to achieve large ranges in the IR region due to the reduced Mie and Rayleigh scattering for longer wavelengths. However, effective remote sensing of hydrocarbons can be achieved using gas correlation imaging as developed in our group [13.122] and now employed in gas processing plants.

Nitrogen oxides are also important pollution gases. In all high-temperature combustion NO is emitted, and rather quickly reacts to NO_2. DIAL measurements for these gases can be made around 226 nm and 450 nm, respectively. Actually, NO_2 is the only pollutant in the atmosphere which has a color (brownish) because it absorbs in the visible region.

Because of its paramount importance for shielding the earth from hard-UV radiation ozone has been studied much by LIDAR techniques. The stratospheric ozone layer at 20–30 km height is being depleted due to catalytic reactions with fluorinated hydrocarbons (freons), which rise to high altitudes as they are inert and do not undergo atmospheric chemistry in the troposphere. Much LIDAR work has been performed both with fixed and airborne installations. Actually, due to atmospheric chemistry involving hydrocarbons, ozone concentrations at ground levels are frequently elevated, causing damage to health and vegetation.

13.3.4 LIDAR Monitoring of Condensed Targets

Laser Altimeters and Bathymeters

As discussed in the introduction, laser ranging by observing the elastically backscattered echo from a solid target is a straightforward application of lasers. With pulsed lasers a time-of-flight measurement is performed, while the phase shifts on reflected modulated CW beams can also be used. Then modulation must occur at many different frequencies, where information from the low-frequency components gives a crude distance estimation, while the higher frequencies determine the distance with increasing accuracy. Since many distances modulo the modulation wavelength are compatible with a particular high-frequency phase shift, the successively slower modulations ascertain that the right multiple is chosen. A scanning airborne system can map out surface topography with great precision. Laser ranging towards the retro-reflectors placed by the Apollo astronauts provides distance measurements to the moon to an accuracy of about 1 cm. The geoscience laser altimeter system (GLAS) is part of the ICESat satellite launched in 2003 and was mainly intended for accurate height measurements, primarily for studying the development of polar ice cover. However, cloud and aerosol data are also obtained. A LIDAR ranging instrument was important in the successful landing of the Japanese space vehicle HAYABUSA on an asteroid, Itokawa in 2006. Orbiting laser range-finders will also be used in missions to Mercury and Mars.

The range resolution of terrestrial laser altimeters is so good that the echo from tree canopies can be resolved from the ground echo. In this way forestry applications have become possible, and biomass assessments can be made in inaccessible areas such as jungles. Related, and preceding this application in time, laser bathymetry of shallow waters has been successfully achieved with airborne LIDAR systems. In order to suppress the strong surface echo and allow the weak bottom return to be picked up, a linearly polarized laser can be used. If detection is made at a polarization perpendicular to the primary one, the polarized surface return is strongly attenuated while the depolarized return from the bottom can be favored. Depths below 40 m are rarely accessible, and normally much shallower waters are measured, of main interest for maritime charting. The preferred laser wavelength in bathymetry applications is 532 nm from a frequency-doubled Nd:YAG laser, since water has maximum transmission in the blue–green spectral region.

Fluorescence and Raman LIDAR Studies of Water, Vegetation and Buildings

As discussed in the introduction, the LIDAR echo from a fixed target consists not only of the strong elastic backscattering, but also of laser-induced fluorescence (LIF) and Raman components. These features, red-shifted with regard to the laser pump frequency, can be isolated with a spectrometer, where additional suppression of the elastic return is provided with a colored-glass long-pass filter.

An example of an arrangement for LIDAR studies of condensed targets is given in Fig. 13.81 [13.123]. Frequency-tripled Nd:YAG radiation at 355 nm effectively induces fluorescence, leaving a sufficiently large Stokes-shifted wavelength range to be captured with available efficient detection systems. Two detection arrangements are shown. In the first, the fluorescence light is captured with an optical fibre in the image plane of

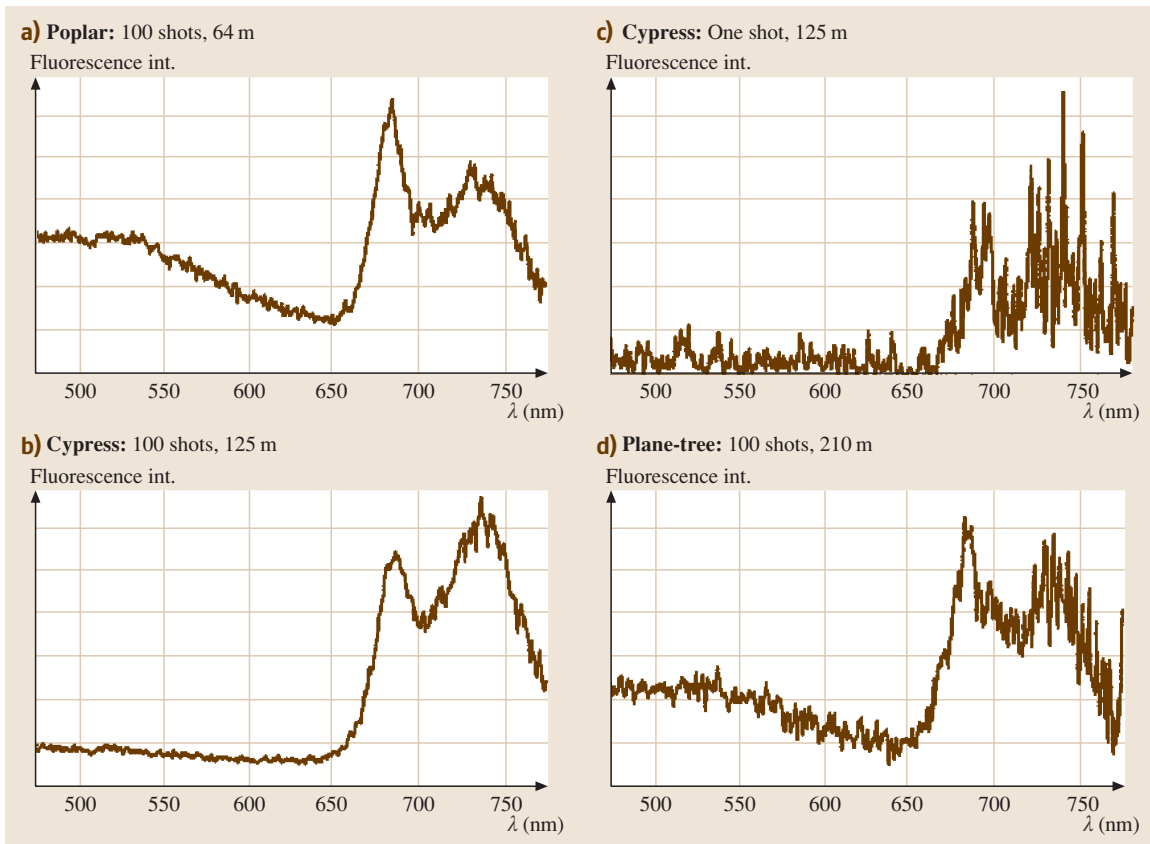
the telescope and brought to the entrance slit of the spectrometer with a gated and image-intensified CCD detector. Frequently, a multi-fibre arrangement is used, where a cylindrical detection area is transformed into a slit shape to match the input of the spectrometer. In a second imaging arrangement, the laser beam is widened to illuminate a larger area on the target and a special beam-splitting optical arrangement [13.124] is used to capture the same image simultaneously, filtered through four individual bandpass filters, leaving the images detected simultaneously in the four quadrants of the CCD detector. Such an arrangement can be used for small targets and at background illumination conditions allowing an expanded laser beam with correspondingly weak signal generation from any individual target point. More of general purpose is to have a few cm diameter beam with intense radiation (outperforming the sun background in that spot) and then to sweep
Fig. 13.81 Fluorescence LIDAR system lay-out for point monitoring and multi-spectral imaging. (After [13.123])


Fig. 13.82 Remote fluorescence LIDAR spectra, recorded at different stand-off ranges. (After [13.125])

this point over the target in a whisk-broom mode. The field is reviewed, e.g., in [13.112].

As an example of individual spectra recorded in such a mode we show in Fig. 13.82 vegetation spectra, captured at distances ranging from 64 to 210 m [13.125]. The dual-peaked chlorophyll signals are clearly seen as well as a blue light distribution related to the leaf wax layer and other leaf structures. The relative intensity of the two red peaks gives information on the chlorophyll concentration, since the first peak is self-absorbed with increasing levels of the pigment. There has been a considerable effort in vegetation monitoring using LIF aiming at the detection of water-related and other environmental stress factors. LIF data may supplement reflectance data now monitored extensively using satellite sensors for land coverage assessment (e.g. LANDSAT, SPOT and ENVISAT sensors).

Cultural heritage studies with spectroscopic methods is an emerging area of laser application. In the same way as specific LIF signatures are obtained from vege-

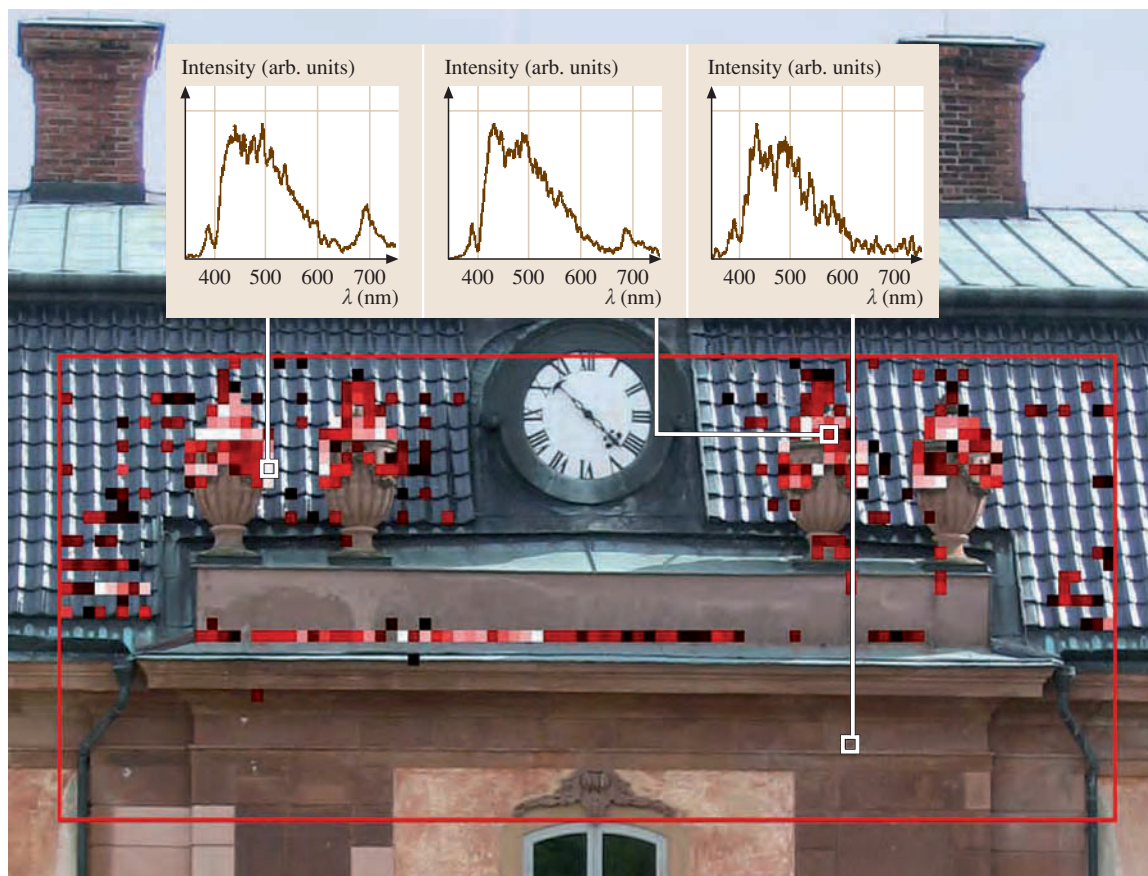
tation targets, the surface of stone monuments, such as cathedrals and castles, may also reveal aspects in fluorescence not visible to the naked eye or in reflectance spectroscopy. Following the first point-monitoring applications by *Raimondi* et al. [13.126] we have extended the techniques to multi-spectral imaging with measurement campaigns performed, e.g. at the Lund cathedral (Sweden) [13.123] and the Parma cathedral and baptistery [13.127]. An example from recent measurements at the Övedskloster castle in Southern Sweden is shown in Fig. 13.83. Here the beam was scanned sequentially line by line from a distance of about 40 m [13.128, 129]. Examples of individual spectra recorded are shown in the figure, featuring different amounts of chlorophyll from mostly invisible algal growth. It can be seen that the edges of the tiles are preferred algal locations as are the upper parts of the ornamental urns. The chlorophyll amount is encoded on the colorscale of the pixels having at least a minimum amount of chlorophyll (black).


Fig. 13.83 Fluorescence LIDAR imaging of a section of the Övedskloster castle, Sweden. Three spectra illustrate the measurements, and an image with a colorscale indicates the amount of algae invasion. (After [13.128, 129])

A final example is given in Fig. 13.84 with data from a recent measurement campaign [13.130, 131] at the Flavian amphitheater Coliseum, inaugurated in Rome in 80 AD. The monument is constructed out of travertine quarried nearby in Tivoli. Spectra show differences in stone surface even if they appear similar. Chlorophyll invasion is very evident in certain places, and corrosion protection on iron bars applied during historical preservation efforts also has a very characteristic appearance, as shown in the figure, which also includes a photograph from the measuring site.

The first application of fluorescence LIDAR techniques were in the field of water monitoring, as reviewed, e.g., in [13.132, 133]. Land-based, ship- as well as air-borne campaigns have been pursued. An important aspect of water fluorescence monitoring is the assessment or the general level of dissolved organic matter (DOM) in water. DOM gives rise to broad, bluish fluor-escence spectrum. By normalizing the DOM signal to the Raman signal due to the water $O-H$ stretch vibrational mode at a Stokes shift of about $3400\,\mathrm{cm}^{-1}$ a convenient intrinsic reference is obtained, which makes the measurement independent of a knowledge of the effective sampling volume. For 355 nm excitation the $O-H$ stretch Raman signal of liquid water occurs at 404 nm. By analyzing the shape of the water Raman peak with a high spectral resolution system it is also possible to measure the depth-resolved water temperature remotely with a bathymetric system.

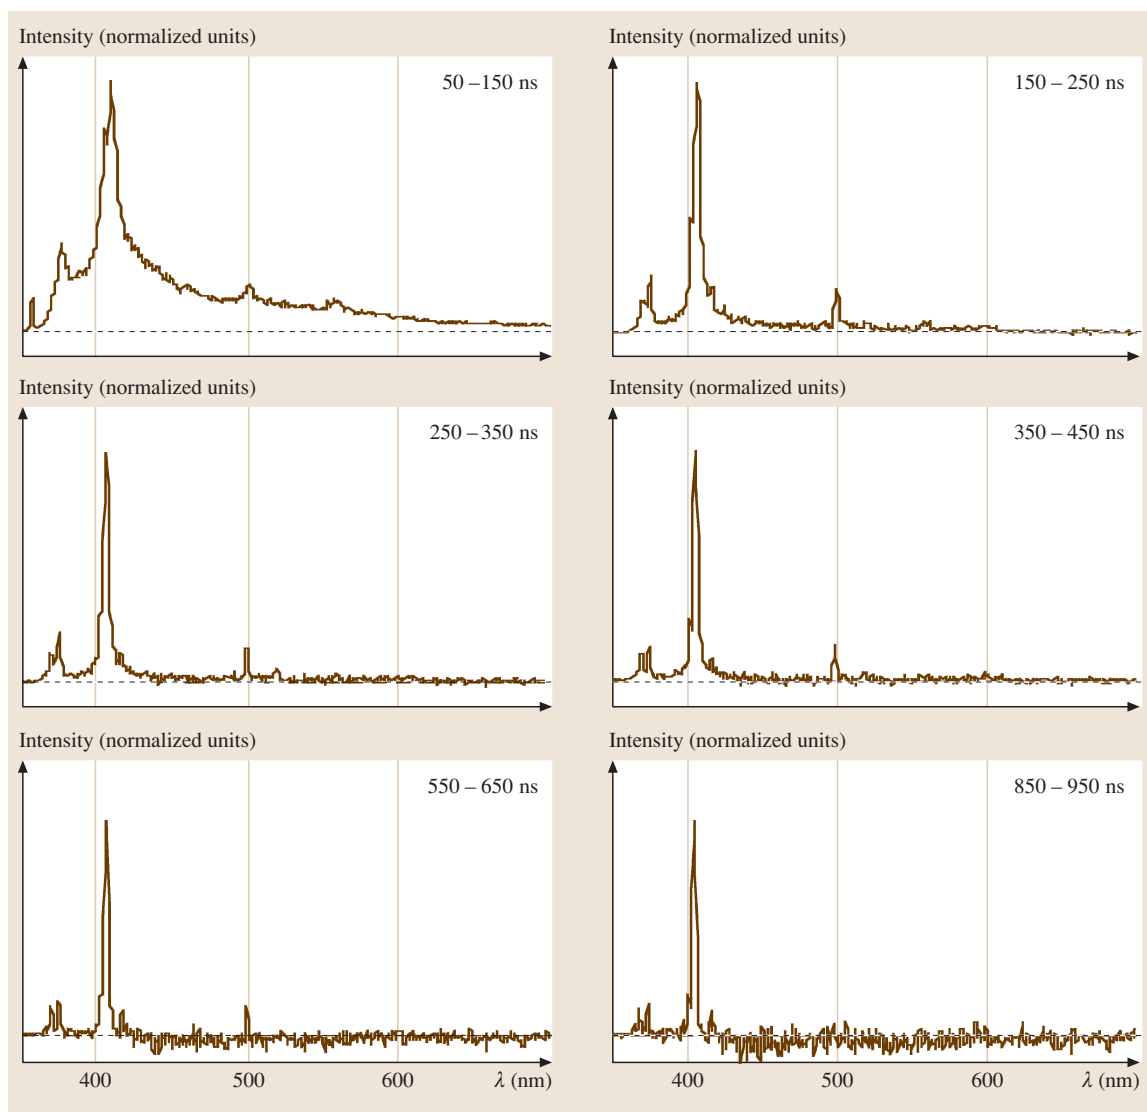
Other prominent spectral features in LIDAR spectroscopic studies of water are due to chlorophyll, which is present in all pelagic algae, and accessory pigments, e.g. phycocyanine and phycoerytrine, which are present in red algae. The characteristic fluorescence of these pigments peak at 690, 660 and 590 nm, respectively.
Fig. 13.84 Fluorescence LIDAR measurements at the Coliseum, Rome. A photograph with the Swedish LIDAR system in measurement position is shown in the upper part of the figure. Below, individual fluorescence spectra are shown to the *left*, while points with a spectral signature similar to A are shown in the *middle*, and points with a spectral signature similar to D are shown to the *right*. (After [13.130, 131])


Fig. 13.85 Laser-induced breakdown spectra (LIBS) recorded with a LIDAR system at 60 m stand-off distance for a lead plate for different time delays. The lines become narrower and more well defined as the plasma cools. (After [13.129])

The strongest signals received in aquatic monitoring are from oil spills covering the surface [13.134]. At the same time as a strong oil fluorescence replaces the DOM signal in the blue–green region, the water Raman signal disappears, since even a layer a few micrometers thick becomes optically thick for the exciting UV radiation. Thus oil spills have a very clear spectral signature. Laboratory studies of different types of crude oils and lighter fractions show that oils of specific origins can be identified. Extensive air-

borne work for oil-spill detection and characterization, complementing data from side-looking airborne radar (SLAR) and synthetic-aperture radar (SAR) has been pursued.

A main limitation of fluorescence LIDAR is its limited range, which makes satellite implementation difficult. However, passive techniques using sunlight-induced fluorescence have been considered for marine oil-slick detection and is now being developed for vegetation monitoring [13.135]. The normal

reflectance spectrum of a ground surface carries the dark and narrow Fraunhofer signature lines from the sun with the same contrast as in direct sunlight. However, fluorescence transfers part of the radiation from short to longer wavelengths due to the Stokes shift, and tends to reduce the Fraunhofer line contrast, a phenomenon directly signaling that fluorescence is present.
Fig. 13.86 Illustration of remote plasma ablation on different samples placed at 60 m distance from the LIDAR system. *Top*: ablation patterns for concrete and Italian alabaster; *Bottom left*: illustration of the cleaning of an Italian garden statue; *right*: a soiled Carrara marble statue before (*upper figure*) and after (*lower figure*) remote laser cleaning. (After [13.136])

Laser-Induced Breakdown Spectroscopy (LIBS) LIDAR

We will finish this section of LIDAR measurements on condensed targets by a discussion of remote laser-induced breakdown spectroscopy (LIBS). The LIBS technique makes use of focused laser beams from pulsed lasers, where a laser spark is produced at the target surface due to strong heating by the pulse [13.137]. The technique is a valuable analytical analysis method for elemental measurements of the same kind as in flame-emission spectroscopy where vaporization occurs due to the thermal heating. By expanding the LIDAR beam and focusing it is possible to reach a sufficiently small spot size to induce plasma breakdown at a considerable distance if the pulse energy is large enough [13.138]. This technique is also being developed for space exploration, e.g., rock characterization from the Mars landers [13.139]. We have recently performed the first imaging LIDAR LIBS measurements at a distance of 60 m and with pulse energies at 355 nm of the order of 200 mJ [13.136]. The same detection system as for LIF is employed, and by gating a few hundred nanoseconds later it is possible to observe the cooling plasma, in which narrow atomic emission lines are obtained rather than broadened structures observed in the early plasma, where strong fields due to electrons etc. are present. This effect is seen in Fig. 13.85, where a LIBS spectrum from a sheet of lead is observed at 60 m distance for different delays [13.129].

Small amounts of material are ablated in the LIBS plasma. This can be utilized for cleaning of soiled surfaces in the cultural heritage sector. Such remote cleaning is illustrated in Fig. 13.86. Here samples of mortar, alabaster and marble were studied from a distance of 60 m. On white marble samples the cleaning process is self-terminating, since no absorption is obtained once the dirty surface is removed from the original white material. The ablation and cleaning process could in principle also be controlled spectroscopically by simultaneously monitoring the plasma spectrum.

13.3.5 Unconventional LIDAR Applications

LIDAR techniques are conventionally associated with long-range atmospheric measurements. However, a key aspect in these measurements is that they are performed time-resolved and non-intrusively. Using topographic (condensed) targets, the range-resolution aspect is also sometimes suppressed. In the measurement of combustion processes optical techniques are used at typical distances 1 m, but motivated by the remote and non-intrusive nature of optical spectroscopy, avoiding the prohibitive heat and pressures that are characteristic of such systems. Elastic scattering, Raman, fluorescence and coherent anti-Stokes Raman scattering (CARS) techniques are employed [13.140]. Range-resolved measurements in large-scale burners are now being developed making the parallels with LIDAR very close [13.141].

Optical mammography for the detection of breast cancer [13.142] can truly be characterized as short-range LIDAR. Biological tissue is a strongly scattering medium, in which molecular compounds can also be detected using differential absorption. It can be convenient to use white laser light generated by self-phase modulation of femtosecond laser pulses in such measurements, and molecules, such as tumor seeking agents can be detected [13.143]. Such techniques can be extended to the monitoring of pharmaceutical tablets that are strongly scattering [13.144, 145]. Using white-light laser bursts the concentration of the active molecular components in the drug can be evaluated from their imprint in the detected scattered light. These examples constitute multiple-scattering cases much similar to those pertaining to cloud physics.

The LIDAR analogy becomes almost complete in the gas in scattering media absorption spectroscopy (GASMAS) technique [13.146, 147], where free gas enclosures (pores) in highly scattering materials such as wood, foods and construction materials are studied. Normally, CW diode-laser spectroscopy is being applied for path-integrated measurements of the free gas signature (e.g. molecular oxygen and water vapor). Gas concentration determination becomes possible if an independent LIDAR measurement of the time history of the photons inside the sample is being made [13.148]. The GASMAS technique also gives interesting insight into everyday processes such as the drying of materials, e.g. wood [13.149]. The technique has recently been extended to the monitoring of oxygen gas inside the human sinus cavities [13.150], where the laser light is launched through the scattering forehead, passes through the sinus, scatters in the brain, with a fraction returning back through the sinus, passing through the forehead and entering the LIDAR detector. The gas is detected through its sharp differential absorption superimposed on the backscattering spectrum from the bulk molecules having a very slow wavelength dependence (as in atmospheric LIDAR). Some illustrations of unconventional LIDAR work are given in Fig. 13.87.

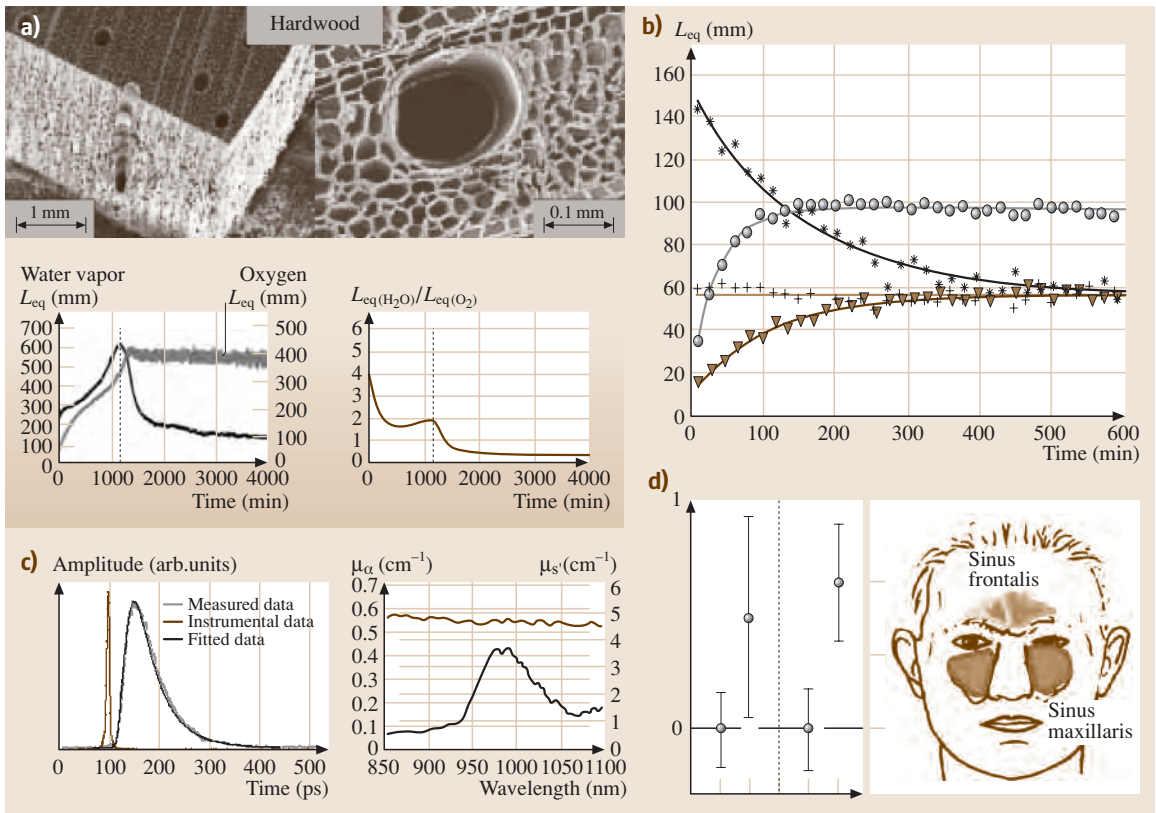
The many parallels between environmental and medical laser spectroscopy have been pointed out, e.g. in


Fig. 13.87a–d Illustration of different kinds of unconventional short-range "LIDAR" measurements **(a)** Monitoring of the drying of wood. Microscope images of wood structure with pores are shown above the temporal development of molecular water and molecular oxygen signals, and their ratio value during a two-day drying process. (After [13.149]) **(b)** Molecular oxygen signals from apple exposed to pure oxygen or nitrogen gas before being taken into ambient air where normal interior gas conditions are restored with a certain time constant. (After [13.147]) **(c)** Time-resolved measurements of light scattered in a white pharmaceutical tablet, and (*right*) observation of the liquid-water absorption spectrum. (After [13.144]) **(d)** Observation of free oxygen gas in the frontal sinus cavities when light is launched into the forehead and backscattered light is detected. Non-zero signals are seen on both sinuses, while zero signal results off the sinuses. (After [13.150])

[13.151], and further aspects of multidisciplinary spectroscopy bridging many disciplines are discussed in [13.152].

13.3.6 Discussion and Outlook

As we have seen, LIDAR techniques provide a wide spectrum of applications regarding the monitoring of the environment. The rapid development of efficient diode-pumped solid-state lasers, sensitive detectors, and fast electronics and data handling have all contributed to make the applications of LIDAR more attractive. With ever more strict considerations regarding the monitor-

ing of the status of the environment, the utilization of LIDARs in surveillance and monitoring systems and networks will be a driving force in the development of the field. Satellite-borne equipment is now planned for many missions, taking advantage of the emerging robustness and reliability of these techniques. A major impact on global atmospheric monitoring and meteorology can be expected.

Recent trends in the LIDAR field include the use of intense laser beams of terawatt peak power and femtosecond duration. Reasonably small, table-top systems have become available after the introduction of the chirped-pulse amplification (CPA) technique [13.153].

Filamentation and channeling due to self-focusing occurs in the atmospheric propagation, keeping the beam together with intense generation of white light through nonlinear effects, most prominently self-phase modulation [13.154]. Free atmosphere measurements, including studies of airborne bio-aerosols, as well as remote LIBS measurements have been demonstrated [13.155, 156]. Clearly, eye-safety considerations are challenging here with laser light present at all wavelengths. LIDAR systems operating outside the human cornea transmission region 400–1400 nm are most convenient for more-general applications due to the greatly relaxed safety aspects.

LIDAR techniques and methods have also stimulated extensions into more unconventional fields, such as biology and medicine. Many LIDAR concepts can be scaled down to the cm level, where new medical diagnostics techniques are now emerging.

14. Quantum Optics

Quantum optics is the study of the quantum theory of light at low energies and interactions with bound electronic systems. We discuss physically achievable states of the electromagnetic field, including squeezed states and single photons states, as well as schemes by which they may be generated and measured. Measured systems are necessarily open systems and we discuss how dissipation, noise and decoherence is treated in quantum optics in terms of Markov master equations, quantum trajectories and quantum stochastic differential equations. Quantum optics has recently proved a valuable test-bed to implement new communication protocols such as teleportation and quantum information processing and we discus some of these new schemes including ion traps and linear optics quantum computing.

Part D | 14

14.1 Quantum Fields

Quantum optics is the study of the quantum theory of light at low energies. It is a special case of quantum electrodynamics (QED) for the electromagnetic field with frequencies ranging from microwave to ultraviolet and electrons bound in atomic systems. We consider first of all the free electromagnetic field described classically by the vector potential $A(x, t)$. As this obeys the wave equation it may be expanded in terms of plane wave states with two orthogonal transverse polarisations. If we assume the field is bound in a box of volume V, with Dirichlet boundary conditions, we find that

$$
\begin{aligned}
&A(x, t) \\
&= \sum_{n,\nu} \sqrt{\frac{\hbar}{2\epsilon_o \omega_n V}} \\
&\quad \times e_{n,\nu}\left(e^{i(k_n \cdot x - \omega_n t)}\alpha_{n,\nu} + e^{-i(k_n \cdot x - \omega_n t)}\alpha_{n,\nu}^*\right),
\end{aligned} \tag{14.1}
$$

where $e_{n,\nu}$ are two orthonormal polarisation vectors ($\nu = 1, 2$) which satisfy $k_n \cdot e_{n,\nu} = 0$, as required for a transverse field, and the frequency is given by the dispersion relation $\omega_n = c|k_n|$. The positive- and negative-frequency Fourier amplitudes are, respectively, $\alpha_{n,\nu}$ and $\alpha_{m,\nu}^*$. The corresponding electric field is given by

$$
\begin{aligned}
&E(x, t) \\
&= i \sum_{n,\nu} \sqrt{\frac{\hbar \omega_n}{2\epsilon_o V}} \\
&\quad \times e_{n,\nu}\left(e^{i(k_n \cdot x - \omega_n t)}\alpha_{n,\nu} - e^{-i(k_n \cdot x - \omega_n t)}\alpha_{n,\nu}^*\right). \tag{14.2}
\end{aligned}
$$

Canonical quantisation [14.1] is now carried out by promoting these Fourier amplitudes to the operators $\alpha_{n,\nu} \mapsto a_{n,\nu}$, $\alpha_{n,\nu}^* \mapsto a_{n,\nu}^\dagger$ with bosonic commutation relations

$$
[a_{n,\nu}, a_{n',\nu'}^\dagger] = \delta_{\nu\nu'}\delta_{nn'} \tag{14.3}
$$

with all other commutations relations zero (we are assuming Coulomb gauge quantisation). The canonical quantisation procedure then gives the Hamiltonian for the free field as

$$
H = \sum_k \hbar\omega_k a_k^\dagger a_k , \tag{14.4}
$$

where the subscript k stands for both the wave number index, n and polarisation index ν. We have explicitly omitted the constant shift due to the vacuum energy of $\hbar\omega_k/2$ per mode. Typically we now take the continuum limit by

$$\frac{1}{\sqrt{V}} \sum_k \mapsto \frac{1}{(2\pi)^{3/2}} \int \mathrm{d}^3 k\, a_\nu(\boldsymbol{k}) . \tag{14.5}$$

The canonical commutation relations then take the form

$$[a_\nu(\boldsymbol{k}), a_{\nu'}^\dagger(\boldsymbol{k}')] = \delta_{\nu\nu'} \delta^3(\boldsymbol{k}-\boldsymbol{k}') . \tag{14.6}$$

In the full theory of QED, the interaction between the electromagnetic field and charged matter is described by coupling between the vector potential and the Dirac spinor field. In quantum optics we only need the low-energy (nonrelativistic) limit of this interaction. This is given by the minimal coupling Hamiltonian [14.2]

$$H = \frac{1}{2m}(\boldsymbol{p} - e\boldsymbol{A})^2 + eV(\boldsymbol{x}) + H_{\mathrm{rad}} , \tag{14.7}$$

where $\boldsymbol{p}$ is the momentum operator for a particle of charge e moving in a Coulomb potential $V(\boldsymbol{x})$. The last term, H_{rad}, is the Hamiltonian of the free radiation field given in (14.4). We now use an occupation-number representation in the antisymmetric sector of the many body Hilbert space for the electronic system based on a set of single-particle states $|\phi_j\rangle$, with position probability amplitudes, $\phi_j(\boldsymbol{x})$, which we take as the bound energy eigenstates of the electronic system without radiation. They could for example be the stationary states of a atom, the quasi-bound states of a single Cooper pair on a mesoscopic superconducting metal island, or the bound exciton states of semiconductor quantum dot. We then define the electronic field operators

$$\hat{\psi}(\boldsymbol{x}) = \sum_j c_j \phi_j(\boldsymbol{x}) , \tag{14.8}$$

where the appropriate commutations relations for the antisymmetric sector are the fermionic forms

$$c_k c_l^\dagger + c_l c_k^\dagger = \delta_{kl} , \tag{14.9}$$

$$c_k c_l + c_l c_k = c_k^\dagger c_l^\dagger + c_l^\dagger c_k^\dagger = 0 . \tag{14.10}$$

In the occupation number representation the Hamiltonian may be written as the sum of three terms, $H = H_{\mathrm{el}} + H_{\mathrm{I}} + H_{\mathrm{rad}}$ where the electronic part is given by

$$H_{\mathrm{el}} = \int \mathrm{d}^3 x\, \hat{\psi}^\dagger(\boldsymbol{x}) \left[-\frac{\hbar^2}{2m}\nabla^2 + eV(\boldsymbol{x}) \right] \hat{\psi}(\boldsymbol{x})$$
$$= \sum_j E_j c_j^\dagger c_j . \tag{14.11}$$

The interaction part may be written as the sum of two terms $H_{\mathrm{I}} = H_{\mathrm{I},1} + H_{\mathrm{I},2}$, where

$$H_{\mathrm{I},1} = \int \mathrm{d}^3 x\, \hat{\psi}^\dagger(\boldsymbol{x})$$
$$\times \left\{ -\frac{e}{2m}[\boldsymbol{A}(\boldsymbol{x})\cdot\boldsymbol{p} + \boldsymbol{p}\cdot\boldsymbol{A}(\boldsymbol{x})] \right\} \hat{\psi}(\boldsymbol{x}) , \tag{14.12}$$

$$H_{\mathrm{I},2} = \int \mathrm{d}^3 x\, \hat{\psi}^\dagger(\boldsymbol{x}) \left\{ \frac{e^2}{2m}[\boldsymbol{A}(\boldsymbol{x})^2] \right\} \hat{\psi}(\boldsymbol{x}) . \tag{14.13}$$

Unless we are dealing with very intense fields for which multi-photon processes are important, the second term $H_{\mathrm{I},2}$ may be neglected.

The dominant interaction energy may then be written as

$$H_{\mathrm{I}} = \hbar \sum_{k,n,m} g_{k,n,m}(b_k + b_k^\dagger) c_n^\dagger c_m , \tag{14.14}$$

where the interaction coupling constant is

$$g_{k,n,m} = -\frac{e}{m} \left(\frac{1}{2\epsilon_0 \hbar\omega_k V} \right)^{1/2}$$
$$\times \int \mathrm{d}^3 x\, \phi_n^*(\boldsymbol{x})(\mathrm{e}^{\mathrm{i}\boldsymbol{k}.\boldsymbol{x}}\boldsymbol{p})\phi_m(\boldsymbol{x}) . \tag{14.15}$$

We now proceed by making the *dipole approximation*. The factor $\mathrm{e}^{\mathrm{i}\boldsymbol{k}x}$ varies on a spatial scale determined by the dominant wavelength scale, λ_0, of the field state. At optical frequencies, $\lambda_0 \approx 10^{-6}$ m. However the atomic wave functions, $\phi_n(\boldsymbol{x})$ vary on a scale determined by the Bohr radius, $a_0 \approx 10^{-11}$ m. Thus we may remove the oscillatory exponential from the integral and evaluate it at the position of the atom $\boldsymbol{x} = \boldsymbol{x}_0$. Using the result

$$[\boldsymbol{p}^2, \boldsymbol{x}] = -\mathrm{i}2\hbar\boldsymbol{p} \tag{14.16}$$

we can write the interaction in terms of the atomic dipole moments

$$\int \mathrm{d}^3 x\, \phi_n^*(\boldsymbol{x})(\mathrm{e}^{\mathrm{i}\boldsymbol{k}.\boldsymbol{x}}\boldsymbol{p})\phi_m(\boldsymbol{x})$$
$$= \mathrm{i}\frac{m}{e}\omega_{nm} \int \mathrm{d}^3 x\, \phi_n^*(\boldsymbol{x})(e\boldsymbol{x})\phi_m(\boldsymbol{x}) , \tag{14.17}$$

where $\omega_{nm} = (E_n - E_m)/\hbar$.

In the interaction picture the interaction Hamiltonian becomes explicitly time dependent,

$$\tilde{H}_{\mathrm{I}}(t) = \hbar \sum_{k,n,m} g_{k,n,m} \left(b_k \mathrm{e}^{-\mathrm{i}\omega(k)t} + b_k^\dagger \mathrm{e}^{\mathrm{i}\omega(k)t} \right)$$
$$\times c_n^\dagger c_m\, \mathrm{e}^{\mathrm{i}\omega_{nm}t} , \tag{14.18}$$

where the tilde indicates that we are in the interaction picture. If the field is in a state for which the dominant frequency is such that $\omega(\boldsymbol{k}_0) \approx \omega_{nm}$, the field is resonant with a particular atomic transition and we may neglect terms rotating at the very high frequency $\omega(\boldsymbol{k}) + \omega_{nm}$. This is known as the *rotating wave approximation*. This assumes that the field strength is not too large and further that the state of the field does not vary rapidly on a time scale of ω_{nm}^{-1}, i.e. we ignore fields of very fast strong pulses. As a special case we assume that the field is resonant (or near-resonant) with a single pair of levels with $E_2 > E_1$. The interaction picture Hamiltonian in the dipole and rotating wave approximation is then given by

$$\tilde{H}_{\mathrm{I}} = \hbar \sum_{\boldsymbol{k}} c_1^{\dagger} c_2 b_{\boldsymbol{k}}^{\dagger} g_{\boldsymbol{k}} \, \mathrm{e}^{-\mathrm{i}(\omega(\boldsymbol{k}) - \omega_{21})t} + \mathrm{h.c} \,, \qquad (14.19)$$

where

$$g_{\boldsymbol{k}} = -\mathrm{i} \, [2\hbar\epsilon_0 \omega(\boldsymbol{k})V]^{-1/2} \, \mu_{21} \, \mathrm{e}^{\mathrm{i}\boldsymbol{k}.\boldsymbol{x}_0} \qquad (14.20)$$

and

$$\mu_{21} = \omega_a \langle \phi_n | e\boldsymbol{x} | \phi_m \rangle \qquad (14.21)$$

with $\omega_a = \omega_2 - \omega_1$.

It is conventional to describe the operator algebra of a two-level system in terms of a peusdo-spin representation by noting that the Pauli operators may be defined as

$$\sigma_z = c_2^{\dagger} c_2 - c_1^{\dagger} c_1 \,, \qquad (14.22)$$

$$\sigma_x = c_2^{\dagger} c_1 + c_1^{\dagger} c_2 \,, \qquad (14.23)$$

$$\sigma_y = -\mathrm{i}\left(c_2^{\dagger} c_1 - c_1^{\dagger} c_2\right) \,, \qquad (14.24)$$

$$\sigma_+ = \sigma_-^{\dagger} = c_2^{\dagger} c_1 \,. \qquad (14.25)$$

The operators $s_\alpha = \sigma_\alpha/2$ (with $\alpha = x, y, z$) then obey the SU(2) algebra for a spin-half system. In terms of

these operators we may write the total Hamiltonian for the system of field plus atom in the dipole and rotating wave approximation as

$$H = \sum_{\boldsymbol{k}} \hbar\omega(\boldsymbol{k}) b_{\boldsymbol{k}}^{\dagger} b_{\boldsymbol{k}} + \frac{\hbar\omega_{\mathrm{a}}}{2} \sigma_z + \hbar \sum_{\boldsymbol{k}} g_{\boldsymbol{k}} b_{\boldsymbol{k}} \sigma_+ + \mathrm{h.c.}$$

$$(14.26)$$

If we further restrict the state of the field to include only a single mode, perhaps using a high-Q optical resonator, we arrive at the *Jaynes–Cummings* Hamiltonian,

$$H = \hbar\omega_0 b^{\dagger} b + \frac{\hbar\omega_a}{2} \sigma_z + \hbar\left(g b \sigma_+ + g^* b^{\dagger} \sigma_-\right) \qquad (14.27)$$

coupling a single harmonic oscillator degree of freedom to a two-level system, which might well be called the standard model of quantum optics [14.3]. The coupling constant g can vary from a few kHz to many MHz. This needs to be compared with the linewidth of the cavity mode, κ, as well as the spontaneous emission rate, γ, of the excited state both of which we have thus far neglected but will discuss in Sect. 14.4. If we can arrange for $g > \kappa, \gamma$ we are in the *strong coupling limit*. This is typically achieved by using very small cavity mode volumes. The resulting physical system is often referred to as *cavity QED*. An example is provided by the experiment of *Aoki* et al. [14.4] in which a cesium atom interacts with the toroidal whispering gallery mode of a micro-resonator as it falls under the action of gravity from a magneto-optical trap. The atomic resonance at is the $6\mathrm{S}_{1/2}$; $F = 4 \to 6\mathrm{P}_{3/2}$; $F' = 5$ transition in cesium. A coupling constant as large as $g/2\pi = 50\,\mathrm{Mz}$ was achieved. The corresponding cavity and atomic decay rates were $(\kappa, \gamma)/2\pi = (17.9 \pm 2.8, 2.6)\,\mathrm{MHz}$.

14.2 States of Light

The simplest state of light is the ground state, or vacuum state of the free-field Hamiltonian in (14.4) defined by the tensor product of all states $|0\rangle_k$ such that $a_k|0\rangle_k = 0$. The excited states of the free field are the photon number states defined by the tensor product $|\boldsymbol{n}\rangle = \Pi_k |n_k\rangle_k$ where n_k is the kth component of $\boldsymbol{n}$ and

$$a_k^{\dagger} a_k |\boldsymbol{n}\rangle = n_k |\boldsymbol{n}\rangle \,. \qquad (14.28)$$

These states are defined in terms of the plane-wave expansion of the free field in (14.1) and are thus very delocalised. We can of course expand the field in a completely different set of spatiotemporal modes and define

photon-number states accordingly. The physical interpretation of the number states depends on what mode expansion we are using.

The interaction Hamiltonian for the classical electromagnetic field coupled to a classical current four-density $j^{\mu}(\boldsymbol{x}, t)$ is

$$H_{\mathrm{c}} = \int \mathrm{d}^3\boldsymbol{x} \, e A_\mu(\boldsymbol{x}, t) j^{\mu}(\boldsymbol{x}, t) \,. \qquad (14.29)$$

In quantum optics this may be approximated by treating the current as classical and using the quantised form of the vector potential. The resulting interaction

Hamiltonian takes the form

$$\tilde{H}_I(t) = i\hbar \sum_k \left(E_k^*(t) a_k e^{-i\omega(k)t} - E_k(t) a_k^\dagger e^{i\omega(k)t} \right) .$$

(14.30)

If the source is a monochromatic plane wave at frequency $\omega_0 = c|k|$ we can write this as

$$\tilde{H}_I(t) = i\hbar(\epsilon a^\dagger - \epsilon^* a) ,$$

(14.31)

where $a = a_{k_0}$. If the free field starts in the vacuum state at $t = 0$, the state at a later time is a vacuum state for all modes $k \neq k_0$ and for mode k_0, the state is

$$|\psi(t)\rangle = \exp[t(\epsilon a^\dagger - \epsilon^* a)]|0\rangle .$$

(14.32)

Expanding the exponential and we see that this state may be written in the number state basis as

$$|\psi(t)\rangle = e^{-|\epsilon t|^2/2} \sum_{n=0}^{\infty} \frac{(\epsilon t)^n}{\sqrt{n!}} |n\rangle_{k_0} .$$

(14.33)

We are thus led to define the *coherent states* of a single mode of the field as

$$|\alpha\rangle = D(\alpha)|0\rangle ,$$

(14.34)

where we have defined the *displacement operator*

$$D(\alpha) = e^{\alpha a^\dagger - \alpha^* a}$$

(14.35)

the name of which is derived from the result

$$D^\dagger(\alpha) a D(\alpha) = a + \alpha .$$

(14.36)

Using this last result it is easy to see that $a|\alpha\rangle = \alpha|\alpha\rangle$.

Consider the field operator evaluated for convenience at $x = 0$ and for now ignore the polarisation degree of freedom. We can express this in terms of sine and cosine amplitudes at a carrier frequency ω_c as

$$A(t) = A_1(t)\cos(\omega_c t) - A_2(t)\sin(\omega_c 0 t) ,$$

(14.37)

where in the interaction picture

$$A_1(t) = \frac{1}{2} \sum_k \sqrt{\frac{\hbar}{2\epsilon_0 \omega_k V}}$$
$$\times \left[a_k(t) e^{-i(\omega_k - \omega_c)t} + a_k^\dagger(t) e^{i(\omega_k - \omega_c)t} \right] ,$$

(14.38)

$$A_2(t) = \frac{-i}{2} \sum_k \sqrt{\frac{\hbar}{2\epsilon_0 \omega_k V}}$$
$$\times \left[a_k(t) e^{-i(\omega_k - \omega_c)t} - a_k^\dagger(t) e^{i(\omega_k - \omega_c)t} \right] .$$

(14.39)

We are thus led to define the *quadrature phase operators* for each mode of the field as

$$X = (a + a^\dagger) ,$$

(14.40)

$$Y = -i(a - a^\dagger) .$$

(14.41)

These operators have the commutation relation $[X, Y] = 2i$, which is isomorphic to the Heisenberg–Weyl algebra of canonical position and momentum operators and so there is an equivalent uncertainty principle, $\Delta X \Delta Y \geq 1$, where $(\Delta A)^2 \equiv \langle A^2 \rangle - \langle A \rangle^2$. States that satisfy the lower bound in this relation are called minimum-uncertainty states. The vacuum state and coherent state are minimum-uncertainty states with $\Delta X = \Delta Y$. Minimum-uncertainty states for which the quadrature phase operator uncertainties are not equal are called *squeezed states*.

Single-mode squeezed states are generated from the vacuum state by a unitary transformation defined by

$$S^\dagger(\xi)(\tilde{X} + i\tilde{Y})S(\xi) = \tilde{X} e^r + i\tilde{Y} e^{-r} ,$$

(14.42)

where $\tilde{X} + i\tilde{Y} = (X + iY)e^{-i\phi}$. Thus the canonical pair $(\tilde{X}, \tilde{Y})$ are related by a rotation to the original canonical pair (X, Y). Clearly the uncertainty in the rotated canonical coordinates are $\Delta \tilde{X} = e^r$, $\Delta \tilde{Y} = e^{-r}$. The squeezed vacuum state is then defined as $|0, \xi\rangle = S(\xi)|0\rangle$, where

$$S(\xi) = \exp \left[\frac{1}{2}(\xi(a^\dagger)^2 - \xi^* a^2) \right] ,$$

(14.43)

where $\xi = r e^{2i\phi}$. The corresponding transformation of the complex amplitude operators is

$$S^\dagger(\xi) a S(\xi) = a \cosh r + a^\dagger e^{2i\phi} \sinh r .$$

(14.44)

We may then add a coherent amplitude by displacing the squeezed vacuum state $|\alpha, \xi\rangle = D(\alpha)|0, r\rangle$.

Of more interest are the two-mode squeezed vacuum states which correlate two modes, a and b, of the field through a generalisation of (14.44),

$$S_2^\dagger(\xi) a S_2(\xi) = a \cosh r + b^\dagger e^{2i\phi} \sinh r ,$$

(14.45)

$$S_2^\dagger(\xi) b S_2(\xi) = b \cosh r + a^\dagger e^{2i\phi} \sinh r ,$$

(14.46)

where $S_2(\xi) = \exp[(\xi a^\dagger b^\dagger - \xi^* ab)]$. The two-mode squeezed vacuum state is then defined as

$$|\mathcal{E}\rangle_{ab} = \exp[(\xi a^\dagger b^\dagger - \xi^* ab)]|0\rangle_a \otimes |0\rangle_b .$$

(14.47)

The two-mode squeezed state is an entangled state of two modes of an optical field. To see this we note that, for $\xi = r$, a real number, the expansion in number eigenstate basis for each oscillator is

$$|\mathcal{E}\rangle 2_{ab} = \sqrt{(1 - \lambda^2)} \sum_{n=0}^{\infty} \lambda^n |n\rangle_a \otimes |n\rangle_b ,$$

(14.48)

where $\lambda = \tanh r$ and $a^\dagger a |n\rangle_a = n|n\rangle_a$ and $b^\dagger b |n\rangle_b = n|n\rangle_b$.

The entanglement of this state can be viewed in two ways. Firstly as an entanglement between pairs of canonically conjugate physical quantities with a continuous spectrum, the quadrature phases, and secondly as an entanglement between number and phase. We will only discuss the former case here (see [14.5] for the latter case). We can easily show that this state approximates the entangled state first considered by Einstein, Podolsky and Rosen (an EPR state) in the limit $\lambda \to 1$ or $r \to \infty$. The correlation between quadrature phase in each mode is easily seen by calculating the variances in an appropriate set of joint observables. We first define the quadrature phase operators for the two modes

$$\hat{X}_a = a + a^\dagger , \tag{14.49}$$

$$\hat{Y}_a = -i(a - a^\dagger) , \tag{14.50}$$

$$\hat{X}_b = b + b^\dagger , \tag{14.51}$$

$$\hat{Y}_b = -i(b - b^\dagger) , \tag{14.52}$$

with canonical commutation relations, $[\hat{X}_\nu, \hat{Y}_\mu] = 2i\delta_{\nu,\mu}$. Then

$$\mathrm{Var}(\hat{X}_a - \hat{X}_b) = 2\,e^{-2r} \tag{14.53}$$

$$\mathrm{Var}(\hat{Y}_a + \hat{Y}_b) = 2\,e^{-2r} \tag{14.54}$$

where $\mathrm{Var}(A) = \langle A^2 \rangle - \langle A \rangle^2$ is the variance. Thus in the limit of $r \to \infty$ the state $|\mathcal{E}\rangle$ approaches a simultaneous eigenstate of $\hat{X}_a - \hat{X}_b$ and $\hat{Y}_a + \hat{Y}_b$. This is the analogue of the EPR state with position replaced by the real quadratures $\hat{X}$ and the momentum replaced by the imaginary quadratures, $\hat{Y}$.

The very strong correlations between the quadrature phase operators for the squeezed state can be seen in the diagonal basis of $\hat{X}_a, \hat{X}_b$

$$\begin{aligned}
\mathcal{E}(x_a, x_b) &= \langle x_a, x_b | \mathcal{E} \rangle \\
&= (2\pi)^{-1/2} \\
&\quad \exp\left[-\frac{e^{2r}}{8}(x_a - x_b)^2 - \frac{e^{-2r}}{8}(x_a + x_b)^2 \right]
\end{aligned} \tag{14.55}$$

with $\hat{X}_\alpha |x_\alpha\rangle_\alpha = x_\alpha |x_\alpha\rangle_\alpha$ and $|x, y\rangle = |x\rangle_a \otimes |y\rangle_b$ and where $\alpha \to a, b$.

We now turn to multimode states of the field to describe more-complex states. To this end we assume that the only modes that are excited have the same plane polarisation and are all propagating in the in same direction, which we take to be the x-direction. All other

modes are in the vacuum state. The positive-frequency components of the electric field for these modes are then

$$E^{(+)}(x, t) = i \sum_{n=0}^{\infty} \left(\frac{\hbar\omega_n}{2\epsilon_0 V} \right)^{1/2} a_n\, e^{-i\omega_n(t - x/c)} . \tag{14.56}$$

In ignoring all the other modes, we are implicitly assuming that all our measurements do not respond to the vacuum state, an assumption which is justified below. Let us further assume that all excited modes of this form have frequencies centred on the *carrier frequency* of $\Omega \gg 1$. Then we can approximate the positive-frequency components by

$$E^{(+)}(x, t) = i \left(\frac{\hbar\Omega_n}{2\epsilon_0 Ac} \right)^{1/2} \sqrt{\frac{c}{L}} \sum_{n=0}^{\infty} a_n\, e^{-i\omega_n(t - x/c)} , \tag{14.57}$$

where A is a characteristic transverse area. This operator has dimensions of electric field. In order to simplify the dimensions we now define a field operator that has dimensions of $\mathrm{s}^{-1/2}$. Taking the continuum limit we thus define the positive-frequency operator

$$a(x, t) = e^{-i\Omega(t - x/c)} \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} d\omega'\, a(\omega')\, e^{-i\omega'(t - x/c)} , \tag{14.58}$$

where we have made a change of variable $\omega \mapsto \Omega + \omega'$ and used the fact that $\Omega \gg 1$ to set the lower limit of integration to minus infinity, and

$$\left[a(\omega_1), a^\dagger(\omega_2) \right] = \delta(\omega_1 - \omega_2) . \tag{14.59}$$

In this form the moment $n(x, t) = \langle a^\dagger(x, t)a(x, t) \rangle$ has units of s^{-1}. As we show in the next section this moment determines the probability per unit time (the count rate) to count a photon at the space–time point (x, t). The field operators $a(t)$ and $a^\dagger(t)$ can be taken to describe the field emitted from the end of an optical cavity, which selects the directionality.

A multimode coherent state is defined by a multimode displacement operator acting on the vacuum $D|0\rangle$, defined implicitly by

$$D^\dagger a(\omega)D = a(\omega) + \alpha(\omega) , \tag{14.60}$$

where consistent with proceeding assumptions, $\alpha(\omega)$ is peaked at $\omega = 0$, which corresponds to a carrier frequency $\Omega \gg 1$. The average field amplitude for this state

is

$$\langle a(x, t)\rangle = e^{-i\Omega(t-x/c)}\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{\infty}\alpha(\omega)e^{-i\omega(t-x/c)}$$

$$\equiv \alpha(x, t)e^{-i\Omega(t-x/c)} \qquad (14.61)$$

which implicitly defines the average complex amplitude of the field as the Fourier transform of the frequency-dependent displacements $\alpha(\omega)$. We can also calculate the probability per unit time to detect a photon in this state at space-time point (x, t). This is given by $n(x, t) = |\alpha(x, t)|^2$. Note that in this case the second-order moment $\langle a^\dagger(x, t)a(x, t)\rangle$ factorises, a result characteristic of fields with first-order coherence. A coherent state is closest to our intuitive idea of a classical electromagnetic field.

The multimode single-photon state is defined by

$$|1\rangle = \int\limits_{-\infty}^{\infty}\nu(\omega)a^\dagger(\omega)|0\rangle . \qquad (14.62)$$

This state has zero average field amplitude but $n(x, t) = |\nu(t-x/c)|^2$, where $\nu(t)$ is the Fourier transform of $\nu(\omega)$. So while the state has zero average field amplitude there is apparently some sense in which the coherence implicit in the superposition of (14.62) is manifest. We discuss in the next section how this coherence is made explicit through fourth-order interference. For this state the function $\nu(\phi)$ is periodic in the phase $\phi = t - x/c$ and it is not difficult to choose a form with a well-defined pulse sequence. However care should be exercised in interpreting these pulses. They do not represent a sequence of pulses each with one photon, rather they represent a single photon coherently superposed over all pulses. Once a photon is counted in a particular pulse, the field is returned to the vacuum state. A single-photon state is a highly nonclassical state with applications to quantum information processing. A review of current efforts to produce such a state may be found in [14.6].

An important example of a multimode two-photon state is

$$|2\rangle_{ab} = \int\limits_{-\infty}^{\infty}d\omega_1\int\limits_{-\infty}^{\infty}d\omega_2\alpha(\omega_1, \omega_2)a^\dagger(\omega_1)b^\dagger(\omega_2)|0\rangle_{ab} ,$$
$$(14.63)$$

where a and b are two distinguishable spatial or polarisation modes. This state is important in the theory of spontaneous parametric down conversion in which a pump photon at frequency 2Ω is absorbed and simultaneously two photons in each of the modes a and b are produced with frequencies ω_1 and ω_2, respectively, such that $\omega_1 + \omega_2 = 2\Omega$, the condition for energy conservation. A good approximation to the state produced can be written as $|0\rangle + \kappa|2\rangle_{ab}$ where κ is related to the down-conversion efficiency [14.7]. As we have shifted all frequencies by the carrier frequency Ω, we can impose energy conservation as $\omega_1 + \omega_2 = 0$, and choose

$$\alpha(\omega_1, \omega_2) = \alpha(\omega_1)\delta(\omega_1 + \omega_2) . \qquad (14.64)$$

In other words photons in the symmetric side bands around the frequency of Ω are correlated. Normalisation of the state in (14.63) requires

$$\int\limits_{-\infty}^{\infty}d\omega|\alpha(\omega)|^2 = 1 . \qquad (14.65)$$

If we ask for the probability per unit time to count a photon from either mode a or b independently it is easily seen to be a constant in time indicating that we will count a photon in either beam at completely random times. However if we count the coincidence correlation rate $C(t, t') = \langle a^\dagger(t)a(t)b^\dagger(t')b(t')\rangle$ we find

$$C(t, t') = |\alpha(t - t')|^2 , \qquad (14.66)$$

where $\alpha(t)$ is the Fourier transform of $\alpha(\omega)$. The quantum coherence implicit in the correlations of (14.63) appear as a two-photon correlation with a maximum for coincidence counting. To put it another way, the two photon correlation is a *fourth-order interference* effect as C depends on a fourth-order moment of the field amplitude operators.

14.3 Measurement

At optical frequencies, all measurements ultimately derive from how the field interacts with matter, and it is some property of the material which is ultimately measured.

ured. For example if the field is directed to a particular kinds of semiconductor material free carriers can be produced, either as electrons or holes, each refereed

to as a photoexcitation event. The resulting charge or current flow may then be amplified to produce a measurable electrical signal which is entirely classical and stochastic. There are two special cases. Firstly if we use light of such low intensity that individual photoexcitation events result in a distinct signal pulse. These pulses can then be counted and different counts recorded per count interval. The statistics of this counting process is ultimately conditioned on the photon-number distribution for the quantum state of the incident light. Secondly we may have light of a higher intensity so that individual counting events cannot be resolved. The classical measurement signal is then a fluctuating current. The noise power spectrum of this current is still conditioned on the quantum state of the input light. This last case occurs if a weak signal is first mixed with a strong coherent light beam by a beam splitter and then the reflected and transmitted beams individually give rise to distinct photocurrents on separate detectors. The strong coherent beam is usually called a *local oscillator*. The interference between the signal and local oscillator enables a phase-sensitive measurement of the field to be made. If it is resonant with the carrier frequency, the photocurrent has a direct current (DC) average signal and we refer to the process as homodyne detection. If the local oscillator is detuned from the signal the photocurrents acquire an alternating current (AC) frequency component equal to the detuning between the local oscillator and the signal carrier frequency. This is called heterodyne detection. We now show how these various classical stochastic signals are conditioned on different field quantities.

14.3.1 Photon Counting

If we assume that the interaction between the detector and signal field is weak, the probability of photoexcitation event per unit time may be calculated from the interaction Hamiltonian and Fermi's golden rule. Typically the interaction Hamiltonian, in the interaction picture takes the form of a dipole interaction in the rotating wave approximation

$$\tilde{H}_I = \hbar\chi(E^{(+)}(\boldsymbol{x}, t)\sigma_+(t) + E^{(-)}(\boldsymbol{x}, t)\sigma_-(t)) ,$$
(14.67)

where g is a typical coupling constant, $E^{(\pm)}(\boldsymbol{x}, t)$ are the positive- and negative-frequency components of the field at space time point $(\boldsymbol{x}, t)$, while $\sigma_\pm(t)$ are the dipole transition operators. We assume the dipole starts in the ground state $|g\rangle$ defined by $\sigma_-|g\rangle = 0$. The probability that the dipole, located at $\boldsymbol{x}$ is excited per unit time, i.e.

the rate of excitation is given by perturbation theory (to second order in χ) [14.8] as

$$p_e(\boldsymbol{x}, t) \propto \langle E^{(-)}(\boldsymbol{x}, t)E^{(+)}(\boldsymbol{x}, t)\rangle .$$
(14.68)

Insofar as an excitation event results in a classical signal, the probability to detect a photon per unit time is then simply,

$$p_1(t) = \gamma\langle E^{(-)}(t)E^{(+)}(t)\rangle ,$$
(14.69)

where $\gamma \propto \chi^2$ and the other factors that depend on the details of the detector (such as area and spectral sensitivity) and its ability to respond to a photoexcitation event with a detectable signal. The counting process is thus seen to be a classical stochastic random variables $dN(t)$ which only takes the values 0, 1 in a sufficiently small time interval dt. This is a Poisson point process. The classical average of this process is $\mathcal{E}[dN(t)] = p_1(t)$. If we now consider a count interval of duration T, the probability to count n photoexcitation events in that time is [14.9]

$$p_n(T) = \left\langle : \frac{[\gamma\bar{I}(T)T]^n}{n!} \exp[-\gamma\bar{I}(T)T] : \right\rangle ,$$
(14.70)

where the operator $\bar{I}$ is defined by

$$\bar{I}(T) = \frac{1}{T}\int_0^T E^{(-)}(t)E^{(+)}(t)\,dt ,$$
(14.71)

where $: \ldots :$ indicates normal ordering, that is the power-series expansion is done by ordering all the negative-frequency components to the right of the positive-frequency components.

If the count rate is too large to resolve individual counting events, we need to consider a photocurrent. We then define the current as

$$i(t) = e\frac{dn(t)}{dt} ,$$
(14.72)

where $n(t) = \sum_{n=0}^{\infty} np_n(t)$ is the average number of counts in time t. In terms of the point process $dN(t, n(t)) = \int_0^t dN(t)$ so that the ensemble average of $i(t)$ is the average current

$$\overline{i(t)} = e\frac{d\mathcal{E}(n(t))}{dt} = \gamma\langle E^{(-)}(t)E^{(+)}(t)\rangle .$$
(14.73)

The stationary two-time correlation function of the current is then the classical ensemble average,

$$G(\tau) = \lim_{t\to\infty} \mathcal{E}[i(t+\tau)i(t)] - \mathcal{E}[i(t+\tau)]\mathcal{E}[i(t)] .$$
(14.74)

If we first consider the case $\tau > 0$, then we need to find $\mathcal{E}[\,dN(t+\tau)\,dN(t)]$. The only way this can be nonzero is for $dN(t) = 1$ at time t. Thus we need the conditional average

$$
\begin{aligned}
\mathcal{E}[\,dN(t+\tau)\,dN(t)] &= \mathrm{Prob}[\,dN(t) = 1] \\
&\quad \times \mathcal{E}[\,dN(t+\tau)|_{dN(t)=1}]\,.
\end{aligned}
\tag{14.75}
$$

The details may be fund in [14.10] The two-time correlation function is then seen to be

$$
\begin{aligned}
G(\tau) &= e\bar{i}\delta(\tau) + \lim_{t\to\infty} e^2\gamma^2\langle E^{(-)}(t)E^{(-)}(t+\tau) \\
&\quad \times E^{(+)}(t+\tau)E^{(+)}(t)\rangle\,.
\end{aligned}
\tag{14.76}
$$

The noise power spectrum is then defined by

$$
S(\omega) = 2 \int_{-\infty}^{\infty} d\tau\, G(\tau) e^{-i\omega\tau}\,.
\tag{14.77}
$$

In the previous section we considered a special case in which almost all field modes were taken in the vacuum state except those propagating in the positive x-direction which could for example describe the directional emission from an optical cavity. We may write the average current and $G(\tau)$ in terms of the field operators $a(t)$ and $a^\dagger(t)$ defined in (14.58)

$$
\overline{i(t)} = e\gamma\langle a^\dagger(t)a(t)\rangle\,,
\tag{14.78}
$$

$$
\begin{aligned}
G(\tau) &= e\bar{i}\delta(\tau) + \lim_{t\to\infty} e^2\gamma^2 \\
&\quad \times \langle a^\dagger(t)a^\dagger(t+\tau)a(t+\tau)a(t)\rangle\,.
\end{aligned}
\tag{14.79}
$$

The delta-correlated term in $G(\tau)$ represents the shot-noise component of the photocurrent.

14.3.2 Homo–/Heterodyne Detection

We now deal exclusively with the positive and negative field operators $a(t)$ and $a^\dagger(t)$ appropriate for directional emission from a cavity. Consider two spatially distinct field modes, $a_i(t)$ and $b_i(t)$, directed onto opposite sides of a dielectric interface, so that each field is partially transmitted and partially reflected. The interaction with the beam splitter is described by an effective unitary scattering process that couples the two input fields to two output fields, $a_o(t)$ and $b_o(t)$, as

$$
\begin{pmatrix} a_o(t) \\ b_o(t) \end{pmatrix} = U^\dagger(\theta, \phi) \begin{pmatrix} a_i(t) \\ b_i(t) \end{pmatrix} U(\theta, \phi)\,,
\tag{14.80}
$$

$$
= \begin{pmatrix} a_i(t)\cos\theta + b_i(t)e^{i\phi}\sin\theta \\ b_i(t)\cos\theta - a_i(t)e^{-i\phi}\sin\theta \end{pmatrix}\,.
\tag{14.81}
$$

The commutation relation for the output fields are the same as the input fields. Suppose now that the field $b(t)$ is prepared in a coherent state, so that we may simply replace $b(t) \mapsto \beta(t)$. We will further assume that $|\beta(t)|^2 \to \infty$ and that $\sin\theta \to 0$ such that $|\beta(t)|^2 \sin^2\theta \equiv |\alpha(t)|^2 \gg 1$ is a finite average photon flux. The probability to detect a photon per unit time in the output field $a_0(t)$ is then given by

$$
n(t) = \gamma\langle[a_i^\dagger(t) + \alpha^*(t)][a_i(t) + \alpha(t)]\rangle\,.
\tag{14.82}
$$

As the coherent component is assumed to be large, we are in the limit of a photocurrent detection scheme. Let us now define a classical stochastic process by subtracting off the background current and normalising by the coherent flux,

$$
h(t)\,dt = \frac{dN(t) - \gamma|\alpha(t)|^2\,dt}{\gamma|\alpha(t)|^2}\,.
\tag{14.83}
$$

The ensemble average of the classical current process $h(t)$ is then well approximated by

$$
\mathcal{E}[h(t)] = \langle a(t)e^{i(\theta+\omega_{\mathrm{LO}}t)} + a^\dagger(t)e^{-i(\theta+\omega_{\mathrm{LO}}t)}\rangle
\tag{14.84}
$$

where we have assumed that $\alpha(t) = |\alpha(t)|\exp[-i(\phi + \omega_{\mathrm{LO}}t)]$ and ω_{LO} is called the *local oscillator* frequency. We may write this average current in terms of the quadrature phase amplitudes defined with respect to the local oscillator carrier frequency and its phase

$$
\mathcal{E}[h(t)] = \langle X_\theta(t)\rangle\cos(\Delta t) + \langle Y_\theta(t)\rangle\sin(\Delta t)\,,
\tag{14.85}
$$

where we have defined the quadrature phase operators

$$
X_\theta(t) = a(t)e^{i(\theta+\omega_s t)} + a^\dagger(t)e^{-i(\theta+\omega_s t)}
\tag{14.86}
$$

$$
Y_\theta(t) = -i(a(t)e^{i(\theta+\omega_s t)} - a^\dagger(t)e^{-i(\theta+\omega_s t)})
\tag{14.87}
$$

where we have anticipated that the signal field has a carrier frequency of ω_s and we have defined $\Delta = \omega_{\mathrm{LO}} - \omega_s$, which is typically a radio frequency. It is then apparent that the in-phase signal at frequency Δ is a measurement of the average quadrature phase amplitude, $\langle X_\theta(t)\rangle$, while the quadrature phase signal is a measurement of the complementary quadrature phase amplitude $\langle Y_\theta(t)\rangle$. Such a measurement is know as the *heterodyne* measurement. If we choose $\Delta = 0$, so that we are monitoring a DC signal, we have the case of *homodyne* measure-

ment [14.11]. The higher-order moments of the current also reveal corresponding higher-order moments of the signal-field quadrature phase amplitudes. For example, The stationary second-order correlation function of the homodyne ($\Delta = 0$) current $h(t)$ is easily seen to be given by the normally ordered correlation function of the quadrature phase operator:

$$G(\tau) = \lim_{t \to \infty} \langle : X_\theta(t), X_\theta(t+\tau) : \rangle . \tag{14.88}$$

The spectrum of this quantity is called the *spectrum of squeezing* as it can only fall below zero if the signal is in a squeezed state [14.12].

14.4 Dissipation and Noise

The interaction between a single mode of an intracavity field and the many modes external to the cavity can be modelled in terms of a local harmonic oscillator coupled to an environment of many harmonic oscillators [14.13, 14] Fig. 14.1. This model is valid when the cavity finesse is large, so that the line width of each cavity resonance is much less than the resonance frequency, and we can separate the total field into local discrete quasi-modes internal to the cavity and many modes outside. This is equivalent to a weak interaction between the cavity quasi-modes and the external field. We can then use second-order perturbation theory and, assuming the external field can be treated as a heat bath at temperature T, we can find a master equation for the dynamics of the density operator for the intracavity field in the Schrödinger picture as

$$\frac{d\rho}{dt} = -\frac{i}{\hbar}[H, \rho(t)]$$
$$+ \kappa(\bar{n}+1)\mathcal{D}[a]\rho(t) + \kappa\bar{n}\mathcal{D}[a^\dagger]\rho(t) , \tag{14.89}$$

where we have defined the action of the super-operator for any operator A as

$$\mathcal{D}[A]\rho = A\rho A^\dagger - \frac{1}{2}(A^\dagger A\rho + \rho A^\dagger A) \tag{14.90}$$

and H is the Hamiltonian for the cavity mode plus any interactions with matter that may be present and $\bar{n}$ is the mean photon number in an external mode at frequency $\omega = \omega_c$ at temperature T. For an empty cavity $H = \hbar\omega_c a^\dagger a$. The average intracavity field amplitude and photon number obey the equations

$$\frac{d\langle a \rangle}{dt} = -i\omega\langle a \rangle + \frac{\kappa}{2}\langle a \rangle , \tag{14.91}$$

$$\frac{d\langle a^\dagger a \rangle}{dt} = -\kappa\langle a^\dagger a \rangle + \kappa\bar{n} . \tag{14.92}$$

The solutions for which are

$$\langle a \rangle(t) = \langle a \rangle(0) e^{-(\kappa/2 + i\omega_c)t} , \tag{14.93}$$

$$\langle a^\dagger a \rangle(t) = \langle a^\dagger a \rangle(0) + \bar{n}(1 - e^{-\kappa t}) . \tag{14.94}$$

Fig. 14.1 An optical cavity with a single output mirror. The cavity is weakly coupled to many external modes, but a particular class of directional input/output modes are defined by the cavity, indicated as $a_i(t)$, $a_o(t)$. The cavity quasi-mode has a field amplitude operator $a(t)$, while γ is the rate at which photons are lost through the end mirror

Taking the Fourier transform of the first of these equations we see that the cavity field amplitude has a Lorentzian spectrum centred at the cavity resonance frequency and with a linewidth of κ. The second equation indicates that in the steady state, while the mean field is zero, the mean photon number in the cavity is the same as the thermal photon number in the environmental mode at the cavity resonance. In fact is is easy to see that in the steady state, the field in the cavity is in the thermal state given by

$$\rho_\infty = \frac{1}{1+\bar{n}} \sum_{n=0}^{\infty} \left(\frac{\bar{n}}{1+\bar{n}}\right)^n |n\rangle\langle n| . \tag{14.95}$$

In the input/output theory of *Gardiner* [14.13], the external field modes are related to the internal mode through the boundary condition

$$a_0(t) = \sqrt{\gamma}a(t) - a_i(t) . \tag{14.96}$$

Note that while $a_{i,o}(t)$ are explicitly many-mode fields, the internal quasi-mode $a(t)$ is represented by a single harmonic-oscillator degree of freedom with frequency ω_c. In an alternative, but equivalent, formulation to the master equation we can represent the dynamics in the Heisenberg picture by a *quantum stochastic differential*

equation

$$\frac{\mathrm{d}a(t)}{\mathrm{d}t} = -\frac{\mathrm{i}}{\hbar}[H_S, a(t)] - \frac{\gamma}{2}a(t) + \sqrt{\gamma}a_{\mathrm{i}}(t) . \quad (14.97)$$

In this formulation, the external field input to the cavity plays the role of a quantum noise term. If these equations are linear,

$$\frac{\mathrm{d}\boldsymbol{a}}{\mathrm{d}t} = A\boldsymbol{a} - \frac{\gamma}{2}\boldsymbol{a} + \sqrt{\gamma}\boldsymbol{a}_{\mathrm{i}}(t) , \quad (14.98)$$

where

$$\boldsymbol{a}(t) = \begin{pmatrix} a(t) \\ a^\dagger(t) \end{pmatrix} , \quad (14.99)$$

$$\boldsymbol{a}_{\mathrm{i,o}}(t) = \begin{pmatrix} a_{\mathrm{i,o}}(t) \\ a_{\mathrm{i,o}}^\dagger(t) \end{pmatrix} . \quad (14.100)$$

We can Fourier transform both sides and ignore initial-value terms, as we are primarily interested in the stationary statistics to obtain a linear system of algebraic equations for the frequency components of the various fields. Combining this with (14.96) we find that

$$\boldsymbol{a}_0(\omega) = -\left[A + \left(\mathrm{i}\omega + \frac{\gamma}{2}\right)I\right]$$
$$\times \left[A + \left(\mathrm{i}\omega - \frac{\gamma}{2}\right)I\right]^{-1}\boldsymbol{a}_{\mathrm{i}}(\omega) . \quad (14.101)$$

In the case of an empty cavity we get an interaction picture defined with respect to some carrier frequency ω_{i} for the input external field,

$$a_{\mathrm{o}}(\omega) = \frac{\frac{\gamma}{2} + \mathrm{i}(\omega - \delta)}{\frac{\gamma}{2} - \mathrm{i}(\omega - \delta)}a_{\mathrm{i}}(\omega) , \quad (14.102)$$

where $\delta = \omega_{\mathrm{c}} - \omega_{\mathrm{i}}$. In other words there is simply a frequency-dependent phase shift of each field mode from input to output. Suppose we input a single-photon state defined by

$$|\psi\rangle_{\mathrm{i}} = \int\limits_{-\infty}^{\infty} v(\omega)a_{\mathrm{i}}^\dagger(\omega)|0\rangle . \quad (14.103)$$

After interacting with the cavity this state is transformed to

$$|\psi\rangle_{\mathrm{o}} = \int\limits_{-\infty}^{\infty} v(\omega)a_{\mathrm{o}}^\dagger(\omega)|0\rangle . \quad (14.104)$$

It is then easy to see that the probability per unit time to detect a single photon in the output field is

$$n(t) = \left| \int\limits_{-\infty}^{\infty} \mathrm{d}\omega \left(\frac{\frac{\gamma}{2} + \mathrm{i}(\omega - \delta)}{\frac{\gamma}{2} - \mathrm{i}(\omega - \delta)}\right) v(\omega)\mathrm{e}^{-\mathrm{i}\omega t} \right|^2 , \quad (14.105)$$

which is a delayed and broadened pulse.

If the quantum Langevin equations are nonlinear the standard procedure is to first find the semiclassical steady states. The semiclassical equations result by ignoring the noise and replacing the creation and annihilation operators by complex numbers, $a \mapsto \alpha$, $a^\dagger \mapsto \alpha^*$. If the steady state, (α_0, α_0^*) is stable fixed point, we write $a = \delta a + \alpha_0$, $a^\dagger = \delta a^\dagger + \alpha_0^*$. The dynamics is then expanded to linear order in δa and $\delta a^\dagger$ and then we proceed as above. An example of this approach is given in [14.15].

Spontaneous emission can also be treated using a master equation. In this case the system is a two-level electronic system, with ground state $|g\rangle$ of energy $\hbar\omega_1$ and excited state $|e\rangle$ with energy $\hbar\omega_2$, representing an electric dipole transition, coupled to the many modes of the radiation field in the dipole and rotating wave approximation. The master equation is

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} = -\frac{\mathrm{i}}{\hbar}[H, \rho] + \gamma(\bar{n}+1)\mathcal{D}[\sigma_-]\rho + \gamma\bar{n}\mathcal{D}[\sigma_+]\rho , \quad (14.106)$$

where $\bar{n}$ is the thermal occupation of the radiation field mode at the atomic resonance frequency $\omega_a = \omega_2 - \omega_1$. We have neglected a small term which gives rise to a shift in the atomic transition frequency and which contributes to the Lamb shift. At optical frequencies, $\bar{n} \approx 0$. In the case of a free two-level atom, $H = \frac{\hbar\omega_a}{2}\sigma_z$ the probability to find the atom in the excited state, $p_{\mathrm{e}}(t) = \langle e|\rho|e\rangle$ satisfies the equation

$$\frac{\mathrm{d}p_{\mathrm{e}}}{\mathrm{d}t} = -\gamma p_{\mathrm{e}}(t) \quad (14.107)$$

with the solution $p_{\mathrm{e}}(t) = p_{\mathrm{e}}(0)\mathrm{e}^{-\gamma t}$, which describes spontaneous emission. The dipole polarisation is proportional to the atomic coherence, $\langle e|\rho|g\rangle = \langle\sigma_-\rangle$, which obeys

$$\frac{\mathrm{d}\langle\sigma_-\rangle}{\mathrm{d}t} = -\left(\mathrm{i}\omega_a + \frac{\gamma}{2}\right)\langle\sigma_-\rangle \quad (14.108)$$

with the solution

$$\langle\sigma_-(t)\rangle = \langle\sigma_-(0)\rangle\mathrm{e}^{-(\gamma/2+\mathrm{i}\omega_a)t} . \quad (14.109)$$

The dipole oscillates at the transition frequency and decays, as it radiates.

The radiated field is related to the input field and the local source through an input/output relation in analogy with the case of a cavity discussed above. The positive-

frequency components of the field operator take the form

$$E_{\mathrm{o}}^{(+)}(\boldsymbol{x}, t) = E_{\mathrm{i}}^{(+)}(\boldsymbol{x}, t) - \frac{\omega_a^2}{4\pi\epsilon_0 c^2 r}\left(\boldsymbol{\mu}\times\frac{\boldsymbol{x}}{r}\right)$$
$$\times\frac{\boldsymbol{x}}{r}\sigma_-(t - x/c)\,, \qquad (14.110)$$

where $r = |\boldsymbol{x}|$ is the distance from the course to the point $\boldsymbol{x}$ and $\boldsymbol{\mu}$ is the atomic dipole moment.

If the atom is driven by a classical radiation field, the Hamiltonian becomes [see (14.27) and replace $b \mapsto \beta$]

$$H = \frac{\hbar\omega_{\mathrm{a}}}{2}\sigma_z + \Omega(\sigma_+ e^{-i\omega_L t} + \sigma_- e^{i\omega_L t})\,, \qquad (14.111)$$

where Ω is the Rabi frequency and ω_L is the carrier frequency of the driving field. The master equation in an interaction picture at the frequency ω_L is

$$\frac{d\rho}{dt} = -i\frac{\Delta\omega}{2}[\sigma_z, \rho] - i\Omega[\sigma_+ + \sigma_-, \rho] + \gamma\mathcal{D}[\sigma_-]\rho\,, \qquad (14.112)$$

where the detuning is $\Delta\omega = \omega_{\mathrm{a}} - \omega_L$. The resulting *Bloch equations* for the atomic moments are linear

$$\frac{d\langle\sigma_-\rangle}{dt} = -\left(\frac{\gamma}{2} + i\Delta\omega\right)\langle\sigma_-\rangle + i\Omega\langle\sigma_z\rangle\,, \qquad (14.113)$$
$$\frac{d\langle\sigma_z\rangle}{dt} = -\gamma\left(\langle\sigma_z\rangle + 1\right) - 2i\Omega(\langle\sigma_+\rangle - \langle\sigma_-\rangle)\,. \qquad (14.114)$$

The solutions for resonance ($\Delta\omega = 0$) are

$$\langle\sigma_z(t)\rangle = \frac{8\Omega^2}{\gamma^2 + 8\Omega^2}\left[1 - e^{-3\gamma t/4}\right.$$
$$\left.\times\left(\cosh\kappa t + \frac{3\gamma}{4\kappa}\sinh\kappa t\right)\right] - 1\,, \qquad (14.115)$$

$$\langle\sigma_+(t)\rangle = 2i\Omega\frac{\gamma^2}{\gamma^2 + 8\Omega^2}\left\{1 - e^{-3\gamma t/4}\right.$$
$$\left.\times\left[\cosh\kappa t + \left(\frac{\kappa}{\gamma} + \frac{3\gamma}{16\kappa}\right)\sinh\kappa t\right]\right\}\,, \qquad (14.116)$$

where

$$\kappa = \sqrt{\frac{\gamma^2}{4} - 16\Omega^2}\,. \qquad (14.117)$$

Clearly there is a threshold at $\Omega = \gamma/8$ below which the solutions monotonically approach the steady state and above which they are oscillating. A similar threshold occurs in the solutions for the two-time correlation function $\langle\sigma_+(t)\sigma_-(t+\tau)\rangle_{t\to\infty}$ which determines the spectrum of

the scattered light. For $\Omega \gg \gamma$ we find that this spectrum has three peaks at $\omega = \omega_{\mathrm{a}}$ and $\omega = \omega_{\mathrm{a}} \pm \Omega$. This is the *Mollow spectrum* [14.16].

The light scattered by a two-level atom also exhibits *photon anti-bunching*. Consider the conditional probability that given a photon is counted at time t another photon will be counted a time τ later. This is proportional to the second-order correlation function

$$G^{(2)}(t, \tau) = \langle a^\dagger(t)a^\dagger(t+\tau)a(t+\tau)a(t)\rangle\,. \qquad (14.118)$$

Usually we are interested in a stationary source so we let $t \to \infty$ and we normalise this by the intensity squared to define

$$g^{(2)}(\tau) = \lim_{t\to\infty}\frac{G^{(2)}(t, \tau)}{\langle a^\dagger(t)a(t)\rangle^2}\,. \qquad (14.119)$$

Using the result in (14.110) we can express this directly in terms of correlation functions for the atomic polarisation. As the equations of motion for the atomic variables are linear, the stationary correlation function $\langle\sigma_+(t)\sigma_+(t+\tau)\sigma_-(t+\tau)\sigma_-(t)\rangle_{t\to\infty}$ obeys the same equations [see below (14.141)]. We then find that

$$g^{(2)}(\tau) = 1 - e^{-3\gamma t/4}\left(\cosh\kappa\tau + \frac{3\gamma}{4\kappa}\sinh\kappa\tau\right)\,. \qquad (14.120)$$

The result $g^{(2)}(\tau = 0) = 0$ indicates *photon anti-bunching*, as the probability to count a second photon, immediately after a first one has been counted, vanishes. This is a direct result of the emission process of the source. Photons are emitted when an excited atom relaxes back to the ground state. If a photon is counted, the atom is likely to be in ground state and thus a finite time must elapse before it is re-excited and capable of emitting another one. This prediction, first made by *Carmichael* and *Walls* [14.17], was one of the earliest examples of how quantum optics would differ from a semiclassical description of light. This result has been seen in the resonance fluorescence of a single trapped atom.

14.4.1 Quantum Trajectories

The master equation describes the dynamics of a subsystem by averaging over (tracing out) the properties of the larger *bath* to which it is coupled. Solving the master equation typically results in a mixed state. Any mixed state admits infinitely many decompositions into convex combinations of (nonorthogonal) pure states. In a stochastic unravelling of a master equation we represent the solution at any time as a convex combination of

pure states each evolving under a stochastic Schrödinger equation such that if we average over the noise we obtain the solution to the original master equation. This approach leads to a powerful numerical simulation tool as much less memory is required to store a pure quantum state at each time step.

Consider a simple harmonic oscillator coupled to a zero-temperature heat bath. The dynamics, in the interaction picture, is given by the master equation, (14.89) with $\bar{n} = 0$. Solving this equation over a small time interval dt we can write

$$\rho(t + dt) = \left\{ \rho(t) - \frac{\gamma}{2} [a^\dagger a \rho(t) + \rho(t) a^\dagger a] \, dt \right\} + \gamma a \rho(t) a^\dagger \, dt \,. \tag{14.121}$$

We can think of this as describing photons leaking from a single-mode cavity at Poisson-distributed times. Suppose there were exactly n photons in the cavity at time t so that $\rho(t) = |n\rangle\langle n|$. Then (14.121) would become

$$\rho(t + dt) = (1 - \gamma n \, dt)|n\rangle\langle n| + \gamma n \, dt |n-1\rangle\langle n-1| \,. \tag{14.122}$$

We can think of this as follows. In a small increment of time dt, two events are possible: either a single photon is lost or no photon is lost. If a photon is lost, the state of the field has one less photon so that it changes from $|n\rangle$ to $|n-1\rangle$ and this event will occur with probability $\gamma n \, dt$. This form results from the last term of (14.121). On the other hand, if no photon is lost the state is unchanged, and this will occur with probability $1 - \gamma n \, dt$, which arises from the first term in (14.121). Thus (14.121) describes a statistical mixture of the two events that can occur in a small time step dt: the first term in square brackets describes the change in the state of the cavity field given that no photon is lost in time interval dt, while the second term describes what happens to the state of the field if one photon is lost in a time interval dt.

If this interpretation is correct it suggests an answer to conditional questions such as: if no photon is lost from time t to $t + dt$, what is the conditional state of the field? In this case we have no contribution from the last term in (14.121) so the conditional state is the solution to

$$\rho(t + dt)_c = \frac{\left\{ \rho(t)_c - \frac{\gamma}{2} [a^\dagger a \rho_c(t) + \rho(t)_c a^\dagger a] \, dt \right\}}{\text{tr} \left\{ \rho_c(t) - \frac{\gamma}{2} [a^\dagger a \rho_c(t) + \rho_c(t) a^\dagger a] \, dt \right\}}$$

$$\approx \rho_c(t) - \gamma \, dt \left\{ \frac{1}{2} [a^\dagger a \rho_c(t) + \rho_c(t) a^\dagger a] - \langle a^\dagger a \rangle_c(t) \rho_c(t) \right\}$$

to linear order in dt, where the subscript c is to remind us that we are dealing with a particular conditional state conditioned on a rather special history of null events and $\langle a^\dagger a \rangle_c(t)$ is the conditional average of the photon number in the state $\rho_c(t)$.

We can now introduce a *classical* stochastic process, a conditional Poisson process, $dN(t)$ which is the number of photons lost in time dt. Clearly

$$dN(t)^2 = dN(t) \,, \tag{14.123}$$

$$\mathcal{E}[dN(t)] = \gamma \langle a^\dagger a \rangle_c(t) \,, \tag{14.124}$$

where $\mathcal{E}$ is an average over the classical stochastic variable. In terms of $dN(t)$ we can now define a *stochastic master equation*

$$d\rho_c(t) = dN(t) \mathcal{G}[a] \rho_c(t) - \gamma \, dt \, \mathcal{H}[a^\dagger a] \rho_c(t) \,, \tag{14.125}$$

where we have defined two new super-operators (that map density operators to density operators),

$$\mathcal{G}[A] \rho = \frac{A \rho A^\dagger}{\text{tr}[A \rho c^\dagger]} - \rho \,, \tag{14.126}$$

$$\mathcal{H}[A] \rho = A \rho + \rho A^\dagger - \text{tr}[A \rho + \rho A^\dagger] \,, \tag{14.127}$$

for any operator A. Note that, if we take the classical ensemble average over the noise process $dN(t)$, we recover the original master unconditional master equation in (14.121). The solution to (14.125) is the conditional state at time t conditioned on an entire fine-grained history of jump events (that is to say, the total number of jumps and the time of each jump event). Denote such a history as the sequence of jump times on the interval $[0, t)$ as $h[t] = \{t_1, t_2, \dots, t_m\}$. The unconditional state is a sum over all such histories

$$\rho(t) = \sum_{h[t]} \Pr(h[t]) \rho_c(h[t]) \,, \tag{14.128}$$

where we have explicitly indicated that the conditional state ρ_c is conditioned on the history of jump events, $h[t]$ in the time interval of interest and $\Pr(h[t])$ is the probability for each history. We have *unravelled* the solution to the master equation in terms of conditional stochastic events. For a point process as considered here the sum over histories has an explicit form in terms of time-ordered integrals [14.18]

$$\rho(t) = \sum_{m=0}^{\infty} \int_0^t dt_m \int_0^{t_m} \dots \int_0^{t_1} \mathcal{S}(t - t_m) \mathcal{J} \mathcal{S}(t_m - t_{m-1})$$

$$\dots \mathcal{J} \mathcal{S}(t_1) \rho(0) \,, \tag{14.129}$$

where the super operators are defined by

$$\mathcal{S}(t)\rho = e^{-\frac{\gamma}{2}ta^\dagger a}\rho\, e^{-\frac{\gamma}{2}ta^\dagger a}\,, \qquad (14.130)$$

$$\mathcal{J} = \gamma a\rho a^\dagger\,. \qquad (14.131)$$

Clearly the probability of a specific jump history is given by

$$\Pr(h[t]) = \text{tr}[\mathcal{S}(t-t_m)\mathcal{J}\mathcal{S}(t_m - t_{m-1})$$
$$\ldots \mathcal{J}\mathcal{S}(t_1)\rho(0)]\,. \qquad (14.132)$$

The form of (14.129) indicates that, if we start in a pure state and have access to the entire history of photon loss events $h[t]$, the conditional state $\rho_c(h[t])$ must still be a pure state. This implies that we can write a stochastic Schrödinger for the damped harmonic oscillator

$$d|\psi_c(t)\rangle = \left[dN_c(t)\left(\frac{a}{\sqrt{\langle a^\dagger a\rangle_c(t)}} - 1\right)\right.$$
$$+ \gamma\, dt\left(\frac{\langle a^\dagger a\rangle_c(t)}{2} - \frac{a^\dagger a}{2}\right)$$
$$\left.- iH\, dt\right]|\psi_c(t)\rangle\,, \qquad (14.133)$$

where we have now included the possibility of a Hamiltonian part to the dynamics. We can show the equivalence between this equation and the stochastic master equation by considering the Ito-like expansion

$$d\left[|\psi_c(t)\rangle\langle\psi_c(t)|\right] = [d|\psi_c(t)\rangle]\,\langle\psi_c(t)| + |\psi_c(t)\rangle$$
$$\times [d\langle\psi_c(t)|] + [d|\psi_c(t)\rangle|]$$
$$\times [d\langle\psi_c(t)|] \qquad (14.134)$$

and retaining all terms to first order in dt, noting that $dN^2 = dN$.

A point process with a large rate parameter γ can be well approximated on a time scale long compared to γ^{-1} by a white-noise process. This suggests that it must be possible to unravel the master equation in terms of white-noise processes as well as the point process $dN(t)$. Such master equations give the conditional dynamics conditioned on homodyne and heterodyne measurements on the field leaving the cavity. Here we simply quote the result and show that averaging over the classical noise returns us to the unconditioned master equation.

In the case of the real valued Weiner process $dW(t)$ we can write the *homodyne* stochastic master equation for a damped simple as

$$d\rho_c(t) = -i[H, \rho_c(t)]\,dt + \mathcal{D}[a]\rho_c(t)\,dt$$
$$+ dW(t)\mathcal{H}[a]\rho_c(t)\,, \qquad (14.135)$$

where

$$\mathcal{D}[A]\rho = A\rho A^\dagger + \frac{1}{2}(A^\dagger A\rho + \rho A^\dagger A) \qquad (14.136)$$

and $\mathcal{H}[a]$ is given by (14.127).

In terms of a complex-valued white-noise process, $dW(t) = dW_1(t) + i\, dW_2(t)$, where $dW_i(t)$ are independent Winer processes, we can write the *heterodyne* stochastic master equation

$$d\rho_c(t) = -i[H, \rho_c(t)]\,dt + \mathcal{D}[a]\rho_c(t)\,dt$$
$$+ \frac{1}{\sqrt{2}}[dW_1(t)\mathcal{H}[a]\rho_c(t)$$
$$+ dW_2(t)\mathcal{H}[-ia]\rho_c(t)\,. \qquad (14.137)$$

There is a connection between the quantum jump process and the two-time correlation function discussed in above. We first define a new stochastic process, the rate or the current, as

$$i(t) = \frac{dN}{dt}\,. \qquad (14.138)$$

This is a rather singular stochastic process, consisting of a series of delta functions concentrated at the actual jump times. In physical terms this is intended to model the output of an ideal photon counting detector, with infinite response bandwidth, that detects every photon that is lost from the cavity. Define the classical current two-time correlation function

$$G(\tau, t) = \mathcal{E}[i(t+\tau)i(t)]\,. \qquad (14.139)$$

Given the nature of a Poisson jump process, $dN(t)$ can only take the values 0 or 1, so it is easy to see that we can write the two-time correlation function in terms of the conditional probability to get $dN(t+\tau) = 1$ given a jump at time t,

$$G(\tau, t)\,dt^2 = \Pr(dN(t+\tau) = 1 | dN(t) = 1)\,. \qquad (14.140)$$

This conditional probability is given by

$$\Pr[dN(t+\tau) = 1 | dN(t) = 1]$$
$$= \gamma^2\text{tr}[a^\dagger a\, e^{\mathcal{L}\tau}a\rho(t)a^\dagger]\,dt^2 \qquad (14.141)$$

where $e^{\mathcal{L}t}$ is the formal solution to the unconditional master equation evolution written in terms of the abstract generator $\mathcal{L}$ as $\dot\rho = \mathcal{L}\rho$. The two-time correlation function is then given by

$$G(\tau, t) = \gamma^2\text{tr}[a^\dagger a\, e^{\mathcal{L}\tau}a\rho(t)a^\dagger]\,. \qquad (14.142)$$

Note that the so-called regression theorem follows directly from the definition of G,

$$\frac{dG(\tau, t)}{d\tau} = \mathcal{L}G(\tau, t) . \tag{14.143}$$

We usually deal with driven damped harmonic oscillators for which the system settles into a steady state, emitting photons according to the conditional Poisson process derived from the steady-state solution $\rho_\infty = \lim_{t\to\infty} \rho(t)$, so we define the *stationary* two-time correlation function for the current as

$$G(\tau) = \gamma^2 \text{tr}\left[a^\dagger a e^{\mathcal{L}\tau} a \rho_\infty a^\dagger\right] . \tag{14.144}$$

14.4.2 Simulating Quantum Trajectories

A mixed state for system with a Hilbert space of dimension N requires that we specify N^2 complex matrix elements. On the other hand a pure state requires that we specify only N complex numbers. For this reason numerically solving the master equation is more computationally difficult than solving the Schrödinger equation. We can use the unravelling of a master equation in terms of a stochastic Schrödinger equation to make the numerical solution of master equations more tractable. In this numerical setting, the method of quantum trajectories was independently developed as the *Monte Carlo wavefunction* method [14.19]. We will illustrate the method using the jump process.

Suppose the state at time t is $|\psi(t)\rangle$. Then in a time interval δt, sufficiently short compared to γ^{-1}, the system will evolve to the (unnormalised) state conditioned on no jump having occurred,

$$|\tilde{\psi}(t + \delta t)\rangle = e^{-iH\delta t - \gamma a^\dagger a \delta t/2}|\psi(t)\rangle . \tag{14.145}$$

To compute this we implement a routine to solve the Schrödinger equation with the effective non-Hermitian Hamiltonian

$$K = H - i\frac{\gamma}{2}a^\dagger a . \tag{14.146}$$

The norm of this state is the probability that no jump has occurred in the time interval δt,

$$p_0 = \langle\tilde{\psi}(t + \delta t)|\tilde{\psi}(t + \delta t)\rangle \tag{14.147}$$

$$= 1 - p , \tag{14.148}$$

where it is easy to see that

$$p = \gamma\delta t\langle\psi(t)|a^\dagger a|\psi(t)\rangle , \tag{14.149}$$

which we understand to be the probability that a jump takes place in this time interval. We need to ensure that $p \ll 1$.

Let us now chose a random number r uniformly distributed on the unit interval. At the end of the time interval, we compare p and r. If $p < r$ (usually the case) we normalise the state

$$|\psi(t + \delta t)\rangle = \frac{|\tilde{\psi}(t + \delta t)\rangle}{\sqrt{p_0}} \tag{14.150}$$

and continue the non-Hermitian evolution for a further time step. If however $p > r$, we implement a quantum jump via

$$|\tilde{\psi}(t + \delta t)\rangle \to |\psi(t + \delta t)\rangle = \frac{\sqrt{\gamma}a|\tilde{\psi}(t + \delta t)\rangle}{p/\delta t} . \tag{14.151}$$

Based on our previous discussions we see that $p/\delta t = \gamma\langle\psi(t)|a^\dagger a|\psi(t)\rangle$, and the jump operation is as described by the first term in (14.133). As the simulation proceeds we accumulate the record of times at which particular jump events occur. That is to say, we have access to a sample fine grained history of the jump process, $h[t]$. However we are primarily interested in solving the master equation. We thus run K trials up to time t, starting from an identical initial state each time, and then form the mixed state

$$\bar{\rho}(t) = K^{-1}\sum_{k=1}^{K}|\psi_k(t)\rangle \tag{14.152}$$

as a uniform average over the K trials. Strictly speaking the probability of each of the K trials is not uniform, however one can show that, for K sufficiently large, $\bar{\rho}(t) \approx \rho(t)$, with an error that scales as $K^{-1/2}$. In *Mølmer* et al. [14.19] more-general cases are discussed including how to simulate non-zero-temperature master equations or master equations with multiple jump processes.

14.5 Ion Traps

The ability to trap an individual ion and cool it close to the ground state of vibrational motion has enabled precise quantum control to be achieved together with

very high-efficiency measurement. The technology originated some three decades ago in the effort to develop ultra-high-precision spectroscopy with particular appli-

cation to frequency standards. In recent years ion trap technology has led the field in efforts to implement quantum information processing following the seminal proposal of *Cirac* and *Zoller* in 1995 [14.20]. The technology is now entering an even more exciting phase with the development of smaller and more effective traps, ion trap arrays for coherently processing a large number of ions and the integration of traps and optical cavities.

One of the keys to the success of ion traps is the ability to detect the electronic state of a single ion with high efficiency. This is done by laser-induced fluorescence on a dipole-allowed transition, scattering millions of photons per second. The idea goes back to a proposal of *Dehmelt* in 1975 [14.21] and appears in various applications such as electron shelving, cycling transitions and quantum jumps [14.22]. Another key to the success of ion traps is the invention of sub Doppler cooling techniques, particularly resolved side band cooling. This makes it possible to prepare a single ion in a state with very few quanta of vibrational excitation, even so few as to reach the vibrational ground state. A single trapped ion is well approximated by a particle moving in a three-dimensional harmonic potential. It is possible to remove vibrational energy stochastically by laser-induced Raman transitions coupling electronic and vibrational degrees of freedom. In effect, heat is removed from the vibrational motion of of the ion and pumped into the very low temperature heat bath associated with the much higher frequency of the fluorescent radiation.

It is not possible to trap a charged particle in a static potential. This is because the Laplace equation implies there is always one unstable (not trapped) direction in the electrostatic potential. However a time-dependent electric potential can produce an effective harmonic potential for a charge particle.

The quantum description of the centre of mass motion of the ion is given in terms of the eigenstates of the Hamiltonian

$$H = \hbar v a_z^\dagger a_z + \hbar v_t \left(a_x^\dagger a_x + a_y^\dagger a_y \right) . \tag{14.153}$$

The motion is thus separable into axial (ω_z) and transverse motion and, to be specific, we now concentrate on the axial motion alone, although much of the discussion can be applied to the transverse motion as well. Henceforth, as we neglect the transverse motion, we will drop the subscript on a_z, $a_z^\dagger$.

Many different kinds of ions can be trapped but availability of lasers limits the kinds of ions that can be easily laser cooled. For example, the Wineland group at NIST Colorado uses ^{9}Be$^+$ while the Blatt group in Innsbruck

uses ^{40}Ca$^+$. When the ion is first trapped it is in a highly excited state of its vibrational motion, corresponding to a temperature of the order of 10^4 K. Cooling typically proceeds in two stages. The first stage is based on Doppler cooling and is very efficient, the second stage is based on resolved sideband cooling.

Ion traps are a remarkably versatile quantum devices for a number of reasons. Firstly, it is possible to coherently couple the vibrational motion and the internal electronic state using an external laser. Secondly, resolved sideband cooling enables the vibrational motion to be prepared in its ground state with probability approaching unity. This is done using an external laser to induce Raman transitions between the ground and excited internal electronic state which absorb one photon and one phonon of vibrational per excitation cycle. Finally, the method of fluorescence shelving enables the internal electronic state of a single trapped ion to measured with efficiency approaching unity. In order to understand these three features we need to begin with a description of how an external laser can couple the vibrational and electronic degrees of freedom.

We will assume that the external laser can couple two internal electronic states, the ground state $|g\rangle$ and the excited state $|e\rangle$. This might involve a direct dipole transition. However for quantum information applications it typically involves a Raman two-photon transition connecting the ground state to an excited metastable state. In either case the Hamiltonian describing the system is

$$\begin{aligned} H &= \hbar v a^\dagger a + \frac{\hbar \omega_A}{2} \sigma_z \\ &+ \frac{\hbar \Omega}{2} \left(\sigma_- \, \mathrm{e}^{\mathrm{i}(\omega_L t - k_L \hat{q})} + \sigma_+ \, \mathrm{e}^{-\mathrm{i}(\omega_L t - k_L \hat{q})} \right) , \end{aligned}$$

$$\tag{14.154}$$

where $\hat{q}$ is the operator for the displacement of the ion from its equilibrium position in the trap, v is the trap (secular) frequency, Ω is the Rabi frequency for the two-level transition, ω_A is the atomic transition frequency, and ω_L, k_L are the laser frequency and wave number. There are three frequencies in the problem: v, ω_A and ω_L. A wide variety of processes can be made dominant by carefully choosing relationships between these three frequencies. Note that the phase of the laser field as seen by the ion is dependent upon the position of the ion. As the ion moves harmonically in the trap the phase is thus modulated at the trap frequency. As we shall see this leads to sidebands in the absorption spectrum for the two-level system.

The ion position operator, in terms of the vibrational raising and lowering operators, is

$$\hat{q} = \left(\frac{\hbar}{2m\nu}\right)^{1/2} (a + a^\dagger) . \tag{14.155}$$

We now define the Lamb–Dicke parameter, η

$$\eta = k_\mathrm{L} \left(\frac{\hbar}{2m\nu}\right)^{1/2} = 2\pi \Delta x_\mathrm{rms}/\lambda_\mathrm{L} \tag{14.156}$$

where the root-mean-square (r.m.s.) position fluctuations in the oscillator ground state is Δx_rms. Then moving to an interaction picture via the unitary transformation

$$U_0(t) = \exp(-\mathrm{i}\nu a^\dagger a\, t - \mathrm{i}\omega_\mathrm{A}\sigma_z t) , \tag{14.157}$$

the interaction Hamiltonian can be written as

$$H_I(t) = \frac{\hbar\Omega}{2} \left\{ \sigma_- \exp[-\mathrm{i}\eta(a\mathrm{e}^{-\mathrm{i}\nu t} + a^\dagger\, \mathrm{e}^{\mathrm{i}\nu t})] \right.$$
$$\left. \times \exp[-\mathrm{i}(\omega_\mathrm{A} - \omega_\mathrm{L})t] + \mathrm{h.c} \right\} \tag{14.158}$$

The exponential of exponentials make this a complicated Hamiltonian system. However in most ion trap experiments the ion is confined to a spatial region that is significantly smaller than the wavelength of the exciting laser so that we may assume that the Lamb–Dicke parameter is small $\eta < 1$ (typically $\eta \approx 0.01-0.1$). Expanding the interaction to second order in the Lamb–Dicke parameter gives

$$H_I(t) = \frac{\hbar\Omega}{2}(1 - \eta^2 a^\dagger a) \left(\sigma_- \mathrm{e}^{-\mathrm{i}\delta t} + \sigma_+ \mathrm{e}^{\mathrm{i}\delta t}\right)$$
$$- \mathrm{i}\frac{\hbar\Omega\eta}{2}\left(a\mathrm{e}^{-\mathrm{i}\nu t} + a^\dagger\, \mathrm{e}^{\mathrm{i}\nu t}\right)\mathrm{e}^{-\mathrm{i}\delta t}\sigma_-$$
$$+ \mathrm{i}\frac{\hbar\Omega\eta}{2}\left(a\mathrm{e}^{-\mathrm{i}\nu t} + a^\dagger\, \mathrm{e}^{\mathrm{i}\nu t}\right)\mathrm{e}^{\mathrm{i}\delta t}\sigma_+$$
$$- \frac{\hbar\Omega\eta^2}{4}\left(a^2\, \mathrm{e}^{-2\mathrm{i}\nu t} + (a^\dagger)^2\, \mathrm{e}^{2\mathrm{i}\nu t}\right)$$
$$\times \left(\mathrm{e}^{-\mathrm{i}\delta t}\sigma_- + \mathrm{e}^{\mathrm{i}\delta t}\sigma_+\right) ,$$

where the detuning of the laser from the atomic frequency is $\delta = \omega - \omega_\mathrm{L}$.

By carefully selecting δ to be positive or negative integer multiples of the trap frequency, various resonant terms may be extracted and all time dependent terms neglected. In the first case, known as the carrier excitation, $\delta = 0$, and the resonant terms are

$$H_\mathrm{c} = \hbar\Omega(1 - \eta^2 a^\dagger a)\sigma_x \quad \text{(carrier excitation)} , \tag{14.159}$$

where $\sigma_x = (\sigma_- + \sigma_+)/2$. If we choose $\delta = \nu$ so that the laser frequency is detuned below (to the red of) the

carrier frequency by one unit of trap frequency, $\omega_\mathrm{L} = \omega_\mathrm{A} - \nu$, the resonant terms are

$$H_\mathrm{r} = \mathrm{i}\frac{\hbar\eta\Omega}{2}\left(a\sigma_+ - a^\dagger\sigma_-\right)$$
$$\text{(first red sideband excitation)} . \tag{14.160}$$

This is just the Jaynes–Cummings Hamiltonian except that it involves the absorption of a trap *phonon* as well as one laser photon. On the other hand we can choose $\delta = -\nu$ so that $\omega_\mathrm{L} = \omega_\mathrm{A} + \nu$ and the laser is detuned one unit of vibrational frequency to the blue of the carrier, the resonant interaction Hamiltonian is

$$H_\mathrm{b} = \mathrm{i}\frac{\hbar\eta\Omega}{2}\left(a^\dagger\sigma_+ - a\sigma_-\right)$$
$$\text{(first blue sideband excitation)} . \tag{14.161}$$

This describes an excitation process that absorbs one photon from the laser and *emits* one trap phonon. Continuing in this way we can define the second red sideband excitation $\delta = 2\nu$ and second blue sideband excitation $\delta = -2\nu$, and so on. Figure 14.2 shows an energy-level diagram that represents the carrier, red and blue sideband excitations.

Once excited to $|e\rangle$ the ion can spontaneously decay to the ground state. For a dipole-allowed transition this can be quite fast, thus enabling another excitation process to occur. In the case of red sideband excitation the net result is to remove one phonon per excitation cycle. This is the basis of sideband cooling. In effect the external laser has coupled the vibrational motion to a very-low-temperature heat bath: the vacuum radiation field at frequency ω_A. Of course it is only possible to address the sidebands if the laser can be accurately tuned to each. As each transition is homogeneously broadened by a width equal to the spontaneous emission rate, γ, we require that $\nu > \gamma$ for resolved sideband cooling. An explicit expression for the spectrum of resonance fluorescence for a single trapped ion follows from the
Fig. 14.2a–c Energy-level diagram for **(a)** carrier **(b)** first red sideband and **(c)** first blue sideband excitation

methods given in Sect. 14.4. A detailed calculation in the low intensity limit ($\Omega < \gamma$) for a traveling-wave field was given by *Cirac* et al. [14.23].

Resolved sideband cooling requires that the exciting laser be tuned one unit of trap frequency below the atomic transition frequency. The atom is then excited by the absorption of one laser photon and one trap phonon. In the Lamb–Dicke limit relaxation is dominated by spontaneous emission into the spectral peak at the carrier frequency ($\omega = \omega_A$). Thus on each excitation cycle one unit of vibrational energy is removed on average. A simple rate equation method suffices to understand this phenomenon. We find that the rate of change of the average phonon number is given by

$$\frac{d\bar{n}}{dt} = -\gamma \left(\frac{\eta^2 \Omega^2 \bar{n}}{2\eta^2 \Omega^2 \bar{n} + \gamma^2} \right) . \tag{14.162}$$

Note that, as the cooling proceeds, the rate decreases until the vibrational ground state is a steady state. In a more careful treatment we need to consider heating mechanisms, for example off-resonant excitation of the blue sideband [14.24], and the probability of populating the vibrational ground state in the steady state is less than unity. Despite this, resolved sideband cooling care prepare an ion in the vibrational ground state with a probability greater than 99%. Ground state cooling in all three dimensions was first achieved by the NIST group in *Boulder* [14.25]. Other heating mechanisms due to experimental artifacts are often important. For example, fluctuating charge distributions on the trap electrodes lead to a stochastic displacement of the centre of the trap.

In order to read out the state of the ion, an additional auxiliary level can be coupled by a strong laser to one or the other of the ground or excited states, to be specific let us say the ground state Fig. 14.3. If the ion is in the ground state when the probe laser is turned on, fluorescent photons are scattered in all directions and can easily be detected. On the other hand if the ion is in the excited state, it is not resonant with the probe laser and no photons are scattered: the ion remains dark.

If we now apply a weak laser to couple the ground and excited states, incoherent transitions occur $|g\rangle \leftrightarrow |e\rangle$. The net result is that the fluorescent signal due to the probe laser blinks on and off in fashion of a random telegraph process. A typical signal is also shown in Fig. 14.3. In so far as fluorescence indicates that the ion is in the ground state, the random switching of the fluorescence is a direct indicator of *quantum jumps* be-
Fig. 14.3 Energy-level diagram showing fluorescence readout of the ground atomic state. A strong probe laser drives a dipole-allowed transition between the ground state $|g\rangle$ and an auxiliary state $|a\rangle$ which decays back to the ground state at a rate Γ scattering many many photons. Also shown (*right*) is the fluorescent signal on the probe transition when a weak laser couples the ground and excited state (after *Leibfried* et al. [14.24] with permission)

tween the ground and excited states. These jumps were first reported in a number of laboratories [14.22].

The efficiency of the readout is a function of the integration time of the fluorescence signal, that is to say, how long we need to monitor the fluorescence to be sure that we are in period of high intensity. This time must be at least of the order of the average time between photon emission events. In an experiment however there are other sources of error, such as dark counts in the detector and typically the minimum time to distinguish ground and excited states is of the order of 2 ms. We capture the quality of the readout in an overall efficiency is η which is the conditional probability for the ion to be detected in the ground state given that it was prepared in the ground state before the probe laser was turned on.

We now return to the experimental determination of the efficiency of sideband cooling. The objective is to determine the state of vibrational motion by coupling it to the internal state of the ion and then using the fluorescent readout technique described above. At the end of a cooling stage, the electronic state of the ion to is first coupled to its vibrational motion for a time T using the first red and blue sideband transitions. If we write the probability for the atom to found in the excited state after time T as $P_e^R(T)$ and $P_e^B(T)$ for red and blue sideband excitation respectively it can be shown that the mean phonon number $\bar{n}$ is given by $\bar{n}/(1+\bar{n}) = P_e^R(T)/P_e^B(T)$. Thus measurement of the ratio of excitation probability on the first red and blue sideband yields $\bar{n}$ directly.

14.6 Quantum Communication and Computation

Quantum teleportation is a new communication task enabled by quantum entanglement. It permits the transfer of an unknown quantum state from a *client* system (C) provided to a *sender* (A), to a remote *receiver* (B). The sender and receiver share a maximally entangled state, and they can communicate via a classical channel. The original proposal of *Bennett* et al. [14.26] was posed in terms of systems with a two-dimensional Hilbert space (qubits [14.27]). *Furasawa* et al. [14.28], using a proposal of *Braunstein* and *Kimble* [14.29], have demonstrated that the method can also be applied to entangled systems with an infinite-dimensional Hilbert space, specifically for harmonic oscillator states. In that work, a coherent state was teleported using an entanglement resource that consisted of a two mode squeezed vacuum state. The joint measurements required for teleportation are joint quadrature phase on the client system and that part of the entangled resource be shared by the receiver.

Teleportation of continuous variables is possible using a perfect quadrature phase quantum nondemolition (QND) measurement between two optical modes, A and B, to create the entanglement resource. The state that is produced is an optical analogue of the EPR state which had previously been shown by *Vaidman* [14.30] to enable teleportation of continuous observable. The EPR state is not a physical state because quadrature phase eigenstates are infinite-energy states. However we can use arbitrary close approximations to these states in terms of a squeezed vacuum state (14.163). This is essential feature exploited in the scheme of Furasawa et al.

Suppose that at some prior time a two-mode squeezed vacuum state is generated and that one mode is available for local operations and measurements at the sender's location A by observer Alice, while the other mode is open to local operations and measurements in the receiver's location B, by observer Bob. Alice and Bob can communicate via a classical communication channel. Thus Alice and Bob each have access to one of the two entangled subsystems described by

$$|\mathcal{E}\rangle_{AB} = \sqrt{(1-\lambda^2)} \sum_{n=0}^{\infty} \lambda^n |n\rangle_A \otimes |n\rangle_B \qquad (14.163)$$

This state is generated from the vacuum state by the unitary transformation

$$U(r) = e^{r(a^\dagger b^\dagger - ab)}, \qquad (14.164)$$

where $\lambda = \tanh r$ and where a, b refer to the mode accessible to Alice and the mode accessible to Bob, respectively.

The sender, Alice, has access to another quantum system, the client (C), in state $|\psi\rangle_C$. Perfect (projective) measurements are made of the joint quadrature phase quantities, $\hat{X}_C - \hat{X}_A$ and $\hat{Y}_C + \hat{Y}_A$ on the client mode and the Alice's part of the entangled mode, A, with the results X and Y, respectively. The conditional state resulting from this joint quadrature measurement is described by the projection onto the state $|X, Y\rangle_{CA}$ where

$$|X, Y\rangle_{CA} = e^{-\frac{i}{2}\hat{X}_A \hat{Y}_C} |X\rangle_C \otimes |Y\rangle_A . \qquad (14.165)$$

The (unnormalised) conditional state of total system after the measurement is then seen to be given by

$$|\tilde{\Psi}^{(X,Y)}\rangle_{out} = {}_{CA}\langle X, Y|\psi\rangle_C |\mathcal{E}\rangle_{AB} \otimes |X, Y\rangle_{CA} . \qquad (14.166)$$

The state of mode B at the receiver, denoted as Bob, is the pure state

$$|\phi^{(X,Y)}(r)\rangle_B = [P(X, Y)]_{CA}^{-1/2} \langle X, Y|\psi\rangle_C \otimes |\mathcal{E}\rangle_{AB} \qquad (14.167)$$

with the wave function (in the $\hat{X}_B$ representation),

$$\phi_B^{(X,Y)}(x) = \int_{-\infty}^{\infty} dx' \, e^{-\frac{i}{2}x'Y} \mathcal{E}(x, x') \psi(X + x') \qquad (14.168)$$

where $\psi(x) = {}_C\langle x|\psi\rangle_C$ is the wavefunction for the client state we seek to teleport. The kernel is simply the wave function for the two-mode squeezed-state resource.

The state in (14.168) is clearly not the same as the state we sought to teleport. However in the limit of infinite squeezing, $r \to \infty$, we find that $\mathcal{G}(x_1, x_2; r) \to \delta(x_1 + x_2)$ and the state of mode B approaches

$$|\phi_{XY}(r)\rangle_B \to e^{-\frac{i}{2}Y\hat{X}_B} e^{\frac{i}{2}X\hat{Y}_B} |\psi\rangle_B \qquad (14.169)$$

which, up to the expected unitary translations in phase space, is the required teleported state.

For finite squeezing the state after Bob's conditional control is not an exact replica of the client state. We can quantify the fidelity of the reproduction by computing the probability that the state received by Bob, after displacement, is the same as the client state. This probability is called the *fidelity* and is given by

$$F = |\langle\psi|e^{\frac{i}{2}\mu\hat{X}_B} e^{-\frac{i}{2}\nu\hat{Y}_B}|\phi^{(X,Y)}\rangle|^2 \qquad (14.170)$$

with $\mu = gY$ and $\nu = gX$, which allows for some flexibility in the choice of displacements in the nonideal case. The quantity g is called the *gain*. In the limit of infinite squeezing we expect $g \to 1$.

In the experimental context, imperfections in the measurements, noise in the classical communication channel, degradation of the entanglement, and imperfections in the local unitary transformations, mean that Bob's state is not precisely the same as the state of the client C. A final step in any teleportation protocol is to check to see to what extent the state is teleported. In other words we need to determine the probability that the teleported state is the one we want, that is we need the fidelity. This of course requires knowledge of the actual state of the mode C. As the fidelity is a probability it must be adequately sampled, so the verification stage requires repeated measurements upon the output state of the teleportation scheme at mode B. The previously mentioned errors act independently from trial to trial which means we must describe the teleported state as a mixed state ρ_B in general. In this case the fidelity is given by

$$F = \langle \psi | \rho_B | \psi \rangle . \tag{14.171}$$

We can also define an overall measure of performance in terms of the average fidelity $\bar{F}$ obtained by averaging the fidelity over all possible client states $|\psi\rangle$ with some appropriate measure on the set of pure states. We first need to specify the class of client states and the ensemble from which they are drawn. In the case of client states drawn from an ensemble of coherent states we can obtain an explicit result. If A and B share no entanglement $\bar{F} = \frac{1}{2}$. This is the classical boundary for teleportation of a coherent state. A quantum protocol would need to give an average fidelity greater than 0.5.

Quantum teleportation using squeezed states has been demonstrated by the group of *Kimble* at Caltech [14.28]. Related experiments have been performed by the group of di Martini in Rome [14.31] and *Zeilinger* in Innsbruck [14.32]. In order to understand the Caltech experiment we need to explain how some of the formal steps in the preceding analysis are done in the laboratory. We will also need to understand how imperfections, such as photon loss, and noise are included.

In order to effect a joint measurement of the combined quadratures $\hat{X}_C - \hat{X}_A$, $\hat{Y}_C + \hat{Y}_A$, the experiment first combined the client and sender field amplitudes on a 50/50 beam splitter, followed by direct homodyne measurements of the output fields after the beam splitter. After the beam splitter we then make a homodyne measurement of X-quadrature on mode C and

the Y-quadrature on mode A. In the case of homodyne detection, the actual measurement records are two photocurrents (I_X, I_P). For unit efficiency detectors, this is an optimal measurement of the corresponding quadratures $\hat{X}_C$, $\hat{Y}_A$. In reality however efficiency is not unity and some noise is added to the measurement results. We shall return to this point later.

The measured photocurrents are a classical stochastic processes and may be sent to the receiver B over a standard communication channel. On receipt of this information the receiver must apply the appropriate unitary operator, a displacement, to complete the protocol. Displacement operators are quite easy to apply in quantum optics. To displace a mode, say B, we first combine it with another mode, prepared in a coherent state with large amplitude, $\alpha \to \infty$, on a beam splitter with very high reflectivity, $R \to 1$, for mode B. If $|\phi\rangle_B$ is the state of B, then after the combination at the beam splitter the state of B is transformed by

$$|\phi\rangle_B \to D(\beta)|\phi\rangle_B , \tag{14.172}$$

where $D(\beta) = \exp(\beta b^\dagger - \beta^* b)$ is the unitary displacement operator, and

$$\beta = \lim_{R \to 1} \lim_{\alpha \to \infty} \alpha\sqrt{1-R} . \tag{14.173}$$

In terms of the quadrature operators for B the displacement operator can be written

$$D(x, y) = e^{iy\hat{X}_B + ix\hat{Y}_B} \tag{14.174}$$

with $\beta = x + iy$. A suitable choice of β will produce the required displacements to complete the teleportation protocol. This was achieved by using the measured photocurrents to control the real and imaginary components of the displacement field using electrically controlled modulators. As the measurement records, the photocurrents, are classical stochastic processes they can be scaled by a gain factor, g, to produce the required β.

The experiment included an additional step to verify to what extent the state received by Bob faithfully reproduced the stat of the client field. In this experiment the state of the client was a coherent state. In essence another party, Victor, is verifying the fidelity of the teleportation using homodyne detection to monitor the quadrature variances of the teleported state.

The key feature that indicates success of the teleportation is a drop in the quadrature noise seen by Victor when Bob applies the appropriate unitary operator to his state. This is done by varying the gain g. If Bob simply does nothing to his state ($g = 0$), then Victor simply gets one half of a squeezed state. Such a state has a quadrature

noise level well above the vacuum level of the coherent state. As Bob varies his gain, Victor finds the quadrature noise level fall until, at optimal gain, the teleportation is effected and the variance falls to the vacuum level of a coherent state. In reality of course extra sources of noise introduced in the detectors and control circuits limit the extent to which this can be achieved.

In a perfect system the fidelity should be peaked at unit gain. However photon loss in the shared entanglement resource and detector inefficiencies reduce this. In the experiment, the average fidelity at unit gain was found to be $F = 0.58 \pm 0.002$. As discussed previously, this indicates that entanglement is an essential part of the protocol.

14.6.1 Linear Optical Quantum Computing

In 1982 *Feynman* [14.33] suggested there were certain problems that would be difficult to preform on a computer running according to classical mechanics but which would be easy to do on a computer running according to quantum principles. In 1985 *Deutsch* [14.34] showed in more detail what would be required for a quantum computer (QC) and gave examples of problems that might be solved more efficiently on such a machine compared to a classical machine. The promise of quantum computation suggested by Feynman and elaborated by Deutsch was made very apparent in the factoring algorithm of *Shor* in 1994 [14.35]. Shor's algorithm is an efficient factoring algorithm for a quantum computer, while all known algorithms for factoring on a classical computer require an exponentially increasing number of steps as the size of the integer to be factored increases.

How does a quantum computer achieve this enormous increase in efficiency? The answer lies in the quantum superposition principle. Suppose we wish to evaluate a function f on some binary input string x to produce a binary output string $f(x)$. We can code the input and output binary string as the product state of N qubits. The output qubits however are preset to zero. Now we set up a machine so that under unitary quantum evolution the state transforms as

$$|x\rangle |0\rangle \rightarrow |x\rangle |f(x)\rangle . \tag{14.175}$$

Why do we demand that the transformation be unitary? Consider what happens when we prepare the input qubits in a uniform superposition of all possible input states;

$$\sum_x |x\rangle |0\rangle \rightarrow \sum_x |x\rangle |f(x)\rangle . \tag{14.176}$$

If the dynamics is unitary the linearity of quantum mechanics ensures that (14.175) implies (14.176). It would appear that in a single run of the machine we have evaluated all possible values of the function.

This is not quite as interesting as it seems. If we measure the output qubits we will get one value at random. That does not seem very useful. To see why it is useful to do this let us ask; when would we ever want to evaluate every value of a particular function? The answer, is when we are not so much interested in a particular value of the function as a *property* of the function. How can we use the superposition state in (14.176) to determine properties of functions? To see this consider a function f that maps the binary numbers $\{0, 1\}$ to $\{0, 1\}$. There must be four such functions, two of which are constant functions with $f(0) = f(1)$, and two have $f(0) \neq f(1)$, so called balanced functions. Suppose now the problem involves determining if a function is balanced or constant. On a classical computer to answer this we need to make two evaluations of the function, $f(0)$ and $f(1)$. We would then need to run the computer twice. However a quantum computer can determine this property in only a single run.

Suppose we have two qubits. One qubit will be used to encode the input data and the other qubit, the output qubit, will contain the value of the function after the machine is run. The output qubit is initially set to 0. The machine might then run according to (14.175). However there is a problem with this expression. If f is a constant function we have two distinct input states unitarily transformed to the same output state. Clearly this is not a reversible transformation and thus cannot be implemented unitarily. The problem is easily fixed however by setting up the machine to evolve the states according to

$$|x\rangle |y\rangle \rightarrow |x\rangle |y \oplus f(x)\rangle , \tag{14.177}$$

where the addition is defined modulo two and we have allowed all possible settings of both qubits. The unitary transformation which realises this operation has been called the f-controlled NOT gate [14.36]. The input qubit x is the control qubit while the output qubit y is the target. If the value of f on the control qubit is one, the bit on the target is flipped; thus the name. Every unitary transformation on qubits can be realised as suitable networks of simple one- and two-qubit gates using primitive gate operations.

The quantum algorithm that solves this problem is a version of a quantum algorithm first proposed by Deutsch. It proceeds as follows. In the first step we prepare the output qubit in the state $|0\rangle - |1\rangle$ (we ignore

normalisation in what follows for simplicity). This can be done using a single-qubit rotation $|1\rangle \rightarrow |0\rangle - |1\rangle$. Such a rotation is called a Hadamard transformation. In the second step the input qubit is prepared in the 0 state and is then subjected to a Hadamard gate as well, which immediately produces a superposition of the two possible inputs for the function f. In the third step we couple the input and output qubit via the f-controlled NOT gate. The transformation is

$$
\begin{aligned}
(|0\rangle + |1\rangle)&(|0\rangle - |1\rangle) \\
&\rightarrow [(-1)^{f(0)}|0\rangle + (-1)^{f(1)}|1\rangle](|0\rangle - |1\rangle) .
\end{aligned}
$$
(14.178)

In the last step we apply a Hadamard gate to the input qubit so that

$$
\begin{aligned}
[(-1)^{f(0)}|0\rangle &+ (-1)^{f(1)}|1\rangle](|0\rangle - |1\rangle) \\
&\rightarrow (-1)^{f(0)}|f(0) \oplus f(1)\rangle(|0\rangle - |1\rangle) .
\end{aligned}
$$
(14.179)

Thus the input qubit is in state 0 if f is constant and is in state 1 if f is balanced and measurement of the qubit will determine if the function is balanced or constant with certainty in a single run of the machine.

There is a simple quantum optical realisation of this algorithm based on a Mach–Zehnder interferometer, see Fig. 14.4. The interferometer couples two modes of the field, labelled upper (U) and lower (L). A single photon in mode U encodes logical 1 while a single photon in mode L encodes logical 0. At the input a single photon in mode U is transformed by the first beam splitter into a superposition state in which it is in either mode 1 or mode 0. If we encode our qubits so that a $|1\rangle$ corresponds to the photon in mode 1 and a $|0\rangle$ corresponds to a photon in mode 0, the first beam splitter performs a Hadamard transformation. Now we insert into each arm a phase
Fig. 14.4 An optical realisation of the Deutsch algorithm in terms of a Mach–Zehnder interferometer. The phase shifts are chosen according to the values of a binary function f as $\phi_0 = f(0)\pi$, $\phi_1 = f(1)\pi$

shift ϕ_i which can only be set at 0 or π phase shift. We encode the value of the functions as $\phi_0 = f(0)\pi$ and $\phi_1 = f(1)\pi$. Set the interferometer so that in the absence of the phase shift the photon emerges with certainty at the upper detector, which encodes a 1. The lower detector encodes a zero. It is then clear that if $f(0) = f(1)$ a single photon will emerge at the upper detector, while if $f(0) \neq f(1)$ the photon will be detected at the lower detector, that is the result is a 0.

The previous example illustrates the key features of a quantum algorithm. Firstly it involves unitary transformations of pure quantum states. Secondly we need both single qubit and two qubit interactions to produce entangled states. These were the Hadamard transformation (H-gate) and a controlled NOT transformation (CNOT gate). It turns out that suitable networks of an arbitrary single qubit rotations, together with a controlled NOT gate, can perform any computation involving arbitrarily many qubits.

In the interferometric implementation of Deutsch algorithm we used a simple physical qubit based on a single-photon excitation of one of a pair of spatial modes. This is know as a *dual-rail* logic. The relationship between logical states and the physical photon number state is

$$
|0\rangle_L = |1\rangle_1 \otimes |0\rangle_2 ,
$$
(14.180)

$$
|1\rangle_L = |0\rangle_1 \otimes |1\rangle_2 .
$$
(14.181)

The modes could be two input modes to a beam splitter distinguished by the different directions of the wave vector, or they could be distinguished by polarisation. In the case of a beam splitter a single qubit gate is easily implemented by the linear transformation

$$
a_i(\theta) = U(\theta)^\dagger a_i U(\theta)
$$
(14.182)

with $U(\theta) = \exp\left[\theta(a_1 a_2^\dagger - a_1^\dagger a_2)\right]$. Thus

$$
a_1(\theta) = \cos\theta a_1 - \sin\theta a_2 ,
$$
(14.183)

$$
a_2(\theta) = \cos\theta a_2 + \sin\theta a_1 .
$$
(14.184)

The description in the logical basis becomes,

$$
|0\rangle_L \rightarrow \cos\theta_1 |0\rangle_L - \sin\theta_1 |1\rangle_L ,
$$
(14.185)

$$
|1\rangle_L \rightarrow \cos\theta_1 |1\rangle_L + \sin\theta_1 |0\rangle_L .
$$
(14.186)

While single-qubit gates are readily implemented by linear optical devices such as beam splitters, quarter-wave plates, phase shifters etc., two-qubit gates are difficult. In order to implement the controlled phase gate (CSIGN) defined by

$$
|x\rangle_L |y\rangle_L \rightarrow U_{CP}|x\rangle_L |y\rangle_L = (-1)^{x \cdot y}|x\rangle_L |y\rangle_L .
$$
(14.187)
Fig. 14.5 A conditional state transformation conditioned on photon counting measurements

In a dual-rail single-photon code, this can be implemented using a two-mode Kerr nonlinearity. The two-mode generalisation is described by the Hamiltonian

$$H = \hbar \chi a_1^\dagger a_1 a_2^\dagger a_2 . \tag{14.188}$$

At the level of single photons this Hamiltonian produces the transformation, $|x\rangle|y\rangle \to e^{-ixy\chi t}|x\rangle|y\rangle$ and it is a simple matter to implement the CSIGN gate in the logical basis for the dual-rail single-photon code.

There are at least two problems in pursuing this approach: (a) the difficulty of realising number states in the laboratory, and (b) the difficulty of producing one-photon phase shifts of the order of π. The second difficulty is very considerable. Third-order optical nonlinearities are very small for a field with such a low intensity as a single photon. However experimental advances may eventually overcome this [14.37, 38].

A quite different approach to achieve large single-photon conditional phase shifts is based on the nonunitary transformation of a state that results when a measurement is made. Consider the situation shown in Fig. 14.5. Two modes of an optical field are coupled via a beam splitter. One mode is assumed to be in the vacuum state (a) or a one-photon state (b), while the other mode is arbitrary. A single-photon counter is placed in the output port of mode 2. What is the conditional state of mode 1 given a count of n photons?

Consider two modes, a_1 and a_2, coupled with a beam-splitter interaction, described by the one-parameter unitary transformation, given in (14.183), (14.184) We now assume that photons are counted on mode a_2 and calculate the conditional state for mode a_1 for two cases: no count and also for a single count at mode a_2. The conditional state of mode a_1 is given by (unnormalised),

$$|\tilde{\psi}^{(i)}\rangle_1 = \hat{\Upsilon}(i)|\psi\rangle_1 , \tag{14.189}$$

where

$$\hat{\Upsilon}(i) =_2 \langle i|U(\theta)|i\rangle_2 , \tag{14.190}$$

with $i = 1, 0$. The probability to observe each event is given by

$$P(i) = \langle \psi|\Upsilon^\dagger(i)\hat{\Upsilon}(i)|\psi\rangle_1 \tag{14.191}$$

which fixes the normalisation of the state,

$$|\psi^{(i)}\rangle_1 = \frac{1}{\sqrt{P(i)}}|\tilde{\psi}^{(i)}\rangle_1 . \tag{14.192}$$

We find that

$$\hat{\Upsilon}(0) = \sum_{n=0}^{\infty} \frac{(\cos\theta - 1)^n}{n!} (a_1^\dagger)^n a_1^n ,$$

$$\hat{\Upsilon}(1) = \cos\hat{\Upsilon}^{(0)} - \sin^2\theta a_1^\dagger \hat{\Upsilon}^{(0)} a_1 .$$

This can be written more succinctly using normal ordering,

$$\hat{\Upsilon}(0) =: e^{\ln(\cos\theta)} : . \tag{14.193}$$

In order to see how we can use these kind of transformations to effect a CSIGN gate, consider the situation shown in Fig. 14.6. Three optical modes are mixed on a sequence of three beam splitters with beam splitter parameters θ_i. The *ancilla* modes, a_1 and a_2 are restricted to be in the single-photon states $|1\rangle_2$ and $|0\rangle_3$, respectively. We will assume that the *signal* mode a_0 is restricted to have *at most* two photons, thus

$$|\psi\rangle = \alpha|0\rangle_0 + \beta|1\rangle_0 + \gamma|2\rangle_0 . \tag{14.194}$$

This captures the fact that in the dual-rail encoding a general two-qubit state can have at most two photons. The objective is to chose the beam splitter parameters so that when the two detectors at the output of modes 2 and 3 detect 1 and 0 photons respectively (that is detect no change in their occupation), the signal state is transformed as

$$|\psi\rangle \to |\psi'\rangle = \alpha|0\rangle + \beta|1\rangle - \gamma|2\rangle \tag{14.195}$$
Fig. 14.6 A conditional state transformation on three optical modes, conditioned on photon counting measurements on the ancilla modes a_2, a_3. The signal mode a_1 is subjected to a π phase shift

with a probability that is *independent* of the input state $|\psi\rangle$. This last condition is essential as, in a quantum computation, the input state to a general two-qubit gate is completely unknown. We will call this transformation the NS (for nonlinear sign shift) gate. This can be achieved using: $\theta_1 = -\theta_3 = 22.5°$ and $\theta_2 = 65.53°$. The probability of the conditioning event ($n_2 = 1, n_3 = 0$) is 1/4. Note that we cannot be sure in a given trial if the correct transformation will be implemented. Such a gate is called a *nondeterministic* gate. However the key point is that success is heralded by the results on the photon counters (assuming ideal operation).

We can now proceed to a CSIGN gate in the dual-rail basis. Consider the situation depicted in Fig. 14.7. We first take two dual-rail qubits encoding for $|1\rangle_L|1\rangle_L$. The single-photon components of each qubit are directed towards a 50/50 beam splitter where they overlap perfectly in space and time and produces a state of the form $|0\rangle_2|2\rangle_3 + |2\rangle_2|0\rangle_3$, a effect known as the Hong-Ou-Mandel (HOM) interference [14.39]. We then insert an NS gate into each output arm of the HOM interference. When the conditional gates in each arm work, which occurs with probability 1/16, the state is multiplied by an overall minus sign. Finally we direct these modes towards another HOM interference. The output state is thus seen to be $-|1\rangle_L|1\rangle_L$. One easily checks the three other cases for the input logical states to see that this device implements the CSIGN gate with a probability of 1/16 and successful operation is heralded.

Clearly a sequence of nondeterministic gates is not going to be much use: the probability of success after a few steps will be exponentially small. The key idea in using nondeterministic gates for quantum computation is based on the idea of gate teleportation of *Gottesmann* and *Chuang* [14.40]. In quantum teleportation an unknown quantum state can be transferred from A to B provided A and B first share an entangled state. Gottesmann and Chuang realised that it is possible si-

multaneously teleport a two-qubit quantum state and implement a two-qubit gate in the process by first applying the gate to the entangled state that A and B share prior to teleportation.

We use a nondeterministic NS gate to prepare the required entangled state, and only complete the teleportation when the this stage is known to work. The teleportation step itself is nondeterministic but, as we see below, by using the appropriate entangled resource the teleportation step can be made near-deterministic. The near deterministic teleportation protocol requires only photon counting and fast feedforward. We do not need to make measurements in a Bell basis.

A nondeterministic teleportation measurement is shown in Fig. 14.8. The client state is a one-photon state in mode 0 $\alpha|0\rangle_0 + \beta|1\rangle_0$ and we prepare the entangled ancilla state

$$|t_1\rangle_{12} = |01\rangle_{12} + |10\rangle_{12} , \qquad (14.196)$$

where mode 1 is held by the sender A and mode-2 is held by the receiver B. For simplicity we omit normalisation constants wherever possible. This an ancilla state is easily generated from $|01\rangle_{12}$ by means of a beam splitter.

If the total count is $n_0 + n_1 = 0$ or $n_0 + n_1 = 2$, an affective measurement has been made on the client state and the teleportation has failed. However if $n_0 + n_1 = 1$, which occurs with probability 0.5, teleportation succeeds with the two possible conditional states being

$$\alpha|0\rangle_2 + \beta|1\rangle_2 \quad \text{if } n_0 = 1, n_1 = 0 , \qquad (14.197)$$
$$\alpha|0\rangle_2 - \beta|1\rangle_2 \quad \text{if } n_0 = 0, n_1 = 1 . \qquad (14.198)$$

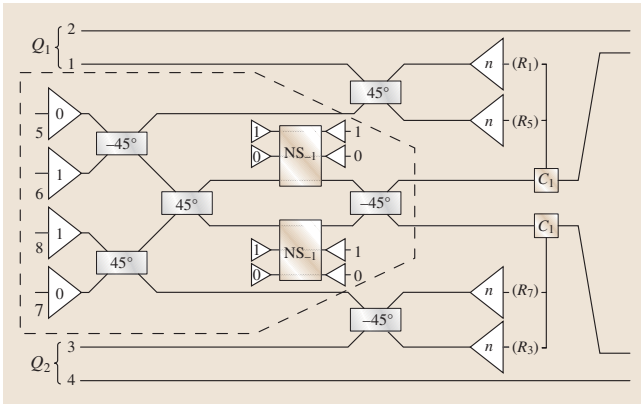
This procedure implements a partial Bell measurement and we will refer to it as a nondeterministic teleportation protocol, $T_{1/2}$. Note that teleportation failure is detected and corresponds to a photon-number measurement of the state of the client qubit. Detected number
Fig. 14.7 A conditional state transformation conditioned on photon counting measurements. A CSIGN gate that works with probability of 1/16. It uses HOM interference and two NS gates
Fig. 14.8 A partial teleportation system for single-photons states using linear optics


Fig. 14.9 A CSIGN two-qubit gate with teleportation to increase the success probability to 1/4. When using the basic teleportation protocol (T_1), we may need to apply a sign correction. Since this commutes with CSIGN, it is possible to apply CSIGN to the prepared state before performing the measurements, reducing the implementation of CSIGN to a state-preparation (outlined) and two teleportations. The two teleportation measurements each succeed with probability 1/2, giving a net success probability of 1/4. The correction operations C_1 consist of applying the phase shifter when required by the measurement outcomes

measurements are a very special kind of error and can be easily corrected by a suitable error correction protocol. For further details see [14.41]

The next step is to use $T_{1/2}$ to effect a conditional sign flip csign$_{1/4}$ which succeeds with probability 1/4. Note that to implement csign on two bosonic qubits in modes 1, 2 and 3, 4 respectively, we can first teleport the first modes of each qubit to two new modes (labelled 6 and 8) and then apply csign to the new modes. When using $T_{1/2}$, we may need to apply a sign correction. Since this commutes with csign, there is nothing preventing us from applying csign to the prepared state before performing the measurements. The implementation is shown in Fig. 14.9 and now consists of first trying to prepare two copies of $|t_1\rangle$ with csign already applied, and then performing two partial Bell measurements. Given the prepared state, the probability of success is $(1/2)^2$. The state can be prepared using csign$_{1/16}$, which means that the preparation has to be retried an average of 16 times before it is possible to proceed.

To improve the probability of successful teleportation to $1 - 1/(n+1)$, we generalise the initial entanglement by defining

$$|t_n\rangle_{1...2n} = \sum_{j=0}^{n} |1\rangle^j |0\rangle^{n-j} |0\rangle^j |1\rangle^{n-j} . \qquad (14.199)$$

The notation $|a\rangle^j$ means $|a\rangle|a\rangle \ldots$, j times. The modes are labelled from 1 to $2n$, left to right. Note that the state exists in the space of n bosonic qubits, where the kth qubit is encoded in modes $n + k$ and k (in this order).

To teleport the state $\alpha|0\rangle_0 + \alpha|1\rangle_0$ using $|t_n\rangle_{1...2n}$ we first couple the client mode to half of the ancilla modes by applying an $n + 1$ point Fourier transform on modes 0 to n. This is defined by the mode transformation

$$a_k \rightarrow \frac{1}{\sqrt{n+1}} \sum_{l=0}^{n} \omega^{kl} a_l , \qquad (14.200)$$

where $\omega = e^{i2\pi/(n+1)}$ This transformation does not change the total photon number and is implementable with passive linear optics. After applying the Fourier transform, we measure the number of photons in each of the modes 0 to n. If the measurement detects k bosons altogether, it is possible to show [14.41] that, if $0 < k < n+1$, then the teleported state appears in mode $n + k$ and only needs to be corrected by applying a phase shift. The modes $2n - l$ are in state 1 for $0 \le l < (n - k)$ and can be reused in future preparations requiring single bosons. The modes are in state 0 for $n - k < l < n$. If $k = 0$ or $k = n + 1$ an effective measurement of the client is made, and the teleportation fails. The probability of these two events is $1/(n+1)$, regardless of the input. Note that again failure is detected and corresponds to measurements in the basis $|0\rangle, |1\rangle$ with the outcome known. Note that both the necessary correction and the receiving mode are unknown until after the measurement.

The linear optics quantum computing (LOQC) model described above can be drastically simplified by adopting the cluster state method of quantum computation [14.42]. The cluster state model was developed by *Raussendorf* and *Breigel* [14.43] and is quite different from the circuit models that we have been using. In cluster state QC, an array of qubits is initially prepared in a special entangled state. The computation then proceeds by making a sequence of single-qubit measurements. Each measurement is made in a basis that depends on prior measurement outcomes. Nielsen realised that the LOQC mode of [14.41] could be used to efficiently assemble the cluster using the nondeterministic teleportation t_n. As we saw the failure mode of this gate constituted an accidental measurement of the qubit in the computational basis. The key point is that such an error does not destroy the entire assembled cluster but merely detaches one qubit from the cluster. This enables a protocol to be devised that produces a cluster that grows on average. The LOQC cluster state

method dramatically reduces the number of optical elements required to implement the original LOQC scheme. Of course if large single-photon Kerr nonlinearities were available, the optical cluster state method could be made deterministic [14.44].

A number of LOQC protocols have been implemented in the laboratory. The first was experiment was performed by *Pittmann* and *Franson* [14.45]. This used entangled ancillas that are readily produced as photon pairs in a spontaneous parametric down conversion process. A simplified version of the LOQC model was implemented by *O'Brien* et al. [14.46], based on a proposal of *Ralph* et al. [14.47] for a CNOT gate. The simplification results by firstly setting the beam splitter parameters θ_1 and θ_3 to zero in the NS gate implementation and secondly only detecting photon coincidences at the output. This gate performs all the operations of a CNOT gate but requires only a two-photon input. Detecting only coincidences means that the device must be configured so that correct operation leads to a coincidence detection of both photons at the output. The gate is nondeterministic but gate failures are simply not detected at all. In essence, the control (C) and target (T) qubits act as their own ancilla.

In the University of Queensland (UQ) experiment the two modes of each qubit are distinguished by orthogonal polarisations. This may be converted to spatial mode encoding by using polarising beam splitters and a half-wave plate. The key advantage in using a gate based on two-photon coincidence detection is that spontaneous parametric down-conversion (SPDC) may be used in

place of true single-photon sources. An SPDC produces a photon pair in two distinct spatiotemporal modes at random times. There is a small probability of producing more than two photons, but this can be neglected.

A diagnostic of the fidelity of gate operation is provided by state tomography, a reconstruction of the full density matrix of the output state [14.48], when the output is entangled. State tomography requires sampling of the statistics for the measurement outcomes of 16 different two-qubit projections. Given these statistics data inversion can be devised to reconstruct the density matrix for the output state. Given the density matrix, we can then compute its overlap, or fidelity, with respect to the pure ideal entangled state $|\psi^-\rangle$ that the ideal gate would produce. In the case of $|\psi^-\rangle$ the fidelity obtained in the UQ experiment was 0.87 ± 0.08. This is sufficiently high that such a state were it not destroyed in the detection process, would violate a Bell inequality test.

More recent experiments have improved on these early experiments. An NS gate close to the original proposal, was implemented in the Zeilinger group, using a polarization encoding and the four-photon state emitted by spontaneous parametric down-conversion [14.49]. As in the UQ experiment, a coincidence detection configuration was used to signal correct operation of the gate. The experimentally observed conditional phase shift was $1.05 \pm 0.06)\pi$. Future progress on linear optical quantum computing schemes will most likely be based on cluster state implementations. A four-photon cluster state implementation was recently implemented by the Zeilinger group [14.50].

15. Nanooptics

Nanooptics deals with optical near fields, the electromagnetic fields that mediate the interaction between nanometric particles located in close proximity to each other. The projection–operator method is a theoretical description of how a virtual exciton–polariton is exchanged between these particles, corresponding to the nonresonant interaction. The optical near field mediates this interaction, and is represented by a Yukawa function, which means that the optical near-field energy is localized around the nanometric particles like an electron cloud around an atomic nucleus. Its decay length is proportional to the particle size. This chapter is primarily a review of nanophotonics, a leading branch of nanooptics, which is the technology utilizing the optical near field. The true nature of nanophotonics is to realize qualitative innovation in photonic devices, fabrication, and systems by utilizing novel functions and phenomena caused by optical near-field interactions, which are impossible as long as

conventional propagating light is used. As evidence of such qualitative innovation, this chapter describes novel nanophotonic devices, nanophotonic fabrication, nanophotonic systems, and extensions related to science.

15.1 Basics

Nanooptics deals with the light generated in or on nanometer-sized particles. It has been applied to open an innovative field of technology, i. e., *nanophotonics*, in order to develop novel photonic devices, fabrications, and systems, as proposed by *Ohtsu* [15.1]. Nanophotonics is a means, for example, to reduce the size of photonic devices, improve the resolution of optical fabrications, and increase the storage density of optical disk memories.

Considering photonic devices, the technologies listed below, which bear some relation to nanophotonics, have recently been developed. Nevertheless, they cannot reduce the size of these devices beyond the diffraction limit of light.

1. **Photonic crystal** [15.2] This is a filter device used to control optical interference and light scattering by installing a subwavelength-sized periodic structure in the device material, as is the case for a diffraction grating. Constructive interference between the scattered light takes place at the center of the material, concentrating the optical energy. In contrast, at the edge of the material, the scattered light interferes destructively. In order to maintain the destructive interference, the rim must be sufficiently larger than the wavelength of light; otherwise the constructive interference is not maintained, and light concentrated at the center leaks to the rim. This means that a photonic crystal involves conventional wave-optical technology and the minimum size of the device is limited by diffraction.

2. **Plasmonics** [15.3] This technology utilizes the resonant enhancement of the light in a metal by exciting free electrons. The optical energy can be concentrated as a plasmon on the metal surface as a result

of the strong interaction with free electrons. However, this technology is based on wave optics in the metal, and so is again limited by diffraction. Related technologies, such as metaoptics [15.4] and optics in materials with a negative refractive index [15.5], are also limited by diffraction.

3. **Silicon photonics** [15.6] This technology involves developing narrow-striped optical waveguides using high-refractive-index silicon crystals to confine the light effectively. This is also an application of wave optics in silicon, and is limited by diffraction.

4. **Quantum-dot laser** [15.7] This is a laser device that uses nanometer-sized semiconductor quantum dots as the gain media. Since the quantum dots are much smaller than the wavelength of light, the light cannot be confined in an individual quantum dot efficiently due to scattering and diffraction. To solve this problem, a large number of quantum

dots are installed in a conventional laser cavity, which means that the device size is limited by diffraction.

Although the four examples listed above have been popular subjects of study in recent years, they are all based on diffraction-limited wave optics. Even if novel or nanometer-sized materials are used in the future, the size of a photonic device cannot be reduced beyond the diffraction limit as long as propagating light is used for its operation. This also applies to improvements in the resolution of optical fabrication and for increasing the storage density of optical disk memories. To go beyond the diffraction limit, one needs non-propagating nanometer-sized light to induce primary excitation in a nanometer-sized material in such a manner that the spatial phase of the excitation is independent of that of the incident light.

15.2 Nanophotonics Principles

The use of optical near fields has been proposed as a way to transcend the diffraction limit imposed on optical science and technology [15.8]. This proposal holds that an optical near field can be generated on a subwavelength-sized aperture by irradiating the propagating light. It also holds that the size of the spatial distribution of the optical near-field energy depends not on the wavelength of the incident light, but on the aperture size. Although these claims are no more than those in the framework of primitive wave optics, optical near fields have been applied to realize diffraction-free, high-resolution optical microscopy (i. e., optical near-field microscopy), which achieved rapid progress after high-resolution, high-throughput fiber probes were invented and fabricated in a reproducible manner [15.9, 10]. However, in the early stage of these studies, the concept of optical near fields was not clearly discriminated from that of an evanescent wave on a planar material surface (i. e., a two-dimensional topographical material) or that of a guided wave in a subwavelength-sized cross-sectional waveguide (i. e., a one-dimensional topographical material).

In order to distinguish these clearly, note that an evanescent wave is generated by the primary excitations, i. e., electric dipoles, induced near the two-dimensional material surface, which align periodically depending on the spatial phase of the incident light. In contrast, the guided wave in a subwavelength-sized cross-sectional waveguide is generated by the electronic dipoles in-

duced along the one-dimensional waveguide material. They align periodically depending on the spatial phase of the incident light. Examples are the silicon and metallic waveguides used for silicon photonics and plasmonics, respectively. The two-dimensional evanescent wave and one-dimensional guided wave are both light waves, which are generated by periodic alignment of electric dipoles depending on the spatial phase of the incident light.

Unlike these waves, an optical near field is generated by the electronic dipoles induced in a nanometric particle (i. e., a subwavelength-sized zero-dimensional topographical material). Their alignment is independent of the spatial phase of the incident light because the particles are much smaller than the wavelength of the incident light. Instead, it depends on the size, conformation, and structure of the particles. Due to this independence and dependence, optical science and technology beyond the diffraction limit can be realized only by an optical near field, not by an evanescent wave or a guided wave.

Classical electromagnetics explains the mechanisms of optical near-field generation described above (Fig. 15.1): electric dipoles are induced by irradiating a nanometric particle with the incident light. Among the electric lines of forces originating from these electric dipoles, the optical near field is represented by those that originate from the positive charge of the electric dipole

and terminate on the negative charge. This does not propagate to the far field. Since the particle is much smaller than the wavelength of the incident light, the alignment of the electric dipoles is determined independently of the spatial phase of the incident light. Therefore, the spatial distribution and decay length of the optical near-field energy depend not on the wavelength of the light, but on the size, conformation, and structure of the particle. Moreover, the scattered light is represented by the closed loop of the electric line of forces, and propagates to the far field.

Methods such as Green's function, numerical calculation using the finite-difference time domain (FDTD) method, have been developed for semiquantitative description of the optical near field based on conventional optical theories (i. e., the theories discussed in other chapters of this handbook) [15.11]. However, conventional optics theories do not provide any physically intuitive pictures of non-propagating nanometric optical near fields because these theories have been developed to describe light waves propagating through macroscopic space or materials. For nanooptics and nanophotonics, a novel theory has been developed based on a framework that is completely different from those of the conventional theories.

This novel theory is based on how one observes an optical near field, i. e., the interaction and energy transfer between nanometric particles via an optical near field. This perspective is essential because the interaction and energy transfer are indispensable for nanophotonic devices and nanophotonic fabrications. That is, in order to observe a non-propagating optical near field, a second particle is inserted to generate observable scattered light by disturbing the optical near field (Fig. 15.2). However, the real system is more complicated than that shown in Fig. 15.2 because the nanometric subsystem (the two particles and the optical near field) is buried in the macroscopic subsystem consisting of the macroscopic substrate material and the macroscopic electromagnetic fields of the incident and scattered light (Fig. 15.3).

The premise behind the novel theory is to avoid the complexity of describing all of the behaviors of nanometric and macroscopic subsystems rigorously, since we are interested only in the behavior of the nanometric subsystem. The macroscopic subsystem is expressed as an exciton–polariton, which is a mixed state of material excitation and electromagnetic fields. Since the nanometric subsystem is excited by an electromagnetic interaction with the macroscopic subsystem, the projection-operator method is effective for describing the quantum-mechanical states of these systems [15.12].
Fig. 15.1 The generation of optical near fields
Fig. 15.2 The observation of optical near fields
Fig. 15.3 A nanometric subsystem composed of two particles and an optical near field, buried in a macroscopic subsystem

Under this treatment, the nanometric subsystem is regarded as being isolated from the macroscopic subsystem, while the functional form and magnitude of the effective interactions between the elements of the nanometric subsystem are influenced by the macroscopic

Fig. 15.4 The exchange of a real exciton–polariton and a virtual exciton–polariton

Fig. 15.5 Nanophotonics for realizing qualitative innovation

tion, which is represented by a Yukawa function. The Yukawa function represents the localization of the optical near-field energy around the nanometric particles like an electron cloud around an atomic nucleus whose decay length is equivalent to the material size [15.12]. The latter corresponds to the resonant interaction mediated by the conventional propagating scattered light, which is represented by a conventional spherical wave function.

As described, the optical near field is an electromagnetic field that mediates the interaction between nanometric particles located in close proximity to each other. Nanooptics deals with this field. Nanophotonics is the technology that utilizes this field to realize novel device, fabrications, and systems. That is, a photonic device with a novel function can be operated by transferring the optical near-field energy between nanometric particles. In such a device, the optical near field transfers a signal and carries the information. Novel photonic systems become possible by using these novel photonic devices. Furthermore, if the magnitude of the transferred optical near-field energy is sufficiently large, structures or conformations of nanometric particles can be modified, which suggests the feasibility of novel photonic fabrication.

Note that the true nature of nanophotonics is to realize qualitative innovation in photonic devices, fabrications, and systems by utilizing novel functions and phenomena caused by optical near-field interactions, which are impossible as long as conventional propagating light is used (Fig. 15.5). On reading this note, one may understand that the advantage of going beyond the diffraction limit, i. e., quantitative innovation, is no longer essential, and is only a secondary nature of nanophotonics. In this sense, one should also note that optical near-field microscopy, i. e., the methodology used for image acquisition and interpretation in a nondestructive manner, is not an appropriate application of nanooptics and nanophotonics because the magnitude of the optical near-field energy transferred between the probe and sample must be extrapolated to zero.

Although few examples of qualitative innovations in nanooptics exist, nanophotonics has already realized this innovation by correctly utilizing the true nature of the optical near-field interaction, which is reviewed in the following sections.

subsystem. That is, the two nanometric particles can be considered as being isolated from the surrounding macroscopic systems and as interacting by exchanging the exciton–polariton energies.

Since the time required for this local electromagnetic interaction is very short, the uncertainty principle allows the exchange of a virtual exciton–polariton between the two nanometric particles, as well as that of a real exciton–polariton (Fig. 15.4). The former exchange corresponds to the nonresonant interaction between the two particles. The optical near field mediates this interac-

15.3 Nanophotonic Devices

For the operation of nanophotonic devices, it is essential to transfer the signal and fix the transferred signal

magnitude at the output terminal, which can be achieved by transferring and dissipating the optical near-field en-

ergy, respectively [15.13]. Several research groups have recently begun similar discussions on this operation (for example, refer to [15.14]). A pair of two closely spaced equivalent quantum dots is used as the input terminal of the nanophotonic device (Fig. 15.6). As a result of the optical near-field interaction between the two quantum dots driven by the input optical signal, the quantized energy levels of the exciton in the quantum dots are split into two. One corresponds to the symmetric state of the exciton, and the other is the antisymmetric state. They represent the respective parallel and antiparallel electric dipole moments induced in the two quantum dots.

The third, larger quantum dot, installed proximal to the input terminal (Fig. 15.7), is used as the output terminal of the device. The higher energy level of the exciton in this quantum dot is tuned to that of the symmetric state of the input terminal, which is made possible by adjusting the size of the third quantum dot. As a result of this tuning, optical near-field energy can be transferred from the input to the output terminal, allowing signal transfer. The excitation transferred to the output terminal is relaxed immediately to the lower energy level in the third quantum dot by coupling with phonons, which fixes the magnitude of the transferred signal.

A device utilizing the symmetric state of the input terminal in the manner shown in Fig. 15.7 is called a *phonon-coupled device*. Examples of phonon-coupled devices include nanophotonic switches, logic
Fig. 15.6 Two closely spaced quantum dots to be used as the input terminal of a nanophotonic device
Fig. 15.7 Optical near-field energy transfer from the input to the output terminal and successive fast relaxation

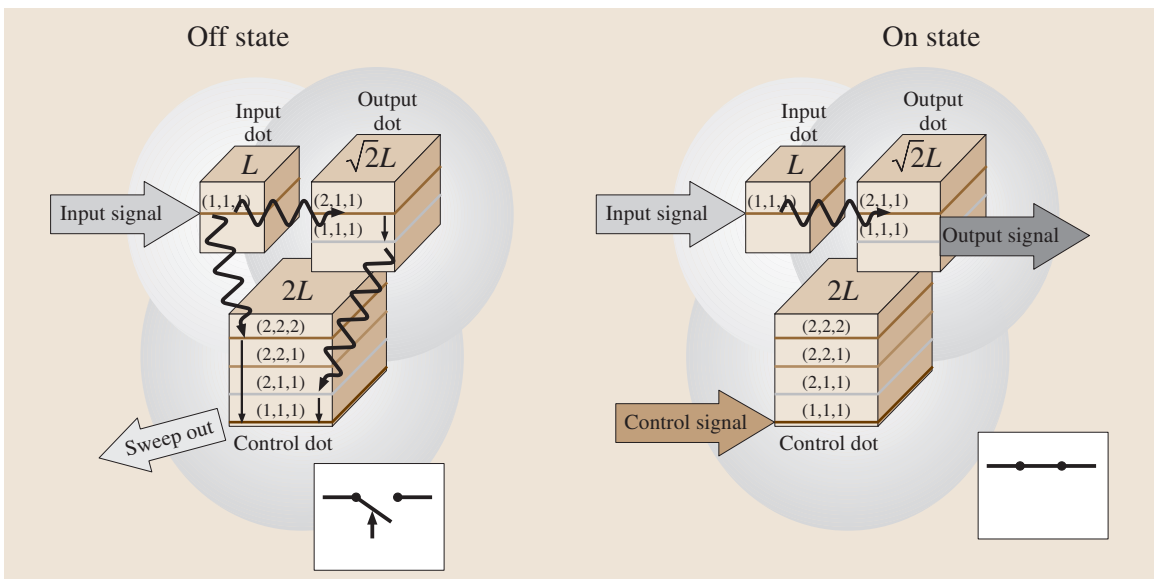
gates, such as AND and NOT gates [15.15], content-addressable memory [15.16], and digital-to-analog


Fig. 15.8 The structure of a nanophotonic switch. L is the size of the quantum dot used as the input terminal
Fig. 15.9 The spatial distribution of the output signal energy at the output terminal of the nanophotonic switch. This switch used three cubic CuCl quantum dots with sizes of 4, 6, and 8 nm, separated by a fixed distance of 3 nm

converters [15.17]. Conversely, a device utilizing the antisymmetric state is called a *propagating light-coupled device*; for example, optical buffer memory and superradiant-type optical pulse generators [15.18].

As an example of a phonon-coupled device, Fig. 15.8 shows a nanophotonic switch whose operation has been modified slightly from that shown in Fig. 15.7 [15.19]. Three cubic quantum dots with a size ratio of $1 : \sqrt{2} : 2$ are used as the input, output, and control terminals, respectively. This device utilizes the optical near-field energy transfer between the resonant energy levels of the exciton and successive fast relaxation. Note that the conventional optical transition between two resonant exciton levels in the adjacent quantum dots, e.g., the $(1,1,1)$ and $(2,1,1)$ energy levels of the input and output terminals, is forbidden. That is, no energies are transferred as long as the propagating light mediates the interaction between the quantum dots. In contrast, when using an optical near field, this transition is allowed due to the exchange of the virtual exciton–polariton. This is an example of a qualitatively innovative device operation because it is impossible as long as conventional propagating light is used. Figure 15.9 shows the spatial distributions of the output signal energy on the output terminal for the off and on states of the switching operation. The device is as small as 15 nm. Figure 15.10 represents the dynamic behavior of the output signal, which agrees well with the calculated results based on the virtual exciton–polariton model.

A figure of merit has been used as an important parameter for evaluating device performance. In the case of a switch, it is defined as a combination of device volume, switching time, switching energy, the ratio between on- and off-signal magnitudes, etc. The figure of merit for the nanophotonic switch is 10–100 times larger than those
Fig. 15.10 Dynamic behavior of the output signal of a nanophotonic switch. The figure on the *bottom* shows the experimental and theoretical curves of the part of the output signal identified by the ellipse in the figure on the *top*

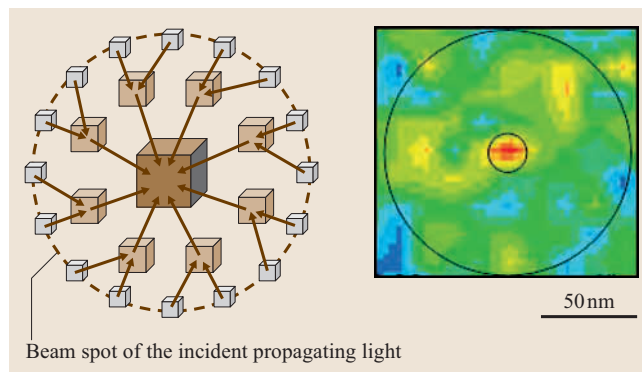
of conventional photonic switches operated using propagating light (e.g., devices using optical micromirrors, Mach–Zehnder interferometer-type waveguides, optically nonlinear media, and the quantum sublevels in a quantum dot). Furthermore, the magnitude of the heat dissipated from the nanophotonic switch is estimated to be as low as 10^{-12} W in the case of 1 GHz repetitive operation, which is only 10^{-5} times that of a conventional semiconductor transistor. Such a large figure of merit and the ultralow heat dissipation suggest a variety of applications to novel computation and information processing systems.

For applications to advanced systems, nanophotonic devices must be connected to conventional macroscopic photonic devices, such as optical fibers or semiconductor lasers. Figure 15.11 shows a novel device developed for this interconnection that concentrates the propagating light energy to a nanometric region [15.20]. It has

Fig. 15.11 The structure of an optical nanofountain and the spatial distribution of the optical signal energy, which used CuCl quantum cubes of 2–10 nm

Beam spot of the incident propagating light

50 nm

smaller quantum dots on the circular rim, medium-sized quantum dots installed inside, and the largest quantum dot fixed at the center. The propagating light energy incident into this circular device is concentrated to the largest quantum dot at the center due to both successive optical near-field energy transfer from the smaller to the larger quantum dots and fast relaxation, as in the case of the nanophotonic switch. This device has been named an *optical nanofountain* and its equivalent numerical aperture is as high as 40.


15.4 Nanophotonic Fabrications

Optical fabrications beyond the diffraction limit are required to produce a variety of conventional devices and to fabricate the nanophotonic devices reviewed in Sect. 15.3. To fabricate nanophotonic devices, several capabilities are required. A variety of materials must be deposited on a substrate and the inaccuracy of their sizes and positions must be as low as 1 nm for efficient, reproducible optical near-field energy transfer. However, conventional fabrication technologies using electron beams, ion beams, and propagating light cannot meet these requirements due to their low resolution, contamination, damage to the substrate, and low throughput.

To meet these requirements, novel technologies must be developed that can be realized by utilizing optical near-field energy transfer. Representative examples of such nanophotonic fabrications are reviewed in this section.

15.4.1 Photochemical Vapor Deposition

Photochemical vapor deposition is a way to deposit materials on a substrate using a photochemical reaction that pre-dissociates metalorganic molecules by irradiating gaseous molecules or molecules adsorbed on the substrate with ultraviolet light. Consequently, the electrons in the molecules are excited to a higher energy level following the Franck–Condon principle. This is an adiabatic process because no molecular vibrations or rotations are excited; i.e., the Born–Oppenheimer approximation is valid. After excitation, the electron transits to the dissociative energy level. As a result of this transition, the molecule is dissociated and the atoms

composing the molecule are deposited on the substrate. By using an optical near field as the light source for this deposition scheme, nanometric materials can be fabricated whose size and position are accurately controlled by the spatial distribution of the optical near-field energy. Nanometric metallic particles of Zn and Al and light-emitting semiconductor particles (e.g., ZnO and GaN) have been deposited with size and positional accuracies beyond the diffraction limit [15.21–25]. This is an example of a quantitative innovation.

Although an ultraviolet light with high photon energy must be used for the aforementioned adiabatic process, it has been found that an optical near field with a much lower photon energy (i.e., visible light) can dissociate the molecule. This has been explained by a theoretical model of the virtual exciton–polariton exchange between a metalorganic molecule and the fiber probe tip used to generate the optical near field. In other words, this exchange excites not only the electron, but also molecular vibration. This is a nonadiabatic process, which does not follow the Franck–Condon principle, and therefore the Born–Oppenheimer approximation is no longer valid. Several experimental results have been reported, including the nonadiabatic dissociation of diethylzinc (DEZn) molecules by a visible optical near field and the deposition of nanometric Zn particles [15.26]. The virtual exciton–polariton model explains this nonadiabatic process quantitatively by introducing the contribution of a phonon excited in the fiber probe tip [15.27].

The presented nonadiabatic process suggests that the large, expensive ultraviolet light sources that are

indispensable for conventional photochemical vapor deposition are no longer required. It also suggests that the process can even dissociate optically inactive molecules (i. e., inactive to the propagating light), which is advantageous for environment protection because most optically inactive molecules are chemically stable and harmless. For example, optically inactive $Zn(acac)_2$ molecules have been dissociated nonadiabatically using an optical near field to deposit nanometric Zn particles [15.28].

15.4.2 Photolithography

Photolithography is a technology used to carve substrate material. After coating the substrate with a thin film of a photoresist, light is irradiated through a photomask to induce a photochemical reaction in the photoresist. When the aperture on the photomask is smaller than the wavelength of the light, the transmission of the propagating light is sufficiently low while an optical near field is generated at the aperture. Using the photochemical reaction between the optical near field and the photoresist, a nanometric pattern beyond the diffraction limit is formed on the photoresist, and a chemical etching process is subsequently used to carve the substrate. Practical nanophotonic technologies, such as using a two-layered photoresist, have been developed to form deep patterns and to realize a quantitative innovation (Fig. 15.12) [15.29].

As long as an adiabatic process is used for photolithography, ultraviolet light with a high photon energy is required to induce the photochemical reaction via the optical near field. However, photolithography using a nonadiabatic process is possible, as was the case
Fig. 15.12 The structure of the photolithography system and the cross-sectional profile of the photoresist after development. The photographs were supplied courtesy of R. Kuroda, Canon Corp
Fig. 15.13 Top view of a photoresist with a corrugated pattern that was fabricated nonadiabatically using optical near fields

in Sect. 15.4.1; i. e., a photochemical reaction can even be induced using visible light with a very low photon energy. Figure 15.13 shows a narrow corrugated pattern fabricated using nonadiabatic photolithography [15.30], which has been analyzed theoretically based on a virtual exciton–polariton model by introducing the contribution of phonons. This result represents a qualitative innovation in photolithography, suggesting that large, expensive ultraviolet light sources are no longer required, and that harmless, chemically stable molecules can be used as the photoresist, even if they are optically inactive. As an example, an optically inactive resist film has been used for electron-beam lithography. Although this film is optically inactive, a photochemical reaction is induced and fine patterns can be fabricated by using a photomask consisting of a two-dimensional array of circular disks (Fig. 15.14) [15.30].

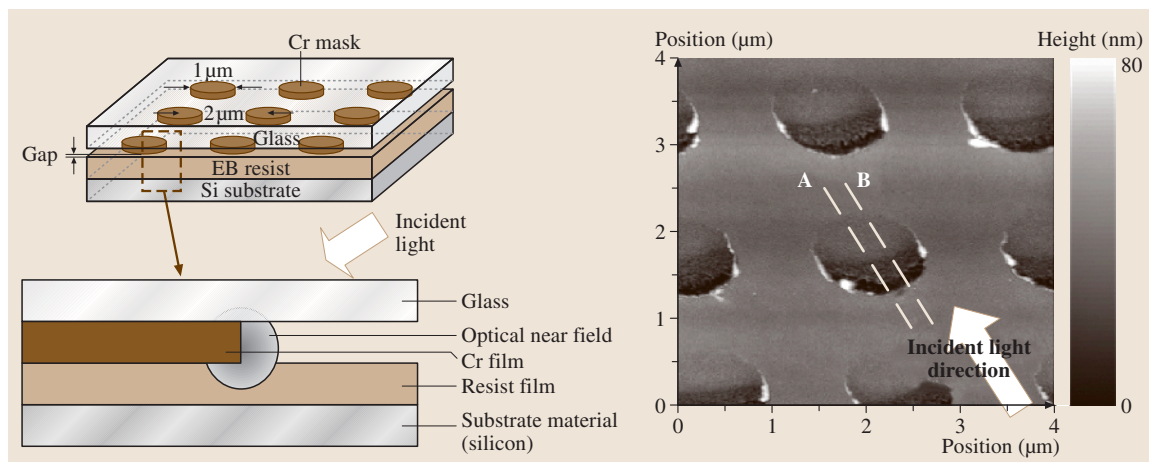
Fabrication using the adiabatic process suffers from the contribution of the small amount of propagating light transmitted through the aperture on the photomask and the plasmon generated on the photomask. This limits the resolution of fabrication and the pattern contrast. In contrast, since the nonadiabatic process is free from these contributions, greater resolution, higher contrast,


Fig. 15.14 Bird's-eye view of the optically inactive resist film used for electron-beam lithography, fabricated nonadiabatically using optical near fields

and a variety of patterns (e.g., Ts, Ls, and rings) have been realized [15.30].

15.4.3 Self-Organized Deposition and Nanoimprinting

Self-organized deposition is a way to deposit nanometer-sized particles, as discussed in Sect. 15.4.1. In this case, however, a fine structure, e.g., a narrow groove, is first patterned on the substrate instead of using a fiber probe or photomask (Fig. 15.15) [15.31]. While sputtering metallic particles on this patterned substrate, irradiation with propagating light is used to desorb the deposited particles. This irradiation generates an optical near field in the groove, which excites free electron oscillations in the deposited metallic particles. The size of the deposited metallic particles increases with continued sputtering. As a result, the center frequency of the electron oscillation spectrum shifts and its spectral linewidth increases due to the finite path length of the free electrons and resultant damping of the resonant oscillation. The magnitudes of the center frequency shift and linewidth increase are nearly proportional to the particle size if it is sufficiently small [15.32].

When the shifted center frequency is tuned to the optical near-field frequency (i. e., the particle grows to a specific size), the magnitude of the optical near-field energy absorbed by the particle is maximal at this size-dependent optical absorption resonance. Moreover, the desorption rate is maximal under this resonant condition, so a further increase in particle size is prohibited by the balance between the magnitudes of sputtering

and desorption [15.33, 34]. Since the size of a deposited particles depends on the photon energy of the optical
Fig. 15.15 The principle of self-organized deposition

Part D | 15.4

near field as the result of this balance, the size can be controlled accurately.

This accurate size-control method forms the first particle, on which a new optical near field is subsequently generated because the propagating light is still being irradiated. As a result of this secondary optical near field, a second particle forms next to the first one, and the size of the second particle is equivalent to that of the first because of size-dependent resonant optical absorption [15.33]. Because this formation process occurs successively, a chain of the metallic particles is formed along the groove within the area irradiated by the prop-agating light (Fig. 15.16). Note that this chain is formed in a self-organized manner, and neither a fiber probe nor a photomask is used. The sizes and separations of these particles are determined accurately by the photon energy of the optical near field.

As a recently developed fabrication technology, light-assisted nanoimprinting has enabled the formation of nanometric structures, without the requirement for a development process [15.35]. By using optical near fields, the adiabatic process forms a pattern that is even smaller than that of the mold [15.36]. Further progress is expected if a nonadiabatic process can also be utilized.

15.5 Extension to Related Science and Technology

Nanophotonics has led nanooptics and realized qualitative innovation. As examples of its extension to related science and technology, this section reviews applications to novel photonic systems and atom photonics.

Nanophotonic systems utilize nanophotonic devices. For example, novel architectures have been proposed for optical signal transmission systems and their performance has been confirmed experimentally. They include interconnections and summation involving an optical nanofountain [15.16], computing using nanophotonic switches and an optical nanofountain [15.17], and broadcasting using multiple nanophotonic switches [15.37]. They have realized quantitative innovations by decreasing the device size and power consumption beyond the diffraction limit. More importantly, qualitative innovation has been realized as a consequence of the novel functions of nanophotonic devices, which are impossible with conventional photonic devices.

An optical/magnetic hybrid disk storage system with a storage density of $1\,\text{Tb/in}^2$ has been devel-oped. Quantitative innovation has already been realized by transcending the diffraction limit of optical storage density [15.38]. Qualitative innovation in optical storage and readout has been also proposed by applying the hierarchy in optical near fields to memory retrieval [15.39].

An example of an extension to related science is atom photonics, which controls the thermal motion of neutral atoms in a vacuum using optical near fields [15.40]. Theoretical studies have examined single-atom manipulation based on the virtual exciton–polariton model [15.41]. Recent experimental studies have examined atom guidance through a hollow optical fiber [15.42], atom-detecting devices [15.43], atom deflectors [15.44], and an atomic funnel [15.45]. Atom photonics will open a new field of science that examines the interaction between virtual exciton–polaritons and a single atom. Furthermore, it can be applied to novel technologies for atomic-level material fabrication.

15.6 Summary

As a result of the development of nanophotonics, which utilizes the local electromagnetic interactions between nanometric particles mediated by optical near fields, nanooptics now exists as a novel field of optics in nanometric space. However, the name nanophotonics is occasionally used for photonic crystals, plasmonics, silicon photonics, and quantum-dot lasers using conventional propagating lights. Here, one should consider a stern warning by C. Shannon on the casual use of the term information theory, which was a trend in its study during the 1950s [15.46]. The term nanophoton-ics has been used in a similar way, although some work in nanophotonics is not based on optical near-field interactions. For the true development of nanophotonics, one needs deep physical insights into the virtual exciton–polariton and the nanometric subsystem composed of electrons and photons. It is both unethical and misleading to use the name nanophotonics in a casual manner, for example, to obtain a research grant. Since nanooptics should be defined as a field of optical science and technology including nanophotonics, Shannon's warning should be extended to the term nanooptics.

16. Optics far Beyond the Diffraction Limit: Stimulated Emission Depletion Microscopy

In this chapter we show that stimulated emission depletion (STED) microscopy and its derivative concepts are able to radically overcome the diffraction barrier in far-field fluorescence imaging, thus disclosing fluorescent details on the macromolecular scale even with diffracted beams of light.

The optical microscope is an invaluable tool in the life sciences because it is able to noninvasively image structures within cells and tissues. Unfortunately, due to the fact that light propagates as a wave, the smallest possible size of a focal spot in a far-field light microscope is limited by diffraction, putting a lower limit on the size of the structures which can be observed. Concretely, this means that for a lens of semiaperture angle α, the full-width-half-maximum (FWHM)

Δr of the main diffraction maximum of the point-spread function (PSF) in the focal plane of the lens is $\Delta r = \lambda/(2n\sin\alpha)$, with λ and n denoting the wavelength of light and the refractive index, respectively [16.1]. If the distance between two objects is smaller than this FWHM, the objects cannot be readily resolved from one another. The diffraction resolution limit is particularly disadvantageous in the life sciences where about 80% of all microscopy applications are carried out with far-field fluorescence systems.

Part D | 16

It is sometimes argued that confocal and multiphoton excitation provide subdiffraction resolving power in fluorescence microscopy; in reality neither breaks the diffraction barrier. Confocal microscopy can, in principle, attain a 1.4-fold reduction of the effective FWHM of the focal spot [16.2], because the consecutive point-like illumination and detection in a confocal fluorescence microscope yields an effective PSF that is the product of the excitation and detection PSFs. The PSF multiplication doubles the bandwidth of the optical transfer function of the system. However, this bandwidth increase is rarely realized because the larger spatial frequencies are heavily damped, and therefore swamped by noise. If they are not, the resolution can be improved with the help of a linear image deconvolution by a factor of 2, but no more. Hence, this technique is also conceptually diffraction-limited.

Two- or three-photon excitation fluorescence microscopy benefits from the quadratic or cubic dependence of the fluorescence signal on the focal intensity. While the nonlinearity provided by multiphoton absorption indeed shifts the generation of the signal to the inner part of the excitation spot slightly, a narrowing of the effective spot is usually not obtained. The reason is that the energy gap of the excitation band of the fluorophore to be imaged is finite. Hence it is bridged by the instant absorption of m photons of $1/m$ the energy, which inevitably entails a wavelength of the excitation light m times longer than in the single-photon excitation case. The m-times-longer wavelength renders the focal spot m-times larger, which is not compensated by the nonlinear excitation near the focal center [16.3]. In fact, the resulting spot scales as $\sqrt{m}$. Thus, multiphoton processes do not improve the resolution in absolute terms, and so it is not surprising that multiphoton processes did not open up a new chapter in far-field optical resolution, despite their common use for more than 15 years [16.4]. Moreover, even in the hypothetic case that the requirement for a longer wavelength is not present, a quadratic or cubic intensity dependence would only expand the optical transfer function by a factor of two or three, respectively. Thus, the diffraction barrier would just be shifted but not broken.

The lack of viable concepts for a substantial far-field resolution improvement led to the development of near-field optical microscopy, which abandons focusing altogether [16.5]. Here the spatial resolution is improved by confining the interaction of the sample and the probing light to sub-λ dimensions using a sub-λ-sized scanning aperture or tip. This approach requires tight control of the nanosized stylus, and is limited to imaging surfaces, substantially restricting its range of applicability.

16.1 Principles of STED Microscopy

Stimulated emission depletion (STED) microscopy is the first far-field microscopy concept whose resolution is no longer limited by diffraction [16.6–8]. While a STED microscope still relies on diffracted beams the effective PSF of this microscope can be as sharp as a single molecule and, theoretically, its optical bandwidth can be infinitely large. The key to this surprising feature is a nearly exponential depletion of the fluorescent state by a further beam of light optimized for stimulated emission. Realized at comparatively low intensities, the huge nonlinearity connected with the exponential depletion allows one to squeeze the fluorescent spot to a size corresponding to a fraction of λ. To date, practical STED fluorescence microscopy has displayed a spatial resolution of 33 nm ($\lambda/23$) along the optic axis [16.9]. In the transverse direction in the focal plane, a lateral FWHM of 15–20 nm has been demonstrated with single molecules [16.10] and also in biological samples [16.11]. STED microscopy retains the advantages of far-field optical microscopy, employing regular lenses, and can be used to noninvasively image samples in three dimensions (3-D). In this chapter we briefly explain the physical principles of this emerging technique and illustrate its power by showing recent applications in biological imaging.

In polyatomic organic molecules, stimulated emission is most effective between the vibrationally relaxed sublevel of the first electronic singlet state S_1 and a vibrational sublevel of the ground state S_0^* (Fig. 16.1a) [16.12, 13]. When not subjected to quenching processes, S_1 spontaneously emits a photon within its typical lifetime τ_{fl} of a few nanoseconds, and the S_0^* decays nonradiatively within $\tau_{vib} < 1$ ps. A difference of three orders of magnitude between these lifetimes maintains a population inversion between the two states. Deliberate depletion of the S_1 by stimulated emission [16.6] in these molecules can be optimized by temporally separating the excitation from the stimulated emission. In our fluorescence microscope, the excitation of the fluorescent markers to Franck–Condon vibrational levels in the first singlet state, i.e. $S_0 \rightarrow S_1^*$ (Fig. 16.1a), is performed by pulsed illumination. The molecules are excited by single-photon absorption, followed by ultrafast nonradiative decay to the fluorescent state S_1. For effective depletion of S_1, the molecules are subjected to a synchronized red-shifted STED pulse of duration $\tau_{STED} \approx 300$ ps $< \tau_{fl}$. Since $\tau_{vib} \ll \tau_{STED}$, the vibrational decay in the ground state empties the S_0^* more effectively than the STED pulse could pos-

sibly re-excite the molecules to the fluorescent state S_1. Moreover, the S_1 population of molecules residing at a spatial coordinate r decreases exponentially with the fluence $h_{STED}(r)$ of the STED pulse, expressed in photons per area per pulse (Fig. 16.1b) [16.7, 9, 14]. Denoting the molecular cross section for stimulated emission by σ, the normalized probability of stimulating an excited molecule to fluoresce at r is given by $F(r) = \exp[-\sigma h_{STED}(r)]$.

Here we describe the standard set up of a typical STED microscope (Fig. 16.2). An objective with a high numerical aperture (≈ 1.4) is used to both illuminate and gather light from the sample. Filters and the dichroic beam splitters are optimized for the ideal excitation and stimulating-emission wavelengths of the fluorescent dye used to mark the sample. Excitation is performed with a laser with pulses typically on the order of tens of picoseconds. A quarter-wave plate ensures that the excitation light at the lens is circularly polarized for uniform excitation of the fluorescent markers. The fluorescent light is collected by the same lens and focused onto the core of a fiber guiding the fluorescent light to an avalanche photodiode, where detected photons are counted. Imaged into the focal plane of the objective lens, the core diameter corresponded to ≈ 0.7 times the Airy disk. As a result, the probability of detecting a fluorescent photon is weighted spatially by the detection PSF, $h_{det}(r)$, which is the normalized diffraction-limited image of the fiber core. Thus when no STED beam is present, the set up can function as a normal scanning confocal fluorescence microscope of finite pinhole size (given by the core diameter of the fiber, which functions
Fig. 16.1a,b Saturated depletion of fluorescent molecule (**a**) Excitation, fluorescence and stimulated emission (STED) in the energy diagram. (**b**) Quenching of the fluorescence depending on the STED intensity, normalized by the saturation intensity
Fig. 16.2 A typical STED microscope. Excitation light forms a regular Airy disk in the lens focal plane (adjacent panel *in blue*) and is overlapped with a *red-shifted* doughnut spot for STED. The doughnut is produced by applying a helical phase delay on the STED beam wavefront exp(iϕ), with $0 \le \phi \le 2\pi$. The linear helical progression of the phase from 0 to 2π ensures that the light field from opposite parts of the entrance pupil of the lens interferes destructively on the optic axis. Overlap of the two spots confines the focal area in which fluorescence is possible to the doughnut centre, yielding the effective fluorescent spot of subdiffraction size displayed in the lower row panel (*in green*). All spots represent measured data and are drawn to scale. The profile of the green effective spot displays a FWHM of 16 nm and a sharp peak

as a pinhole), facilitating the comparison of the normal confocal imaging mode with the STED mode. In the latter, the excitation pulse is immediately followed by a STED pulse of several hundred picoseconds in length. This pulse duration not only avoids the re-excitation from the S_0^* (Fig. 16.1a), but also the two-photon excitation and excessive nonlinear photobleaching of the dye [16.15].

In a regular scanning fluorescence microscope, the fluorescence spot is given by the main maximum of the excitation PSF, i.e., the normalized function $h_{exc}(r)$ describing the diffraction-limited intensity spot of the excitation light (Fig. 16.2) [16.2]. The purpose of the STED pulse is to reduce the focal area in which fluorescence is emitted. To attain quenching of only the periphery, the STED pulse is modified to form a zero at the focal center, i.e. a doughnut: $h_{STED}(r = 0) \cong 0$ (Fig. 16.2).

To realize the doughnut shape of $h_{STED}(r)$, the planar wavefront of the STED beam is subjected to a helical phase delay $P(\phi) = \exp(i\phi)$, with $0 < \phi < 2\pi$ being an angle centered around the optic axis (Fig. 16.2) [16.16]. The phase delay is produced using a spatial light modulator located optically conjugate to the entrance pupil of the lens. The objective transforms this wavefront into a doughnut in the focal plane. Following the exponential dependence on intensity $F(r) = \exp[-\sigma h_{STED}(r)]$, the STED pulse suppresses the fluorescence at every point

in the focal region, except at the very point $r = 0$, where $h_{STED}(r)$ equals zero (Fig. 16.2).

The effective PSF $h_{eff}(r)$ of this confocalized scanning far-field microscope is given by the product of the excitation and detection PSF, multiplied by the fluorescence probability $F(r)$:

$$h_{eff}(r) = h_{exc}(r)h_{det}(r)F(r)$$
$$\equiv h_{conf}(r)\exp[-\sigma h_{STED}(r)] . \qquad (16.1)$$

By increasing the power of the STED pulse, the fluorescent spot remaining in the center becomes smaller. We define $h_{STED}^{max} \equiv \max[h_{STED}(r)]$ as the maximum intensity present in the STED PSF and $h_{STED}^{sat} \equiv 1/\sigma$ as a saturation scaling factor, at which a fraction of $(1 - 1/e)$ of the fluorophores have been stimulated into the ground state. Subdiffraction resolution prevails for saturation factors $\varsigma \equiv h_{STED}^{max}/h_{STED}^{sat} = \sigma h_{STED}^{max} \gg 1$ [16.17]. Since the function $h_{STED}(r)$ is parabolic at $r = 0$ to a first approximation, the fluorescent spot size scales with the square root of the STED pulse fluence [16.17, 18]. A Taylor-series expansion of $h_{eff}(r)$ yields the FWHM of the effective PSF of the STED microscope as

$$\Delta r \approx \frac{\lambda}{2n \sin\alpha\sqrt{1+\varsigma}} . \qquad (16.2)$$

Here λ denotes the wavelength of the depletion pulse, because it is the doughnut that is responsible for

the final size of the spot. Under the assumption that the excitation wavelength and λ are not very different, Δr elegantly converges towards the diffraction-limited spot size in the absence of STED, while for $\varsigma \to \infty$ the fluorescence spot size converges to zero. Scanning with a fluorescent focal spot of subdiffraction size Δr delivers images of the same subdiffraction resolution.

It is important to note that, for a significantly narrowed spot ($\varsigma > 5$), the comparatively broad detection PSF $h_{\text{det}}(r)$ of the system does not play a role anymore. Therefore, STED microscopy does *not* rely on confocalization, and it is *not* an expansion of confocal microscopy. Conceptually, the confocal pinhole is redundant, because the confinement of the spot to subdiffraction dimensions is due to the STED beam. The confocal pinhole is used to provide other advantages to the system, such as confocal optical sectioning and stray-light suppression. The pinhole does not play any role in breaking the diffraction barrier.

Besides $h_{\text{exc}}(r)$ and $h_{\text{STED}}(r)$, Fig. 16.2 depicts the measured $F(r)$ for the STED intensity employed in this experiment, leading to a very narrow region of remaining fluorescence detection. This figure visualizes that for strong enough fluences $h_{\text{STED}}(r)$, the spatial extent of $h_{\text{eff}}(r)$ is solely determined by the exponential suppression factor. Neither the excitation nor the detection PSF really matters. In consequence, the same assertion holds for the excitation and the fluorescence wavelength as well as for the presence of the confocal pinhole. Thus, despite the diffraction-limited extent of the local minimum in $h_{\text{STED}}(r)$, the exponential factor $F(r)$ allows one to squeeze the focal fluorescence spot in principle down to the size of a molecule [16.7].

Challenges toward maximizing both $h_{\text{STED}}^{\max}$ and the detected fluorescent signal in the center of the scanning spot are elevated photobleaching of the fluorescent marker [16.19] and the actual value of the doughnut minimum $h_{\text{STED}}(0)$, which may not be zero. Nonfulfillment of the second condition reduces the desired signal by $1 - \exp[-\zeta h_{\text{STED}}(0)]$. Therefore, $h_{\text{STED}}(0) < 0.02\, h_{\text{STED}}^{\max}$ is imperative to attain high spatial resolution. Photobleaching can be minimized by attending to the population of the molecular triplet state. Elimination of the excitation of molecules trapped in this state has significantly reduced photobleaching in STED microscopy. With this approach, far-field fluorescence microscopy with a focal-plane resolution of 15–20 nm in biological samples has been obtained [16.11]. This corresponds to a 10–12-fold multilateral increase in resolution below the diffraction barrier.

Employing pulse repetition rates <1 MHz usually allows enough time for relaxation of the triplet state between subsequent excitation–depletion cycles. In a number of dyes, this measure enables up to a 30-fold increase in the fluorescent signal compared to earlier 80 MHz STED illumination schemes in which each spot on the sample receives many consecutive excitation and STED pulses. Triplet-state relaxation can also be realized by increasing the scanning speed such that the buildup of the triplet state is prevented. We have termed this illumination scheme triplet-relaxation (T-Rex) STED.

16.2 Nanoscale Imaging with STED

The resolution attainable under T-Rex conditions was first demonstrated on yellow–green beads emitting in the 500–530 nm range (Fig. 16.3). Specified by the manufacturer using electron microscopy, the beads varied by 4 nm around a mean diameter of 24 nm. Whereas confocal recording (Figs. 16.3a,c) yielded undefined blobs, the STED images (Figs. 16.3b,d) discerned virtually every bead in the focal plane [16.11]. Figures 16.3g,h depict line profiles through beads located 42 nm and 39 nm apart, respectively; both are clearly separated.

The function describing the bead image was determined by averaging over 75 beads that were comparatively isolated and of lesser brightness. The result is displayed in Fig. 16.3e, exhibiting a full-width-half-maximum (FWHM) of (22.3±2) nm. As given by the convolution of the bead object function with the PSF of the microscope, the bead image function in Fig. 16.3e is just an upper bound for the actual PSF. The actual resolution of the STED microscope is below 20 nm. If the PSF and the bead function are coarsely approximated by a Gaussian, we can assess the actual focal-plane resolution as $22.3/\sqrt{2} = (15.8 \pm 4)$ nm. Comparison of this value with the resolution limit given by Abbe's criterion in an epifluorescence microscope, $\lambda_{\text{fl}}/2n \sin \alpha = 190$ nm, demonstrates a ≈ 12-fold gain in focal-plane resolution.

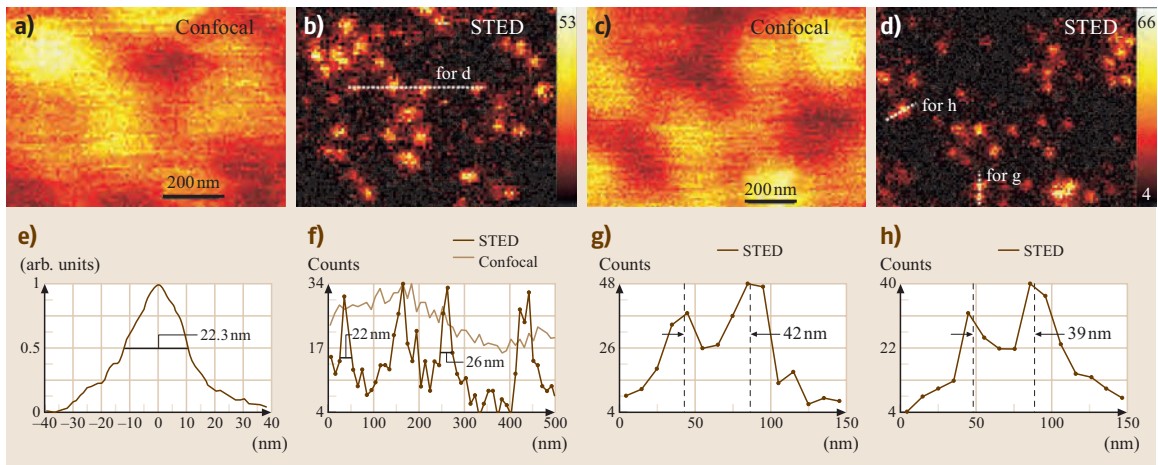
We also imaged self-assembling colloidal silica nanospheres on the surface of a glass cover slip in the non-T-Rex mode, precisely at a pulse rate of 80 MHz. The nanospheres were prepared with a fluorescent core


Fig. 16.3a–h Resolution ≤ 20 nm in the focal plane of a STED microscope While the confocal imaging mode ((**a**), (**c**)) fails to resolve the bead agglomeration, the corresponding STED recording ((**b**) and (**d**)) discerns every 24 nm bead. (**e**) Averaged profile of bead images. The 22.3 nm FWHM indicates a lateral resolution of ≈ 16 nm in the focal plane (after extraction of the bead size). (**f**) Data as indicated by the dashed line in panel (**b**), both for the confocal and the STED recording. Note the sharp peaks resulting from STED superresolution. of 68 nm and a non-fluorescent shell of 132 nm diameter, as shown in Fig. 16.4c. The STED beam was adjusted to 14 mW of average power and was tuned to $\lambda = 615$ nm. Whereas the confocal image (Fig. 16.4a) is almost featureless, the STED image in Fig. 16.4b fully disclosed the semicrystalline order of the nanoparticles [16.20]. In particular, grain boundaries, point defects, disclinations, and dislocations became clearly visible.

STED microscopy does not require any mathematical postprocessing. Still, one can take advantage of its optical transfer function (OTF) to strengthen the higher spatial frequencies gained by STED with a linear deconvolution. The OTF is obtained by a Fourier transformation of the effective PSF $h_{\text{eff}}(\boldsymbol{r})$, which unlike in the confocal microscope, depends on the saturation factor ζ and hence on the dye in use. We established $h_{\text{eff}}(\boldsymbol{r})$ for Atto532, and, for the same power, using single labeled antibodies (size < 15 nm). The result is shown in Fig. 16.4d along with the associated OTF. Both the FWHM of 67 nm as well as the enlarged OTF mark a substantial gain in optical bandwidth. The subsequent linear deconvolution of the STED image yields a significantly improved contrast in the image (Fig. 16.4e).

We also deconvolved the confocal image, as shown in the inset of Fig. 16.4a. However, the deconvolved confocal image failed to resolve the nanoparticles, let alone the crystal defects. In fact, the raw STED image pro-

vides a higher resolution. Changing the physics of image formation is the more powerful approach.

We also demonstrated the resolution of T-Rex STED microscopy (0.25 MHz pulse rate) with biological immunofluorescence imaging. We labeled secondary antibodies with Atto532, which were then coupled, via primary antibodies, to the proteins of interest. Figure 16.5 displays the protein *heavy subunit of neurofilaments* (NF-H) in the human neuroblastoma cell line SH-SY5Y (retinoic acid-BDNF-differentiated) which establishes crosslinks to organize and stabilize neurofilaments in axons [16.21]. Neurofilaments play an essential role in many neurodegenerative diseases such as Parkinsons'. In contrast to the confocal (Fig. 16.5a) image, the STED (Fig. 16.5d) image identifies neurofilamental substructures of 20–30 nm size [16.11]. This is particularly apparent in Fig. 16.5e, which shows a partial area of (Fig. 16.5d) at a larger magnification, as well as in (Fig. 16.5c) where the details are further enhanced by a linear deconvolution. The line plots of raw data in (Fig. 16.5f) prove that substructures that are only 45 nm apart are separated by a dip of 50%.

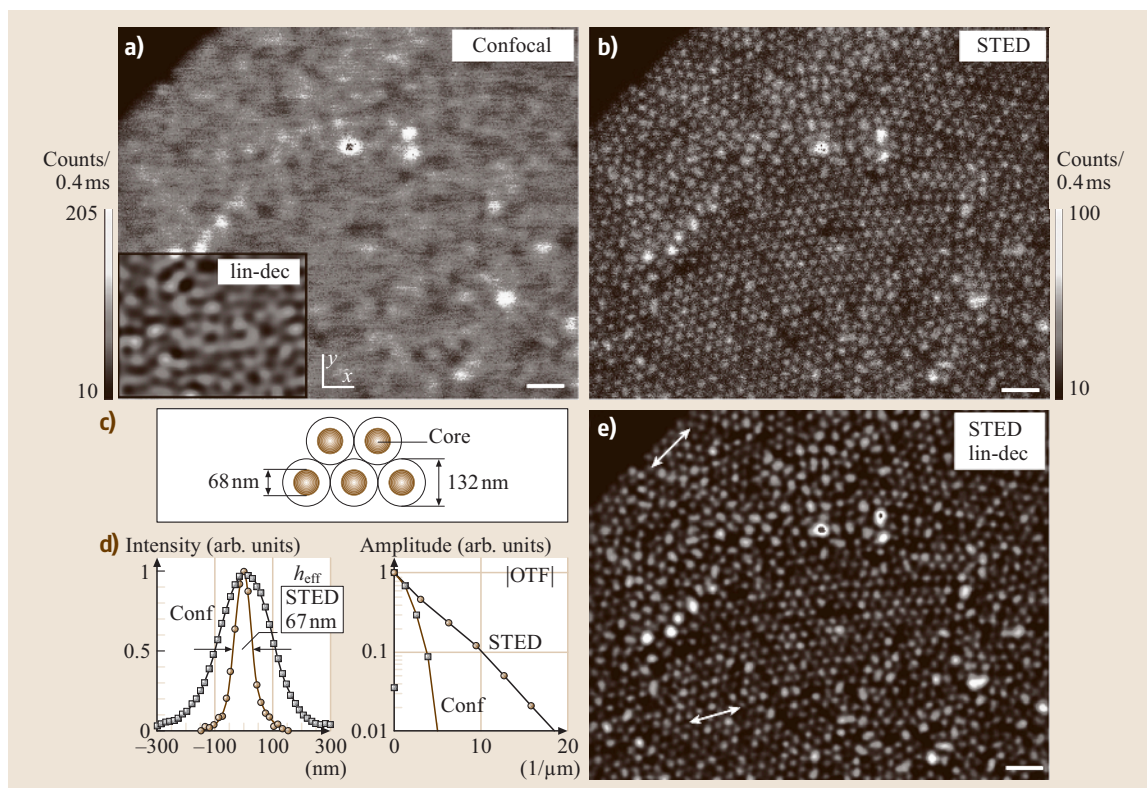
The intensity profiles in Figs. 16.3 and 16.5 featuring a FWHM of 22–30 nm demonstrate the fundamental progress in resolution brought about by T-Rex STED microscopy [16.11]. Representing the convolution of the microscope's PSF with the spatial extent of the label-


Fig. 16.4a–e Imaging the spatial order of colloidal nanoparticles **(a)** Confocal image and **(b)** corresponding STED image. **(c)** Sketch of silica nanoparticles featuring a fluorescent shell core (dye Atto 532, emission 540–620 nm). **(d)** The effective PSF and OTF, determined from fluorescent point-objects of the same fluorophore as in the core are utilized to enhance the STED-image by linear deconvolution; the result is displayed in panel **(e)** The *double-headed arrows* mark different orientations of the colloidal nanoparticles. For comparison, the *inset* of panel **(a)** shows the linearly deconvolved confocal data. Despite this, only the STED-images (**(b)** and **(e)**) reveal grain boundaries, defects and dislocations in the semicrystalline nanoparticle formation. Scale bars = 500 nm

ing, the FWHM of the profiles are just an upper limit for the actual imaging resolution. In fact, with a complex size of 6–8 nm, the secondary antibodies form an estimated 12–16 nm-diameter volume around the similarly sized primary antibody [16.22]. Thus, the resolution has attained values that are close to the limits set by the labeling itself.

The full subdiffraction imaging potential of STED remains to be realized, and the technique continues to improve after nearly a decade of use. T-Rex STED, for example, can be further improved with relatively simple modifications to increase the image acquisition time and retain its increased resolving power. Though the repetition rate in the T-Rex case (0.25 MHz) is reduced by 320, the effective increase in recording time was only 5- to 10-fold as compared to the 80 MHz case [16.11].

Due to the stronger excitation pumping and triplet-state relaxation, the typical dwell time in our images was 3–8 ms per 10 nm pixel. T-Rex can also be realized by scanning with a speed that exceeds the speed given by the spot size times the pulse repetition rate, e.g. 200 nm × 80 MHz = 16 μm/μs, so the molecules do not encounter successive pulses. A compelling advantage of fast scanning is that the total sample illumination of 80 MHz scanning is maintained and the signal gain is still obtained. The recording time can be further reduced by the factor given by the signal gain, i.e., by 150–300 times compared to the scheme used in this work.

Powerful approaches exist to improve the axial resolution as well: the implementation of STED in a 4Pi-microscope [16.7,9,23] or the additional application
Fig. 16.5a–f Imaging neurofilaments in human neuroblastoma Contrary to the confocal (**a**), the STED (**d**) recording displays details < 30 nm, as highlighted by the comparison of image subregions shown in (**b**) and (**e**) bordered by dashed lines in (**a**) and (**d**). ((**b**) and (**c**)) Subregion after linear deconvolution. Note that the deconvolved confocal image (**b**) does not yield a substantial gain in information. (**f**) Profiles of raw data demonstrate the ability of (undeconvolved) STED data to reveal object structures that are far below the wavelength of light.

of a $h_{\text{STED}}(\mathbf{r})$ with strong values above and beneath the focal plane [16.8]. The first alternative involves the addition of the aperture of two opposing lenses, whereas the latter can be realized in a single lens. In fact, $h_{\text{STED}}(\mathbf{r})$ functions have been described which improved the axial resolution of a single lens by a factor of about six. As two STED pulses of different structure can be applied simultaneously (within the lifetime of the fluorescent state) the spot can be squeezed both axially and laterally at the same time.

It is important to emphasize that STED is only one possible avenue for attaining resolution enhancement using the concept of the optical switching of fluorescent markers labeling the sample [16.17, 18, 24–26].

The concept of STED microscopy can be generalized to the concept of reversible saturable optical fluorescence transitions (RESOLFT), which can be applied to any switchable fluorescent marker such as the family of fluorescent proteins [16.26]. Moreover, the excitation and reversible-quenching illumination patterns need not be pointwise. As long as the quenching light distribution features locations of zero intensity, the region of fluorescence can be reduced to subdiffraction dimensions according to the square-root law for resolution enhancement derived for STED. Much remains to be done in the field of biological imaging, and developments will no doubt progress quickly in the coming years as the utility of this technique is realized.

17. Ultrafast THz Photonics and Applications

Ultrafast THz photonics the topic of this chapter describes the union of optical and ultrafast laser capability with electronics to achieve frequency performance and bandwidths extending well into the THz frequency range. With the demonstrated capability to create and to measure subpicosecond electrical signals that are much faster than those produced and measured by any other method, THz photonics will help determine the direction for the development of new materials and ultra high performance technologies of the future.

In the Guided-Wave THz Photonics Section the generation, measurement and applications of these very short electrical pulses are described. They can be used as probes for short electrical pulse studies and the consequent characterization of transmission lines is described, including the measurement of Cherenkov radiation. The performance of transmission lines is compared with metal THz waveguides, whose characterization is also presented. Results for superconducting transmission lines and dielectric THz waveguides are given.

In the Freely Propagating Wave THz Photonics Section recent work demonstrating the generation of freely propagating THz radiation $(1\,\mathrm{THz} = 33.3\,\mathrm{cm}^{-1} = 4.1\,\mathrm{meV})$ via material and electronic excitation by ultrashort laser pulses is presented. The generation of short pulses of THz radiation, by the passage of a short optical pulse through a nonlinear optical material, is also described. A cw photomixer capable of producing tunable radiation by beating together two laser beams is presented. The most developed THz application is THz time-domain spectroscopy

(THz-TDS) which is described in detail. The combination of THz-TDS with THz beams will be shown to have some powerful advantages compared to traditional c.w. spectroscopy. The efficacy of THz-TDS is demonstrated by the presented characterizations of water vapor, flames, sapphire, high-resistivity silicon, n and p-type semiconductors, normal and high Tc superconductors, molecular vapors and liquids.

Ultrafast THz photonics describes the union of optical and ultrafast laser capability, for which the elementary excitation is the photon, with electronics to achieve frequency performance and bandwidths extending well into the THz frequency range. Optoelectronics, which is a subfield of photonics, has demonstrated the capability to create and to measure electrical signals that are much faster than those produced and measured by any other method. The subpicosecond electrical pulses produced optoelectronically are more than ten times faster than today's most advanced transistors, which have switching times on the order of 10 ps. The genera-

tion of short electrical pulses via optical methods has for some time been accomplished by shorting photoconductive gaps with very short laser pulses [17.1]. The same optical methods can measure the generated electrical pulses by sampling techniques. An alternate measurement approach has been to use the electrooptic effect in a crystal [17.2, 3]. In this case, the field of the electrical pulse is sampled through the rotation of the polarization of the short optical sampling pulse. Both the photoconductive and polarization rotation techniques have been extended into the subpicosecond regime [17.2–11].

Given the capability of generating and measuring these very short electrical pulses, they can be used as probes for short electrical pulse studies. For example, the study of the propagation of such pulses on transmission line structures is an important concern for future ultrahigh-performance VLSI (very large scale integration) technologies. In addition to the considerable amount of work that has been done with these short pulses to understand the high-frequency behavior of transmission line structures, they are now being put to use in other areas as well. Because these pulses are much faster than the fastest transistors, they provide a powerful means of studying their switching transients. They can be used to directly measure the impulse response of ultra-high-performance silicon and gallium-arsenide devices [17.7–9, 12–19]. They can be used to evaluate the high-frequency behavior of semiconductor package connectors essential to future generations of computers. In summary, optoelectronic techniques are providing the capability to generate and measure electrical signals in the subpicosecond regime. This optoelectronic capability provides a tool to better understand the properties of existing materials and the components of existing high-performance VSLI technologies. Clearly, this capability will help determine the direction for the development of new materials and ultra-high-performance technologies of the future.

Recently, there has been a great deal of work demonstrating the generation of THz radiation (1 THz = $33.3 \, \text{cm}^{-1} = 4.1 \, \text{meV}$) via material and electronic excitation by ultrafast laser pulses. Modern integrated circuit techniques have made possible the precise fabrication of micron-sized dipoles, which when photoconductively driven by fs laser pulses, can radiate well into the THz regime [17.20–22]. An alternative and complimentary approach has been to extend radio and microwave techniques into the THz regime through the use of optoelectronic antennas [17.23–32]. The generation of short pulses of THz radiation, by the passage of a short optical pulse through a nonlinear optical material, was

demonstrated many years ago [17.33]. A related source is based on the emission of an electromagnetic shock wave due to a volume dipole distribution moving faster than the phase velocity, i. e., electrooptic Cherenkov radiation[17.34, 35]. THz radiation has been generated by photoconductively driving the surface field of semiconductors [17.36, 37] and the intrinsic region of large aperture silicon p-i-n diodes [17.38] with ultrafast laser pulses. A cw photomixer capable of producing tunable radiation has been demonstrated by beating together two laser beams with frequencies above the band gap of a semiconductor [17.39–43].

One type of these sources is based on an optical-type approach, whereby a transient point source of THz radiation is located at the focus of a dielectric collimating lens, followed by an additional paraboloidal focusing and collimating mirror [17.21, 22, 29, 31, 44]. This type of source produces well collimated beams of THz radiation. Matched to an identical receiver, the resulting system has extremely high collection efficiency, a time resolution of less than 150 fs and a frequency range from 0.2 THz to more than 5 THz. This optoelectronic THz system is presently one of the most highly developed and will be the one described in most detail in this chapter, although the alternative systems will also be presented.

Applications of THz optoelectronic systems include THz imaging[17.45–47], THz ranging[17.48, 49] and THz time-domain spectroscopy (THz-TDS) [17.50–52]. Presently, THz-TDS is the most developed and has been shown to be the technique of choice for many research measurements. Consequently, THz-TDS will be the major application described in this article, by means of selected examples of significant measurements. The THz-TDS technique measures two electromagnetic pulse shapes, the input pulse and the propagated pulse, which has changed shape due to its passage through the sample under study. Consequently, via numerical Fourier analyses of the input and propagated pulses, the frequency-dependent absorption and dispersion of the sample can be obtained. The useful frequency range of the method is determined by the initial pulse duration and the time resolution of the detection process. Therefore, with each reduction in the generated electromagnetic pulse width, and/or the time resolution of detection, there is a corresponding increase in the available frequency range.

The combination of THz-TDS with THz beams will be shown to have some powerful advantages compared to traditional continuous wave (cw) spectroscopy. Firstly, the coherent detection of the THz radiation is extremely sensitive. In terms of average power this

sensitivity exceeds that of the incoherent liquid-helium-cooled bolometers, by more than 1000 times [17.53]. Secondly, because of the gated and coherent detection, the thermal background, which plagues traditional measurements in this frequency range, is observationally absent [17.53–56].

17.1 Guided–Wave THz Photonics

In this section we will initially present an overview of experimental efforts to obtain a THz ultra-wideband transmission channel. The importance of ultrafast optoelectronics will be shown to be paramount in this effort, whereby the combination of optics, ultrafast laser pulses and electronics has enabled bandwidth and performance increases of as much as 100 times when compared to purely electronic techniques. We will describe in detail how subpicosecond electrical pulses are generated and detected using the photoconductive and electrooptic approaches and go on to discuss how such pulses can be used to study the high-frequency behavior of transmission line structures. The importance of complete characterization of transmission lines and waveguides will be illustrated by select examples, where the characterization was achieved by THz time-domain spectroscopy. For these characterizations it was imperative that single-mode excitation and propagation was achieved. Sliding contact excitation of coplanar transmission lines will be shown to be such a single-mode excitation method. For the THz waveguide investigations, quasioptical coupling techniques were shown to be capable of exciting only a single mode of both metal and dielectric waveguides, even though the many THz bandwidth of the incoming pulse covered as much as 30 waveguide modes. Applications to the study of materials and devices will also be mentioned.

17.1.1 Subpicosecond Electrical Pulses

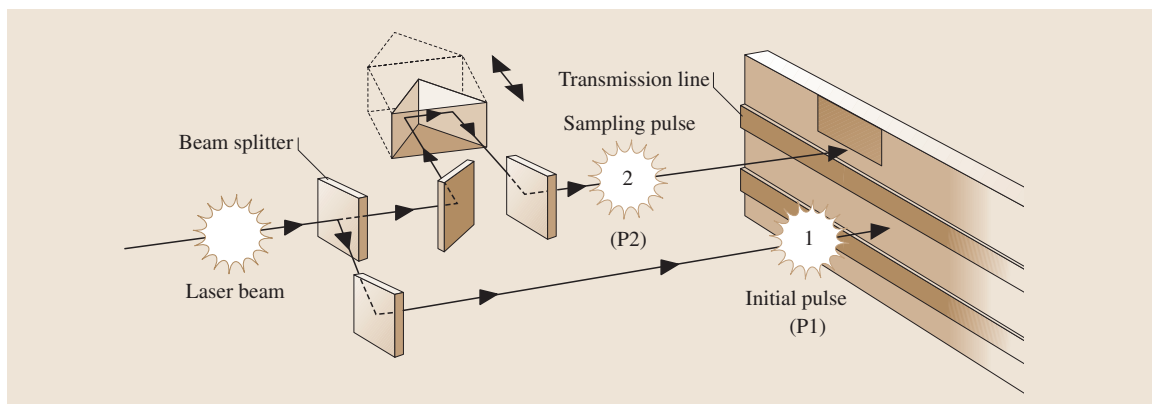
A typical experimental arrangement for the photoconductive generation and measurement of the subpicosecond electrical pulses is shown pictorially in Figs. 17.1 and 17.2 [17.5, 6]. The pulses are generated on a transmission line structure consisting of two parallel aluminium lines of micron dimensions on a thin silicon layer. As indicated in the diagram, an incoming laser beam consisting of a continuous stream of 0.1 ps (or less) ultrafast light pulses at a repetition rate of typically 100 MHz is divided into two synchronized beams P1 and P2, by a partially transparent mirror. Because the beams follow different paths, the relative timing between P1 and P2 can be precisely adjusted by movement of the prism: 0.15 mm corresponds to 1 ps. The initial (excitation) light pulse P1 strikes the photoconductive substrate (silicon) between the two aluminium lines, shorting them for a fraction of a ps and creating electrical pulses that travel in both directions on the transmission line. The sampling light pulse P2 drives the photoconductive gap at the detection electrode, sampling the electrical pulse as it propagates down the transmission line. The electrical pulse is characterized by measuring the collected electrical charge as a function of the time delay between P1 and P2. Representative electrical pulses measured in this way are shown in Fig. 17.3, where the ps time scale of the phenomena is indicated.


Fig. 17.1 Experimental arrangement for the optoelectronic generation and measurement of subpicosecond electrical pulses
Fig. 17.2 (a) Experimental geometry, **(b)** cross section of SOS wafer

17.1.2 Sample Fabrication

The aluminium transmission line structures are fabricated using techniques similar to those used to form the interconnect wiring on semiconductor logic and memory chips. The starting substrate is a commercially available insulating silicon-on-sapphire (SOS) wafer with a $0.5\,\mu m$ layer of pure undoped silicon epitaxially grown on top, as shown in the cross section in Fig. 17.2b. Typical linewidths are in the range of $0.5{-}10.0\,\mu m$. The metal thickness is in the range of $0.2{-}1.0\,\mu m$, and the length of the line structures varies from $5{-}25\,mm$. Numerous contact pads are fabricated along with the line structures to permit attachment of leads. Many different line dimensions and geometries can be fabricated simultaneously on a single $76\,mm$ diameter wafer, since the area occupied by a single line structure is very small compared to the total surface area of the wafer.

At room temperature there are very few free electrons or holes in the silicon layer, and it behaves like an insulator. When an area of the film is struck by an ultrafast $0.1\,ps$ laser pulse, a large number of photocarriers, electrons and holes, are generated almost instantaneously, rendering the area conductive for some length of time thereafter. This time can be made very short by bombarding the film with high-energy oxygen ions to produce crystal damage throughout the $0.5\,\mu m$ thick silicon layer [17.57].

17.1.3 Generation and Measurement of the Pulses

Once fabrication is complete, chips with one or more transmission line structures are cut from the wafer. The chip to be measured is mounted on a fixture and wire bond connections are made to the contact pads to allow biasing of the transmission line at a voltage V, typically a few volts, and collection of the charge transferred to the detection electrode. The sample is then positioned on an optical table together with the laser, and the beams P1 and P2 are carefully aligned so as to strike the sample as shown in Figs. 17.1 and 17.2. The spot size of the laser is typically $5\,\mu m$.

The optoelectronic method of generation of the ultrafast electrical pulses is more precisely illustrated in Fig. 17.2a. This electrical arrangement was driven by $70\,fs$ ultrafast optical laser pulses from a compensated, colliding-pulse, passively mode-locked dye laser producing pulses at a $100\,MHz$ repetition rate. During operation, the P1 pulses short the transmission line by producing carriers in the silicon. These carriers are then trapped (disappear) in less than $600\,fs$ [17.57]. The light pulses essentially turn on and off; they act as a very fast switch. When off, the resistance of the switch is many $M\Omega$, but when on, its resistance is on the order of $1\,k\Omega$. This transient shorting of the line produces an approximately $0.5\,ps$ electrical pulse, which propagates down the transmission line. The generated pulses are measured by the P2 sampling pulses at the detection gap. As the electrical pulse traverses the line adjacent to the detection gap a voltage appears across this gap. If this gap is then photoconductively connected to the line by the P2 pulse, current will flow during the time of this connection. The amount of collected charge will be proportional to the voltage across the gap during the sampling interval. Consequently, the collected charge is measured against the relative time delay between the P1 and P2 pulses, which is mechanically scanned by moving an air-spaced retro-reflector with a computer-controlled stepper motor.

This sampling technique enables measurements down to the subpicosecond regime even though the wires bonded to the chip are low-frequency connections. All of the important time information is contained in the relative time delay between the two laser beams, which can be controlled with great precision. Because the excitation and sampling pulses come at a rate of one every $10\,ns$, while the relative timing between P1 and P2 is typically swept at a rate of $0.1\,ps/s$, the consequent slowly varying current reading represents an average of a large

number (10^9) of identical events. Although the generated electrical pulses reflect off the end of the transmission line and then echo back and forth on the line, the 10 ns between events allows time for about 100 reflections for complete dissipation due to resistive losses. Thus, the system is electrically quiet prior to being excited with each P1 pulse.

For the generated pulse shown in Fig. 17.3a, the excitation site was very close to the sampling gap so that propagation effects were absent. This measurement illustrates the exceptionally clean pulses and high signal-to-noise ratios that can be obtained with this technique. This short electrical pulse had an amplitude of about 10 mV, and a measured half-width of less than 1 ps. The same pulse is shown on a 10× expanded scale, where the signal-to-noise ratio (S/N) of 500 : 1 (in a single scan) can be seen. In Fig. 17.3b, the

Fig. 17.4 (a) Electrooptic sampler arrangement. (b) Measured electrical response of the Cr:GaAs photoconductive switch. The 10–90% rise time is 460 fs (Adapted from [17.2, 3])

Fourier transform (amplitude spectrum) of this pulse illustrates the bandwidth available for spectroscopic measurements.

17.1.4 Electrooptic Sampling of Pulses on Transmission Lines

Another measurement technique known as electrooptic sampling[17.2,3,7–12], can measure repetitive electrical transients with subpicosecond resolution and microvolt sensitivity. The technique is based on an electric field coupling between the electrooptic "sampling gate" and the circuit under evaluation and does not require that charge be removed from the circuit. Consequently, electrooptic sampling is a minimally interfering technique that, in certain configurations, can sample electrical

Fig. 17.3 (a) Measured ultrafast electrical pulse (*lower trace*), 10× expanded scale (*upper trace*). (b) Amplitude spectrum of (a)

signals with micron spatial resolution without making physical contact.

In the example presented in Fig. 17.4, electrooptic sampling was used to measure an electrical transient on a coplanar transmission line generated by photoconductively shorting a 50 μm gap biased at 50 V with the excitation pulse [17.8]. The Cr:GaAs and LiTaO$_3$ crystals were mounted side by side on a glass plate and were ground and polished together to a thickness of 500 μm in order for later fabrication. The transmission line was made by evaporating 0.5 μm of aluminium onto the smooth surface and then using standard photolithographic techniques to define the pattern. The measured 460 fs rise time (10% to 90%) is shown in Fig. 17.4b for which the 50 μm excitation gap was located 200 μm from the sampling point. The probe beam was aligned perpendicularly to the substrate and was focused to a 11 μm diameter between the two 50 μm wide lines separated from each other by 50 μm. The amplitude of the switched signal was 30 mV; the good signal-to-noise ratio indicates the sensitivity of the technique.

Electrooptic sampling reached the impressive combination of a demonstrated rise time of 290 fs and a 40 μm square footprint in the 1 THz bandwidth probestation developed by *Valdmanis* [17.9]. In other work, a 260 fs rise time electrical transient was measured using electrooptic sampling with a thin lithium tantalate crystal plate overlying a coplanar transmission line [17.10]. An impressive rise time of 150 fs has been demonstrated using a combination of photoconductive excitation and electrooptic sampling together with the total internal reflection probe [17.11]. Using the approach of [17.12] for GaAs circuitry, the chip itself can be used as the nonlinear crystal.

17.1.5 THz Shockwave Generation on Nonlinear Transmission Lines

The phenomenon of shockwave generation on a fully distributed nonlinear transmission line (NLTL) was first discussed by *Landauer* [17.59] with respect to its use as a parametric amplifier. The shockwave properties were later more fully analyzed [17.60] and the case of periodically loaded [17.61] NLTLs were discussed. Previous studies [17.62] have demonstrated the generation of 3.5 ps shockwaves on a GaAs NLTL having Schottky diodes with uniform doping. In this section the fabrication and results from NLTLs with hyperabrupt varactor diodes will be discussed [17.58]. The increased capacitance variation in hyperabrupt diodes permits using
Fig. 17.5 (a) Photomicrograph of part of a hyperabrupt-diode nonlinear transmission line showing the taper between the larger-scale and final small-scale sections. **(b)** A 2.5 ps measured fall time shockwave generated on an NLTL with a 25 dBm, 10 GHz sinusoidal input. In the *insert*, the full 100 ps period saw tooth waveform is shown. (Adapted from [17.58])

lower loss NLTL designs, that result in a shockwave with higher amplitude and decreased fall time.

The monolithic GaAs NLTL circuit consists of a high-impedance coplanar waveguide (CPW) transmission line with characteristic impedance Z_1 that is periodically loaded at spacing τ (in units of time), by Schottky varactor diodes, producing a synthetic transmission line whose propagation velocity is voltage dependent. Several variations of this mixed structure (Fig. 17.5a) having different numbers of large-scale diodes were fabricated with a minimum feature size of 2 μm on GaAs molecular beam epitaxy material with a total active layer thickness of 0.3 μm and a 1.0 μm buried n$^+$ layer (6×10^{18}/cm^3 doping) for the diode cathode connection.

As a negative-going input voltage transition, with initial voltage V_h, final voltage V_f, and initial fall time t_{in}, propagates along the line, the fall time will decrease with distance due to the differential group delay, $\Delta t = t(V_h) - t(V_f)$, along the wavefront. As the
Fig. 17.6 An 880 fs measured-fall-time shockwave generated on a nonlinear transmission line and measured by an on-chip diode sampler at $T = 77$ K. The *inset* is a quarter period of the waveform. (Adapted from [17.63])

fall time decreases, dispersion arising from the varactor cutoff frequency and the periodic-line cutoff frequency competes with the compression arising from the voltage-dependent propagation velocity. An asymptotic final fall time t_{min} is reached, at which point the fall time compression per line section is equal to the fall time broadening per section so that the resulting shockwave then propagates unchanged.

The circuit performance was evaluated by direct electrooptic (EO) sampling[17.12] of the voltage waveforms launched onto the line through microwave wafer probes. Figure 17.5b shows a measured waveform for 25 dBm sine wave excitation of a NLTL consisting of 30 large diodes and 40 small diodes with a measured $\Delta t = 49$ ps and a total length of 7.8 mm. The 10 GHz input had a 10–90% fall time of 30 ps, while the output shock wave had a measured 2.5 ps fall time. The shock amplitude was determined to be about 6 V by calibration of the optical signal to a reference electrical signal.

The first subpicosecond shockwaves generated and measured by entirely electronic means are shown in Fig. 17.6 [17.63]. This measurement was performed with a monolithic NLTL/sampler chip. At room temperature, an approximately 1 V, 1.8 ps fall time was observed with less than 20 fs of jitter for a 25 dBm, 6.56 GHz input. The packaged assembly was then lowered into a dewar flask of liquid nitrogen. Steady improvement in both amplitude and fall time was noted until the packaged circuit was completely immersed, resulting in the minimum fall time of 880 fs with a 3.5 V amplitude.
Fig. 17.7 Electrical field lines for the propagating TEM mode

The liquid nitrogen did not significantly load the circuits because of its relatively low permittivity $\varepsilon_r = 1.4$.

17.1.6 Transmission Line Theory

We will now discuss some general aspects of transmission line theory in the quasistatic limit for which the wavelengths involved are large compared to the transverse dimensions of the line [17.64, 65]. For this case the number of transverse electromagnetic (TEM) modes is one less than the number of metal lines making up the transmission line. Consequently, a two line transmission line has a single propagating TEM mode, for which the electric field distribution (shown in Fig. 17.7) is the same as for the static case when the lines are equally and oppositely charged. Any pulse propagating on this line can be described mathematically as a Fourier sum of single frequency components, all with this same TEM modal distribution.

Consideration of the sliding contact excitation site shows that, to first order, charge is simply transferred from one line to the other creating a symmetrical field distribution with respect to the two lines. During the excitation process a current flow is induced between the lines. Localized charge accumulations of opposite sign build up on the segments of the two metal lines under the laser excitation spot, creating a dipolar field distribution similar to that illustrated in Fig. 17.7 and thereby efficiently coupling the sliding contact excitation to the TEM mode.

A most important feature of coplanar transmission lines (of negligible thickness) on an infinite dielectric half-space is that for a constant voltage between the two conducting lines, the electric field lines are the same as for the lines immersed in free space. This result is due to the geometric symmetry with respect to the dielectric

boundary and is a consequence of the fact that no electric field lines cross this boundary.

For this simple situation, it has been shown that the phase velocity is given by

$$v_p = c \{2/[\varepsilon(\omega) + 1]\}^{1/2} . \tag{17.1}$$

If we define the effective index $n_e = c/v_p$, the expression for the group velocity becomes

$$v_g = c/[n_e + \omega(\mathrm{d}n_e/\mathrm{d}\omega)] . \tag{17.2}$$

The power absorption coefficient α for the transmission line can be written as the sum of the absorption due to the metal lines α_{ml} and that due to the dielectric α_{dl}:

$$\alpha = \alpha_{ml} + \alpha_{dl} . \tag{17.3}$$

The dielectric loss of the line can be written in the very general form for guided waves

$$\alpha_{dl} = f_f \alpha_d v_{gd}/v_g , \tag{17.4}$$

where the filling factor f_f is defined as the ratio of the energy per unit length in the dielectric to the total energy per unit length on the coplanar line; α_d is the power absorption coefficient in the bulk dielectric and v_{gd} is the group velocity in the dielectric. For the simple case of the coplanar waveguide with the same field pattern in the air and in the dielectric, f_f is given by $f_f = \varepsilon/(1 + \varepsilon)$; $v_{gd} = c/\varepsilon^{1/2}$, and α_{dl} is evaluated to be

$$\alpha_{dl} = \alpha_d[\varepsilon/(2 + 2\varepsilon)]^{1/2} . \tag{17.5}$$

17.1.7 THz–TDS Characterization of Transmission Lines

The powerful technique of THz time-domain spectroscopy (THz-TDS) is especially appropriate for characterizing dielectrics, ultra-wideband transmission lines and waveguides [17.52, 66]. With this technique, two electromagnetic pulse shapes are measured, the input pulse and the propagated pulse, which has changed shape due to its passage through the sample under study. Consequently, via Fourier analyses of the input and propagated pulses, the frequency dependent absorption and dispersion of the sample can be obtained.

The subpicosecond electrical pulses generated on coplanar transmission lines can be used for THz-TDS characterization of the transmission line itself. For the layout shown in Figs. 17.1 and 17.2, the point at which the pulse is generated can be moved with respect to the detection electrode by repositioning the exciting laser

beam. This separation can be continuously adjusted and is the equivalent of a "sliding contact." For THz-TDS studies it is important that the pulses propagate as a single mode of excitation on the transmission line. This feature is enabled due to the micron-sized dimensions of the coplanar line and to the sliding contact method of excitation, [17.5], which matches the TEM transverse electromagnetic mode of the transmission line. Thus, as the ultrafast electrical pulse propagates down the transmission line, its pulse shape will only change due to the frequency dependent electrical and magnetic properties of the transmission line, e.g., the metal of the line and the dielectric substrate and radiation processes. Consequently, via THz-TDS, the absorption and dispersion vs. frequency of the line can be obtained [17.67].

The performance of lithographically defined planar transmission lines will be shown to be limited by the resistive loss of the metal lines, Cherenkov radiation loss from the propagating pulse, and absorption by the underlying dielectric. Typically, for THz bandwidth pulses, Cherenkov radiation is the dominant loss process, which can be so severe that after propagating only 1 mm, power at 0.8 THz is reduced to $1/e$ of its original value. Various techniques have been demonstrated to reduce this radiation. The most straight-forward approach, which is compatible with VLSI processing, is to reduce line dimensions (linewidths and separations) to below 1 μm. However, for such dimensions resistive loss of the lines restricts the bandwidth. Normal superconductors can solve this problem for low frequency applications typically up to a band gap frequency of 0.7 THz, above which the line shows severe loss. As an added benefit, cryogenic temperatures usually lower the THz absorption loss of crystalline substrates. To achieve high-frequency response with submicron linewidths, the high-T_c superconductors with band gaps above 15 THz appear as a possible solution. Early attempts to achieve THz bandwidths with high-T_c transmission lines were limited by the extremely high absorptive loss of the lattice matched YSZ substrate [17.68]. Later investigations used lattice matched lanthanum aluminate substrates with much lower loss and achieved significantly lower propagation loss up to 1 THz at cryogenic temperatures for a high-T_c coplanar transmission line compared to an identical transmission line with gold lines [17.69]. However, a more recent investigation of high-T_c coplanar transmission lines fabricated on a lattice matched MgO substrate gave the disappointing result that at 77 K the attenuation was higher for the high-T_c line than for an identical gold line [17.70]. This situation must be resolved if high-T_c lines are going to realize their promise
Fig. 17.8 The Cherenkov cone in the dielectric half-space

as the future material for the VLSI interconnect with dimensions below 1 μm and with THz bandwidths.

Cherenkov Radiation

By studying the frequency dependent loss on an Al transmission line on SOS, where the coplanar lines were separated by 15 μm, a powerful radiation process was observed due to a type of Cherenkov radiation [17.71]. When charges move faster than the phase velocity for electromagnetic radiation in a material, Cherenkov radiation is emitted as an electromagnetic shock wave [17.72]. The initial analysis of this effect was for electric monopoles, but the physical picture holds true for higher-order moments as well. The electrical pulses were produced by transferring approximately 2000 electrons between the two lines at the generation site. Consequently, two dipoles with charges of $1000 \, e$ and separations of 15 μm move down opposite directions of the line at the measured group velocity of $c/2.45$, significantly faster than the phase velocity of approximately $c/3.3$ for THz radiation in sapphire. Thus, in the dielectric, the situation shown in Fig. 17.8 occurs, which generates radiation of an electromagnetic shock wave in the form of a Cherenkov-type cone.

THz-TDS measurements have characterized this loss process, which is so severe that after propagating only 1 mm the power at 0.8 THz is reduced to $1/e$ of its original value. Previous frequency domain studies have calculated the radiative loss for single-frequency transmission on coplanar metal lines on dielectrics [17.73].

Fig. 17.9 (**a**) Measured initial pulse. (**b**) Measured pulse after 6 mm propagation. (**c**) Amplitude spectrum of pulse (*dots*) compared to propagated pulse (*squares*). (**d**) Experimental amplitude absorption coefficient (*dots*) compared with theory. (Adapted from [17.71])
These results have been confirmed by experimental measurements up to 1 GHz [17.73], where the radiation loss is only 10^{-9} of that presented here. The observed frequency-dependent absorption remains in good agreement with this calculation, even though the THz-TDS measurement extends up to 1 THz. At these high frequencies, the time-domain Cherenkov picture provides a simple intuitive description of the generation of the electromagnetic shock wave and of the radiation process associated with the propagating ultrafast electrical pulse.

In Fig. 17.9a, the measured initial subpicosecond electrical pulse is shown [17.71]. In this case, the spatial separation between the exciting and sampling beams was approximately 50 μm, while the laser spot diameters were 15 μm. When the sliding contact was moved 6 mm from the optical sampling gap the pulse propagation effects shown in Fig. 17.9b were observed. The Fourier analyses of these pulses are shown in Fig. 17.9c, where it is seen that the amplitude spectrum of the initial pulse extends beyond 1 THz and that the transmitted pulse has suffered a significant frequency-dependent loss. From these spectra it is straight-forward to obtain the absorption coefficient as a function of frequency, as shown in Fig. 17.9d.

Evaluating the predicted loss ("absorption") for these conditions [17.71,73,74], the amplitude absorption coefficient is obtained as $\alpha = (0.4\,\mathrm{mm}^{-1})f^3$, where f is the frequency in THz. This result should be compared with the measurements in Fig. 17.9d. The solid line fit to the data in Fig. 17.9d is given by the relationship $\alpha = (0.2\,\mathrm{mm}^{-1})f^{1/2} + (0.65\,\mathrm{mm}^{-1})f^3$. The first term gives the frequency-dependent loss due to the resistive skin effect for the Al lines, while the second term with the f^3 dependence describes the loss due to the radiation. The measured loss due to the radiation is approximately 1.5 times the calculated value. This good agreement, and especially the cubic-frequency dependence, definitely confirms the nature of the effect.

Methods to Eliminate Cherenkov Radiation from Transmission Lines

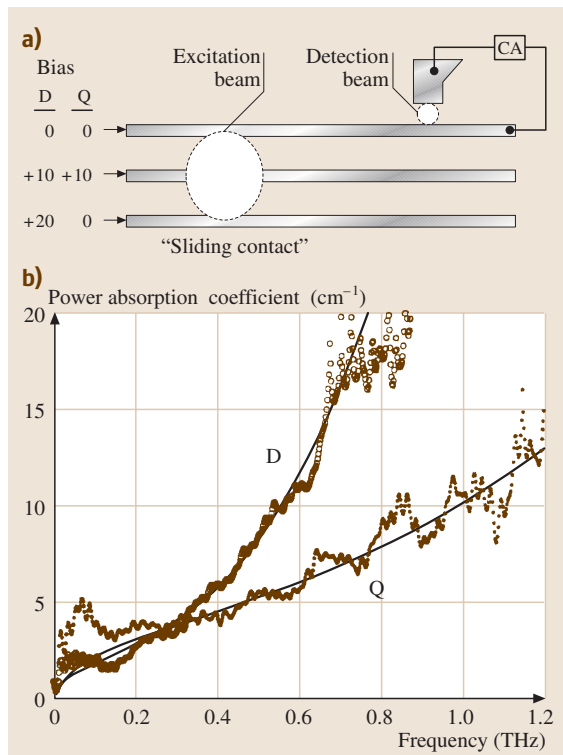
The Cherenkov radiation loss has been eliminated by the use of silicon-on-insulator materials with a microstrip geometry [17.75] and thin-film microstrip lines [17.76], but the total observed loss owing to the dielectric and the metal was still approximately the same as for the coplanar transmission line. A variety of transmission line structures have been designed to reduce the permittivity mismatch responsible for the Cherenkov radiation [17.77–80]. The ideal transmission line would


Fig. 17.10 **(a)** Three line coplanar transmission line. The aluminium lines are 4 μm wide separated by 15 μm. Quadrupole electrical pulses are generated with bias Q, dipole pulses with bias D. **(b)** Measured power absorption coefficient compared to theory (Q) quadrupole (odd mode) and (D) dipole even mode pulses. (Adapted from [17.74])

have no substrate/superstrate mismatch. Along these lines, coplanar air transmission (CAT) lines have been fabricated [17.77]; these coplanar striplines are edge supported by a 200 nm layer of SiO_2 on GaAs. The GaAs below the transmission line is etched away leaving the striplines supported in free space. Rise times as short as 0.8 ps after a propagation length of 2.8 mm were obtained [17.77]. Coplanar striplines have also been fabricated on low permittivity substrates and membranes, on the order of microns thick, demonstrating significantly reduced loss and higher bandwidths [17.78–80].

A new approach to the reduction of radiative loss from transmission lines has been demonstrated [17.74]. Instead of reducing the permittivity mismatch, the mode characteristics of a three line stripline were utilized to generate a quadrupole electrical pulse with significantly reduced loss and dispersion compared to that of the dipole pulse. As shown in Fig. 17.10a, through appro-

priate bias of the striplines, either the even mode, where the electric fields are parallel between each gap with a dipole field pattern, or the odd mode, which has the antiparallel electric fields in the gaps with a quadrupole field pattern, can be exclusively excited.

Using THz-TDS analysis, the amplitude absorption coefficient $\alpha(f)$ for the quadrupole pulse and dipole pulse are shown in Fig. 17.10b. The absorption for the quadrupole is dramatically reduced over that of the dipole; at 0.8 THz a factor of two difference between the two coefficients is observed. Both curves are fit with the relationship $\alpha(f) = A_{res} f^{1/2} + A_{rad} f^3$, where the resistive A_{res} and the radiative A_{rad} loss coefficients are adjustable parameters. For the dipole pulse A_{res} is $6 \, cm^{-1}$, compared to $7 \, cm^{-1}$ for the quadrupole. For the dipole pulse, the strong f^3 dependence is seen with a radiative coefficient $A_{rad} = 32 \, cm^{-1}$, whereas the quadrupole pulse has the much smaller coefficient $A_{rad} = 3 \, cm^{-1}$. This order of magnitude reduction clearly demonstrates that the radiative loss for an electric quadrupole pulse is significantly less than that of a dipole pulse. It is instructive to compare the measured $A_{rad} = 32 \, cm^{-1}$ for the $30 \, \mu m$-sized dipole with that expected from the measurements of Fig. 17.9, where $A_{rad} = 6.5 \, cm^{-1}$ for a $15 \, \mu m$ dipole. Because the radiation loss is proportional to the square of this length, Fig. 17.9 would predict an $A_{rad} = 28 \, cm^{-1}$ for a $30 \, \mu m$-sized dipole in good agreement with observation.

Superconducting Transmission Lines

One of the early applications of THz-TDS was the study of superconducting niobium metal lines [17.81]. Niobium has a superconducting transition temperature of 9.4 K and was cooled in a cryostat to temperatures in the range of 2−8 K. The cryostat had optical windows that allowed for the laser beams to pass through. For the experiment, the same pattern was fabricated in niobium metal on an SOS wafer, which was then ion implanted as before.

With the exciting beam striking very close to the detection electrode, the results are much the same as for aluminium at room temperature. Above the superconducting transition temperature $T_c = 9.4 \, K$ for niobium, the propagated pulse was severely broadened by the highly resistive Nb transmission line.

Fig. 17.11 (**a**) Initial electrical pulse. (**b**) Electrical pulse after 2 mm propagation on Nb superconducting transmission line at 2.6 K. (**c**) Fourier transforms of initial and propagated pulses at different temperatures. (**d**) Absorption spectra of transmission line versus temperature

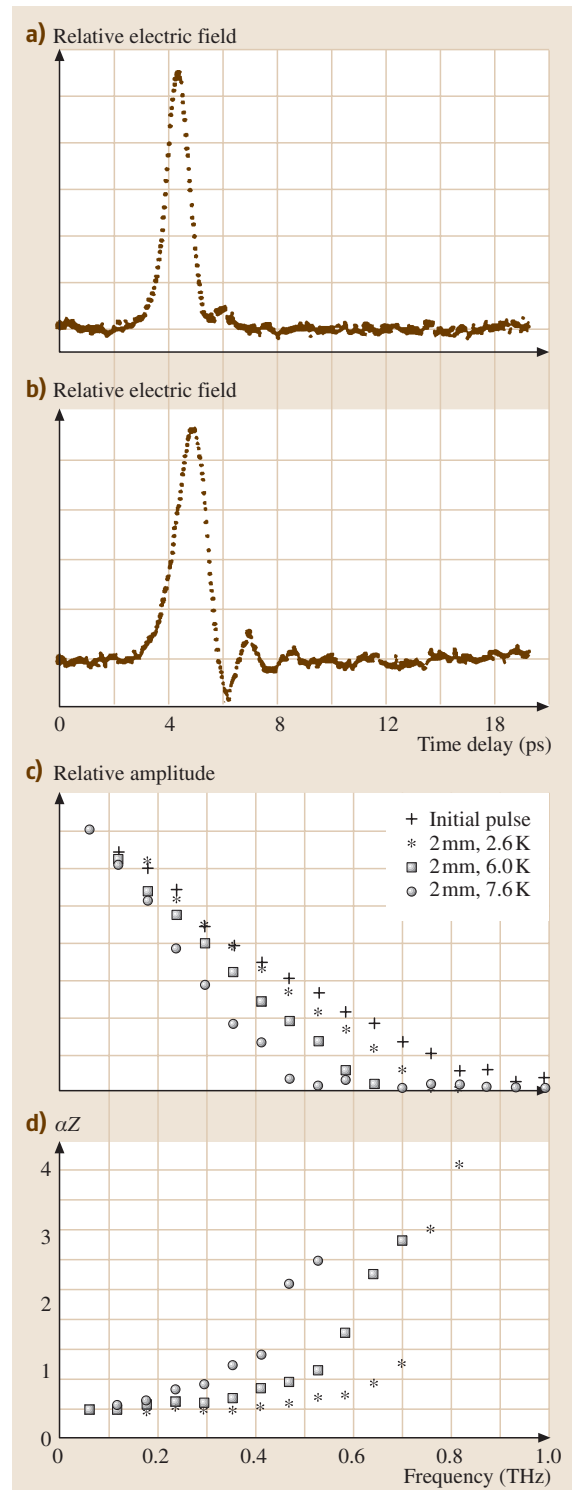

Figure 17.11a shows the pulse shape at 2.5 K and 0.5 mm from the point of excitation. The pulse broadens with propagation and develops a distinct oscillation at the leading edge, as shown in Fig. 17.11b. This oscillatory behavior is characteristic of a superconductor. While a superconductor has no losses at low frequencies, it has significant loss at and above the superconducting gap frequency, corresponding to the energy with which pairs of electrons are bound in the superconducting state. For niobium at 2.6 K this onset is at about 0.7 THz, which is close to the oscillation frequency shown in Fig. 17.11b. When the input and propagated pulses are frequency analyzed, the absorption coefficient has a sharp step at 0.7 THz, corresponding to the superconducting band gap. This result clearly identifies the band gap and illustrates the power of the method. The fact that for frequencies above the band gap, the line behaves as a normal metal has the important technical implication that ordinary superconducting lines cannot be used to propagate 1 ps pulses.

17.1.8 Guided–Wave THz–TDS Characterization of Dielectrics

The frequency-dependent dielectric properties of a material may be measured by placing the material on the transmission line and into the field lines of the propagating pulses. For a typical line composed of $5\,\mu m$ lines separated by $10\,\mu m$, this requires that the material be brought within several microns of the line. For paths several mm long, this is not an easy task. An optoelectronic test that indicates the quality of the optical contact is the measured group velocity v_g of the pulse in the section of the transmission line covered by the dielectric sample. With no sample in place for an SOS chip $v_g = c/2.45$. The expression for the group velocity is easily generalized to the two dielectric case as $v_g = c/[2/(\varepsilon_1 + \varepsilon_2)]^{1/2}$, where ε_1 refers to the substrate and ε_2 refers to the dielectric under study. Consequently, with typical high dielectric constant ($\varepsilon_2 = 10$) samples v_g should be approximately $c/3$. An estimate of the contact with the transmission line is given by a comparison between this calculated value and the measured value. The result can be used to estimate a "filling factor" for the absorption measurement.

An early example of a THz-TDS measurement of a material brought into contact with the transmission line was the observation of some magnetic resonances in erbium iron garnet (ErIG)[17.82]. It is of interest to note here that the interaction is with the magnetic field of the propagating electrical pulse in contrast to the usual
Fig. 17.12 (a) Electrical pulses after 4 mm propagation on the line covered with EIG powder. **(b)** Spectrum of propagated pulse with and without ErIG. (Adapted from [17.82])

case where it is the electric field responsible for the observed effects. For this study, an approximately 3 mm section of the line was covered with fine garnet powder. When the ultrafast pulse was propagated through this powder a new dramatic oscillatory time dependence was observed on the output pulse shown in Fig. 17.12a. When this output pulse was frequency analyzed, two well-defined absorption lines appeared as shown in Fig. 17.12b. The line at $10\,cm^{-1}$ had been measured earlier by more traditional spectroscopic techniques and identified as the exchange resonance [17.83], while the line at $4\,cm^{-1}$ had previously not been observed. Earlier measurements using YbIG showed a line at $3\,cm^{-1}$ due to the ferrimagnetic resonance [17.84]. By extrapolating

these results to ErIG, the newly observed line appears to be the corresponding ferrimagnetic resonance.

17.1.9 THz Waveguides

THz waveguides have been recently demonstrated to be an alternative to transmission lines [17.85–90]. For bandwidths up to 3.5 THz the attenuation coefficient of metal waveguides has been shown to be less than 1/10 that of lithographically defined transmission lines on dielectric substrates. Within the passband of the waveguide, the measured power coupling into the waveguide was typically 40% of the incoming THz power. Although these waveguides should be quite useful for narrow band or THz-TDS applications, they have very high group velocity dispersion (GVD), which precludes subpicosecond pulse propagation. For the single conductor circular and rectangular metal waveguides the excessive THz pulse broadening is caused by the extreme GVD near the cutoff frequency. This pulse broadening would not occur for the TEM modes of a two-wire coplanar line, a coaxial line, or a parallel-plate metal waveguide, that do not have a cutoff frequency. The group and phase velocities of such TEM modes are determined solely by the surrounding dielectric. Quasioptic coupling techniques are not effective for the complex field patterns of the TEM mode of the two-wire coplanar line or the coaxial line, but are effective for the simple field pattern of the TEM mode of the parallel-plate metal waveguide.

Recent experiments have shown efficient quasioptic coupling of freely propagating subpicosecond pulses of THz radiation into a parallel-plate metal waveguide and the subsequent low-loss, single TEM mode propagation exhibiting negligible GVD [17.89, 90]. Consequently, the ideal THz interconnect [17.66], capable of propagating subpicosecond pulses with minimal loss and no distortion, has been realized.

A promising application of THz metal waveguides appears to be surface-specific frequency-dependent absorption measurements using THz-TDS. For an air-filled waveguide, the observed frequency-dependent absorption coefficient determines the frequency-dependent conductivity, which is difficult to obtain by other techniques. Long-path surface-specific measurements of molecular adsorption to the metal waveguide walls is another area of promise. From experimental measurements made on the absorption of water, we believe that for similar polar molecules, THz-TDS has the sensitivity to characterize the absorption of nanogram quantities of samples of toxic or precious gases contained in a tubular, single conductor THz waveguide. Such enclosed wave-

guides would also make excellent low-volume sample cells for high-pressure, long-path spectroscopic measurements of toxic or reactive gases and liquids. THz waveguides could enable the observation of nonlinear effects with relatively modest powers, due to the small diameters combined with the long-path, low-loss propagation.

In addition to the above possibilities, THz pulses propagating in the TEM mode open the door to other new research applications. The metal plates could be easily coated with films of other metals and alloys to measure their conductivities. Superconducting plates could be easily characterized. Shorter length waveguides could be constructed of highly doped semiconductors that are typically opaque to THz radiation, thereby enabling the measurement of their frequency-dependent complex conductivity. Simple thin films, more complex Langmuir–Blodgett films, and conducting polymers could coat the waveguide and be characterized by THz-TDS. A unique application for high-power TEM THz pulses would be the study of nonlinear pulse propagation, demonstrating nonlinear coherent effects of samples filling the space between the metal plates. Here, for the first time, a THz pulse can maintain its spatial focus for arbitrarily long paths without temporal broadening, thereby enormously increasing the effects of nonlinear interactions. This situation is similar to the nonlinear enhancement obtained with optical fibers.

Dielectric waveguides do not have the sharp low-frequency cutoff of metal waveguides and thereby extend the low-frequency limit. The initial demonstration [17.87] used single crystal sapphire fibers and achieved single HE_{11} mode propagation with large GVD caused by the extent of the fringing fields increasing with wavelength. The waveguide absorption was that of bulk sapphire. Given a suitable low loss dielectric, such as high-resistivity silicon with a power absorption coefficient of less than $0.05 \, \text{cm}^{-1}$, dielectric waveguides could have much less absorption than metal waveguides. Such dielectric single-mode THz waveguides would have the promise of an extremely low-loss, flexible interconnect and communications channel, with advantages similar to that of single-mode optical fiber.

Planar dielectric waveguides appear to be especially well adapted for the proposed THz-TDS characterization of surface layers, due to the extensive fringing fields of the propagating THz waves outside the waveguide. For guided wave propagation there is an enormous increase in sensitivity to a thin sample layer, compared to a simple reflection or transmission. Appropriate easily applied samples would include adsorbed molecules, sur-

Metal Waveguides

Experimental investigations using quasioptical methods to efficiently couple freely propagating subpicosecond pulses of THz radiation into single-conductor, submillimeter metal waveguides and to consequently measure the transmitted pulses from these waveguides have been recently reported [17.85, 86]. Dispersive propagation with low-loss over the frequency band from 0.65 to 3.5 THz was observed with frequency dependent group velocities v_g ranging from $c/4$ to c and phase velocities v_p from $4c$ to c, where $(v_g v_p = c^2)$. Even though the input spectrum overlapped the cutoff frequencies of more than 25 waveguide modes, the linearly polarized incoming THz pulses only significantly coupled into the TE_{11}, TM_{11} and the TE_{12} modes for observations using 24 mm long and 4 mm long stainless steel (SS) tubes with inside diameters of 240 μm and 280 μm, respectively. As shown in Fig. 17.13 [17.91–93], at 1 THz the power absorption coefficient for the dominant TE_{11} mode is $\alpha = 0.7\,\text{cm}^{-1}$ for a 240 μm diameter. The SS waveguide is approximately $1/10$ of the loss compared to lithographically defined coplanar transmission lines [17.66].

The experimental setup for THz waveguides is similar to that of the optoelectronic THz beam system described in the next section, except that at the beam waist centered between the two parabolic reflectors a lens–waveguide–lens system is placed as shown in Fig. 17.14a. For the waveguide system the silicon lens focuses the THz beam to a frequency-independent $1/e$-waist diameter of approximately $200\,\mu m$, which is coupled into and propagated through the waveguide and is coupled out with the second silicon lens. The reference THz pulse is measured by removing the waveguide and then moving the two silicon lenses to their common focus (the confocal position). Such a reference THz pulse is shown in Fig. 17.14b, where the corresponding amplitude spectrum shown Fig. 17.14c extends from 0.1 THz to 4 THz.

The observed transmitted signal from the 24 mm long waveguide dramatically demonstrated the strong group velocity dispersion of the waveguide [17.85, 86]. The 1 ps input pulse was stretched to about 70 ps, with the high frequencies arriving earlier in time corresponding to negative chirp. The transmitted pulse from a 4 mm long waveguide displays comparatively less cumulative dispersion in Fig. 17.15a (dots). The pulse is spread over 30 ps and shows fewer oscillations. The spectrum of this pulse, Fig. 17.15b (dots), shows the lowest frequency cutoff at about 0.65 THz, which is also calculated to be 0.65 THz for the TE_{11} mode. The comparison of the relative amplitude spectrum of this pulse with that of the reference pulse in Fig. 17.14c, where they both have the same normalization, illustrates the excellent amplitude coupling of the freely propagating THz pulse into the waveguide. Multimode interference was observed to be stronger in the shorter waveguide, starting at about 1.3 THz. The dominant TE_{11} mode has a cutoff frequency of 0.65 THz (77%); the coupled TM_{11} mode has a cutoff at 1.31 THz (20%), and the weakly TE_{12} coupled mode has a cutoff at 1.81 THz (3%). The percent of the total coupled power into each mode is in parentheses.

Using the spectrum of the reference pulse, the output spectrum from the 4 mm waveguide was calculated including the three coupled modes, their respective complex amplitude coupling, as well as their frequency-dependent complex propagation vectors, obtainable as from Fig. 17.13. This calculation overlays as the solid line the measured spectra in Fig. 17.15b; good agreement is obtained for the interference oscillations and the other features of the spectra. The calculated time-domain output pulse (solid line) is given by the inverse Fourier transform of the calculated complex output am-

plitude spectrum $E_{out}(\omega, z)$ and is compared favorably with the experiment in Fig. 17.15a.

TEM THz Parallel–Plate Metal Waveguide
In the initial observation [17.89] shown in Fig. 17.16, a freely propagating beam of 0.3 ps FWHM THz pulses was efficiently coupled into a parallel-plate copper waveguide (with a plate separation of $108\,\mu m$), and low-

loss, single TEM mode undistorted pulse propagation was observed within the bandwidth from 0.1–4 THz for a length of 24.4 mm. The experimental setup incorporated planocylindrical lenses to couple the energy into and out of the guide. The lens at the input of the guide

is used to focus the beam only along one dimension producing an approximately Gaussian beam having an elliptic cross-section with a frequency-independent $1/e$-amplitude minor axis of 200 μm at the beam waist, where the entrance face of the guide is located. An identical arrangement is used at the output face.

A more recent demonstration [17.90] is shown in Fig. 17.17, where the FWHM was 0.22 ps for the input reference pulse, 0.25 ps for the output pulse after $L = 125$ mm of TEM propagation, and 0.39 ps for the output pulse after $L = 250$ mm of TEM propagation. Characteristic of TEM propagation, the output pulses exhibit no dispersive pulse broadening [17.89, 90]. The minimal broadening of the output pulses is due to the relative loss in the high-frequency content as seen in the amplitude spectra. As shown in Fig. 17.17d, the FWHM of the amplitude spectra are 1.62 THz, 1.14 THz, and 0.74 THz for the reference, $L = 125$ mm, and $L = 250$ mm pulses, respectively. The smoothness of the output spectra revealing no low-frequency cut-off, confirms single TEM mode propagation [17.85–90]. The associated low loss for this TEM propagation is presented in Fig. 17.18, which gives the measured amplitude attenuation constant compared with theory.

Dielectric Waveguides

An alternative approach to low-loss, guided wave, THz propagation would be to use dielectric waveguides. Such waveguides do not have the sharp low-frequency cut-off of metal waveguides and would thereby extend the low-frequency limit. Dielectric waveguide propagation of subpicosecond THz pulses (in single-crystal sapphire fibers) has now been achieved [17.87]. An incident THz pulse of approximately 0.6 ps duration was observed to undergo considerable reshaping due to the absorptive and dispersive waveguide propagation, resulting in transmitted chirped pulse durations of 10–30 ps. Good agreement between theory and experiment was obtained by analyzing the propagation in terms of the single HE_{11} waveguide mode.

The THz dielectric waveguide work has been extended to planar waveguides based on films, such as high-density polyethylene. This material has low THz absorption and gives very low-loss propagation. Dispersive, low-loss propagation was observed for 2 cm wide by 150 μm thick ribbon waveguides made of high-density polyethylene (HDPE) [17.88]. The large GVD caused extensive THz pulse reshaping and broadening, resulting in positively chirped output pulses. The measured propagated THz pulse through a 10 mm long HDPE waveguide broadened to over 15 ps and showed strong reshaping indicating a frequency chirp. In contrast, the corresponding amplitude spectrum shows much less change. The reference pulse was a half-cycle pulse with a peak to peak pulse width of less than 1 ps; its amplitude spectrum extended from 0.1 to about 3 THz. The amplitude spectrum of the propagated pulses, compared to the spectrum of the reference pulse, clearly exhibits efficient wave-guiding characteristics.

This study demonstrated the feasibility of the plastic ribbon waveguide as a low-loss, single-mode transmission channel for the THz region, capable of utilizing efficient quasioptic coupling. Ultralow loss lines are possible by reducing the thickness of the ribbon such that most of the guided wave energy propagates outside the core region. The performance could be further enhanced by the use of a very low-loss material, such as high-resistivity silicon with a power absorption coefficient of much less than $0.05\,\text{cm}^{-1}$ up to 2 THz [17.51]. Consequently, dielectric waveguides could have much less absorption than metal waveguides. Due to the ability to change the group velocity dispersion (GVD) by changing the thickness of the ribbon waveguide, large-frequency regions with essentially no GVD can be obtained.

17.2 Freely Propagating Wave THz Photonics

Recently, there has been a great deal of work demonstrating the generation of THz radiation via material and electronic excitation by ultrafast laser pulses. Modern integrated circuit techniques have made possible the precise fabrication of micron-sized dipoles, which when photoconductively driven by fs laser pulses can radiate well into the THz regime [17.20–22]. An alternative and complimentary approach has been to extend radio and microwave techniques into the THz regime through the use of optoelectronic antennas [17.23–30, 32]. The generation of short pulses of THz radiation by the passage of a short optical pulse through a nonlinear optical material was demonstrated many years ago [17.33]. A related source is based on the emission of an electromagnetic shock wave due to a volume dipole distribution moving faster than the phase velocity, i. e., the electrooptic Cherenkov radiation [17.34, 35], and the electromagnetic shock wave radiated by a surface-dipole distribution propagating faster than the phase velocity [17.71]. THz radiation has been generated by photoconductively driving the surface field of semiconductors [17.36, 37] and the intrinsic region of large aperture silicon p-i-n diodes [17.20] with ultrafast laser pulses. A quite efficient source of broadband THz radiation involves the generation of photocarriers in trap-enhanced electric fields with ultrafast laser pulses [17.44, 94]. A cw photomixer capable of producing tunable radiation has been demonstrated by beating together two laser beams with frequencies above the band gap of a semiconductor [17.39–43].

Some of these sources are based on an optical type approach whereby a transient point source of THz radiation is located at the focus of a dielectric collimating lens, followed by an additional paraboloidal focusing and collimating mirror [17.21, 22, 29, 31, 95]. Although this system will be the one described in most detail, alternative approaches will also be presented. One of the most useful versions of the system is based on repetitive, subpicosecond optical excitation of a Hertzian dipole antenna imbedded in a charged coplanar transmission line structure [17.21, 22, 29, 31, 95]. The burst of radiation emitted by the resulting transient dipole is collimated by a THz optical system into a diffraction-limited beam and focused onto a similar receiver structure, where it induces a transient voltage and is detected. The THz optical system gives exceptionally tight coupling between the transmitter and receiver, while the excellent focusing properties preserves the subpicosecond time dependence of the source.

The combination of THz optics with the synchronously-gated, optoelectronic detection process has exceptional sensitivity for repetitively pulsed beams of THz radiation. Via two stages of collimation, a THz beam with a frequency-independent divergence is obtained from the THz transmitter. The THz receiver with identical optical properties collects essentially all of this beam. The resulting tightly coupled system of the THz transmitter and receiver can give strong reception of the transmitted pulses of THz radiation after many meters of propagation. Another reason for the exceptional sensitivity is that the THz receiver is gated. The gating window of approximately 0.6 ps is determined by the laser pulse width and the carrier lifetime in ion-implanted silicon-on-sapphire (SOS). Thus, the noise in the comparatively long time interval (10 ns) between the repetitive THz pulses is not seen by the receiver. A final important feature of the detection method is that it is a coherent process; the electric field of a repetitive pulse of THz radiation is directly measured. Because a repetitive signal is synchronously detected, the total charge (current) from the signal increases linearly with the number of sampling pulses, while the charge (current) from noise increases only as the square root of the number of pulses.

17.2.1 An Optoelectronic THz Beam System

This section describes the optoelectronic generation and detection of freely-propagating femtosecond pulses of THz electromagnetic radiation. Via optoelectronic excitation, a transient point source of THz radiation is generated at the focus of a dielectric collimating lens, followed by an additional paraboloidal focusing and collimating mirror. This source produces well-collimated beams of subpicosecond pulses of THz radiation. Matched to an identical receiver, the resulting system has extremely high collection efficiency. With a demonstrated signal-to-noise ratio of 1000, a time resolution of less than 150 fs, and a frequency range from 0.2 THz to more than 6 THz, the performance of this optoelectronic THz system is limited only by the ballistic acceleration of the photocarriers.

The setup used to generate and detect beams of short pulses of THz radiation is presented in Fig. 17.19. For this example, the transmitting and receiving antennas are identical, each consisting of the antenna imbedded in a coplanar transmission [17.31], as shown in Fig. 17.19a. The antenna is fabricated on an ion-implanted SOS wafer.

The Experimental Setup

The 20 μm wide antenna structure is located in the middle of a 20 mm long coplanar transmission line consisting of two parallel 10 μm wide, 1 μm thick, 5 Ω/mm, aluminium lines separated from each other by 30 μm. In the initial demonstration of this system a colliding-pulse mode-locked (CPM) dye laser, produced 623 nm, 70 fs pulses at a 100 MHz repetition rate in a beam with 10 mW average power. The 5 mW excitation beam was focused onto the 5 μm wide photoconductive silicon gap between the two antenna arms. The 70 fs laser creation of photocarriers causes subpicosecond changes in the conductivity of the antenna gap. When a dc bias voltage of typically 10 V is applied to the transmitting antenna, these changes in conductivity result in pulses of electrical current through the antenna and consequently bursts of electromagnetic radiation are produced. A large fraction of this radiation is emitted into the sapphire substrate in a cone normal to the interface with the radiation pattern presented in [17.95]. The radiation is then collected and collimated by a dielectric lens attached to the backside (sapphire side) of the SOS wafer [17.31]. The dielectric lenses were made of high-resistivity (10 kΩ cm) crystalline silicon with a measured absorption of less than 0.05 cm^{-1} in the presented frequency range [17.51]. The silicon lens is a truncated sphere with a 10 mm diameter and a focal point located at the antenna gap when attached to the back side of the chip. As shown in Fig. 17.19b, after collimation by the silicon lens, the beam diffracts and propagates to a paraboloidal mirror, where the THz radiation is recollimated into a highly directional beam, with beam diameters (10–70 mm) proportional to the wavelength. Thereafter, all of the frequencies propagated with the same 25 mrad divergence. After a typical 50 cm propagation distance this THz beam is detected by the THz receiver, where the paraboloidal mirror focuses the beam

onto a silicon lens, which focuses it onto a SOS antenna chip, similar to the one used in the emission process. The electric field of the focused incoming THz radiation induces a transient bias voltage across the 5 μm gap between the two arms of this receiving antenna, directly connected to a low-noise current amplifier. The amplitude and time-dependence of this transient voltage is obtained by measuring the collected charge (average current) versus the time delay between the THz pulses and the delayed CPM laser pulses in the 5 mW detection beam. These pulses synchronously gate the receiver, by driving the photoconductive switch defined by the 5 μm antenna gap.

Measurements of Signal–to–Noise Ratio

An early time-resolved measurement [17.31] is shown in Fig. 17.20a. The clean pulse shape is a result of the fast action of the photoconductive switch at the antenna gap, the broadband response of the ultrafast antennas, the broadband THz optical transfer function of the lenses and paraboloidal mirrors, and the very low absorption and dispersion of the silicon lenses. The measured pulse width of 0.54 ps (FWHM) is only an upper limit to the true pulse width, because no deconvolution has been applied to the measurement to take out the response time of the antenna gap. This time-response will be determined in the next section of this article. In Fig. 17.20b, the Fourier transform of the measured signal (Fig. 17.20a) is shown to stretch from about 0.1 to 2.0 THz. This only represents a lower limit to the true extent of the emitted radiation as it contains the frequency response of the receiver. At the low-frequency end, the efficiency of both the emitter and receiver has been shown to be proportional to the length of the antenna, i.e., proportional to the separation between the two lines of the coplanar transmission line. For extremely low frequencies the size of the paraboloidal mirrors will also limit the efficiency. For the high-frequency limit the efficiency of the antenna is strongly reduced when half the wavelength (in the dielectric) of the emitted radiation is no longer small compared to the antenna length. The high-frequency part of the spectrum is also limited by the finite rise time of the current transient and the non-ideal imaging properties of the THz optics.

In Fig. 17.20c the time-resolved signal is shown on a vertical scale expanded by a factor of 100. The structure observable after the main pulse is reproducible and is due to reflections of the electrical pulse on the transmission line, reflections of the THz pulse from the various dielectric interfaces, and absorption and dispersion of
Fig. 17.21 Measured THz pulse to 27.5 ps with a 100 000 times reduction (compared to Fig. 17.20a) of the THz beam power. (Adapted from [17.31])

residual water vapor. The signal-to-noise ratio in this 4 min scan is more than 10 000 : 1. Another 4 min scan is shown in Fig. 17.21, for which the intensity of the excitation laser beam was reduced to only 15 μW from the 5 mW normally used. The consequent 320-fold reduction in photocurrent indicates a reduction in the power of the THz beam by the factor 1/100 000. However, despite this enormous reduction in power, the peak amplitude is still more than 30 times larger than the rms noise. Based on previous calculations [17.31], the average power in the THz beam during this measurement was about 10^{-13} W. If the power of the THz beam were even further reduced, the detection limit of the THz receiver would be reached at 10^{-16} W, for a signal-to-noise-ratio of unity and a 125 ms integration time. Because the generation and detection of the THz (far-infrared) radiation is coherent, the THz receiver is approximately 1000 times more sensitive than an incoherent helium cooled bolometer [17.53].

The Semiconductor Time–Dependent Response Function

In the small antenna limit corresponding to the Hertzian dipole, the generated radiation field is proportional to the time-derivative of the current pulse, which is mainly determined by the intrinsic response of the semiconductor itself. The intrinsic time-domain response function will now be derived for a semiconductor described by the simple Drude formalism. The free carriers are considered as classical point charges subject to random collisions, for which the collision damping is independent of the carrier energy. The frequency-dependent

complex conductivity $\sigma(\omega)$ is given by

$$\sigma(\omega) = \sigma_{dc} \frac{i\Gamma}{\omega + i\Gamma} , \qquad (17.6)$$

where $\Gamma = 1/\tau$ is the damping rate and τ is the average collision time. The dc conductivity is given by $\sigma_{dc} = e\mu_{dc}N$, where e is the electron charge, μ_{dc} is the dc mobility and N is the carrier number density. According to Drude, $\mu_{dc} = e/(m^*\Gamma)$, where m^* is the effective mass. This relationship (17.6) is in good agreement with recent time-domain spectroscopy measurements [17.31] on lightly doped silicon from low frequencies to beyond 2 THz. The following procedure is similar to that of [17.96]. It is helpful to recast the formalism into a frequency-dependent mobility as

$$\mu(\omega) = \mu_{dc} \frac{i\Gamma}{\omega + i\Gamma} . \qquad (17.7)$$

This relationship shows the fundamental limit to the frequency response of the photoconductive switch. It is important to note that at high frequencies compared to Γ, the imaginary part dominates and falls off with frequency as $1/\omega$. Surprisingly, this allows useful material response to reach up to tens of THz. For example if $\tau = 200$ fs, $\Gamma/2\pi = 0.8$ THz and the response at 8 THz is 0.10 that at low frequencies, similarly, the response at 16 THz is 0.05 that at low frequencies. The dc current density is given by $J_{dc} = \sigma_{dc}E$, or equivalently $J_{dc} = eE\mu_{dc}N$, where E is a constant electric field. Because of the linearity of the current in N, for a time-dependent carrier density $N(t)$, the time-dependent current density can be written as

$$J(t) = eE \int_{-\infty}^{t} \mu(t - t') N(t') \, dt' , \qquad (17.8)$$

where $\mu(t - t')$ is the time-domain response function for the mobility. This function is determined by the inverse transform of the frequency-dependent mobility to be the causal function

$$\mu(t - t') = \mu_{dc} \Gamma e^{-\Gamma(t - t')} \qquad (17.9)$$

which vanishes for negative $(t - t')$.

In order to facilitate the understanding of the photoconductive switch it is useful to rewrite the basic equation (17.8) in the equivalent form,

$$J(t) = eEA \int_{-\infty}^{t} \mu(t - t') \int_{-\infty}^{t'} R_c(t' - t'') I(t'') \, dt'' \, dt' , \qquad (17.10)$$

where $I(t'')$ is the normalized intensity envelope function of the laser pulse, A is a constant giving the conversion to absorbed photons/volume and R_c is the response function describing the decay of the photogenerated carriers. By defining a new photocurrent response function $j_{pc}(t - t')$, we can rewrite (17.10) to become

$$J(t) = \int_{-\infty}^{t} j_{pc}(t - t') I(t') \, dt' , \qquad (17.11)$$

where $j_{pc}(t - t')$ is obtained by evaluating (17.10) with a delta function $\delta(t'')$ laser pulse. Assuming the causal function $R_c(t' - t'') = \exp[-(t' - t'')/\tau_c]$, describing a simple exponential decay of the carriers with the carrier lifetime τ_c (significantly longer than the average collision time τ) for positive $(t' - t'')$ and vanishing for negative $(t' - t'')$, and that $\mu(t - t')$ is given by the Drude response of (17.9), the causal response function $j_{pc}(t^*)$ is then evaluated to be

$$j_{pc}(t^*) = \frac{\mu_{dc} e E A \Gamma}{\Gamma - 1/\tau_c} \left(e^{-t^*/\tau_c} - e^{-t^*/\tau} \right) \qquad (17.12)$$

for positive $t^* = (t - t')$ and shown to vanish for negative t^*. In the short-pulse limit of the ultrafast excitation pulses, the time dependence of the photocurrent $J(t)$ is approximately equal to that of the photocurrent response function $j_{pc}(t^*)$ for positive t^*. For a long carrier lifetime, the time dependence of $j_{pc}(t^*)$ is described by a simple exponential rise with a rise time on the order of $\tau = 1/\Gamma$, which is equal to 270 fs and 150 fs for the electrons and holes, respectively, in lightly doped silicon as previously measured [17.97, 98]. As these results show,
Fig. 17.22 Calculated photoconductive response function to 3 ps with the scattering time $\tau = 270$ fs and infinite carrier lifetime τ_c (*upper curve*) and with $\tau_c = 600$ fs (*lower curve*)

the material response can be slow compared to the duration of the ultrafast laser excitation pulses, which can be as short as 10 fs, but is more typically on the order of 60 fs.

The time-dependent response function described by (17.12) is displayed in Fig. 17.22 for the two cases: $\tau = 270$ fs and $\tau_c = \infty$, and $\tau = 270$ fs and $\tau_c = 600$ fs. The result for infinite carrier lifetime has the following intuitive interpretation. After the instantaneous creation of carriers, the initial current and mobility are zero. The carriers then accelerate ballistically, as determined by the applied electric field, their charge and effective mass. This acceleration continues for a time approximately equal to the scattering time τ, after which the velocity and current equilibrate to their steady-state value. This discussion will now be shown to accurately describe the mathematical dependence of (17.12). With $\tau_c = \infty$, (17.12) is equal to

$$j_{pc}(t^*) = \mu_{dc} e E A \left(1 - e^{-t^*/\tau}\right) \tag{17.13}$$

which, for times that are short compared to τ, reduces to

$$j_{pc}(t^*) = \mu_{dc} e E A t^*/\tau . \tag{17.14}$$

Remembering that for Drude theory $\mu_{dc} = e/(m^* \Gamma)$, (17.14) is equivalent to

$$j_{pc}(t^*) = A e t^* (eE/m^*) \tag{17.15}$$

which describes the ballistic acceleration eE/m^*.

Measurements
of the Time–Dependent Response Function

Here the performance of a new type photoconductive receiver with a measured response exceeding 6 THz is described and analyzed by the above Drude [17.99]. This receiver used a prototype composite optoelectronic chip shown in Fig. 17.23. By using an identical receiver in a high-performance optoelectronic THz beam system as the transmitter, we were able to characterize the receiver with exceptional precision. The antenna structure, used for both the transmitter and receiver, is the same as shown in Fig. 17.19a, but with the reduced size of two parallel 5 μm wide lines separated from each
Fig. 17.23 Cross section of the composite chip
Fig. 17.24 (a) THz pulse measured by the ultrafast receiver. **(b)** Measured THz pulse on an expanded time scale (adapted from [17.99])

other by 10 μm. A colliding-pulse mode-locked (CPM) dye laser provided the 5 mW focused beams of 623 nm, 80 fs excitation and sampling pulses. Excellent agreement with the Drude theory model was obtained for the photoconductive response.

Using this receiver, a source spectrum was measured with a FWHM bandwidth almost twice as broad as the initial experimental characterization of a similar system using SOS chips [17.96]. The improved performance was due to the following changes. Firstly, the positions of the paraboloidal mirrors were set to have a unity transfer function for the THz radiation [17.100]. Secondly, exceptional care was taken to match the foci of the silicon lenses to the antenna positions. For on-axis focusing, a series of observations were made using lenses of the same curvature, but with thicknesses varying in steps of 50 μm. In the plane of the chip, the position of the focus was adjusted to ±20 μm. Thirdly, the new composite chip was used to eliminate the absorption of the incoming THz radiation by the sapphire substrate of the

previously used SOS detection chip. The 0.5 μm thick active layer of LPCVD polysilicon of the composite chip was annealed at 1000 °C for 1 h in a nitrogen atmosphere and was later implanted with 200 keV and 100 keV oxygen ions both at a dose of $10^{13}/cm^2$. The underlying 0.7 μm thick thermal oxide layer was grown on a high resistivity silicon substrate.

The THz pulse measured with the ultrafast receiver is shown in Fig. 17.24a. The fall-time (90–10%) from the peak of the pulse to the minimum is only 127 fs, as shown in the expanded view of Fig. 17.24b. This exceptional time resolution demonstrates that a photoconductive receiver can be much faster than is generally realized [17.99], but is consistent with the earlier prediction (for SOS chips) of a 150 fs time resolution [17.96]. The numerical Fourier transform of this pulse peaks at approximately 0.5 THz and extends to 6 THz, as shown

in Fig. 17.25a. Because the measured spectrum is the product of the identical transmitter and receiver amplitude spectra, the receiver amplitude spectrum shown in Fig. 17.25b is simply the square root of the measured spectrum of Fig. 17.25a.

The theoretical understanding of the above results will now be presented. Because of the extremely fast electrical response, the current in the ultrafast antenna follows the current $J(t)$ in the semiconductor, where $J(t)$ is determined by the convolution of the photoconductive response function and the 80 fs (FWHM) $sech^2$-shaped laser driving pulse. Following the proceeding theoretical procedure, the response function is derived from simple Drude theory with a scattering time of 120 fs and a carrier lifetime of 600 fs.

The time-domain response function $j_{pc}(t^*)$ is assumed to be given by (17.12). This response function is then convolved with the laser pulse, as prescribed by (17.11). Using the above parameters the calculated shape

of the current pulse in the photoconductive switch and the Hertzian dipole antenna is presented in Fig. 17.26a. The time derivative of this pulse is given in Fig. 17.26b, where an extremely fast transient, corresponding to the rising edge of the current pulse, is seen. Quantitative evaluation of this time-derivative shows that the Hertzian dipole antenna generates a 150 fs FWHM pulse of THz radiation. Conversely, by the reciprocity principle, 150 fs is also the time resolution of the photoconductive receiver. The numerical Fourier transform of Fig. 17.26b is the predicted amplitude spectrum of the transmitter. In Fig. 17.25b, this spectrum is compared with the measured amplitude spectrum of the receiver. The excellent agreement with experiment shows that, to a very good approximation, the semiconductor response follows Drude theory and that the resulting response time is limited by the ballistic acceleration of the photocarriers. As expected, the calculated amplitude spectrum falls off faster than the intrinsic material response of $\mu(\omega)$ defined by (17.7), due to the 80 fs optical pulsewidth compared to the delta function response.

It has also been shown that the 10 μm long antenna imbedded in the coplanar transmission line has electrical properties much faster than the semiconductor itself. Consequently, the performance is completely determined (and limited) by the intrinsic response time of the semiconductor.

17.2.2 Other THz Transmitters

Because essentially all of the existing and proposed THz applications are constrained by the limiting S/N ratio, any improvement in S/N would provide faster data acquisition rates and would improve the quality of the experimental comparisons. Large increases in S/N would make new applications possible. The most important approach to increase S/N is to increase the transmitter power, while at the same time maintaining or extending the THz bandwidth. This has become particularly appropriate because typical, ultrafast Ti-sapphire mode-locked lasers can produce 500 mW of beam power, compared to the previously used CPM lasers, which produced only on the order of 20 mW of beam power. For example, the GaAs TEF transmitter chip [17.44, 94, 100] (described below) is limited by optical damage to GaAs to a maximum average laser power of only 20 mW in the ultrafast Ti-sapphire driving laser pulse stream. A THz research group at the University of Bath (UK) has attained a 100-fold increase in transmitter power levels from the GaAs TEF chip by focusing a more powerful laser beam (well above the usual operating lim-

its) with a cylindrical lens to produce a highly elliptical focus to minimize saturation and material damage.

A Bell Labs group [17.101], using a field-singularity emitter and a 50 μm dipole receiver antenna fabricated on low-temperature (LT) GaAs, has observed signal strengths of more than 100 times larger than typical results using GaAs or SOS transmitters, and SOS receivers. Although their THz conversion efficiency was essentially the same as for the GaAs TEF transmitter, the increase in THz power and S/N for the Bell Labs work were obtained by driving the LT-GaAs transmitter and the LT-GaAs receiver with optical powers almost an order of magnitude above the allowable operating power levels of the above-described GaAs and SOS transmitter and receiver chips. As shown by this example and earlier work, LT-GaAs has significant potential to extend both the output power and frequency response of photoconductive switches, transmitters and receivers, due to its high resistivity, high carrier mobility and short carrier lifetime [17.41–43, 102–107]. LT-GaAs is much more resistant to optical breakdown than GaAs and is also more resistant to electrical breakdown. In addition, the carrier lifetime can be controlled by annealing temperature and can be made to be lower than 300 fs [17.106, 107]. Currently, the main problem preventing widespread utilization of LT-GaAs is that the commercial LT-GaAs wafer cost is about five times that of either GaAs or SOS.

GaAs Trap Enhanced Field (TEF) THz Source
A different type of high-performance optoelectronic source chip [17.44] is shown in Fig. 17.27d. The simple coplanar transmission line structure consists of two 10 μm wide metal lines separated by 80 μm fabricated on semi-insulating GaAs. Irradiating the metal-semiconductor interface (edge) of the positively biased line with focused ultrafast laser pulses produces synchronous bursts of THz radiation. This occurs because each laser pulse creates a spot of photocarriers in a region of extremely high electric field, called the trap-enhanced field [17.94]. In the initial demonstration of this source, a CPM dye laser provided 60 fs excitation pulses with an average power of 5 mW at 5 μm diameter excitation spot. This GaAs trap-enhanced field (TEF) source chip is completely compatible with the previously described optoelectronic THz beam system. However, this chip is limited only to the transmitter, because of its long carrier lifetime.

The measured THz pulse emitted from the laser excited GaAs TEF source chip with +60 V bias across the transmission line is shown in Fig. 17.27a, and on an ex-

panded time scale in Fig. 17.27b. The measured pulse width with no deconvolution is seen to be 380 fs. At the time these results were obtained [17.44], they were the shortest directly measured THz pulses; the dip on the falling edge was the sharpest feature ever observed with an ion-implanted detector and indicated a response time faster than 190 fs. The amplitude spectrum (numerical Fourier transform) of the pulse extends beyond 3 THz, as presented in Fig. 17.27c. The sharp line structure is due to residual water vapor present in the system.

The GaAs TEF source remains one of the most efficient THz sources today and is the main THz transmitter chip used by the Oklahoma State University Ultrafast THz Research Group. In Fig. 17.28a we show a recent THz pulse measurement using the same type of GaAs

To achieve a lower noise level, the silicon layer was stripped off the SOS chip, except for the active photoconductive switch. The RMS noise level on the leading edge of the pulse is 0.1 pA, thereby giving an amplitude signal to noise ratio of more than 10 000. A Ti: sapphire mode-locked laser producing 60 fs, 780 nm pulses at a 100 MHz repetition rate provided the 10 mW excitation and 10 mW detection beams. As shown in Fig. 17.28b, the amplitude spectrum of this pulse extends from 0.2 to beyond 4.5 THz, allowing THz-TDS measurements in this frequency range.

Large Aperture Planar Photoconductor

In contrast to the Hertzian dipoles and micron-sized transmitter antennas described above, a THz transmitter approach based on large planar photoconductive apertures on the semiconductor surface has been demonstrated [17.108], as illustrated in Fig. 17.29. Here the biasing electrodes are separated by many millimeters and the bias voltages can be many kilovolts. The spot illuminated by the ultrafast exciting laser pulses is many millimeters in diameter, equivalent to many wavelengths of the radiated THz signal. For the experiment described by Fig. 17.29 the optical driving beam had a 4 mm diameter, and the photoconductive material was ion-implanted SOS. The CPM dye laser provided 75 fs pulses at 625 nm at a repetition rate of 100 MHz with approximately 10 mW of average optical power in the pump beam and 5 mW in the probe beam. The resulting radiated THz pulse was detected with a 100 μm photoconductive dipole antenna on SOS at the focus of a 3 mm sapphire ball lens.

The detected THz pulse is shown in Fig. 17.29b, and the corresponding amplitude spectrum is shown in Fig. 17.29c. The detector was placed 7 mm from the transmitter and was aligned in the specular direction for maximum signal. When the distance between the THz transmitter and detector was increased, the signal decreased as the inverse of the separation, and the pulse shape changed from the unipolar shape of Fig. 17.29b to a bipolar shape. The important possibility demonstrated by this experiment is the ability to scale up the optical power to very high levels, and thereby obtain very high power beams of THz pulses.

This possibility was realized in the later experimental demonstration of the scaling of these THz pulses to high energy (0.8 μJ), while maintaining both high band-

TEF transmitter chip shown in Fig. 17.27d together with a low-noise, ion-implanted SOS receiver chip with the same antenna pattern as Fig. 17.19a, but with two parallel 5 μm wide lines separated from each other by 10 μm.

width and short pulse duration (450 fs) [17.109]. This work achieved focused peak THz fields greater than 150 kV/cm. Such high-power THz pulses can be used for nonlinear quasioptics, multiphoton spectroscopy and ionization. An important feature of these THz pulses is the large asymmetry of at least 5 : 1 in the magnitude of the positive and negative components. Thus, to a reasonable theoretical approximation, these pulses can be considered to be half-cycle pulses, a situation very important to their utilization to ionize Rydberg atoms [17.110].

The GaAs wafers used to generate the high-power THz pulses were illuminated at normal incidence by 120 fs, 770 nm pulses from a Ti:sapphire chirped-pulse amplifier system, while a pulsed electric field was

applied across the surface [17.109]. The aluminium electrodes, separated from each other by 1 cm, were connected to the GaAs surface with silver paint. Although THz radiation was observed in both the transmitted and reflected directions, only the transmitted radiation was used. The THz pulse energy was measured both with a helium cooled bolometer and a room-temperature pyroelectric detector.

The power spectrum of the generated THz pulses was obtained by Fourier transform spectroscopy using the interferometer shown in Fig. 17.30a. Typical interferograms measured with the bolometer were 600 fs wide, as shown in Fig. 17.30b, independent of the driving laser intensity, laser polarization, and bias field. The Fourier transform of the interferogram yields the spectral width of 1 THz as shown in the inset of Fig. 17.30b.

High–Surface Field Photoconductors

Another photoconductive THz source that has found significant use and interest requires no external bias voltage and no lithography, because it uses the static internal field at the semiconductor surface, which is perpendicular to the surface [17.36]. Consequently, when such a bare semiconductor wafer is illuminated by femtosecond optical pulses, THz pulses are emitted from the surface in the form of freely propagating electromagnetic beams in the inward and outward directions. The amplitude and phase of the radiated THz pulse depend on the carrier mobility, and the strength, direction and polarity of the internal field.

Figure 17.31a shows the semiconductor illuminated by an unfocused optical beam together with the reflected optical beam and the consequent outward THz radiation and transmitted THz radiation. The CPM dye laser produced 2 nJ, 70 fs, 720 nm output pulses at a 100 MHz repetition rate. The CPM optical beam was split into two beams (30 and 70%), where the stronger excitation beam was modulated by a mechanical chopper at 2 kHz. The weaker sampling beam passed through a variable time delay and was used to gate a dipole antenna fitted with a sapphire lens for detection of the radiated THz pulse. Figure 17.31b shows a THz pulse from semi-insulating InP, detected by the dipole antenna in the outward direction (45° relative to the normal) with a 4 mm diameter laser excitation beam. The measured time response is limited by the dipole detector, which has an optimum frequency of 0.6 THz. The transmitted THz pulse through a 0.4 mm thick semi-insulating InP wafer was measured as a function of the angle of incidence of the excitation beam, by rotation of the wafer. These results are shown in Fig. 17.31c and indicate that the direction of

current flow is along the direction of the surface field perpendicular to the wafer surface. Using this surface field technique, THz radiation pulses were generated from InP, GaAs, GaSb, InSb, CdTe, CdSe, and Ge, but not from Si [17.36]. Semi-insulating InP showed the strongest THz radiation; the radiation strength of ⟨100⟩ InP is 2.5 times larger than ⟨111⟩ InP.

It was demonstrated some time ago that the application of an external magnetic field could enhance the THz pulse generation from the surface field [17.111, 112]. Renewed interest in this effect was stimulated by claims that very large enhancements in the average-power of the THz pulse generation result with the application of a large magnetic field [17.113]. Although later investigations showed that these claims were overstated by approximately 100 times, many investigations were performed to characterize all the attributes of the enhancement effect [17.114–116].

Recently, a relatively simple explanation of the B field enhancement has been provided by two groups [17.117, 118]. Firstly, the application of the B field does not increase the transient dipole responsible for the THz radiation. Secondly, the transient dipole and the consequent radiation pattern are reoriented by the B field, with respect to the surface boundaries of the semiconductor crystal. This reorientation of the radiation pattern can dramatically increase the output coupling from the crystal to free space. The coupling problem is quite important because of the high index of refraction of the crystal, which can lead to trapping of the THz radiation in the crystal.

Tunable cw THz Generation by PhotoMixing

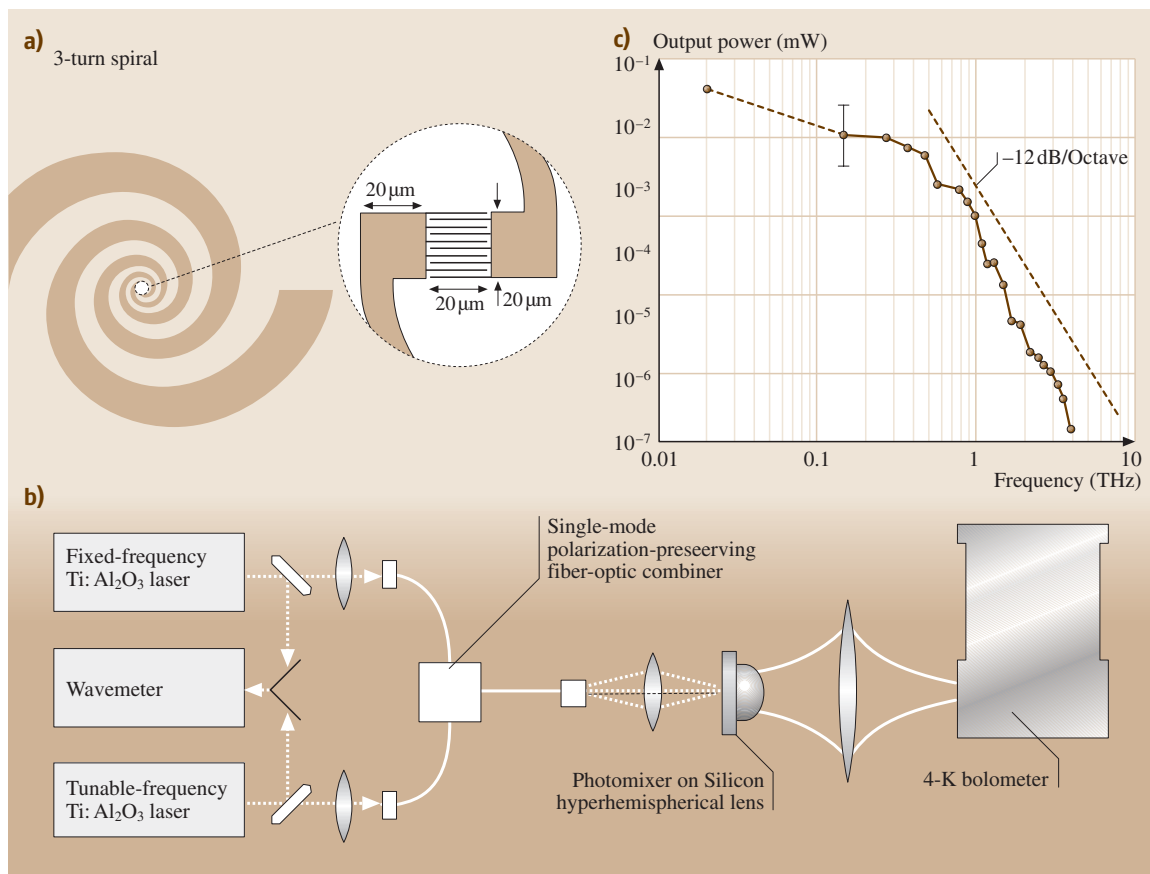
A cw photomixer capable of producing tunable radiation can be realized by beating together two laser beams with frequencies above the band gap of a semiconductor [17.39, 40]. Depending upon the generated photocarrier lifetimes and the techniques used to couple out the generated radiation, this method can produce tunable THz radiation at the difference frequency between the two lasers [17.41–43]. The experimental demonstration of cw coherent output over the frequency range from 0.2 to 3.8 THz utilized a low-temperature-grown GaAs (LTG-GaAs, more commonly designated as LT-GaAs) photomixer [17.41–43]. The advantages of LT-GaAs are its short photocarrier lifetime, determined to be 0.27 ps, and the high electrical breakdown field. As shown in the inset of Fig. 17.32a, the LT-GaAs wafer was fabricated with a pattern of interdigitated electrodes covering an area of $20 \times 20\,\mu m$ and connected to opposite $20 \times 20\,\mu m$ bonding pads. After electron-beam lithography, the pads


Fig. 17.32 (a) Three-turn self-complimentary spiral antenna. The *inset* shows an expanded view of the interdigitated-electrode photomixer structure. **(b)** Experimental setup for the LT-GaAs photomixer. **(c)** Measured output power from the photomixer. (Adapted from [17.43])

were connected to a three-turn self-complimentary spiral antenna shown in Fig. 17.32a, for which the low frequencies radiate from the outer extent of the spiral and the high frequencies from the inner extent. For the inner radius (40 μm) and outer radius (1.8 mm) of the actual antenna, the operating range was estimated to be approximately 60 GHz to 1.0 THz. The photomixer was characterized by the setup shown in Fig. 17.32b, for which the tunable optical pump power was provided by two Ti:Al$_2$O$_3$ lasers operating near 780 nm and with 25 mW in each laser beam. The photocurrent generates THz radiation at the tunable difference frequency between the two lasers from the antenna with a bias voltage of 25 V. The emitted radiation propagates predominantly into the GaAs substrate and then into a high-resistivity silicon lens in contact with the backside of the substrate. The THz output beam from the lens is subsequently fo-

cused by a plastic lens onto a liquid-helium-cooled Si bolometer. The measured THz output power is shown in Fig. 17.32c.

Electrooptic THz Generation

The generation of pulses of THz (far-infrared radiation) by the passage of a short optical pulse through a nonlinear optical material was demonstrated many years ago [17.33]. For this pioneering experiment 2 ps optical pulses from a mode-locked Nd:glass laser were focused onto and transmitted through millimeter-thick LiNbO$_3$ crystals. The resulting THz radiation was split into two beams. One beam was used for spectral analysis by either a Michelson or a Fabry–Perot interferometer; the other beam was used for normalization. Both beams were separately detected by two n-type InSb (Putley) detectors at 1.5 K in a magnetic field of 5.4 kG. The resultant
Fig. 17.33 Far-infrared (THz) power spectrum generated by mode-locked pulses in LiNbO$_3$. (Adapted from [17.33])

signals were displayed on an oscilloscope. An example of these early results is shown by the measured far-infrared power spectrum in Fig. 17.33. The experimental points were obtained from the Michelson interferogram and the solid curve is from a theoretical calculation assuming Gaussian laser pulses with a 1.8 ps pulse width. The spectrum can be understood as a product of (1) the spectral content of the mode-locked pulses, (2) a radiation efficiency curve, and (3) a phase-matching curve centered at zero frequency.

The propagation of fs optical pulses in electrooptic materials is also accompanied by the radiation of an extremely fast electromagnetic transient [17.34, 119, 120]. This phenomenon, arising from the inverse electrooptic effect, produces a Cherenkov cone of pulsed radiation having a duration of approximately one cycle and a frequency in the THz range. Although closely resembling classical Cherenkov radiation from relativistic charged particles in dielectric media, it is due to a nonlinear op-

Fig. 17.34 (a) Schematic of the experiment used to generate and detect short bursts of Cherenkov THz radiation from fs optical pulses in lithium tantalate. The Cherenkov radiation cone propagates away from the "pump" pulse in a direction θ_c determined by the ratio of the low-frequency phase velocity ($c/6.53$) to the optical group velocity ($c/2.33$). **(b)** Measured electric field (*solid line*) of the THz transient compared with theory (*dashed line*). **(c)** Amplitude spectra of the experimental (*solid line*) and theoretical (*dashed line*) waveforms of **(b)**. (Adapted from [17.119])
tical effect. The charge state of the effective source is neutral, being an extended dipole moment, rather than a point charge; the velocity of the source significantly exceeds the radiation velocity. This situation, indicated in Fig. 17.34a, produces the characteristic Cherenkov conical shock wave. Because the spatial extent of the radiation source is proportional to the intensity envelope of the optical pulse, the radiation field depends on both the time duration and the beam waist of the optical pulse.

As indicated in Fig. 17.34a, two optical pulses were used, one to generate the radiation field, and the other to

a) Absorbance (cm⁻¹)

b) Index of refraction
Fig. 17.35 (a) Absorbance of lithium tantalate. **(b)** Index of refraction. The *dots* are the measurements and the *solid lines* are the results of fitting the experimental points to a classical single-oscillator model. (Adapted from [17.121])

detect it. The 100 fs, 625 nm optical pulses were obtained from a CPM mode-locked dye laser, with a relatively low pulse energy of 0.1 nJ at a repetition rate of 150 MHz. The configuration of Fig. 17.34a uses electrooptic sampling [17.2, 3, 7–12] to measure the small birefringence produced by the electric field of the radiation pulse. A unique feature of the experiment is the automatic synchronism of the velocities of the radiation field and the probing pulse. As indicated in Fig. 17.34a, the probing pulse "surfs" along the Cherenkov wavefront enabling it to measure the electric field at a stationary point in the waveform by integrating the birefringence along the entire path through the crystal. To obtain the measured waveform, the timing of the probing pulse was slowly swept relative to the generating pulse by a computer controlled variable path length. The measured Cherenkov waveform shown in Fig. 17.34b is extremely fast and approximates a single cycle of frequency of 1.5 THz. The corresponding amplitude spectrum of this waveform is shown in Fig. 17.34c.

The coherent nature of the detection process enables the measurement of the far-infrared properties of materials by observing the change in the waveform due to their dispersion and absorption. Since the time reference is accurately known, phase information is measured as well, and consequently both the real and the imaginary parts of the dielectric function can be obtained [17.121, 122]. Such measurements of the absorption and index of refraction of lithium tantalate are presented below in Fig. 17.35 [17.121].

When a semiconductor is illuminated by an ultrafast laser pulse the sample can emit a THz radiation pulse, as shown in Fig. 17.31. This radiation can be due to the acceleration of the photocarriers in the surface field and for some semiconductors can be also due to optical rectification. It is possible to distinguish between the two processes by directing the incoming light beam at normal incidence to the semiconductor surface. For this case, the radiation from the photocarriers is not coupled out of the semiconductor, and the observed THz pulse radiated in the forward direction is due only to the optical rectification effect. This situation is demonstrated by the results shown in Fig. 17.36 [17.123]. For these results, the mode-locked Ti:sapphire laser illuminating the ⟨111⟩ GaAs sample had output pulse energies greater than 10 nJ, pulse durations of less than 200 fs and a repetition rate of 76 MHz. The laser beam was split into two parts by a beam splitter with a 0.05/0.95 reflection/transmission ratio. The stronger optical beam passed through a variable time delay stage and illuminated the semiconductor sam-

ple with a spot diameter of approximately 6 mm. The weaker optical beam, typically $< 20 \, \text{mW}$ was used for optical gating a photoconducting $50 \, \mu\text{m}$ dipole antenna for detection of the emitted THz pulse.

The optical rectification signal was observed to change dramatically when the laser energy was tuned near the GaAs band gap. A more than 100-fold increase

in the signal was measured when the laser energy was tuned from 1.40 to 1.46 eV. The peak signal is reached when the laser energy is just above the band gap. As proof of the nonlinear nature of the effect, the THz signal was measured as a function crystal orientation with respect to the polarization of the laser beam and the expected threefold rotation symmetry was observed as shown in Fig. 17.36c. This work demonstrates the importance of optical rectification as a source of very short THz pulses, whose pulse widths are fundamentally limited only by the driving laser pulse width [17.123].

In another demonstration of optical rectification of ultrafast laser pulses by GaAs, coherent far-infrared THz pulses were generated with a measured spectrum extending from 7 to 15 μm [17.124]. A Ti:sapphire laser, delivering 10–15 fs pulses at a 100 MHz repetition rate, was focused at normal incidence to a spot size of typically 20 μm diameter using a spherical mirror onto a 0.1 mm thick $\langle 1, 1, 0 \rangle$ GaAs plate. The resultant THz emission in the forward direction (transmitted through the sample) was directed onto a nitrogen-cooled HgCdTe detector sensitive to wavelengths up to 15 μm. A maximum THz power of 30 nW was measured for an incident laser power of 175 mW. The far-infrared THz spectra were obtained using a modified Michelson interferometer setup, synchronous detection, and numerical Fourier transforms. Figure 17.37a presents the THz power spectrum obtained for the generated THz pulse. The observed strong cutoff at 15 μm originates from the drop off of the spectral sensitivity. Figure 17.37b shows the electric field amplitude constructed from the spectrum of Fig. 17.37a, assuming a constant spectral phase. This work demonstrated that single-cycle THz generation can be extended to the near-infrared [17.124].

Using optical rectification and electrooptic sampling in $\langle 110 \rangle$ ZnTe for both the generation and coherent detection of freely propagating pulses of THz radiation, a wideband coherent THz-TDS system has been demonstrated [17.125], as shown in Fig. 17.38a. A mode-locked Ti-sapphire laser producing 130 fs pulses at 800 nm with a 76 MHz repetition rate was used to generate and detect the THz pulses. The 2 mm diameter pump beam, with an average power of 350 mW, was chopped and drove a 0.9 mm thick $\langle 110 \rangle$ ZnTe crystal at normal incidence. The pump beam was polarized at an angle of 60° to the $\langle 110 \rangle$ crystallographic direction in order to maximize the nonlinear response. The generated THz pulse was incident on an identical ZnTe crystal, after passage through a blocking Teflon filter. The incoming THz field was polarized parallel to the $\langle 001 \rangle$

ally biased at the quarter wave point by a Soleil–Babinet compensator and a crossed polarizer arrangement was used to improve the sensitivity.

The measured 270 fs (FWHM) THz electric field pulse is shown in Fig. 17.38b. The small oscillations

after the main peak were due, in part, to the free in-duction decay of the ambient water vapor excited by passage of the THz beam. In this geometry, both beams underwent multiple internal reflections within the sampling crystal, which were excluded from the data. The amplitude spectrum of the temporal waveform shown in Fig. 17.38c, demonstrates the wideband capability of the system. For this experiment the coherence length decreased rapidly beyond 2 THz due to the THz crystal dispersion.

Another all-optical THz generation and detection system with a bandwidth of 7 THz has been reported [17.126], as shown in Fig. 17.39a. The ultra-broadband THz radiation was generated via optical rectification from ⟨110⟩ oriented GaAs, and coher-ently detected via free-space electrooptic sampling using a 150 μm thick, ⟨110⟩ GaP crystal. The Ti:sapphire laser source had an output power of up to 2 W and a min-imum pulse width of 45 fs. An uncoated 2 μm thick pellicle beam splitter, transparent to the THz beam was used to reflect about 50% of the optical probe beam collinearly along the THz beam into the GaP sensor. An optical chopper modulated the pump laser beam at 1.5 kHz for phase sensitive detection by a lock-in ampli-fier. Excess common-mode laser noise was effectively canceled by using a pair of identical photodetectors in a balanced detection scheme, so that the detection is pri-marily shot-noise limited. The laser pump beam with an average power of 1.5 W and 50 fs pulses was focused at normal incidence with a 25 cm focal length lens onto a ⟨110⟩ oriented GaAs crystal directly attached to the flat surface of a 12 mm diameter silicon collimating lens. The peak intensity at the emitter was about $1 \, GW/cm^2$, limited by optical damage to the emitter surface.

Figure 17.39b displays the measured THz pulse. After an average of four consecutive scans, the peak-to-peak noise floor $\Delta I / I$ was below 10^{-8} as shown in the inset. The measured 185 fs THz pulse width (FWHM) was the shortest directly measured pulse du-ration at that time. The corresponding Fourier transform in Fig. 17.39c shows a 3 dB bandwidth of 3.6 THz with the upper frequency response reaching 7 THz.

17.2.3 Other THz Receivers

The bandwidth of the photoconductive THz receiver is limited most fundamentally by the ballistic accelera-tion of the generated carriers. In addition, the antenna response can be another limitation. An attractive alterna-tive is based on electrooptic detection, where the receiver response is determined by the very fast electronic nonlin-

poled polymer film in their electrooptic sampling element and achieved an approximate 1 ps time resolution with a signal-to-noise ratio of 10. The RPI group [17.127] used a 500 μm thick LiNbO$_3$ crystal as their nonlinear element also achieving an approximate 1 ps rise time with a S/N = 10. These initial observations have been markedly improved upon by the same groups, as illustrated by their complete electrooptic THz systems shown in Figs. 17.38 and 17.39. Electrooptic (EO) detection of pulses of THz radiation [17.126, 129] has now demonstrated impressive bandwidths out to 70 THz [17.130]. However, as shown by the recent THz-TDS characterization of the important EO crystal ZnTe [17.131] and another THz-TDS characterization of other EO crystals [17.132], the EO technique is constrained by the THz absorption of the EO crystal, group-velocity matching between the measured THz pulse and the optical probing pulse, and the frequency-dependent nonlinearity [17.130, 131, 133]. This situation requires very thin EO crystals to obtain high-frequency response, concomitant with a reduction in S/N.

An example of these considerations is shown in Fig. 17.40, which describes the THz receiver of the system indicated in Fig. 17.39. Figure 17.40a shows the calculated frequency-dependent efficiency of the electrooptic THz measurement as a function of the GaP crystal thickness. The experimentally measured THz pulses using crystals of different thicknesses are shown in Fig. 17.40b and the corresponding amplitude spectra are shown in Fig. 17.40c.

A very high bandwidth, completely electrooptic system is shown in Fig. 17.41. Here, the measured frequency response extends to 37 THz. For these results the 12 fs Ti:sapphire laser delivered an average power of nearly 500 mW at 800 nm. A 0.45 mm thick ⟨110⟩ oriented GaAs wafer was used as the emitter and a 30 μm thick ⟨110⟩ oriented ZnTe crystal as the electrooptic receiver. A laser power of 350 mW was focused on the GaAs emitter by a gold-coated off-axis parabolic mirror with a 5 cm effective focal length. The resultant THz pulse generated by optical rectification in GaAs was collimated and then focused by the off-axis paraboloidal mirrors. The measured THz pulse is shown in Fig. 17.41b, where the shortest period of oscillation is 31 fs. Figure 17.41c shows the measurement

earity. Consequently, the THz receiver bandwidth could in principle be extended to tens of THz.

Electrooptic Detection

The first two demonstrations of electrooptic detection of freely propagating THz radiation were submitted for publication within a few days of each other [17.127, 128]. The Columbia group [17.128] used a 10 μm thick

on a longer time scan, and Fig. 17.41d shows the corresponding amplitude spectrum. The highest frequency response reaches to 37 THz. The strong absorption between 5 and 10 THz was caused by the Restrahlen bands of ZnTe and GaAs. The dip around 17 THz was explained in terms of velocity mismatching.

Interferometric Techniques Using Power Detection

An alternative method of source characterization is shown in Fig. 17.30a, which bypasses the problems of receiver bandwidth, and is based on far-infrared interferometric techniques using a power detector. This approach was first demonstrated for THz radiation sources [17.134] by measuring autocorrelation signals with a full-width-at-half-maximum (FWHM) of 230 fs for the THz radiation pulse from laser created carriers accelerated by the surface field of a photoconductive semiconductor. This approach used a single THz radiation source, illuminated by a 10 Hz repetition rate, amplified, 100 fs pulses from a CPM dye laser, together with a Martin–Puplett interferometer and a liquid-helium cooled bolometer. A different interferometric approach, using unamplified, 100 MHz repetition rate, CPM dye laser pulse excitation of a two-source interferometer has since been demonstrated [17.100]. Via this approach, together with fast, scanning-delay-line averaging, orders of magnitude improvements in the signal-to-noise ratio of the measured interferograms were obtained. Using this method, the THz radiation source described in Fig. 17.27d was shown to produce radiation to 6 THz. In addition, a 230 fs FWHM autocorrelation signal and an average power of 30 nW for 4 mW of laser excitation power were measured for this source [17.100]. Other work has used interferometric techniques together with incoherent bolometric detection to study THz emission from cold plasma oscillations [17.135].

17.2.4 THz–TDS with Freely Propagating THz Pulses

The combination of the THz-TDS technique with THz beams has some powerful advantages compared to traditional cw spectroscopy. Firstly, the coherent detection

of the far-infrared radiation is extremely sensitive. Although the energy per THz pulse is very low (0.1 fJ), the 100 MHz repetition rate and the coherent detection measures the electric field of the propagated pulse with a S/N ratio of about 10 000 for an integration time of 125 ms [17.31]. In terms of average power this sensitivity exceeds that of liquid-helium-cooled bolometers, by more than 1000 times [17.53]. Secondly, because of the gated and coherent detection, the thermal background, which plagues traditional measurements in this frequency range, is observationally absent. Comparing time-domain spectroscopy with Fourier-transform spectroscopy (FTS), it should be clear that the frequency resolution of the two techniques are similar, as they are both based on a scanning delay line, where to first order the frequency resolution is determined by the reciprocal

of the time scan. However, the fact that THz-TDS scans a delay line with a well collimated optical beam does present some experimental advantages. Although for now FTS is superior, being above 4 THz (133 cm^{-1}), the limited power of the radiation sources and the problems

with the thermal background favor THz-TDS below 4 THz.

We will now describe several different measurement types that illustrate the generality and usefulness of THz-TDS.

THz–TDS Characterization of Water Vapor

The first THz-TDS measurements with the now standard THz optoelectronic system shown in Fig. 17.19 was the characterization of water vapor from 0.25 THz to 1.5 THz, for which the cross-sections of the nine strongest lines were measured with the best accuracy to date [17.50]. For these early measurements 30 μm long source and detector antennas on ion-implanted SOS substrates were used together with MgO [17.68] lenses instead of the currently used, more optimal high-resistivity silicon [17.51]. Figure 17.42a displays the detected THz radiation pulses after propagating through pure nitrogen. This measurement was made in a single 10 min scan of the 200 ps relative time delay between the excitation and detection pulses. When 1.5 Torr of water vapor, corresponding to 8% humidity at 20.5 °C, was added to the enclosure, the transmitted pulse changed to that shown in Fig. 17.42b. The additional fast oscillations are caused by the combined action of the dispersion and absorption of the water vapor lines. The slower and more erratic variations seen in Figs. 17.42a,b result from reflections of the main pulse. They are reproducible and divide out in the data analysis. The inset shows the data on a 20× expanded vertical scale. Here, the oscillations are seen to decay approximately exponentially with an average coherent relaxation time T_2.

The amplitude spectra of Figs. 17.42a,b are compared in Fig. 17.43a, where the strong water absorption lines are clearly observable. The additional structure on

both spectra is not noise but results from spurious reflections of the main pulse. At each line the measured frequency with an estimated error of ± 0.001 THz and, in parentheses, the literature value are indicated. The corresponding absorption coefficients are displayed in Fig. 17.43b as the negative of the natural logarithm of the ratio of the two amplitude spectra in Fig. 17.43a. Because the electric field is directly measured, the relative phase shift between the two spectra is also obtained as plotted in Fig. 17.43c, without the need for the Kramers–Kronig relations. As expected for a Lorentzian line, the magnitude of the jump in phase, experienced at each resonance, equals the peak absorption.

THz–TDS Characterization of Flames (Hot Water Vapor)

The first comprehensive THz (far infrared) absorption measurement of flames, covering the region from 0.2 to 2.65 THz ($7-88 \, \text{cm}^{-1}$) has been accomplished by THz-TDS [17.54]. Such measurements have not been possible with the alternative method of Fourier-transform spectroscopy, because the incoherent bolometric (liquid-helium cooled) detection is overwhelmed by the copious amounts of far-infrared radiation emitted by flames. In contrast, the THz-TDS system is blind this incoherent thermal radiation. For flames, many of the expected constituents, H_2O, CO, OH, NO, and NO_2, have permanent electric-dipole moments and can thereby be simultaneously probed by THz-TDS with approximately 2 GHz spectral resolution. In this THz-TDS observation of a premixed propane–air flame, a large number of absorption lines were initially identified as those of water, CH, and NH_3 [17.54]. The flame temperature of 1300 K was determined by comparing the relative strengths of the water-vapor lines. It was later shown that, except for the one remaining line at 2.865 THz, all of the observed THz spectral, absorption lines in the propane–air flame are from water vapor, and that previously unidentified lines in the flame are due to pure rotational transitions in the ν_2 (010) vibrational state of hot water vapor [17.55].

Later, via THz-TDS and a propane–air flame, measurements of the collisionally broadened pure rotational linewidths of water vapor at high temperatures were performed [17.56]. More than 40 rotational lines were observed in the ground and $\nu_2 = 1$ vibrational levels over the spectral bandwidth from 1 to 2.5 THz ($33-83 \, \text{cm}^{-1}$). The measured linewidths agree in magnitude with calculated values at the measured temperature of 1490 K; however, contrary to predictions, a pronounced energy

The *inset* shows the THz pulse in more detail. **(b)** Close-up of the region before the arrival of the THz pulse both with and without the flame. **(c)** Amplitude spectrum of the transmitted THz pulse. (Adapted from [17.55])

The experimental configuration used in this investigation is shown in Fig. 17.44. The path length through the flame was 20.7 cm, and the premixed flame was supported on a 24.8 cm × 17.8 cm sintered bronze water-cooled burner. The burner assembly was enclosed to prevent contamination from room air. The THz transmitter and receiver were enclosed in separate chambers isolated from the burner. The THz beam was coupled into the burner enclosure through 100 μm thick quartz windows fused to 5 cm diameter quartz tubes, permitting the windows to be inserted directly into the flame.

A representative measurement of the flame is shown in Fig. 17.45a; the inset shows the main THz pulse in detail. As illustrated in Fig. 17.45b, there was no increase in background noise with the flame on. Despite the high temperature within the flame, the gated coherent detection and the small acceptance of the THz optics are effective in blocking the incoherent THz radiation that is incident upon the receiver. The normalized amplitude spectrum of the pulse in Fig. 17.45a is shown in Fig. 17.45c. The 0.75 THz oscillatory structure in the spectrum is due to etalon effects of the 100 μm thick quartz windows. The power absorption spectrum, measured by taking the ratio of an average of three scans with the 1 : 30 propane–air flame on to that with the flame off and the burner enclosure purged with dry air, is shown in Fig. 17.46. The measurements fit the calculated line positions to an accuracy of 1 GHz. Twenty-two rotational absorption lines in the ν_2 band were observed; the measured strengths and linewidths agree well with calculations.

THz–TDS Characterization of Sapphire and Silicon

The early THz-TDS measurements [17.51] on single crystal sapphire and silicon were motivated at that time by the need to find the best material for THz lenses in contact with the emitting and detecting chips. The available published data were inadequate for this. Absorption of the THz radiation by the lens material (initially sapphire) imposed an upper limit on the bandwidth of the entire system. The use of silicon lenses, inspired by these measurements of unusually low absorption and dispersion, immediately increased the system bandwidth from

dependence was observed. No temperature shift of line centers was observed, and line strengths were in reasonable agreement with tabulated values. The demonstrated ability of THz-TDS to measure linewidths of pure rotational transitions in hot samples can be extended to other samples and gas mixtures. Dopants can be added to the incoming fuel stream to look for important free radicals, transient species and reactants.

Fig. 17.46 Measured (*dots*) power absorption coefficient of hot water vapor compared with that calculated for the vibrational ground state (*solid curves*) and the first ν_2 vibrational state (*solid curves* offset by 0.01). The single unidentified line is indicated by the *arrow*. (Adapted from [17.55])

2 to 3 THz and gave smoother THz pulses with less ringing structure.

The single crystal sapphire sample was a polished, 57 mm diameter disc, 9.589 mm thick, and with the c-axis in the plane of the disc. A typical THz input pulse incident upon the sample is shown in Fig. 17.47a, and the output pulse (normalized to the input pulse) after propagation through the sample is shown in Fig. 17.47b for which the c-axis of the crystal was perpendicular to the polarization. The reduction in amplitude is due to the reflective loss at both surfaces and to the absorption during passage through the sapphire. The pulse at 73.4 ps delay is the ordinary pulse, while the smaller pulse at 85.1 ps delay is the extraordinary pulse. The ratio of the peak of the ordinary pulse to that of the extraordinary pulse is approximately 25 : 1 and gives the polarization sensitivity of the system. In terms of amplitude, the polarization ratio of the generated THz beam is 5 : 1. The 11.8 ps separation between the two pulses is a measure of the birefringence of sapphire and, neglecting the correction to group velocity due to dispersion, directly gives

the difference in the index of refraction between the extraordinary and ordinary ray to be $n_o = 0.37$ compared to the literature value of 0.34 [17.136, 137]. When a full frequency analysis is performed, excellent agreement is obtained with the literature value. The 73.4 ps time delay of the ordinary pulse with respect to the 7.1 ps time delay of the pulse with no sample in place gives the ordinary index of refraction $n_o = 3.07$ in agreement with the literature value [17.136–138]. The absorption coefficient versus frequency determined from these pulses is shown in Fig. 17.48a. Here, we see a monotonic increase in absorption with increasing frequency with the expected quadratic dependence. Due to excessive attenuation caused by the sample being too thick for the weak higher frequency components, the data is considered to be accurate only up to 1.75 THz. Some of the previous work [17.136–138] has been indicated on the curve, and shows rough agreement (within a factor of 2) with the THz-TDS measurement. The relative phases of the Fourier components determine the index of refraction versus frequency as presented in Fig. 17.48b, which
Fig. 17.47 (**a**) Measured input THz pulse. (**b**) Measured THz pulse transmitted through the sapphire crystal. (Adapted from [17.51])

compares reasonably well with the indicated earlier results [17.136–138].

Crystalline silicon is optically isotropic eliminating concern about the polarization of the incident THz beam and crystal orientation. Although there is significant literature concerning the far-infrared properties of silicon below 2 THz there are noteworthy discrepancies among the published data with variations in the measured absorption coefficients of up to 10 times. The main reason

Fig. 17.48a–d THz-TDS measurements of crystalline sapphire and silicon. The *circles* are the data of [17.136, 137]; the *asterisks* are data from [17.138]. (**a**) Power absorption coefficient (ordinary ray) of sapphire. (**b**) Index of refraction (ordinary ray) of sapphire. (**c**) Power absorption coefficient of high-resistivity silicon. (**d**) Index of refraction of high-resistivity silicon. (Adapted from [17.51])
for this confusion is that below 2 THz the results are extremely sensitive to the presence of carriers. THz-TDS measurements [17.97, 98] have shown that for $1 \, \Omega \, cm$, n-type silicon the peak absorption is $100 \, cm^{-1}$, and that for $10 \, \Omega \, cm$, n-type, the absorption is $12 \, cm^{-1}$. Extrapolating these values to $100 \, \Omega \, cm$, $\alpha = 1 \, cm^{-1}$, at $1 \, k\Omega \, cm$, $\alpha = 0.1 \, cm^{-1}$, and at $10 \, k\Omega \, cm$, $\alpha = 0.01 \, cm^{-1}$. Consequently, unless high-purity, high-resistivity material is used, what is measured is not the properties of the intrinsic semiconductor but that of the carriers due to residual impurities. This problem is most prevalent in the earlier work on silicon with resistivities of $10 \, \Omega \, cm$ [17.136] to $100 \, \Omega \, cm$ [17.138].

The above TDS measurements were made on a 50 mm diameter, 20.046 mm thick single crystal of high-resistivity (greater than $10 \, k\Omega \, cm$), float-zone silicon. For this material an unprecedented transparency was measured together with a remarkably flat dispersion curve. Throughout the range from low frequencies up to 2 THz the measured absorption coefficient is less than $0.05 \, cm^{-1}$, while the index of refraction changes by less than 0.001.

THz–TDS Characterization of n–Type and p–Type Silicon

A THz-TDS measurement of device-grade, doped silicon wafers [17.97, 98] showed that the frequency-dependent absorption and dispersion were completely due to the carriers and not to the host crystal. Consequently, the complex conductance could be characterized over the widest frequency range to date. The samples used were a 283 μm thick wafer of $1.15 \, \Omega \, cm$; n-type and a 258 μm thick wafer of $0.92 \, \Omega \, cm$ p-type silicon. The measured absorptions shown in Fig. 17.49a are more than 2000 times greater than that of the host crystal. The clear difference between the n- and p-type material is due to the different dynamic behavior of the electrons and holes. For these measurements the oscillations due to the etalon effects of the sample geometry have been removed numerically. As shown in Fig. 17.49b, the index of refraction is strongly frequency dependent. The agreement with the Drude theory (solid line) is exceptional.

As the THz optical properties of the samples are essentially completely determined by the carrier dynamics,

Fig. 17.49a–d THz-TDS results for $1.15 \, \Omega \, cm$, n-type (*dots*) and $0.92 \, \Omega \, cm$, p-type (*circles*) silicon. (**a**) Power absorption. (**b**) Index of refraction. the complex electric conductivity of the doped silicon has also been measured independently of conduction theory and relying on only very general assumptions [17.97, 98]. The electric conductivity is obtained (without any fitting parameters) from the data of Figs. 17.49a and 17.49b; the real part of the conductivity is shown in Fig. 17.49c and the imaginary part in Fig. 17.49d. The extrapolated dc conductivities are 0.89 Ω cm for the p-type material and 1.13 Ω cm for the n-type, compared to the directly measured values of 0.92 Ω cm (p-type) and 1.15 Ω cm (n-type).

The final agreement with Drude theory (solid line) is quite acceptable with the two Drude parameters, the plasma angular frequency ω_p and the damping rate Γ, determined within 5% accuracy from the fits to the data. For 0.92 Ω cm p-type silicon $\omega_p/2\pi = 1.75$ THz and $\Gamma/2\pi = 1.51$ THz, while for 1.15 Ω cm n-type silicon $\omega_p/2\pi = 1.01$ THz and $\Gamma/2\pi = 0.64$ THz. The measured damping rates and the known effective carrier masses [17.97, 98], determine mobilities of 1680 cm^2/V s for the electrons and 500 cm^2/V s for the holes. The measured plasma frequencies and effective carrier masses determine the carrier number densities of 1.4×10^{16} cm^{-3} for the p-type and 3.3×10^{15} cm^{-3} for n-type silicon.

More recent definitive THz-TDS measurements of the complex conductivity $\sigma(\omega)$ from dc to 2.5 THz on doped silicon have been recently performed [17.139], as displayed in Fig. 17.50. Compared to the above earlier experimental studies of doped silicon [17.97, 98], these new results have sufficient frequency range and precision to test alternative theories [17.140–143] for the conductivity. However, for both n-type and p-type silicon and over a measured range of more than two orders of magnitude of the carrier density N, agreement was not found with any standard theory, including Drude, lattice-scattering and impurity-scattering theories [17.97, 98, 140–143]. For the first time, a modified $\sigma(\omega)$ of Drude theory to include the Cole–Davidson (C–D) fractional exponent β [17.144], achieved an exceptional fit to all of the measurements. This first application of a C–D type distribution [17.144] to fit $\sigma(\omega)$ of well-ordered crystalline semiconductors extends the demonstrated frequency range of this type distribution by more than three orders of magnitude and demon-

Part D | 17.2

strates that fractal conductivity is not just found in disordered material. A later THz-TDS characterization of a very low carrier density sample of n-type neutron-doped float zone silicon obtained an excellent fit with the complex conductivity described by the C–D distribution with $\beta = 0.83$ [17.145].

THz–TDS Characterization of n–Type Gallium Nitride

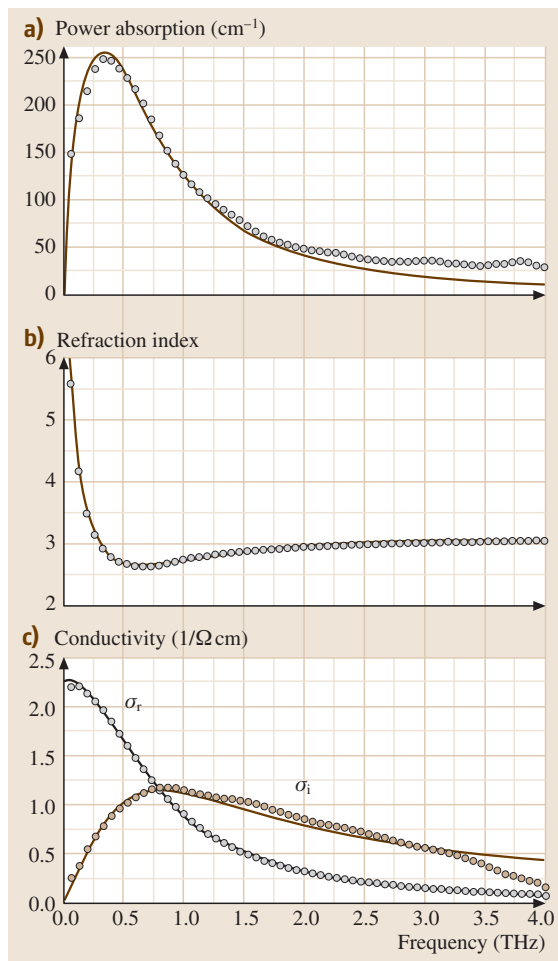
The THz-TDS characterization of the complex electric conductivity and dielectric response of n-type GaN over the frequency range from 0.1 to 4.0 THz has recently


Fig. 17.51a–c THz-TDS measurements of GaN (*open circles*) compared with Drude model (*solid lines*). (**a**) Power absorption coefficient α; (**b**) real part of refractive index n_r; (**c**) Complex electric conductivity σ_r and σ_i. (Adapted from [17.146])

been performed [17.146]. The measured conductivity is well fit by the simple Drude model.

The GaN sample was an unintentionally doped, n-type, $5\,\text{mm} \times 5\,\text{mm} \times 180\,\mu\text{m}$ freestanding crystalline plate. Originally grown on c-plane sapphire by the hydride-vapor-phase epitaxy technique (HVPE), the GaN layer was removed from the sapphire substrate by laser liftoff [17.147, 148]. The c-axis is perpendicular to the main planes of the sample. The sample was attached to a thin brass plate and centered over a 4 mm diameter hole in the plate, which defines the optical aperture. Another identical clear hole is used to take reference signal designated as the input pulse. For this measurement the standard THz-TDS system was realigned into a $4f$ confocal geometry that enabled excellent beam coupling between the THz transmitter and receiver. In order to compress the THz beam to a diameter comparable to the size of the GaN sample while preserving the low-frequency components, a pair of 25 mm focal length, high-resistivity, silicon lenses, separated by the confocal distance of 50 mm, were placed on the axis of the THz beam between the two paraboloidal mirrors. As a result, midway between the two lenses, a frequency independent 2.8 mm diameter THz beam waist was obtained, on which the 4 mm sample clear aperture was centered.

The resulting measured power absorption coefficient of the sample is shown in Fig. 17.51a, and the measured index of refraction in Fig. 17.51b, as the open circles. The real and imaginary conductivity shown in Fig. 17.51c were obtained from the experimentally determined α and n curves shown in Figs. 17.51a and 17.51b.

The measured absorption, index of refraction and complex conductivity were then theoretically fit using the simple Drude model [17.97, 98]. Three parameters were used to obtain a good fit to the experimental data: $\omega_p/2\pi = 1.82\,\text{THz}$, $\Gamma/2\pi = 0.81\,\text{THz}$ and the real part of dielectric constant $\text{Re}(\varepsilon_d) = 9.4$. Given the reduced mass $m^* = 0.22\,m_0$ for electrons in GaN [17.149], these parameters correspond to a number density of $N = 0.91 \times 10^{16}/\text{cm}^3$ and a mobility $\mu = 1570\,\text{cm}^2/\text{V s}$. In Fig. 17.51a, the material absorption of intrinsic GaN, is responsible for the difference between the Drude fitting curve and the measurement of power absorption at frequencies higher than 2 THz.

THz–TDS Characterization of Normal and High–T_c Superconducting Films

An important subject area is the complex conductivity of normal metal, and normal and high-T_c superconduct-

ing films. Here, the large dynamic range of the THz systems is the key to transmission measurements with extremely large attenuations from low frequencies up to approximately 6 THz. Consequently, thicker films can be measured and thereby results are obtained which are closer to the desired bulk properties of these materials. With THz-TDS it becomes possible to measure, by non-contact means, the complex conductivities of normal metal and superconducting films. It is to be noted that the THz beams are easily focused to millimeter and even submillimeter spot sizes and thereby can be passed through the windows of optical dewars capable of cooling to cryogenic temperatures.

Direct measurements of the energy gap of normal superconductors have been performed on thin films of niobium [17.150] and lead [17.151]. In the early investigations of high-T_c films, the complex conductivity [17.152] and the real and imaginary parts of the surface impedance [17.153] were measured in both the normal and superconducting states. In another work [17.154], where the real and imaginary parts of the sub-bandgap conductivity σ of $YBa_2Cu_3O_7$ films were directly measured in the frequency range from 0.45 to 2.4 THz ($15-80\,cm^{-1}$), a peak was observed in the real part σ_1 similar to the coherence peak expected in an s-wave BCS superconductor. More recent measurements have extended both the accuracy and frequency range of these measurements [17.155–165].

THz–TDS Characterization of High–T_c Substrates, Nonlinear Crystals and Polymers

The THz transparency of the underlying dielectric substrate is essential to realize the goal of a high-speed coplanar transmission line capable of transmitting a subpicosecond electrical pulse a distance on the order of 10 mm. These considerations become especially important with respect to the realization of a high-bandwidth coplanar transmission line fabricated out of the new high-T_c superconducting materials. The THz-TDS characterization at both room temperature and 85 K of three dielectric substrates used with high-T_c coplanar transmission lines, namely, magnesium oxide, yttria-stabilized zirconia (YSZ), and lanthanum aluminate provided limits on the realizable bandwidths obtainable [17.68]. More recent measurements have characterized another high-T_c substrate [17.166].

Although ZnTe has been the primary EO detection crystal, and even though detailed simulations have been compared with experimental results, the frequency dependent absorption and dispersion of ZnTe had not been measured. Recently, via THz-TDS, extensive meas-

urements of the index of refraction and absorption of ZnTe from low frequencies to 4.5 THz were performed [17.131]. In contrast to what has been previously assumed, it was found that the absorption below 4.5 THz is not dominated by the strong TO-phonon line at 5.3 THz, but instead the measured absorption shows several new phonon lines. In fact, below 3.5 THz no significant absorption from the low frequency wing of the TO-phonon line was observed. However, as previously expected, the behavior of the index of refraction is dominated by the TO-phonon resonance. Another group has reported the THz-TDS characterization of the important electrooptic crystals: $LiNbO_3$, $LiTaO_3$, ZnTe and CdTe [17.132]. This same group has more recently reported the THz-TDS characterization of the nonlinear organic crystal DAST [17.167].

THz–TDS Characterization of Molecular Vapors

Early studies of coherent transients excited by THz pulses involved the use of THz-TDS techniques with N_2O vapor [17.168, 169] and methyl chloride vapor [17.170]. Using a subpicosecond pulse of THz radiation to excite the vapor, the subsequent emission from the vapor of coherent THz pulse trains extending as long as 1 ns was observed. THz-TDS, rotational line-shape investigations have been performed to gain insight into the actual collision process [17.171–173], by measuring the far-wing absorption line profile of ensembles of collision broadened ground state rotational lines of methyl halide vapors out to more than 200 linewidths from resonance, corresponding to frequency offsets as much as 5× the resonant frequency. These observations extend from the regime of the van Vleck–Weisskopf theory to the regime of the Lorentz theory. These measurements have experimentally established the new molecular response theory, which explicitly includes the molecular orientation time during a collision [17.173].

More recent work has studied collision induced tunneling in the methyl halides [17.172] and ammonia [17.174]. In other work the use of THz-TDS for gas sensing has been presented and discussed [17.175, 176]. A gas filter correlation instrument for the THz monitoring has been developed [17.177], and an all electronic THz absorption spectrometer has been demonstrated [17.178].

17.2.5 THz–TDS of Liquids

The efficacy of THz-TDS measurements on liquids has been demonstrated in a series of measurements

of the absorption and index of refraction of acetone [17.179], acetonitrile [17.179, 180], liquid ammonia [17.181], benzene [17.182, 183], carbon tetrachloride [17.182, 184], cyclohexane [17.182], ethanol [17.181], methanol [17.179, 181], 1-propanol [17.181], water [17.179, 181, 185–188], and heavy water [17.188]. In addition, nonaqueous mixtures of dipolar liquids have been characterized [17.189], as well as solvated

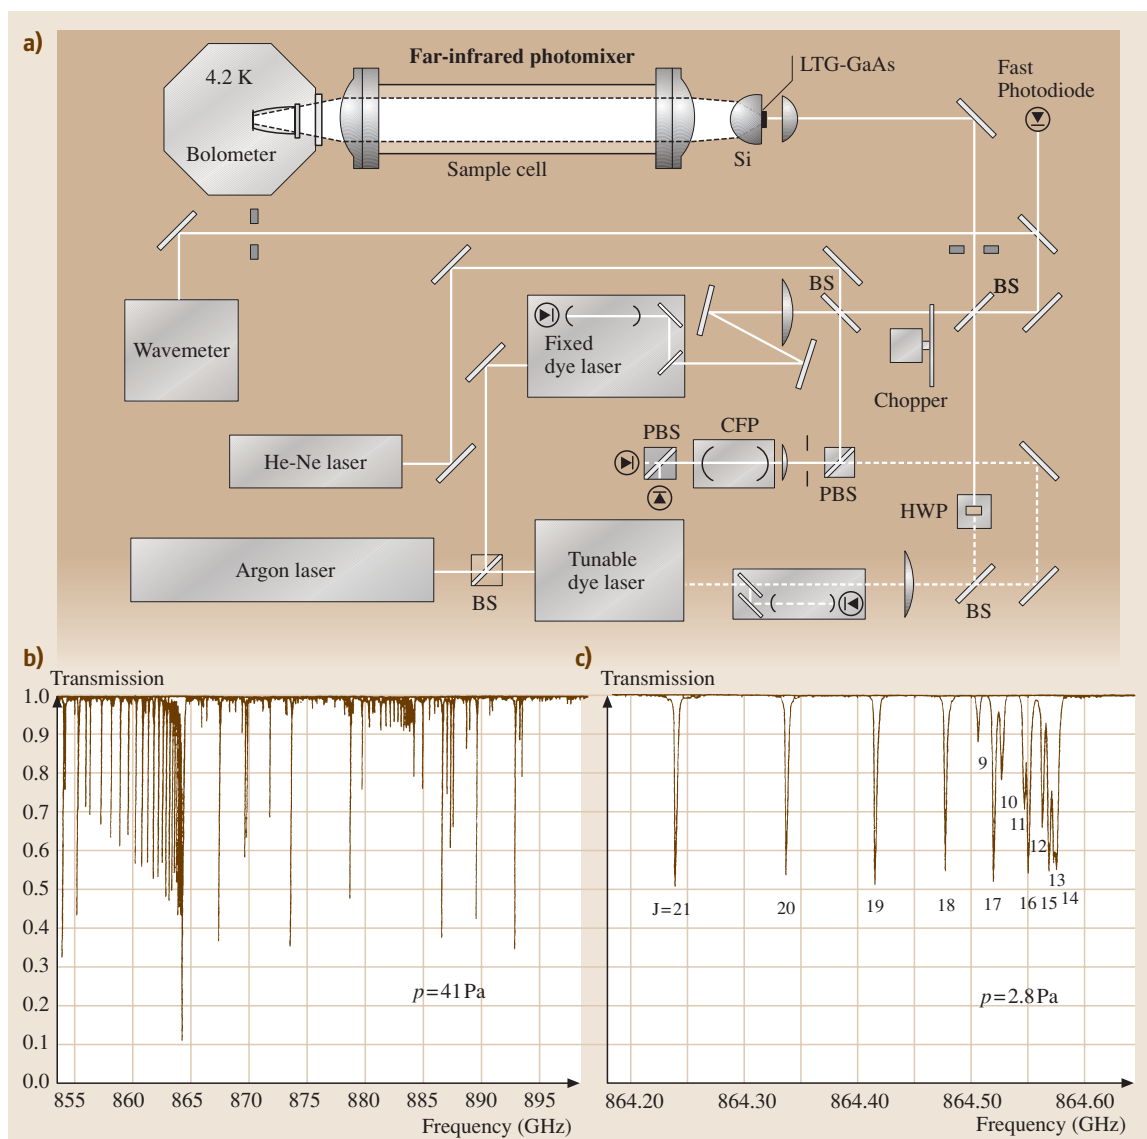
HCl [17.190], and mixtures of water with acetone, acetonitrile, and methanol [17.179]. The obtained spectra typically covered the region from 0.1 to 2 THz, where the dielectric response of the nonpolar liquids is dominated by collision-induced dipole moments. The complex dielectric behavior of liquids in the THz region is different for polar and nonpolar molecules. The absorption in po-


Fig. 17.52 (a) Schematic diagram of the photomixer spectrometer (BS: beam splitter, PBS: polarizer beam splitter, CFP: confocal Fabry–Perot, HWP: half-wave plate). **(b)** Survey scan of SO_2 near the $^rQ_8$ subbranch. **(c)** High-resolution scan of $^rQ_8$ subbranch head. (Adapted from [17.191])

lar molecules is due to the electronic interaction of the incoming field with the molecular permanent dipole moments. The dipoles are aligned by the incoming THz field, while at the same time this alignment is opposed by collision processes. The collision induced relaxation of the polarization has a time constant in the picosecond range, ideal for the THz probing pulses. The much smaller absorption of nonpolar molecules originates in the transient dipole moments induced by collisions in the liquid. The complex dielectric constant can be measured by THz-TDS for both types of liquid samples and useful information thereby obtained.

17.2.6 cw THz Photomixing Spectroscopy

A tunable cw far-infrared (THz) difference-frequency spectrometer has been developed and demonstrated by mixing two single-mode visible dye lasers separated by THz frequencies in an ultra-high-speed photoconductor [17.191]. The photomixer device was fabricated with submicron interdigital electrodes driving a broadband spiral antenna on epitaxial low-temperature-grown GaAs [17.41–43]. The coherent far-infrared radiation was coupled out the backside of the GaAs substrate using an aplanatic Si lens and was detected by a Si-composite bolometer at $T = 4.2$ K. Usable S/N ratios were obtained for radiation from 0.1 to 1.0 THz, using two 584 nm dye lasers. The instrumental linewidth was about 2 MHz, limited by the frequency jitter of the dye lasers. Baseline normalization was nec-

essary to compensate for the laser amplitude fluctuations and for the strong fringes due to standing waves between the source and detector and within the detector dewar. The schematic of the entire system is shown in Fig. 17.52a. The generated THz radiation traverses a 50 cm sample vapor cell using Teflon lenses as windows, from which it is detected by a Si-composite bolometer operated at $T = 4.2$ K. All of the obtained spectra were normalized against laser amplitude fluctuations by dividing the bolometer signal from the THz radiation by the product of the incident laser powers.

The instrument was used to obtain SO_2 self-broadening coefficients for pure rotational transitions in several Q branches. Figure 17.52b shows a 45 GHz scan of the $SO_2(P = 41$ Pa) ^rQ_s subbranch region near 865 GHZ normalized to an empty cell trace, each recorded in 5 min with 6000 sample points. Since each point represented 7.5 MHz, it was necessary to pressure broaden the lines slightly to increase the instrumental response because of the 40 ms lock-in time constant. The Doppler width for SO_2 at this frequency is only 1.3 MHz FWHM. Along the zero transmission baseline, the detector noise level in this trace when the lasers are blocked is also shown. The ^rQ_s subbranch head is shown expanded in Fig. 17.52c at lower pressure and with a slower scan rate. A turn around is observed at $J = 14$, whose spacing from the $J = 13$ line of approximately 2.5 MHz is clearly resolved with the instrumental linewidth of 2 MHz.

18. X-Ray Optics

Due to the weak interaction of hard X rays with matter it is generally difficult to manipulate X rays by optical components. As a result, there have been many complementary approaches to making X-ray optics, exploiting refraction, reflection, and diffraction of X-rays by matter. In this chapter, we describe the physics that underly X-ray optics and explain the work principles and performances of a variety of X-ray optics, including refractive X-ray lenses, reflective optics, such as mirrors and wave-

guides, and diffractive optics, such as multilayer and crystal optics and Fresnel zone plates.

In the last 10 years outstanding progress has been made in X-ray optics. This development has been triggered by the availability of high-brilliance synchrotron radiation sources. Well-known optical schemes have been improved and new ones have been invented. Important fields of application for these optics are collimation and focusing, both at laboratory and synchrotron radiation sources, and hard X-ray microscopy, which is a growing field mainly at synchrotron radiation sources.

Although there is a large variety of X-ray optics with very different designs, they are all based on the same physical principles, i. e., elastic scattering of X-rays in matter. Refractive X-ray lenses make use of refraction inside the lens material, while mirror optics, capillaries, and waveguides use total external reflection, closely related to the refraction inside the optic's material. Diffractive optics, such as Fresnel zone plates, make use of attenuation and refraction to reduce and shift the amplitudes of the X-rays to generate a desired interference pattern, e.g., a small focal spot in the focal plane. Multilayer or crystal optics exploit Bragg reflection to focus X-rays. These physical mechanisms that underlie X-ray optics are reviewed in Sect. 18.1.

At laboratory X-ray sources, e.g., X-ray tubes, X-ray optics are mostly used to capture the radiation from a large solid angle and concentrate it either on the sample or on a detector. For this purpose very efficient optics are required that capture a large solid angle, such as for example polycapillary, multilayer or crystal optics. At modern synchrotron radiation sources, hard X-ray microscopy has developed quickly over the past decade. Both full-field and scanning techniques find a grow-

ing number of applications, requiring both imaging and focusing optics. The most important X-ray optics are reviewed in this chapter (Sect. 18.2).

For imaging, i. e., in full-field microscopy, Fresnel zone plates and refractive X-ray lenses are most commonly used. They are used as objective lens, generating a magnified image of the specimen on the detector. In this way, spatial resolutions in the range of 100 nm and below can be achieved. The key strength of this type of microscopy is the large penetration depth of hard X-rays in matter, which allows one to image the interior of an object without destructive sample preparation. By combining this technique with tomography, the three-dimensional inner structure of an object can be reconstructed at high spatial resolution.

Scanning microscopy, on the other hand, allows one to perform with high spatial resolution hard X-ray analytical techniques, such as diffraction, fluorescence analysis, or absorption spectroscopy, that yield the local (nano-)structure, the elemental composition, or the chemical state of an element in the sample, respectively. When combined with tomography, spectroscopic information from inside a specimen can be obtained. The small beam for these scanning techniques is often generated by means of an X-ray optic, such as zone plates, refractive lenses, or curved total reflection or multilayer mirrors. Currently, all these optical schemes are capable of generating intensive beams with a lateral extension well below 100 nm at third-generation synchrotron radiation sources. In addition to scanning microscopy applications, the small beam can also be used as a small source for magnified projection mi-

croscopy. This scheme is recently used in full-field microscopy to obtain magnified high-resolution images of a specimen using Kirkpatrick–Baez mirrors or waveguides.

Currently, all X-ray optics are technology limited in their performance, but significant technological ad-

vances have been made, approaching physical limits. Recently, these limits have been addressed theoretically for several X-ray optics, such as waveguides, refractive lenses, and Fresnel zone plates. While beams in the range from $1-10$ nm are conceivable with ideal optics, atomic resolution, e.g., at 1 Å seems to be out of reach.

18.1 Interaction of X-Rays with Matter

A hard X-ray photon interacts with an atom mainly through scattering at its electrons or by absorption. Scattering can be both elastic or inelastic. In the cases of inelastic scattering, also called Compton scattering, and photoabsorption the photon is lost for image formation, while elastic scattering is responsible for refractive and diffractive effects.

The refraction of hard X-rays in matter is typically expressed by the index of refraction given in the form

$$n = 1 - \delta + i\beta, \tag{18.1}$$

where δ describes the deviation of the real part of the refractive index from unity and is referred to as the *index of refraction decrement*. As (18.1) suggests (with positive δ), the refractive index of hard X-rays in matter is smaller than unity, i. e., the vacuum is X-ray optically denser than matter. Figure 18.1b illustrates this effect as compared to the refraction of visible light in glass (Fig. 18.1a).

For a given atomic species, δ is given by [18.2]

$$\delta = \frac{N_a}{2\pi} r_0 \lambda^2 \rho \frac{Z + f'(E)}{A}, \tag{18.2}$$

where N_a is Avogadro's constant, r_0 is the classical electron radius, λ and E are the wavelength and energy of

the X-rays, respectively, ρ is the mass density of the material, $Z + f'(E)$ is the real part of its atomic form factor in the forward direction, and A is the material's atomic mass. Figure 18.2a shows δ/ρ for different materials as a function of X-ray energy. Away from absorption edges, $f'(E)$ is small and δ is proportional to $\lambda^2 \sim E^{-2}$ and ρ. Since Z/A does not vary much between most elements,
Fig. 18.1 (a) For visible light, the refractive index n in matter is larger than one. Therefore, light rays are refracted toward the surface normal when entering matter from the vacuum. **(b)** For hard X-rays, the refractive index n of matter is smaller than one. Therefore, X-rays impinging from vacuum onto a surface are refracted away from the surface normal. **(c)** If the angle of incidence θ_1 falls below the critical angle of total reflection, the X-rays do not propagate deeply into the material but are totally reflected at the surface
Fig. 18.2 (a) δ/ρ (the index of refraction decrement divided by the density of the material) for Be, Al, and Ni as a function of X-ray energy. **(b)** mass attenuation coefficient μ/ρ for the same elements. After [18.1]

δ/ρ varies very little as a function of the atomic species away from absorption edges. As compared to that of visible light in glass, the refraction of hard X-rays is several orders of magnitude weaker. While δ/ρ is of the order of $10^{-6} \, \mathrm{cm}^3/\mathrm{g}$ for hard X-rays between 10 and 20 keV (Fig. 18.2a), that of visible light in glass is about $-\delta/\rho \approx 0.2 \, \mathrm{cm}^3/\mathrm{g}$.

Due to this extremely small refraction, the reflectivity at a surface or interface is extremely low. Therefore, there are no mirrors for hard X-rays reflecting at large angles. However, when an X-ray beam impinges on a plane interface between vacuum (or air) and a medium of index n under a sufficiently small angle θ_1, it is totally reflected (Fig. 18.1c). This total external reflection occurs for θ_1 smaller than the critical angle for total reflection θ_c, i. e.,

$$\theta_1 < \theta_c = \sqrt{2\delta}. \tag{18.3}$$

For hard X-rays, this angle lies below about 0.5 degrees for all materials. In other words, total reflection occurs only at grazing incidence.

The imaginary part β of the refractive index in (18.1) describes the attenuation of X-rays in matter and is related to the linear attenuation coefficient μ by

$$\beta = \frac{\mu\lambda}{4\pi}. \tag{18.4}$$

Lambert-Beer's law

$$I(z) = I_0 \cdot \mathrm{e}^{-\mu z} \tag{18.5}$$

describes the transmitted intensity $I(z)$ through a homogeneous piece of material of thickness z, given an incident intensity I_0. The linear attenuation coefficient μ is the inverse of the characteristic length of this exponential decay.

β and μ include photoabsorption as well as the attenuation of the incident beam by elastic (Rayleigh) and inelastic (Compton) scattering. The dependence of μ/ρ on the X-ray energy is shown in Fig. 18.2b. At low energies, photoabsorption τ dominates μ/ρ. As opposed to refraction, photoabsorption is strongly dependent on the atomic number. Between absorption edges it scales approximately like $\tau \sim Z^3/E^3$. With increasing X-ray energy, Compton scattering contributes increasingly to μ/ρ. Compton scattering is only weakly dependent on the atomic species and limits the mass attenuation coefficient from below to about $\mu/\rho > 0.1 \, \mathrm{cm}^2/\mathrm{g}$ in the energy range from a few keV to several hundred keV. As a consequence, there is no material that is as transparent for hard X-rays as is glass for visible light. For comparison, the attenuation of visible light in glass can
Fig. 18.3 Bragg scattering of hard X-rays from a crystalline material. The lattice planes have a spacing d and the X-rays impinge on the lattice planes under the angle θ

be as small as $\mu_{\mathrm{silica}} \approx 10^{-7} \, \mathrm{cm}^{-1}$ for pure silica used for fiber optics [18.3].

In the general case, elastic scattering contributes little to the attenuation of the transmitted beam. In some cases, however, when for example a Bragg reflection is excited in a crystalline material, elastic scattering can significantly attenuate the transmitted beam. In that case, the X-ray beam can be efficiently diffracted away from the forward and into another direction. Figure 18.3 illustrates this situation, in which the scattered amplitudes from a large number of atoms interfere constructively. This is the case when the path length difference $2d \sin\theta$ between amplitudes reflected from neighboring lattice planes is an integer multiple m of the wavelength λ of the X-rays, i. e.,

$$m\lambda = 2d \sin\theta. \tag{18.6}$$

While elastic scattering preserves the wave number ($k = 2\pi/\lambda$), the wave vector changes its direction

$$k' = k + G, \tag{18.7}$$

where $G = mG_0$ is the reciprocal space vector associated with the lattice planes and the reflection order m (Fig. 18.3). For arbitrary alignment of a monocrystalline sample in a monochromatic beam, this virtually never occurs. However, some X-ray optics, such as crystal or multilayer optics, exploit this effect to monochromatize and focus the X-rays.

18.2 X-Ray Optical Components

A large number of X-ray optical components are described in literature. One reason for this is the difficulty in manipulating X-rays due to their weak interaction with matter. There have been many complementary approaches to this problem, but none has proven significantly superior to the others. Indeed, as technology advances, approaching the physical limits, the performances of different optics become very similar. In this chapter, the most common X-ray optics are described.

18.2.1 Refractive Optics

Rotationally Parabolic Refractive X-ray Lenses
While refractive optics are most common for visible light, the interplay between weak refraction and relatively strong absorption inside the lens material makes the design of refractive lenses for hard X-rays difficult (Sect. 18.1). For instance, at 45°, the angular deviation of the refracted beam is δ, which is typically of the order of 10^{-6} rad, compared to some 17 degrees for visible

Fig. 18.4 (a) Parabolic refractive X-ray lenses. A large number of individual lenses are stacked behind each other to form a refractive X-ray lens. **(b)** Partially assembled parabolic refractive X-ray lens made of beryllium

light at an air–glass interface. From the discovery of X-rays to the 1990s it was therefore believed that refractive lenses for hard X-rays could not be made [18.4–7]. In 1996 it was first demonstrated experimentally that refractive lenses can be fabricated and work despite this weak refraction and relatively strong absorption [18.8]. Since then, a variety of refractive X-ray lenses have been designed [18.9–18].

As the refractive index of hard X-rays is smaller than one ($n < 1$) in any lens material, a focusing lens has to have a concave shape (Fig. 18.4a), and since the refraction of hard X-rays in matter is about six orders of magnitude weaker than that of visible light in glass, the effective lens curvature must be accordingly stronger. For example, a biconvex lens for visible light with a radius of curvature of $R = 1$ m for both surfaces has a focal length of about $f = R/2(n-1) \approx 1$ m. A single X-ray lens with the same focal distance would need to have a radius of curvature R in the micrometer range. It is difficult to fabricate such a lens, in particular with a sufficiently large aperture. This difficulty can be overcome by making the radius of curvature R of an individual lens larger and compensating the lack of refraction by stacking many of these lenses behind each other, as shown in Fig. 18.4a.

As the radius of curvature R has to be as small as possible to limit the number of single lenses, the spherical-lens approximation that is successfully applied in visible light optics does not apply to most X-ray lens designs. It would limit the aperture $2R_0$ of the lens to be much smaller than the radius of curvature R (Fig. 18.4a). To avoid spherical aberration and to allow for apertures that are as large as possible, the lens surfaces have to have a parabolic shape [18.9, 10, 15]. In the paraxial approximation this is the optimal aspherical lens shape. For parabolic lenses the aperture $2R_0$ can be chosen independently of the radius of curvature R Fig. 18.4a.

Attenuation inside the lens is significant for all lens materials (Sect. 18.1), as there is no material that is as transparent in the hard X-ray range as glass is for visible light. Besides a reduction of the transmitted radiation, the attenuation inside the lens material reduces the aperture of the lens, since the thicker material in the outer parts of the lens (Fig. 18.4a) absorbs the X-rays more strongly than the thin material on the optical axis. In order to optimize the transmission and aperture it is thus important to choose the lens material carefully. As μ/ρ increases strongly with increasing atomic number Z ($\mu/\rho \sim Z^3$), atomic species with low Z, such as Li,
Be, B, C, and compounds thereof, are good lens materials [18.8, 10]. In addition, the lenses should be made as thin as possible, reducing the distance d (Fig. 18.4a) between the apices of the parabolas to a minimum.

Ideal for imaging applications, in particular in X-ray microscopy, are rotationally parabolic lenses. At Aachen University, they are made by embossing the lens shape from both sides into the lens material, such as beryllium or aluminium. For the current lens design, the radius of curvature is $R = 200\,\mu m$ and the aperture $2R_0 \approx 1\,mm$. Typical focal distances lie in the range $0.3-10\,m$, depending on the application. Figure 18.4b shows a partly assembled beryllium lens. A single lens is held and centered by a hard metal ring of well-defined diameter. These coin-like single lenses are stacked along two parallel polished shafts to align their optical axes. In this design, the number of lenses can be adjusted starting from a single lens up to 300 lenses in one stack, allowing one to control the optical properties, e.g., focal length, within a wide range in a large energy interval (5 to $> 100\,keV$). The lens is kept in an inert gas atmosphere to avoid corrosion of the beryllium in the intensive X-ray beam.

As the attenuation increases towards the outer parts of the lens, the rays passing the lens in these parts do not contribute as much to the image as those traveling through the lens close to the optical axis. Therefore, the effective aperture D_{eff} describing diffraction at the lens is smaller than the geometric aperture $2R_0$. It typically lies in the range of a few hundred micrometers. Attenuation inside the lens material also reduces the transmission T_p of the optic. Details about these quantities can be found in [18.10, 19].

These optics are ideal for imaging applications with hard X-rays above 5 keV, such as hard X-ray microscopy. They are free of spherical aberration. 100 nm spatial resolution has been achieved with beryllium lenses at 12 keV in an X-ray microscope [18.20]. Potentially, the diffraction limit of these optics can be pushed to below 50 nm. The lenses can be used to generate a small and intensive microbeam, by imaging the X-ray source onto the sample in a strongly reducing geometry. Besides for X-ray microscopy, these optics are commonly used for beam conditioning at third-generation synchrotron radiation sources, since they can withstand the high heat load of modern undulator sources and match their beam size very well. In addition, they find wide application in scanning microscopy, where they are used to generate intensive hard X-ray microbeams.

According to (18.2) the refractive index depends on the X-ray energy, leading to chromatic aberration. For the many experiments carried out with monochromatic synchrotron radiation, chromatic effects are irrelevant. There are, however, also many experiments which require a broad X-ray spectrum or scanning the energy while keeping the focus unchanged. If the energy range is sufficiently small, a slight defocusing of the lenses can be tolerated in some cases [18.21]. In others, one should resort to genuinely achromatic optics, such as total reflection mirrors (Sect. 18.2.2).

Nanofocusing Refractive X-Ray Lenses

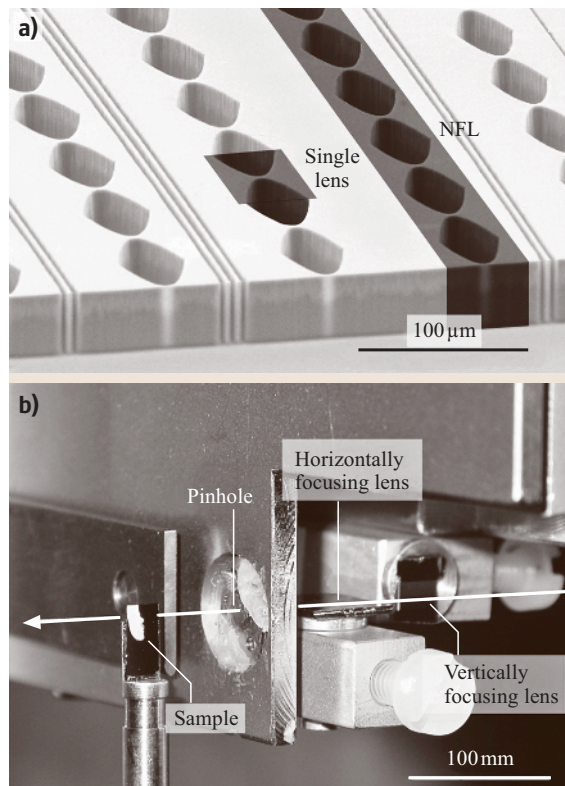
To generate beams with a lateral extension well below one micrometer, the geometric image of the source must be made sufficiently small. This is possible by reducing the focal length f of a refractive lens, thus increasing the demagnification ratio. In addition, the diffraction limit decreases with decreasing focal length for refractive lenses. As it is difficult to reduce the focal length of the rotationally parabolic lenses to well below $0.3\,m$,


Fig. 18.5 (a) Scanning electron micrograph of nanofocusing lenses. A single lens and a nanofocusing lens are outlined by *dark shaded areas*. (b) Nanoprobe setup: the X-ray beam is focused onto the sample by two crossed nanofocusing lenses

Part D | 18.2

a new type of parabolic lenses with extremely short focal distance was developed [18.22].

In order to achieve focal length in the centimeter range at hard-X-ray energies, the radii of curvature of the individual single lenses (cf. Fig. 18.5a) need to be in the range of a few micrometers. This can for example be achieved with nanofabrication techniques for planar lenses, such as those shown in Fig. 18.5a. They are made of silicon by electron-beam lithography and subsequent deep reactive-ion etching. These planar structures only focus in one dimension. Thus, in order to obtain a point focus, two such lenses with appropriate focal lengths need to be crossed. Figure 18.5b shows a nanoprobe setup based on two crossed nanofocusing lenses (NFLs). With this setup, hard-X-ray beams down to about $50 \times 50 \, \text{nm}^2$ have been generated at the European Synchrotron Radiation Facility (ESRF) in Grenoble, France [18.23].

With optimized parameters, these optics are expected to generate beams with a lateral size between 10 and 20 nm. This is a physical limit for the given lens design. There are more-complicated lens designs that will in principle allow one to overcome this limit and focus hard X-rays down to below 5 nm [18.24].

18.2.2 Reflective Optics

Mirrors

The reflectivity of a surface or interface is negligible for large angles. Only in grazing incidence below the critical angle of total external reflection θ_c are high reflectivities possible (Sect. 18.1). This makes X-ray mirrors and capillaries very slender, i. e., much longer than wide. According to (18.2) and (18.3) θ_c depends mainly on the X-ray wavelength λ and on the density ρ of the mirror material. The higher the X-ray energy ($E = hc/\lambda$) the smaller the critical angle θ_c. In order to have sufficiently large reflection angles, materials with high density, such as palladium or platinum, are often used.

Two effects reduce the ability of a mirror to reflect X-rays without losses: absorption and surface roughness. X-rays penetrate into the mirror surface to a depth of a few nanometers. Here, they are partially absorbed, so that just below the critical angle the reflectivity is often far below 50%. For heavy elements and just above absorption edges this is particularly strong.

The second detrimental effect to the reflectivity is surface roughness. Due to the short wavelength of hard X-rays roughness brings the reflection amplitudes of a photon in the different areas inside each Fresnel zone out of phase, so that the total amplitude and hence the reflectivity are reduced. For high-quality mirror optics, the surface roughness must be in the 0.1 nm range. This effect and the high requirements on form fidelity make X-ray mirrors very expensive optical components.

For a given grazing incidence geometry with reflection angle θ_1, total-reflection mirrors reflect X-rays up to the energy where $\theta_1 = \theta_c$. They act like a low-pass filter for X-rays and are therefore often used to remove the high-energy content from the beam. In conjunction with a crystal monochromator, this allows one to strongly reduce higher harmonic radiation [$m \geq 2$ in (18.6)] and generate a clean monochromatic beam.

To focus or collimate X-rays, mirrors can be curved. To focus the X-rays, i. e., to image the source from point to point, the mirror surface needs have ellipsoidal shape (Fig. 18.6a). For collimation, i. e., generating a parallel X-ray beam, the mirror surface needs to be parabolic (Fig. 18.6b). To achieve focusing or parallelization in two dimensions with a single reflection, the mirror must have the shape of an ellipsoid or paraboloid of rotation, respectively. Due to the very small reflection angle, this rotational body is very elongated (needle-like) having extremely different curvatures in the sagittal and meridional direction. Since such a mirror is extremely difficult to fabricate with high accuracy, there are only a few realizations. These optics are also referred to as elliptical or parabolic monocapillaries.

To avoid strong sagittal curvature, two reflections from flat mirrors are often used to obtain two-
Fig. 18.6 (**a**) Elliptical mirror for focusing form point to point. (**b**) Parabolic mirror to collimate the beam from a point source
Fig. 18.7 Kirkpatrick–Baez focusing geometry: focusing from point to point using two crossed elliptical mirrors

dimensional focusing. Figure 18.7 illustrates this scheme, which was first described by *Kirkpatrick* and *Baez* in 1948 [18.25]. Today, this technique is widespread as a focusing optic for scanning microscopy at synchrotron radiation sources. While it is relatively difficult to align, it has the great advantage of being achromatic for X-rays below a critical energy given by the maximal angle of incidence. This makes these optics particularly useful for white-beam microdiffraction techniques [18.26] and for absorption spectroscopy studies.

Today, these mirrors can be fabricated with extremely small surface roughness and excellent form fidelity, generating hard X-ray beams with a lateral size as small as 30 nm [18.27]. Since the reflection angles are limited by θ_c, the numerical aperture and thus the diffraction-limited focus size is limited, too. It is expected that beam sizes down to below 20 nm can be reached with total reflection mirrors. One way to overcome this limit is to use multilayer mirrors (Sect. 18.2.3) or use more-complicated multiple-reflection schemes.

Waveguides

Another optical component which is based on total reflection and which has been developed recently are X-rays waveguides. They consist of a substrate made of a material with high density (e.g., nickel), a light-element (e.g., carbon) layer on top of it and a cap layer made of a dense material again (Fig. 18.8). The middle layer is the guiding layer, which is typically a few tens of nm thick. The X-rays are confined inside the waveguide by total external reflection at the side walls defined by the denser materials. The device works in analogy to a waveguide for microwaves.

There are two ways to couple X-rays into a waveguide. A well-collimated plane wave can be coupled into the waveguide through the thin cap layer [18.28] or a focused beam can be directly coupled into the waveguide from the side [18.29], as shown in Fig. 18.8a and b, respectively. Only those modes that survive by constructive interference can propagate in the waveguide. Depending on the illumination, different modes can be systematically excited, corresponding to different standing waves in the transverse direction. The first waveguides were planar structures, confining the beam only in one direction. Today, using nanofabrication techniques, two-dimensionally confining wave guides can be made [18.29].

Waveguides are mostly used for two types of applications: to illuminate a sample confined inside the waveguide [18.30] or to generate a very fine beam that is
Fig. 18.8 X-ray waveguide. **(a)** The X-rays are coupled into the waveguide through the cap layer. **(b)** Focused X-rays are directly coupled into the waveguide

emerging from its exit. At the exit, the beam size is comparable to the dimensions of the waveguide. Recently, a beam with lateral dimensions of 25 nm × 45 nm was generated [18.29]. This beam can be used for projection microscopy and has a high degree of lateral coherence. If a single mode is excited inside the waveguide, the exiting beam is perfectly coherent. This can be exploited for coherent imaging experiments and holography. The smallest size that X-rays can be confined to by waveguides is also limited by total-reflection effects and is expected to lie slightly below 10 nm [18.31]. Until now, these components are in the stage of development and have not yet found widespread application.

18.2.3 Diffractive Optics

Multilayer Optics

Multilayer optics consist of a series of alternating layers of high- and low-density materials. Figure 18.9a shows a multilayer made of 75 double layers of Ni and B_4C. Figure 18.9b shows the operating principle of these optics: the X-rays impinging at the angle θ are reflected from the multilayer if the Bragg condition (18.6) for the multilayer is fulfilled, i. e., the path-length difference marked in dark brown in Fig. 18.9b is an integer multiple of the wavelength λ. Here, d is the period of the multilayer, which can be chosen freely and typically lies in the range from about 2 to 20 nm, and the resulting Bragg angles lie in the range of degrees for hard X-rays. The reflectivity can be close to one (70 to 90%) for hard X-rays. It depends on the number of layers and the difference in electron density between the two multilayer materials. As for total-reflection mirrors, the reflectivity is also deteriorated by attenuation inside the optic and by roughness of the interfaces.

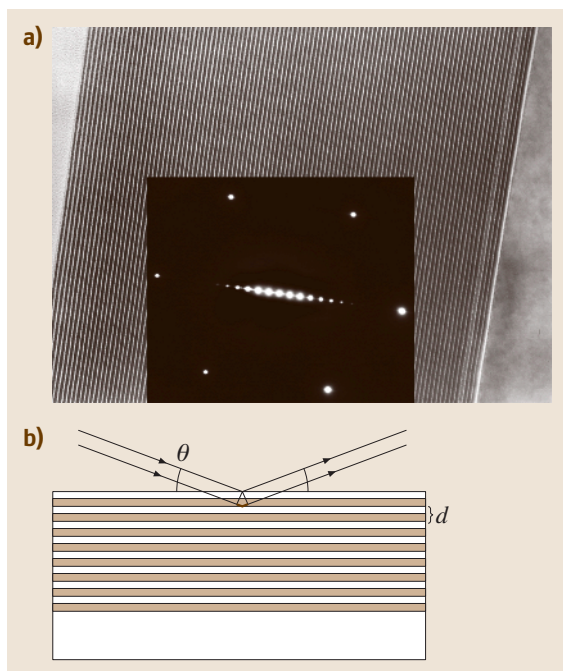
Similar to crystal optics, multilayers can be used to monochromatize the X-ray beam. The monochromaticity and the angular acceptance depend on the number of periods that contribute to the reflection. This number is either limited by the total number of periods N in the


Fig. 18.9 (**a**) High-resolution transmission electron micrograph of a multilayer optic consisting of $N = 100$ double layers of Ni and C. The lattice spacing is $d = 3.2$ nm. The inset shows the electron diffraction pattern from the structure. The clear diffraction peaks along the line through the center of the diffraction pattern and normal to the multilayer stack illustrate the high degree of periodicity. (**b**) Schematic drawing of a multilayer optic. The X-rays are reflected from the multilayer if the Bragg condition (18.6) is fulfilled, i.e. the *dark brown segment* of the lower optical path is an integer multiple of the X-ray wavelength λ

stack or by the extinction length inside the multilayer. A detailed description of the reflectivity of multilayer systems can be found in [18.32].

To use these optics to focus or collimate the X-ray beam in the geometries shown in Fig. 18.10, the spacing d of the multilayer needs to be adapted to the reflection angle that varies along the optic. Such laterally graded multilayers were first introduced by *Schuster* and *Göbel* to capture a large solid angle from an X-ray tube and collimate it for diffraction experiments [18.33, 34]. A variety of optics exist today that either focus or collimate the beam from an X-ray tube. Since the reflection angles are larger than in the total-reflection case (Sect. 18.2.2) there are sagittally curved elliptical and parabolic mirrors in addition to double-bounce systems of Kirkpatrick–Baez (KB) type.

For scanning microscopy, curved multilayer systems in the KB geometry are used with great success, generating very intensive nanobeams down to well below 100 nm [18.35, 36]. These optics have the advantage that they moderately monochromatize the beam at the same time. In this way, an additional crystal monochromator can be avoided. This can be advantageous for experiments that do not require a high degree of monochromatization, since the larger energy band pass leads to a higher flux. Due to the relatively large reflection angles, the numerical aperture of these optics can be relatively large. Ultimately, diffraction-limited foci well below 10 nm are conceivable for this type of optic.

The flexibility in the choice of the lattice parameters and its variation over the mirror open possibilities that cannot be realized with crystal optics. Besides lateral grading of the multilayers, depth grading can also be useful, e.g., to tailor the angular acceptance and energy bandwidth of the device. As there are some applications of these optics in conjunction with laboratory X-ray tubes, there is a larger market for these optics, and they are available from a number of laboratories and commercial companies. Multilayers are also of great importance in the extreme ultraviolet (EUV) range, where they are used in lithographic steppers.

Crystal Optics

The main field of application of crystal optics is monochromatization of X-rays using Bragg reflection (Sect. 18.1). Depending on the crystal, crystal cut, reflection, and the arrangement of different crystals, relative energy bandwidths $\Delta E / E$ from about 10^{-3} to 10^{-7} can be reached, finding wide application at nearly every beam line at synchrotron radiation sources. High energy resolutions are needed in particular in inelastic X-ray scattering and nuclear resonance scattering.

Besides pure monochromatization, crystal optics can also be used to focus X-rays from point to point. As one cannot adjust the d-spacing for varying reflection angles as for multilayer optics (Fig. 18.10) a geometry in which the reflection angle is constant and equal to the Bragg angle θ_B for every point on the optic has to be used. Figure 18.11 shows a bent crystal in the Johann geometry. In the Johann geometry, the Bragg planes are parallel to the crystal's surface. The meridional bending radius R_h is twice the radius of the so-called Rowland circle (Fig. 18.11). To focus also out of plane, the crystal has to be sagittally bent as well. In that direction the bending radius is $R_v = R_h \sin^2 \theta_B$ (Fig. 18.11). Both the source and the focus lie on the Rowland circle, forming an isosceles triangle with the crystal.

a)

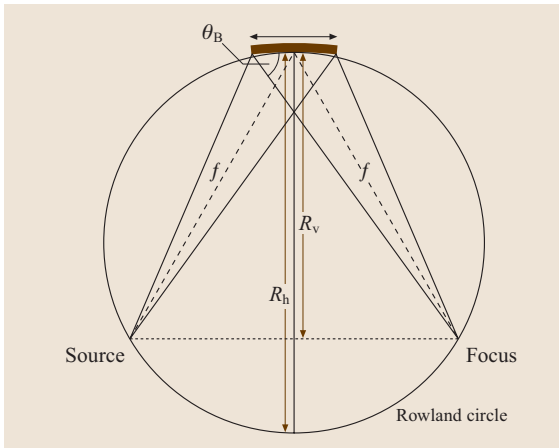
b)
Fig. 18.10 (a) Elliptical graded multilayer for focusing. **(b)** Parabolic graded multilayer for focusing and collimation. The period d changes as a function of position on the optic, locally adjusting the Bragg angle to the angle of reflection


Fig. 18.11 Focusing with a bent crystal optic in the Johann geometry. The source and focus position lie on the Rowland circle

full-field microscopy and to generate a small focus for scanning microscopy.

For larger and larger crystals, the surface deviates increasingly from the Rowland circle. To fulfill the Bragg condition strictly in that case, the crystal needs to be cut to follow the Rowland circle when bent. This is called the Johannson geometry, which is very difficult to realize and is therefore not used very often.

The bending of the crystal optic has to be very accurate in order to stay within the width of the Bragg reflection over the whole surface. In addition, the crystal must not be damaged. As this bending procedure is difficult, these optics are not very widespread.

Fresnel Zone Plates

The most important diffractive optical components are Fresnel zone plates. They have found very widespread applications, particularly at energies below a few keV, like for example in the water window. As a genuine imaging optic, they can be used as objective lens in

Fresnel zone plates consist in their simplest form of a set of alternating transparent and opaque rings (Fig. 18.12), so-called zones, with an optical path difference of $\lambda/2$ between neighboring zones. The amplitudes of all transparent zones superpose constructively when the radii of all zones are given by

$$r_n = \sqrt{n\lambda f + \frac{n^2\lambda^2}{4}}, \quad n = 0, 1, 2, \ldots, \quad (18.8)$$

where the even zones are transparent and odd zones are opaque. Here, f is the focal length of the optic for a given wavelength λ. In first diffraction order, the zone plate is most efficient, and about 10% of the radiation falling onto its aperture can be focused into this diffraction order. The spatial resolution depends on the numerical aperture $\mathrm{NA} = r_n/f$ and is in this case given by

$$d_t = 1.22\frac{\lambda}{2\mathrm{NA}} = 1.22\Delta r_n, \quad (18.9)$$

which is approximately equal to the width of the outermost zone Δr_n. The factor 1.22 comes from the Rayleigh criterion for the spatial resolution of a circular optic [18.37]. This means that the spatial resolution

Part D | 18.2

corresponds to that of the smallest features in the zone plate. For increasing X-ray energy, it becomes increasingly difficult to make a zone plate with opaque zones. Therefore, this type of optic is mostly used in the soft-X-ray regime, in particular in the so-called water window between the absorption edges of carbon and oxygen. As the opaque zones become more transparent, the zone plate loses its efficiency.

For harder X-rays one therefore pursues another scheme. Rather than blanking out the amplitudes of odd zones, one can shift them by π, adding to the constructive interference in the focus. Such phase zone plates are much more efficient than zone plates with opaque zones and have an optimal efficiency of about 40%. Despite this new scheme, the zones still need to have a thickness in the micrometer range for hard X-rays around 10 keV. To reach high spatial resolution efficiently the fabrication of very thin but high zone plate structures is required. While there have been tremendous improvements over the last view years, it is still a challenge to make these structures. However, there are several institutions and commercial sources for these optics. Another phase-shifting optic is a Bragg–Fresnel optic, in which the Fresnel zones are etched into a single crystal surface [18.38]. Tuned to Bragg condition, the X-rays are diffracted from different heights inside the zone plate structure. Refraction introduces the desired phase shift between the even and odd zones.

Currently, in the soft-X-ray range, zone plates with spatial resolution down to 15 nm have been made [18.39]. In the hard X-ray range, the high aspect ratio of the outermost zones currently limits the spatial resolution to about 50 nm [18.40, 41]. For such a high-resolution zone plate, the aperture is typically in the range of a couple of hundred microns and is made of several hundred zones.

As the aspect ratio increases with decreasing outermost zone width, the thin object approximation for the Fresnel zone plates becomes less appropriate. Propagation effects inside the zone plate structure need to be taken into account. It was shown theoretically that the zones of a zone plate need to be tilted to fulfill a local Bragg condition in order not to lose their focusing efficiency for smaller outermost zone widths [18.42]. While these structures are even more difficult to fabricate, they are predicted to be able to generate focal sizes down to 1 nm and below [18.43]. These structures are currently approximated by so-called multilayer Laue lenses [18.44–46]. Focusing down to below 20 nm has been demonstrated with these devices.

19. Radiation and Optics in the Atmosphere

This chapter describes the fundamentals of radiation transport in general and in the Earth's atmosphere. The role of atmospheric aerosol and clouds are discussed and the connections between radiation and climate are described. Finally, natural optical phenomena of the atmosphere are discussed.

There are a multitude of processes in which electromagnetic radiation interacts with the atmosphere:

- Absorption, i.e. radiation is removed from the radiation field and converted into some other form of energy, e.g. heat. Absorption can be due to molecules in the atmosphere (such as ozone, oxygen, or water vapor) or aerosols (such as soot), absorption of solar energy in the atmosphere is an important process in the climate system of the Earth.
- Elastic scattering, which – seen from an individual photon – changes its direction of propagation, but not its energy (and hence wavelength or 'color'). Scattering can be due to molecules (Rayleigh scattering) or aerosol particles (Mie scattering) present in the air.
- Inelastic scattering where, as for elastic scattering, the direction of a photon is changed but where its energy is also changed. Inelastic scattering by molecules is called Raman scattering, where the energy of the scattered photon can be reduced at the expense of energy transferred to the scattering molecule (Stokes scattering). Likewise, energy can be transferred from the (thermally excited) molecules to the photon (anti-Stokes scattering).
- Thermal emission from air molecules and aerosol particles. The emission at any given wavelength cannot exceed the Planck function (or emission from a black body) for the temperature of the atmosphere, thus noticeable thermal emission only takes place at infrared wavelengths longer than several micrometers. Due to Kirchhoff's law only absorbing gases (such as CO_2, H_2O, O_3, but not the main components of air N_2, O_2, Ar), can emit radiation.

- Aerosol fluorescence. Excitation of molecules within aerosol particles by radiation can result in

(broad band) fluorescence; this process will not be further discussed here.

19.1 Radiation Transport in the Earth's Atmosphere

In the following we introduce the basic quantities pertinent to the propagation of radiation in the atmosphere and discuss the fundamental laws governing radiation transport in absorbing and scattering media, i.e. the atmosphere.

19.1.1 Basic Quantities Related to Radiation Transport

A light source will emit a certain amount W of energy in the form of radiation.

1. The radiant flux Φ is defined as the radiation energy W per unit time (regardless of the direction in which it is emitted):

$$\Phi = \frac{\text{radiated energy}}{\text{time interval}} = \frac{\mathrm{d}W}{\mathrm{d}t} \quad \left[\frac{\mathrm{W\,s}}{\mathrm{s}} = \mathrm{W} \right]$$

(19.1)

2. The irradiance B is defined as the radiant flux Φ received by an ('illuminated') area A_e:

$$B = \frac{\Phi}{A_e} \quad \left[\frac{\mathrm{W}}{\mathrm{m}^2} \right] ;$$

(19.2)

3. The radiation intensity is ($\Omega = $ solid angle):

$$I = \frac{\Phi}{\Omega} \quad [\mathrm{W/sr}] ;$$

(19.3)

4. The radiance is ($A_s = $ radiating area):

$$F = \frac{\Phi}{\Omega A_s} \quad \left[\frac{\mathrm{W}}{\mathrm{m}^2\mathrm{sr}} \right] .$$

(19.4)

(All areas are assumed to be oriented perpendicular to the direction of propagation of the radiation.)

19.1.2 Absorption Processes

Radiation is absorbed by molecules in the atmosphere (such as ozone, oxygen, or water vapor), aerosol (such as soot) or liquid and solid water particles (cloud droplets (ice crystals)). Absorption of solar ultraviolet (UV) radiation at wavelengths below about 300 nm by atmospheric O_2 and O_3 is important for life on Earth.

19.1.3 Rayleigh Scattering

Elastic scattering (i.e. scattering without change of the photon energy) by air molecules is called Rayleigh scattering. While this is not an absorption process, light scattered out of the probing light beam will normally not reach the detector, thus for narrow beams it is justified to treat Rayleigh scattering as an absorption process. The Rayleigh scattering cross section $\sigma_R(\lambda)$ (in cm^2) is given by [19.1]:

$$\sigma_R(\lambda) = \frac{24\pi^3}{\lambda^4 N_{\mathrm{air}}^2} \frac{\left[n_0(\lambda)^2 - 1 \right]^2}{\left[n_0(\lambda)^2 + 2 \right]^2} F_K(\lambda)$$

$$\approx \frac{8\pi^3}{3\lambda^4 N_{\mathrm{air}}^2} \left[n_0(\lambda)^2 - 1 \right]^2 F_K(\lambda) ,$$

(19.5)

where: λ denotes the wavelength, $n_0(\lambda)$ is the real part of the wavelength-dependent index of refraction of air, N_{air} is the number density of air (e.g. 2.4×10^{19} molec/cm^3 at $20\,^\circ$C, 1 atm), $F_K(\lambda) \approx 1.061$ is a correction for anisotropy (polarisability of air molecules).

Note that $n_0(\lambda)^2 - 1 \approx 2[n_0(\lambda) - 1] \propto N_{\mathrm{air}}$, since $n_0 \approx 1$ [in fact n_0 (550 nm) = 1.000293], and $n_0 - 1 \propto N_{\mathrm{air}}$, thus $\sigma_R(\lambda)$ is essentially independent of N_{air}. On that basis a simplified expression for the Rayleigh scattering cross section (in cm^2) is given by *Nicolet* [19.2]

$$\sigma_R(\lambda) \approx \frac{4.02 \times 10^{-28}}{\lambda^{4+x}}$$

(19.6)

with

$$x = 0.04$$
$$\text{for} \quad \lambda > 0.55\,\mu\mathrm{m} ,$$
$$x = 0.389\lambda + 0.09426/\lambda - 0.3328$$
$$\text{for} \quad 0.2\,\mu\mathrm{m} < \lambda < 0.55\,\mu\mathrm{m} .$$

For these simple estimates the Rayleigh scattering cross section can be written as

$$\sigma_R(\lambda) \approx \sigma_{R_0} \lambda^{-4}$$
$$\left(\sigma_{R_0} \approx 4.4 \times 10^{-16}\,\mathrm{cm}^2\,\mathrm{nm}^4 \text{ for air} \right) .$$

(19.7)
Fig. 19.1 Polar diagram of the Rayleigh scattering phase function $\Phi(\vartheta)$ for unpolarized incident light (*dashed line*, normalized to 2). The contribution of light polarized parallel to the scattering plane shows the $\sin^2 \vartheta'$ dependence of a Hertz dipole (*dotted line*, normalized to 1), with $\vartheta' = \pi/2 - \vartheta$ being the angle between dipole axis and the Poynting vector of the incident radiation, while the contribution of light polarized perpendicular to the scattering plane (*drawn line*, normalized to 1) is independent of ϑ. (plot by F. Filsinger)

The extinction coefficient due to Rayleigh scattering $\varepsilon_R(\lambda)$ is then given by

$$\varepsilon_R(\lambda) = \sigma_R(\lambda) N_{air} . \tag{19.8}$$

The Rayleigh scattering phase function (see Fig. 19.1) is given by

$$\Phi(\cos \vartheta) = \frac{3}{4}(1 + \cos^2 \vartheta) . \tag{19.9}$$

Taking the anisotropy of the polarisability into account the above equations becomes [19.3]:

$$\Phi(\cos \vartheta) = 0.7629(0.9324 + \cos^2 \vartheta) . \tag{19.10}$$

19.1.4 Raman Scattering

While Raman (and Mie) scattering can be regarded as elastic scattering processes, where no energy is transferred between the scattering particle and the photon, inelastic scattering occurs, if the scattering particle (i. e.

molecule) changes its state of excitation during the scattering process. A part of the photons energy is then passed from the photon to the molecule (Stokes lines, $\Delta J = +2$, S-branch) or vice versa (anti-Stokes, $\Delta J = 2$, O-branch). The term rotational Raman scattering (RRS) is used if only the rotational excitation is affected ($\Delta v = 0$). If the vibrational state also changes, the term (rotational-) vibrational Raman scattering (VRS) is used ($\Delta v = \pm 1$). Only discrete amounts of energy given by the difference between the discrete excitation states can be absorbed/emitted. For air (O_2 and N_2) RRS frequency shifts of up to $\pm 200 \, \text{cm}^{-1}$ occur, for VRS a vibrational shift of $\pm 2331 \, \text{cm}^{-1}$ for nitrogen and $\pm 1555 \, \text{cm}^{-1}$ for oxygen has to be added. The VRS is one order of magnitude weaker than the RRS, and RRS is roughly one magnitude weaker than Rayleigh scattering.

In the following we give a quantitative description of rotational- and vibrational-Raman scattering by O_2 and N_2 [19.4–7]. The scattered power density $I_{v,J \to v',J'}$ in [W/m^2] scattered into the full solid angle 4π involving a transition ($v, J \to v', J'$) is given by [19.8]:

$$I_{v,J \to v',J'}$$
$$= I_0 \sigma_{v,J \to v',J'} L N_{air} g_J (2J+1) \frac{1}{Z} e^{-E(v,J)/kT} , \tag{19.11}$$

where I_0 is the incident power density, N_{air} is the number of molecules in the scattering volume, L is the length of the volume and g_J is the statistical weight factor of the initial rotational state due to the nuclear spin; J and v are the rotational and vibrational quantum numbers, respectively. The factor $(2J+1)$ accounts for the degeneracy due to the magnetic quantum numbers while $\exp[-E(v,J)/kT]$ accounts for the population of the initial state of the molecule at temperature T. The state sum Z is given by the product of the rotational state sum Z_{rot} and the vibrational state sum Z_{vib}. The absolute cross section in (19.11) is given by $\sigma_{v,J \to v',J'}$, which can be obtained by integration of the differential cross section $d\sigma_{v,J \to v',J'}/d\Omega$ over the entire solid angle Ω. Note that the term differential refers to the solid angle. The energy of the molecule is characterized by the vibrational (v) and rotational (J) quantum numbers and given by

$$E(v,J) = E_{vib}(v) + E_{rot}(J)$$
$$= hc\tilde{v}\left(v + \frac{1}{2}\right) + hcBJ(J+1) , \tag{19.12}$$

assuming no coupling between rotation and vibration, B is the rotational constant and $\tilde{v}$ is the wave number in

cm^{-1} of the ground state vibration. Allowed transitions are, in that approximation, $\Delta J = 0, \pm 2$ resulting in the Q-, O- and S-branches and $\Delta v = 0, \pm 1$ for vibrational transitions. Due to the temperatures in the Earth's atmosphere only the ground vibrational state is occupied significantly, thus leading only to Stokes transitions of the vibrational states.

Polarization Properties of Vibrational Raman Scattered Light and Line Filling in

The polarization properties of isotropic and anisotropic component of Raman scattered light are described by (19.13), respectively:

$$\frac{I_{parallel}}{I_{perp}}(\text{anisotropic}) = \frac{6 + \cos^2 \Theta}{7} \ ,$$

$$\frac{I_{parallel}}{I_{perp}}(\text{isotropic}) = \cos^2 \Theta \ , \qquad (19.13)$$

where the terms parallel and perpendicular refer to the plane defined by the sun, the scattering point and the observer. Thus only the isotropic part leads to enhanced polarization of scattered light, especially at large scattering angles ($\approx$ solar zenith angle (SZA)). Since the Q-branch of the vibrational band of the Raman-scattered light consists of an isotropic fraction, this will lead to an enhanced degree of polarization in the centre of a Fraunhofer line. But due to the small cross section of vibrational Raman scattering, this enhancement is very small (e.g. $\cong 0.3\%$ for the Ca–I line at 422.7 nm and a resolution of 0.01 nm) and occurs only at large scattering angles. Thus the observed high degrees of polarization at small solar zenith angles cannot be attributed to vibrational Raman scattering [19.9].

Due to the relative small cross section of vibrational–rotational Raman scattering the additional filling in of Fraunhofer or terrestrial absorption lines is around 10% of the filling in due to rotational Raman scattering (see Table 19.1).

19.1.5 Mie Scattering

Mie scattering is (after [19.10]) defined as the interaction of light with (particulate) matter of dimensions comparable to the wavelength of the incident radiation. It can be regarded as the radiation resulting from a large number of coherently excited elementary emitters (i. e. molecules) in a particle. Since the linear dimension of the particle is comparable to the wavelength of the radiation, interference effects occur. The most noticeable difference compared to Rayleigh scattering is the usu-

Table 19.1 Comparison of the total cross section for the different scattering types for 770 nm, 273 K

Scattering type	Cross section (cm^2)	Ratio (%)
Rayleigh	1.156×10^{-27}	100
O$_2$ RRS	7.10×10^{-29}	6.1
N$_2$ RRS	2.94×10^{-29}	2.5
Air RRS	3.82×10^{-29}	3.3
VRS	–	0.1

ally much weaker wavelength dependence (see below) and a strong dominance of the forward direction in the scattered light. The calculation of the Mie scattering cross section can be very complicated (involving summing over slowly converging series), even for spherical particles, but even more so for particles of arbitrary shape. However, the Mie theory (for spherical particles) is well-developed and a number of numerical models exist to calculate scattering phase functions and extinction coefficients for given aerosol types and particle size distributions see Figs. 19.2, 19.17 [19.11, 12]. The computational effort is substantially reduced by the introduction of an analytical expression for the scattering phase function, which only depends on a few observable parameters. Most common is the Henyey–Greenstein parameterization:

$$\Phi(\cos \vartheta) = \frac{(1 - g^2)}{4\pi(1 + g^2 - 2g \cos \theta)^{3/2}} \ , \qquad (19.14)$$

which only depends on the asymmetry factor g (average cosine of the scattering function):

$$g = \langle \cos \theta \rangle = \frac{1}{2} \int_{-1}^{1} P(\cos \theta) \cos \theta \, d \cos \theta \qquad (19.15)$$

see e.g. [19.11]. For isotropic scattering [$\Phi(\cos \theta) = $ const] the asymmetry factor $g = 0$ while for a tropospheric aerosol a typical value might be as large as $g \approx 10$.

Tropospheric aerosol is either emitted from the surface (e.g. sea salt, mineral dust, biomass burning) or forms in the gas phase by condensation of chemically formed hygroscopic species (primarily sulphates, nitrates, or oxidized organic material). The aerosol load of the atmosphere, i. e. particle number density and size distribution, depends on the aerosol origin and history. Parameters for typical aerosol scenarios (urban, rural, maritime, background) can be found in the database for the radiative transfer model LOWTRAN [19.13], which includes the extinction coefficients and the asymmetry

factors as well as their spectral dependence. Another important aspect is Mie scattering by cloud particles. A radiative transfer model including all cloud effects known to date was, e.g., developed by *Funk* [19.14].

Mie scattering is only partly an absorption process, but by similar arguments as in the case of Rayleigh scattering, for narrow beams it can be treated as an absorption process with an extinction coefficient of

$$\varepsilon_M(\lambda) = \varepsilon_{M0}\lambda^{-\alpha} \qquad (19.16)$$

with the Ångström exponent α being inversely related to the mean aerosol particle radius. Typically α is found to be in the range 0.5–2.5 with an average value of $\alpha = 1.3$ [19.15, 16]. For the ideal case of an exponential aerosol size distribution:

$$\frac{\Delta N}{\Delta r} = r^{-(\nu+1)} .$$

The Ångström exponent is related to the Junge index ν by $\nu = \alpha + 2$ [19.17]. Thus an Ångström exponent of 1.3 would correspond to a Junge index of 3.3.

In summary a more comprehensive description of atmospheric extinction (in the presence of a single trace gas species and neglecting Raman scattering) can be expressed as:

$$I(\lambda) = I_0(\lambda) \exp\left\{ -L[\sigma(\lambda)c + \varepsilon_R(\lambda) + \varepsilon_M(\lambda)] \right\} . \qquad (19.17)$$

Typical extinction coefficients due to Rayleigh and Mie scattering at 300 nm are 1.3×10^{-6} cm^{-1} and $1-10 \times 10^{-6}$ cm^{-1}, respectively.

19.2 The Radiation Transport Equation

In this section we present the basic equations describing the radiation transport (RT) in absorbing and scattering media as described by the above elementary processes. In physical notation the RT equation is a continuity equation with corresponding source and sink terms (Fig. 19.3); these source and sink terms are assumed to be linear in the radiant flux Φ, intensity I, or radiance F (19.1, 19.3, 19.4).

19.2.1 Sink Terms (Extinction)

First we consider the radiant flux Φ per unit space angle Ω and wavelength λ i.e., the incoming intensity I_λ (19.3) which is attenuated within the distance

ds by absorption and scattering. As before we refer to the absorption (a) and scattering (s) coefficients with $\varepsilon_a = N\sigma_a(\lambda)$ and $\varepsilon_s = N\sigma_s(\lambda)$, respectively, with N being the number of absorber or scatterers per volume and $\sigma_i(\lambda)$ being absorption or scattering cross sections. Both processes are commonly referred to as extinction. Accordingly, we obtain the following continuity equation for the incoming intensity traversing the distance ds

$$\begin{aligned} dI_\lambda &= -[\varepsilon_a(\lambda) + \varepsilon_s(\lambda)]I_\lambda \, ds \\ &= -[\sigma_a(\lambda) + \sigma_s(\lambda)]nI_\lambda \, ds , \end{aligned} \qquad (19.18)$$

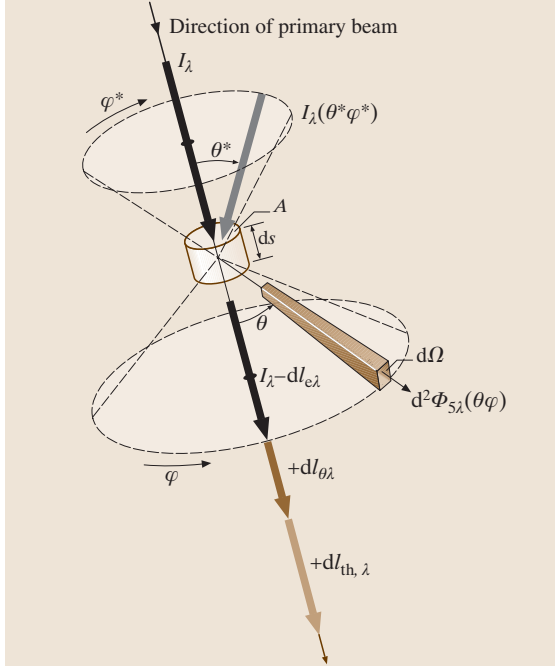
where ε_a is the absorption coefficient, ε_s is the scattering coefficient, $\sigma_a(\lambda)$ is the absorption cross section of the


Fig. 19.3 Schematic drawing of the continuity equation for radiative transfer. The continuity assumes linearity of processes in the intensity I_λ. When passing through a distance ds the incoming radiation I_λ is attenuated by extinction (absorption and scattering), $I_{e,\lambda}$. The source term for the outgoing light is the scattered light $dI^*_{s,\lambda}$ from the space angles θ^* and φ^* and thermal radiation $dI^*_{th,\lambda}$ (courtesy of Rödel, 1999)

absorber (molecule), $\sigma_s(\lambda)$ is the scattering cross section of the absorber (molecule), and n is the number of absorbers per unit volume.

19.2.2 Source Terms (Scattering and Thermal Emission)

In the gas phase there are two sources of radiation: thermal emission and scattering, i.e. the radiation removed from the primary beam due to scattering (19.18) reappears as a radiation source.

Scattering

Evidently, the outgoing light receives some intensity $dI^*_{s,\lambda}$, by scattering from all space angles θ^* and φ^*. We introduce a dimensionless scattering function $S(\theta^*, \varphi^*)$

$$S_\lambda(\theta, \varphi) = \frac{4\pi}{\sigma_s} \frac{d\sigma_s(\lambda)}{d\Omega} \qquad (19.19)$$

which we integrate over all angles weighted with the incoming intensity $I^*_s, \lambda(\theta^*, \varphi^*)$

$$dI^*_s(\lambda) = \varepsilon_s(\lambda) ds \int_0^\pi \int_0^{2\pi} I^*(\lambda, \theta^*, \varphi^*)$$
$$\times \frac{S(\theta^*, \varphi^*)}{4\pi} d\varphi^* \sin\theta^* d\theta^* \qquad (19.20)$$

to obtain the intensity added to the outgoing intensity dI^*_s.

Thermal Emission

Finally the intensity due to thermal emission $dI_{th}(\lambda, T)$ by the volume element ($dV = A\,ds$) is added to the outgoing intensity

$$dI_{th}(\lambda, T) = \varepsilon_a(\lambda) I_p(\lambda, T) ds = \varepsilon_a(\lambda) F_p(\lambda, T) A\,ds \qquad (19.21)$$

where, as before, K_a denotes the absorption coefficient and $F_P(\lambda, T)$ denotes the Planck function

$$dF_P(\lambda, T) = \frac{2hc^2}{\lambda^5} \frac{d\lambda}{e^{hc/\lambda kT} - 1} . \qquad (19.22)$$

Combining the above source and sink terms we obtain the radiation transport equation (19.23):

$$\frac{dI(\lambda)}{ds}$$
$$= -[\varepsilon_a(\lambda) + \varepsilon_s(\lambda)]I(\lambda) + \varepsilon_a(\lambda)I_P(\lambda, T) + \varepsilon_s(\lambda)$$
$$\times \int_0^\pi \int_0^{2\pi} I^*(\lambda, \theta^*, \varphi^*) \frac{S(\theta^*, \varphi^*)}{4\pi} d\varphi^* \sin\theta^* d\theta^*$$
$$\qquad (19.23)$$

19.2.3 Simplification of the Radiation Transport Equation

Frequently simplifications of the radiation transport equation are possible, if only partial systems are of interest.

For instance at short wavelengths (UV, visible) the Planck term can usually be neglected:

$$\frac{dI(\lambda)}{ds} = -[\varepsilon_a(\lambda) + \varepsilon_s(\lambda)]I(\lambda) + \varepsilon_s(\lambda)$$
$$\times \int_0^\pi \int_0^{2\pi} F(\lambda, \theta, \varphi) \frac{S(\theta, \varphi)}{4\pi} d\varphi \sin\theta\, d\theta . \qquad (19.24)$$

If thermal radiation (from the atmosphere) is of interest due to its long wavelength, Rayleigh and Mie scattering

(by aerosol particles and cloud droplets) can frequently be neglected

$$\frac{dI(\lambda)}{ds} = \varepsilon_a(\lambda)[A F_P(\lambda, T) - I(\lambda)] \,. \tag{19.25}$$

With the definition of the optical density $d\tau = \varepsilon_a(\lambda)\,ds$ and after division by A the above equation becomes

$$\frac{dF(\lambda)}{d\tau} = F_P(\lambda, T) - F(\lambda) \,. \tag{19.26}$$

This latter equation is also known as the Schwarzschild equation.

19.2.4 Light Attenuation in the Atmosphere

When considering the question of the attenuation of radiation in the atmosphere, two (extreme) cases can be distinguished, as illustrated in Fig. 19.4: wide beams (WB, as e.g. the illumination of the Earth's atmosphere by the sun) and narrow beams (NB, as e.g. the light beam emitted by a searchlight-type differential optical absorption spectroscopy (DOAS) light source).

Wide Beams (WB) in the Atmosphere: The Two-Stream Model

In the following we consider the transport of solar radiation in the atmosphere. Compared to the general form of the radiation transport equation (19.23) the problem is simplified by assuming a flat, horizontally homogeneous and infinite atmosphere. Therefore only the vertical (z) component of the radiance has to be considered.

When radiation enters the atmosphere from above, its vertical component is counted as 'downwelling radiation' $F_\downarrow(\lambda, z)$; upon interaction with atmospheric constituents (gases or aerosol) this radiation is either absorbed or scattered (Fig. 19.5). These extinction processes reduce the amount of downwelling radiation (according to (19.17) where the extension of the light path for non-vertical rays has to be taken into account). While the absorbed radiation causes no further problems, the scattered radiation appears as a source term, which is split into two parts (taking the phase function into account): A downwelling part, which adds to $F_\downarrow(\lambda, z)$ and an upwelling part, which is added to a second, upwelling radiation flux $F_\uparrow(\lambda, z)$. Thermal emission adds to both, $F_\downarrow(\lambda, z)$ and $F_\uparrow(\lambda, z)$. For practical calculation the atmosphere is divided into layers of thickness dz, which change the

Fig. 19.4 Difference between Wide Beams (WB, *top*) as, e.g., the illumination of the Earth's atmosphere by the sun, and Narrow Beams (NB, *bottom*) as, e.g., the light beam emitted by a searchlight-type light source. In the NB case the probability of a photon being scattered back into the beam after being scattered out of the beam is generally negligible, therefore extinction can be treated like absorption. In the case of a WB the lateral (i.e. perpendicular to the propagation of the incident radiation flux) radiation flux can be neglected. Therefore the scattering has only the effect of reflecting some of the incoming light, as can be calculated by, e.g., a two-stream model (see above)

Fig. 19.5 The two-stream model. In a horizontally homogeneous atmosphere radiation transport can be represented by just two 'streams of radiation', the downwelling flux and the upwelling flux

radiance F traversing it by $\mathrm{d}F$. The net radiance is composed of both components (up- and downwelling radiances)

$$F_n(\lambda, z) = F_\uparrow(\lambda, z) - F_\downarrow(\lambda, z) \,. \tag{19.27}$$

Narrow Beams (NB) in the Atmosphere

In the case of a WB the lateral (i. e. perpendicular to the propagation of the incident radiation flux) radiation flux can be neglected. Therefore the scattering has only the effect of reflecting some of the incoming light, as can be calculated by e.g. a two-stream model (see above).

In contrast, in the case of narrow beams the probability of a photon being scattered back into the beam after being scattered out of the beam is generally negligible (Fig. 19.4), therefore extinction can be treated as absorption.

The attenuation of a light beam by extinction due to atmospheric constituents is in principle described by (19.17). For practical purposes of measurements in the atmosphere, however, (19.17) is oversimplified in that it neglects the presence of other causes of light extinction, including absorption by other molecules present in the atmosphere.

In the natural atmosphere many different molecular species will absorb light. Equation (19.17) must therefore be further extended to

$$\begin{aligned} &I(\lambda) \\ &= I_0(\lambda) \exp\left(-L\{\Sigma[\sigma_i(\lambda)c_i] + \varepsilon_R(\lambda) + \varepsilon_M(\lambda)\}\right), \end{aligned} \tag{19.28}$$

where $\sigma_i(\lambda)$ and c_i denote the absorption cross section and the concentration of the i-th species, respectively.

19.3 Aerosols and Clouds

Aerosols are a natural constituent of the Earth's atmosphere and their origin is mostly natural, although lately the anthropogenic contribution is increasing. An aerosol is defined as a stable suspension of particles, liquid or solid, in a carrier gas like atmospheric air. Therefore dust, haze, smoke, smog, fog, mist, and clouds can be considered to be specific aerosol types. The total mass of natural aerosols was found be four times larger than due to human activity in 1968, and by the year 2000 the anthropogenic contribution is estimated to have doubled. According to *Junge* and *Manson* [19.18], aerosols can be classified by sizes: particles with diameters below 0.1 mm are named Aitken particles, while those with sizes between 0.1−1 mm are "large" particles, and those larger than 1 mm are called "giant" particles. The aerosols may also be classified according to their origin into marine, continental, rural, remote, background, and urban aerosol, where each category has different characteristics like chemical composition, size distribution, shapes and so on. Aitken nuclei, i. e. the smallest atmospheric aerosol particles, are naturally produced from supersaturated vapors by a process called gas-to-particle conversion (GPC), often in connection with photochemical reactions between gas-phase constituents (Fig. 19.6). Anthropogenic activities such as combustion and industrial processes increasingly lead to the release of aerosol particles, or precursor gases from which aerosol particles are formed, into the atmosphere. Large aerosol particles can be produced by combustion processes and other an-

thropogenic or natural processes (e.g. the coagulation of smaller Aitken nuclei). Natural sources for giant particles are bulk-to-particle conversion (BPC) processes like sea-salt aerosol production, or desert dust mobilization, while human activity contributes, for example through emission from industries, mining, biomass and wood burning, and agricultural dust generation.

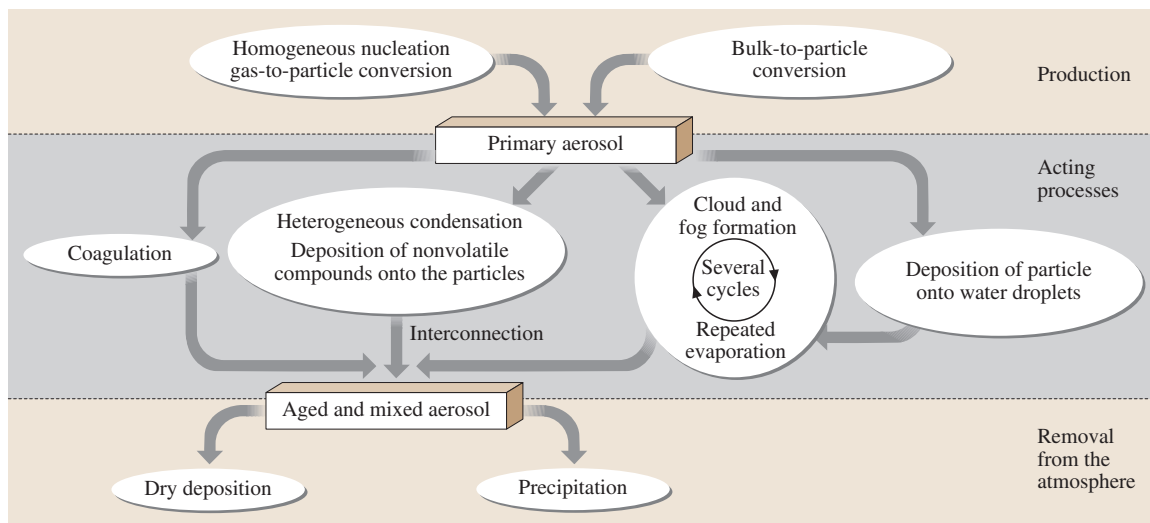
In the atmosphere, typical particle number concentration decreases with increasing particle size since Aitken particles are newly produced; they subsequently coagulate and form fewer larger particles. Accordingly Aitken particles usually dominate the total number of particles in an air sample, but their contribution to the total aerosol volume is small, whilst an increasing contribution is due to the large and giant particles. Conversely, Aitken particles often dominate the surface available for heterogeneous reactions. For particles with sizes ranging from a few nanometers up to tens of micrometers typical number concentrations can be coarsely specified. For example, typical aerosol numbers are: 1) $\approx 1.4 \times 10^4\,\mathrm{cm}^{-3}$ at the (continental) ground level total concentrations, 2) $\approx 6 \times 10^2\,\mathrm{cm}^{-3}$ in remote continental regions, 3) $10^5\,\mathrm{cm}^{-3}$ in large cities, 4) $\approx 3 \times 10^4\,\mathrm{cm}^{-3}$ in small towns, 5) $\approx 5 \times 10^2\,\mathrm{cm}^{-3}$ over remote oceans, 6) $\approx 50\,\mathrm{cm}^{-3}$ in the clean Arctic, and 7) even lower in the remote Antarctica. The vertical aerosol profiles (in number of particles per cubic centimeter of air) frequently show an exponential decay for the lowest 6 km of the atmosphere. Above


Fig. 19.6 Aerosol-related processes in the atmosphere involving particle formation, processes altering particle characteristics, and removal from the atmosphere

this level, background tropospheric aerosol concentrations (in the Aitken mode) are around $200-300$ particles per cm^3. Above the tropopause up to around $30\,km$, the total number concentration decreases again to a minimum below $1-10\,cm^{-3}$ particles in volcanically quiet periods and $1000\,cm^{-3}$ after major volcanic eruptions.

At any time, about 50% of the globe is cloud covered. Atmospheric clouds are volumes of water-supersaturated air containing hydrometeors, which are microscopic objects (e.g. aerosol particles, cloud droplets, ice and snow crystals) as well as macroscopic objects (snowflakes, graupel grains, raindrops, and hailstones). The individual cloud particles have sizes with radii ranging from $0.001\,mm$ to several hundreds of micrometers, or even centimeters, as in the case of hailstones.

Atmospheric clouds can be classified into four major categories: 1) low-level cloud in the lower troposphere ($< 2.5\,km$), 2) middle-level clouds in the middle troposphere ($2.5-8\,km$), 3) higher clouds in the upper troposphere ($8-15\,km$), and 4) middle (stratospheric) and upper (mesospheric) atmospheric clouds, which themselves form 11 major subgroups (1.1 cumulus, 1.2 stratocumulus, 1.3 stratus, 2.1 altocumulus, 2.2 altostratus, 2.3 nimbostratus, 3.1 cirrus and cirrostratus, 3.2 cirrocumulus, 3.3 cumulonimbus, 4.1 polar stratospheric clouds, and 4.2 noctilucent clouds) of some 100 different cloud types in total.

Both aerosols and clouds have a considerable impact on atmospheric photochemistry and radiation. Their effects in atmospheric photochemistry are most noticeably in: 1) the heterogeneous processing of longer-lived and ozone-friendly halogen species ($ClONO_2$, HCl, $BrONO_2$,...) into ozone-harmful halogen oxides (ClO, BrO) on polar stratospheric cloud particles, which is a major reason for the formation of the Antarctic ozone hole, 2) uptake of acids (e.g., H_2SO_4, HNO_3, HCl, HBr,...) and of N_2O_5 on the stratospheric or tropospheric aerosols and cloud particles, 3) in the heterogeneous conversion of SO_2 into H_2SO_4, or NO_3 and N_2O_5 into HNO_3 and 4) the uptake of species such as NH_3HNO_3, or NH_4HSO_4 into atmospheric aerosols and cloud particles. Eventually when these particles grow large enough ($>$ some μm), the respective gases attached or solved inside are efficiently washed out from the atmosphere.

Aerosols and clouds also have a large effect on the radiative budget of the atmosphere, primarily by increasing the scattering of the incoming solar and outgoing thermal radiation. Clouds affect radiation both through their three-dimensional geometry and the amount, size and nature of the hydrometeors which they contain. In climate models these properties translate into cloud cover at different levels, cloud water content (for liquid water and ice) and cloud droplet (or crystal) equivalent radius. The interaction of clouds and radiation also involves other parameters (asymmetry factor of the Mie diffusion) which depend on cloud composition, and most notably on their phase.

Part D | 19.3

In effect, the occurrence of aerosols and clouds increases the planetary albedo A of the solar short-wave (SW) radiation, and thus lead to a net cooling of the Earth. Conversely clouds, and to a much lesser degree aerosols, increase the infrared albedo B of the atmosphere and thus increase the downwelling atmospheric long-wave (LW) radiation which increases the surface temperature. The subtle balance between cloud impact on the SW and terrestrial long-wave radiation altered by a change in any of the aforementioned parameters, the dependence of the radiation budget on altitude at which clouds occur and the solar inclination (latitude and season) make clouds the most sensitive factors to affect the global climate in both directions (cooling/warming).

19.4 Radiation and Climate

The atmospheric radiation budget largely determines the Earth's climate. Evidently the incoming solar or short-wave (SW) radiation shining on the globe has to be balanced by the outgoing long-wave (LW) radiation. This thermal equilibrium between incoming SW and outgoing LW radiation and can be simply expressed by

$$S_0(1 - A)/4 = \varepsilon(1 - B)\sigma T_s^4 \tag{19.29}$$

where S_0 is the solar constant ($1370\,\text{W/m}^2$), A is the terrestrial SW albedo (0.298), the factor 4 coming from geometric considerations, ε is the LW emissivity (0.96), B is the atmospheric LW albedo (0.34), σ is Boltzmann's constant ($5.67 \times 10^{-8}\,\text{W/m}^2/\text{K}$), and T_s is the average temperature ($T_s = 286\,\text{K}$) of the Earth's surface. It thus becomes clear that the globe's surface temperature T_s is given by a delicate balance of the parameters S_0, A, and B. In geological and historic

Table 19.2 Compendium of change in recognized periods in climate change and changes in the solar constant S_0

Time scale/period	Cause	Change in solar constant S_0	Observation/problem
4.5 Ga	Secular trend in solar output	Secular 25–30% increase	'Faint Sun problem', i. e. liquid H_2O should not have been there, but was present since 4 Ga before present
450 ka	Change in orbital eccentricity $\Delta\varepsilon = 0.06$	$< 0.7\,\text{W/m}^2$ (Milankovitch)	Change in ice volume, $\Delta^{18}O/^{16}O$ in H_2O and $CaCO_3$ in foraminifera
100 ka	Change in orbital eccentricity $\Delta\varepsilon = 0.06$	$< 0.7\,\text{W/m}^2$ (Milankovitch)	Change in ice volume, $\Delta^{18}O/^{16}O$ in H_2O and $CaCO_3$ in foraminifera
41 ka	Change in obliquity (axial tilt) due to Earth and Jupiter's orbital plane tilt	June insulation changed by 25% at 80°N, no net change on annual S_0 (Milankovitch)	Change in ice volume, $\Delta^{18}O/^{16}O$ in H_2O and $CaCO_3$ in foraminifera
23 ka		June insulation changed by $100\,\text{W/m}^2$ at 60° N, no net change on annual S_0 (Milankovitch)	Change in ice volume, $\Delta^{18}O/^{16}O$ in H_2O and $CaCO_3$ in foraminifera
1.5 ka	Unclear whether cause is solar, 'eigenmode' of the climate system?		^{14}C and ^{10}Be variation in oceanic sediments, ^{14}C variation in tree rings

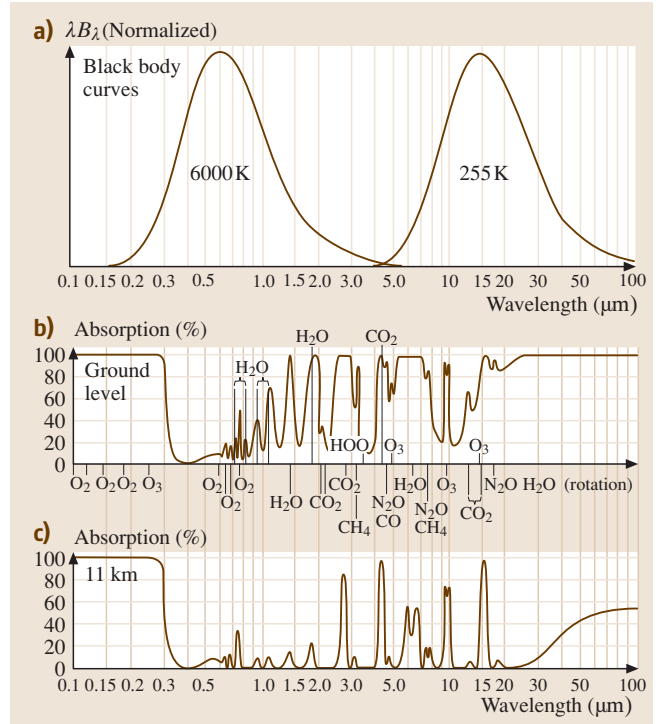
22a	Sun spot 'overtone', eigenmode in solar magnetic field oscillation	$\Delta S_0 \approx 1.5\,\text{W/m}^2$, UV radiation changes by 0.37–0.6%	Change in atmospheric circulation?
11a (Schwabe 1843)	Sun spot 'overtone', eigenmode in solar magnetic field oscillation		Change in atmospheric circulation?
4w (27d)	Sun rotation period	Small	?

Fig. 19.7a−c Schematic overview of the SW (*left part*) and LW (*right part*) radiative transfer in the atmosphere; *upper panel*: **(a)** incoming solar SW and outgoing LW terrestrial spectrum, **(b)** atmospheric absorption from individual gases at ground level (total atmosphere) and **(c)** at 11 km

times, the solar constant is known to have varied on different timescales, mostly given by changes in the Earth's orbital parameters, as suggested by *Milankovitch* in 1941 [19.19] and solar activity (Table 19.2), causing well recognized and significant effects on the Earth's climate. In this context, most notable is that the size ΔS_0 of any of the known processes listed in Table 19.2 has not been sufficiently large to be held solely responsible for documented ΔT_s changes, which were inferred to be as large as some $10\,°C$. Therefore, it is well accepted that the global climate system amplifies external disturbances (forcing) through interacting complicated positive and negative feedback cycles (Table 19.2).

Another factor important for T_s is of course the magnitude and variability of the SW albedo A (19.35). This is largely influenced by the amount of cloud and the abundance of atmospheric aerosol; the latter is either due to increasing directly back reflection of SW radiation to space, or by altering the cloud particle formation processes, a process called the indirect aerosol effect [19.20, 21]. In the recent past changes in the global albedo due to increasing atmospheric aerosol abundances, mostly particles containing sulphuric acid has been well recognized and held partly responsible for lower global T_s between the late 1940s to late


1970s [19.20]. Changing global cloud cover is also likely to have occurred in the past. In the tropics, which are a particularly sensitive region for the global energy budget, the cloud cover appears to be highly variable on timescales ranging from days to decades. Accordingly, satellite-based cloud cover records that began in the late
Fig. 19.8 External factors which force climate change (adopted from IPCC, 2001)

1970s are still insufficiently long to establish unambiguously an observation-based relation between a changing A and T_s [19.22].

The atmospheric LW albedo B is responsible for the greenhouse effect of the atmosphere. If B were zero, then according to (19.35), T_s would be 255 K, clearly cooler than the habitable Earth is able to provide ($T_s = 287$ K). The value of B is due to the combined action of the most important atmospheric greenhouse gases H_2O, CO_2, CH_4, O_3, N_2O, and many others, mostly man-made, trace molecules [19.20]. It appears that, even though each greenhouse gas has its own specific spectrum, they combine in a way that only a small fraction of the outgoing LW radiation is not absorbed in the atmosphere, i.e., radiation in the atmospheric window ($8-14\,\mu$m) (Fig. 19.7).

In 1896, the atmospheric greenhouse effect of CO_2 was already recognized by S. Arrhenius. Accordingly it is undisputed in the scientific community that rising atmospheric CO_2 concentrations affect the atmospheric LW budget and thus T_s. Radiative transfer calculations show that the CO_2 increase from preindustrial 280 ppm to presently 370 ppm alone gives rise to a present radiative forcing of $1.4\,\mathrm{W/m}^2$ and for all greenhouse gases of $2.4\,\mathrm{W/m}^2$ ([19.20], Fig. 19.8). Naively adding the respective radiative forcing in (19.18) leads to a $\Delta T_s = +0.7$ K, precisely the value that is reported for the global average temperature rise in the past 150 y [19.20]. However, due to the complicated interactions in the climate system, it is disputed how the global climate system is and will react in detail to future man-induced LW radiative forcing.

19.5 Applied Radiation Transport: Remote Sensing of Atmospheric Properties

19.5.1 Trace Gases

Measurements of trace gas concentrations (and other quantities such as aerosol distribution or the intensity of the radiation field in the atmosphere) are the experimental prerequisites for the understanding of the physico-chemical processes in the Earth's atmosphere. At the same time the determination of trace gas concentrations in the atmosphere constitutes a challenge for the analytical techniques employed in several respects: It is well known (e.g. *Perner* et al. [19.23]) that species (such as OH radicals) present at mixing rations ranging from as low as 0.1 ppt (one ppt corresponds to a mixing ratio of 10^{-12}, equivalent to about 2.4×10^7 molecules/cm^3) to several ppb (1 ppb corresponds to a mixing ratio of 10^{-9}) can have a significant influence on the chemical processes in the atmosphere. Thus, detection limits from below 0.1 ppt to the ppb range are required, depending on the application. On the other hand, measurement techniques must be specific, i.e. the result of the measurement of a particular species should neither be positively nor negatively influenced by any other trace species simultaneously present in the probed volume of air. Given the large number of different molecules present at the ppt and ppb level, even in clean air, meeting this requirement is also not trivial.

Presently many highly sophisticated techniques for the measurement of atmospheric trace species are in use. Among these, spectroscopic techniques [19.24, 25] offer

a series of unique advantages including high (i.e. ppt-level in many cases) sensitivity, very specific detection of a given molecule, inherent calibration, and wall-free operation. These properties, in combination, are difficult to obtain in techniques based on other principles. Here we describe a particular technique, differential optical absorption spectroscopy (DOAS), which has been successfully used in atmospheric measurements for several decades now, while new applications continue to be introduced.

19.5.2 The Fundamentals of DOAS

The DOAS technique [19.26, 27] makes use of the structured absorption of trace gases. Typically spectra are recorded which encompass several hundred spectral channels. Evaluation is done by fitting the spectral structure of the trace gases, thus making use of all the spectral information. DOAS has proven to be particularly useful for the determination of the concentration of unstable species such as free radicals or nitrous acid. In addition, the abundance of aromatic species can be determined at high sensitivity (see below). DOAS, like all spectroscopic techniques, relies on the absorption of electromagnetic radiation by matter. Quantitatively the absorption of radiation is expressed by the Lambert–Beers law:

$$I(\lambda) = I_0(\lambda) \exp[-L\sigma(\lambda)c] \,, \tag{19.30}$$

where $I(\lambda)$ is the intensity after passing through a layer of thickness L, while $I_0(\lambda)$ denotes the initial intensity emitted by the light source. The species to be measured is present at the concentration (number density) N_c. The quantity $\sigma(\lambda)$ denotes the absorption cross section at the wavelength λ; it is a characteristic property of any species. The absorption cross section $\sigma(\lambda)$ can be measured in the laboratory, while the determination of the light path length L is trivial in the case of the arrangement of an artificial light source and detector (Fig. 19.9, arrangement a). Once those quantities are known, the trace gas concentration c can be calculated from the measured ratio $I_0(\lambda)/I(\lambda)$. In contrast to laboratory spectroscopy, the true intensity $I_0(\lambda)$, as would be received from the light source in the absence of any absorption, is usually difficult to determine when measurements are made in the open atmosphere or in smog chambers. The solution lies in measuring the so-called differential absorption. This quantity can be defined as the part of the total absorption of any molecule rapidly varying with wavelength and is readily observable, as will be shown below. Accordingly, the absorption cross section of a given molecule (numbered i) can be split into two portions:

$$\sigma_i(\lambda) = \sigma_{i0}(\lambda) + \sigma_i'(\lambda) , \tag{19.31}$$

where $\sigma_{i0}(\lambda)$ varies only slowly with the wavelength λ, for instance describing a general slope, while $\sigma_i(\lambda)$ shows rapid variations with λ, for instance due to an absorption line. The meaning of rapid and slow (or rather smooth and structured) variation of the absorption cross section as a function of wavelength is, of course, a question of the observed wavelength interval and the width of the absorption bands to be detected. Note that extinction due to Rayleigh and Mie scattering can be assumed to be slowly varying with λ. Thus (19.30) becomes

$$\begin{aligned} I(\lambda) = {} & I_0(\lambda) \exp\left\{-L\,\Sigma\left[\sigma_i'(\lambda)N_{ci}\right]\right\} \\ & \times \exp\left(-L\{\Sigma[\sigma_{i0}(\lambda)c_i] + \varepsilon_R(\lambda) + \varepsilon_M(\lambda)\}\right) \\ & \times A(\lambda) , \end{aligned} \tag{19.32}$$

where the first exponential function describes the effect of the structured, differential absorption of trace species, while the second exponential constitutes the slowly varying absorption of atmospheric trace gases as well as the influence of Mie and Rayleigh scattering described by the extinction coefficients $\varepsilon_R(\lambda)$ and $\varepsilon_M(\lambda)$, respectively. The attenuation factor $A(\lambda)$ describes the (slow) wavelength-dependent transmission of the optical system used. Thus we can define a quantity I_0' as the intensity in the absence of differential absorption:

$$\begin{aligned} I_0'(\lambda) \\ = {} & I_0(\lambda) \times A(\lambda) \\ & \times \exp\left(-L\{\Sigma[\sigma_{i0}(\lambda)N_{ci}] + \varepsilon_R(\lambda) + \varepsilon_M(\lambda)\}\right) . \end{aligned} \tag{19.33}$$
Fig. 19.9a–c The active DOAS principle can be applied in several light-path arrangements and observation modes using artificial light sources such as arc lamps or incandescent lamps in a searchlight-type arrangement, or lasers. The light-path-averaged trace gas concentration is determined in the 'traditional' setup **(a)**. In situ concentrations are measured with multiple reflection cells **(b)**. The new 'tomographic' arrangement **(c)** employing many DOAS light paths allows mapping of (two- or three-dimensional) trace gas distributions

Fortunately the effect of slowly varying absorbers, i. e. the exponential in (19.33), can be removed by high-pass filtering the spectral data, thus only the first exponential function in (19.32) remains, which is essentially Lambert–Beers law [(19.30) for more than one absorber]. It should be noted that the length of the light path is more difficult to determine – or might actually not have a precise meaning – in applications where direct or scattered sunlight is used (arrangements d, e, and f and Fig. 19.11), in this case the column density S of the trace gas

$$S = \int_0^\infty N_c(l)\,\mathrm{d}l \qquad (19.34)$$

can still be determined. In the case of a constant trace gas concentration $N_{c_0}(l) = c_0$ along a path length L the column density simply becomes $S = N_{c_0}L$.

In order to obtain sufficient sensitivity, light-path lengths L of the order of several 100 m to several 1000 m are usually required. For measurements in the free atmosphere, assuming the arrangement a in Fig. 19.9, the trace gas concentration is averaged over the whole length of the light path, which makes the measurement less susceptible to local emissions. On the other hand measurements must frequently be made in a small volume (e.g. in photo-reactors); in these cases multi-reflection

systems can be used to fold the light path into a small volume [19.28]. An example of detection limits attainable with multi-reflection systems is given in Table 19.3.

19.5.3 Variations of DOAS

The DOAS technique can be adapted to a large variety of measurement tasks; as a consequence there are many variants of the DOAS technique in use. These can be grouped into active techniques, which employ their own light sources (e.g. Xe-arc lamps or incandescent lamps), and passive techniques, which rely natural light sources (e.g. sunlight, moonshine or starlight).

The most common active DOAS light-path arrangements include (Fig. 19.9):

a) The traditional active long-path systems (usually folded once);
b) Active systems using multi-reflection cells (e.g. white cells);
c) Recently the first tomographic systems allowed the determination of 3-D trace gas distributions by multiple-beam active DOAS.

The most common passive DOAS light path arrangements include (Fig. 19.10):

d) Zenith scattered light (ZSL)-DOAS is well-suited to study stratospheric trace gases. For instance a global network of ZSL-DOAS instruments continuously watches the distribution of stratospheric species (e.g. O_3, NO_2, BrO, OClO).
e) Multi-AXis (MAX)-DOAS allows determination of trace gases and their vertical distribution in e.g. the atmospheric boundary layer or the detection of plumes from cities, stacks, or volcanoes. In addition Airborne Multi-AXis (AMAX)-DOAS is a new technique for application from aircraft.
f) Direct sunlight observation of trace gases from balloon platforms allows the determination of trace gas profiles.

An extremely important, new application is satellite-borne DOAS, pioneered by the GOME and SCIA-MACHY instruments [19.29, 30] that allow observation of global stratospheric and tropospheric trace gas distributions (Fig. 19.11):

g) The most basic observation geometry is the nadir view. Here, sunlight backscattered from the Earth and its atmosphere is analyzed by DOAS to yield trace gas slant column densities. Ideally all light
Fig. 19.10d–f The passive DOAS technique can be applied in several light path arrangements and observation modes using natural light sources such as sunlight or moonlight. The zenith scattered light (ZSL-DOAS) set-up **(d)** is most suited for the determination of stratospheric species, while the Multi-AXis (MAX-DOAS) arrangement **(e)** provides highly sensitive trace gas measurements in the atmospheric boundary layer. Direct sunlight observation of trace gases from balloon platforms **(f)** allows the determination of trace gas profiles in the atmosphere

recorded by the satellite spectrometer traversed the atmosphere twice.

h) Satellites also allow the observation of scattered sunlight in a limb-viewing geometry. This allows the determination of trace gas profiles (although generally only for the stratosphere).

i) Occultation (sunset, sunrise or starlight) measurements from satellites are an attractive possibility.

In addition it is now possible to determine the photon path-length distribution in clouds by ground-based observation of O_2 and O_4 bands. Here effectively DOAS is reversed: instead of the usual configuration where an unknown concentration is measured while the length of the light path is (at least approximately) known, the photon path-lengths are determined by observing the absorption due to an absorber with known concentration, such as oxygen (O_2) or oxygen dimers (O_4).

19.5.4 Atmospheric Aerosols

The atmospheric aerosol concentration is frequently monitored by light detection and ranging (LIDAR) instruments operated from the ground, aircrafts, or satellites [19.32]. In their most basic configuration they measure the ratio of total extinction due to Mie and
Fig. 19.11g−i Satellite-based DOAS has become an important technique for probing the atmospheric composition on a global scale. The most basic observation geometry is the nadir view (**g**), here sunlight backscattered from the Earth and its atmosphere is analyzed by DOAS to yield trace gas slant-column densities. Ideally all light recorded by the satellite spectrometer traversed the atmosphere twice. Satellites also allow the observation of scattered sunlight in a limb-viewing geometry (**h**). This allows the determination of trace gas profiles (although generally only for the stratosphere). Occultation (sunset, sunrise or starlight) measurements (**i**) from satellite are another attractive possibility to determine trace gas vertical profiles

Table 19.3 Selection of species of atmospheric relevance measurable by DOAS and detection limits. Differential absorption cross-sections and corresponding detection limits (assuming 32 passes in a multi-reflection cell with a 8 m base path) for a series of species to be investigated by DOAS in the Valencia smog chamber. A dielectric mirror coating or DOAS measurements in the open atmosphere would allow longer light paths, resulting in correspondingly improved detection limits

Species	Wavelength of prominent band (nm)	Differential abs. cross section (σ_i') (10^{-20} cm^2/molec.)	Detection limit $L = (40 - 8) \times 8$ m $= 256$ m (ppt)

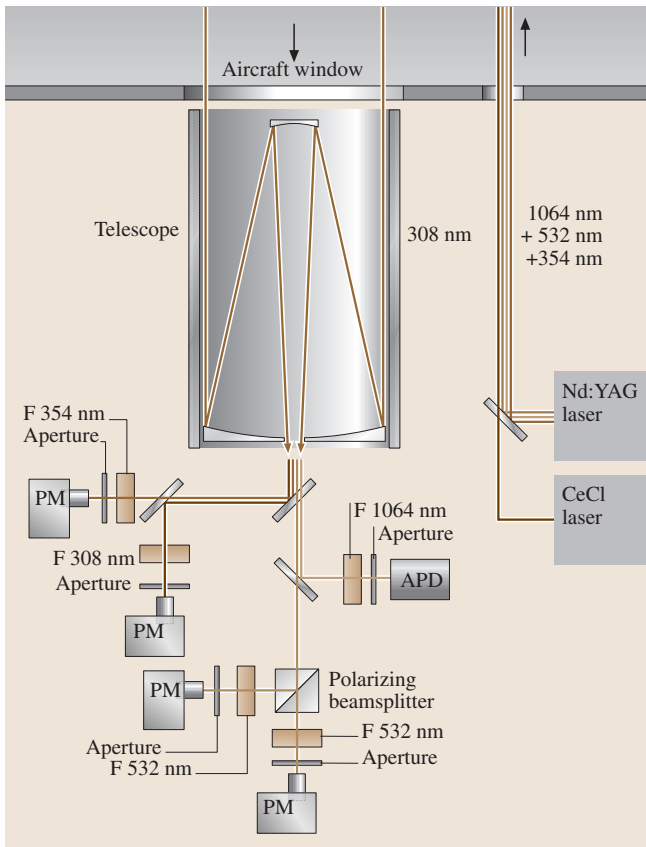

Fig. 19.12 Schematic setup of the DLR-Oberpfaffenhofen aircraft-borne LIDAR system (OLEX). APD: avalanche photo diode; PM: photomultiplier (courtesy G. Ehret/DLR Oberpfaffenhofen)

The Ozone Lidar EXperiment (OLEX) LIDAR is used as an aerosol and ozone LIDAR (Fig. 19.12). The system consists of two laser transmitters: 1) a Nd:YAG laser operating at a repetition rate of 10 Hz in the fundamental, second harmonic, and third harmonic with output energies of 200 mJ at 1064 nm, 120 mJ at 532 nm, and 180 mJ at 355 nm, and 2) a XeCl laser operating at 10 Hz, emitting 200 mJ at 308 nm. The receiver system is based on a 35 cm Cassegrain telescope with a field of view (FOV) of 1 mrad and a focal length of 500 cm. The system uses five detection channels: one channel for 1064 nm, two channels for 532 nm in two polarization planes, one channel for 355 nm, and one for 308 nm. The 308 and 355 nm channels are specifically dedicated to ozone profiling in the stratosphere, while the other wavelengths are used for aerosol and cloud monitoring. The acquisition electronics can acquire each single signature, with the lasers firing at a 50 Hz repetition rate, and the aerosol distributions measured by the system are available in real time. The total weight of the system is about 270 kg and the total power consumption above 1.6 kW.

In the present example, the OLEX LIDAR was assembled on board the DLR-Falcon aircraft in a down-looking mode that enabled aerosol backscattering measurements below the aircraft cruise altitude. On 24 September 1999, a flight was undertaken leading from Oberpfaffenhofen near Munich to the Adriatic Sea. The

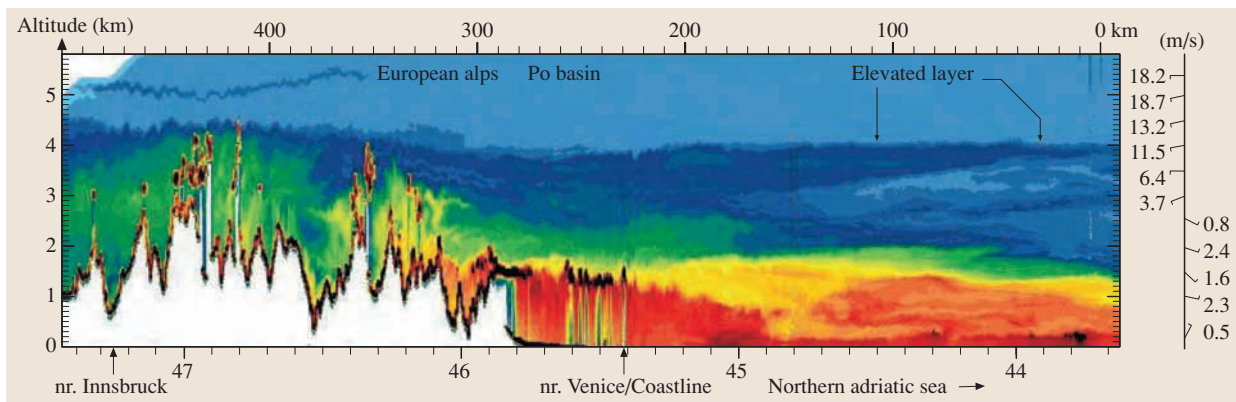

Fig. 19.13 Tropospheric aerosol distribution recorded by OLEX at $\lambda = 1024$ nm during a flight of the Falcon aircraft from Oberpfaffenhofen to the Adriatic Sea on 24 September 1999. The color codes qualitatively indicates the aerosol concentration with the large aerosol concentrations given in yellow and the small in blue color

main scientific objective was to investigate the spatial distribution of made-man aerosols emitted from traffic, industry and house burning into the lower troposphere.

The major detected features were inhomogeneously aerosol-loaded air masses located in the alpine mountain valleys and the fairly uniform planetary boundary layer (PBL) stretching over the whole alpine ridge (Fig. 19.13). Both aerosol layers nicely mark the vertical layering of a vertically layered lower troposphere typical for a high-pressure system at mid-latitudes in fall. Another interesting feature was the structure of the planetary boundary layer (PBL) located over the Adriatic Sea (≈ 2000 m above sea level), which overlaid a very thin marine boundary layer ($250-300$ m above sea level). This feature resulted from an advection of polluted PBL air masses originating from the North Italian Apennines and the Po Basin by synoptic westerly winds [19.33].

19.5.5 Determination of the Distribution of Solar Photon Path Lengths

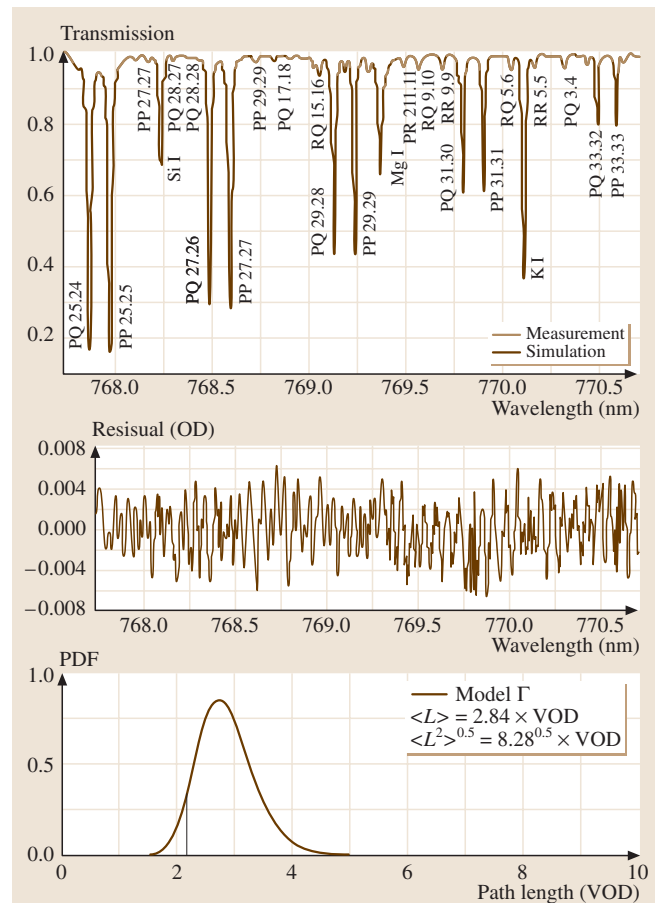
A novel application of differential optical absorption spectroscopy (DOAS) is the measurements of path-length distributions of solar photons (photon PDF) transmitted to the ground [19.34–38]. The knowledge of a photon PDFs is of primary interest in the cloudy atmospheric radiative transfer, atmospheric absorption of solar radiation energy and thus for climate. The method relies on the analysis of highly resolved oxygen A-band ($762-775$ nm) spectra (Fig. 19.14) observed with a telescope with a small field of view ($1°$) in zenith-scattered sky light. It uses the fact that solar photons are randomly scattered by molecules, aerosols and cloud droplet during their atmospheric transport. Since a fraction of the solar photons become absorbed in the atmosphere, largely depending on the atmospheric opacity for a given wavelength, for each wavelength solar photons travel on different average, long distances in the atmosphere. Spectral intervals with a largely changing atmospheric opacity but known absorber concentration and spectroscopic constants, such as that given by the oxygen A-band, thus contain information on the photon PDFs. Recent studies have been showing that the atmospheric photon PDFs are highly correlating with the total amount of liquid water in the atmosphere, the spatial arrangement of clouds, cloud inhomogeneity and solar illumination [19.34–38]. For example, for thunder-


Fig. 19.14 Measured and modeled oxygen A-band spectrum (*upper panel*), inferred residual spectrum (*middle panel*) and inferred photon PDF for the observation between 12:32 and 12:33 UT over Cabauw/NL on 23 September 2001. The *black vertical line* indicates the optical path for the direct sunlight. Photon path lengths are given in units of vertical atmosphere (VOD) or air mass (AM)

storm Cb (cumulus nimbus) clouds, average photon path lengths of up to 100 km have been observed, while for Sc (stratus clouds) typically photon paths are $50-100\%$ larger than for the direct and slant path of the sun's rays. Moreover, it appears that even though the spatial distribution of cloud droplets is inhomogeneous with the moments of the density behaving like multi-fractals, photon PDFs tend to be mono-fractals, mostly due to the so-called radiative smoothing of optically thick clouds [19.39].

19.6 Optical Phenomena in the Atmosphere

Phenomena based on atmospheric optics can be observed nearly every day and everywhere. Examples are rainbows, halos, mirages, coronas, glories, the colors of the sky, sunsets and twilight phenomena, green flashes, noctilucent clouds, polar lights, and many more. All these different phenomena are due to interaction of light with matter present in the atmosphere (Fig. 19.15).

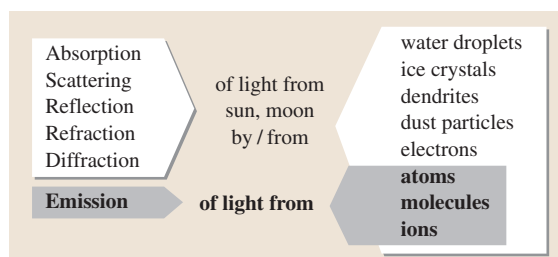
In the following, a brief survey of light scattering by molecules and particles with regard to optical phenomena in the atmosphere will be given. More details on light scattering by particles can be found in a number of monographs [19.40–43]. Several books have focussed on one or more optical phenomena (e.g. [19.44–54]). Some older original publications are available as a collection of articles [19.55] and the proceedings of the regular conferences on atmospheric optics have been published in special issues of the journals of the Optical Society of America [19.56–63], most of them recently put together on a CD-ROM [19.64]. Several videos and movies deal with selected phenomena [19.65–69], some articles focus on connections to the fine arts [19.70–73], a number of books focus on simple experiments as well as observations [19.74,75] and a number of internet sites with a lot of material are also available, Table 19.4.


Fig. 19.15 Possible interaction processes of light with constituents of air

19.6.1 Characteristics of Light Scattering by Molecules and Particles

Nearly all optical phenomena in the atmosphere are due to light scattering – mostly sunlight and sometimes moonlight – with the constituents of air. In the following, a brief general survey of light scattering processes in the atmosphere will be given. Consequences for various optical phenomena of the atmosphere will be systematically discussed in the respective sections according to the constituents of the air that are responsible (Table 19.5).

Table 19.5 Classification of optical phenomena of the atmosphere. Depending on the homogeneity of the air, different light interaction processes correspond to various phenomena, which are indicated by examples

1. Pure homogeneous air

- refraction $\Rightarrow$ mirages, shape changes of sun/moon at horizon Sect. 19.6.2
- scattering $\Rightarrow$ blue sky Sect. 19.6.3

2. Inhomogenous atmosphere: Air plus water droplets

- refraction and reflection $\Rightarrow$ rainbows Sect. 19.6.4
- forward scattering/diffraction $\Rightarrow$ coronas Sect. 19.6.5
- backward scattering/diffraction $\Rightarrow$ glories Sect. 19.6.5

3. Inhomogenous atmosphere: Air plus ice crystals

- refraction and reflection $\Rightarrow$ halos Sect. 19.6.6
- forward scattering/diffraction $\Rightarrow$ coronas Sect. 19.6.5

4. Inhomogenous atmosphere: Air plus aerosols

- absorption, scattering $\Rightarrow$ sky colors Sect. 19.6.7
- absorption, scattering $\Rightarrow$ visibility Sect. 19.6.8
- forward scattering/diffraction $\Rightarrow$ coronas Sect. 19.6.5

5. Ionized air

- ionization/excitation by solar wind, emission $\Rightarrow$ auroras Sect. 19.6.9
- ionization/excitation by discharges, emission $\Rightarrow$ lightning Sect. 19.6.9

Molecular Scattering

For pure air, scatterers are mostly N_2 and O_2 molecules, the greenhouse gases CO_2 and H_2O as well as some traces of other gases such as Ar [19.76]. These scatterers are all much smaller than the wavelength of visible light and one speaks of a molecular atmosphere [19.77]. The vertical distribution of the gaseous components of air follows the barometric formula with a scaling height of about 8 km. The scattering of sunlight from the bound electrons of atoms/molecules is usually called Rayleigh scattering [19.1, 78, 79]. (For historical notes on the problem of the blue sky, see [19.80].)

Scattering from Particles

Normal air usually also contains a variety of different particles, the most predominant being water droplets, ice crystals and snow flakes (dendrites). The size of the water droplets ranges from several micrometers (cloud droplets) to well above 1 mm (raindrops); ice crystals are very often of hexagonal symmetry with sizes on the order of $10-100\,\mu m$.

In addition, the atmosphere also contains other liquid and solid particles called aerosols [19.20, 76, 81, 82]. These include many types of particles from dust, oil droplets from forest fires, volcanic ashes as well as

anthropogenic droplets/particles with an enormous variety in composition. Typical aerosol particles have size distributions in the range $0.1-10\,\mu m$ with an average around $1\,\mu m$ (e.g. [19.83]). The vertical distribution of the particle components of air may also be described by some kind of exponential formula [19.77], however, the scaling height of $1-2$ km is much smaller than that for molecules.

The scattering of light from particles in these size ranges differs dramatically from molecular scattering, since the particle size is comparable to or larger than the wavelength of the light. Since atoms/molecules within particles are very close to each other, they are excited coherently, i. e. the total scattering from all molecules within a particle is quite different from the sum of the scattering of all individual molecules within the particle. In 1908, *G. Mie* gave the solution of classical electrodynamics for the simplest case, referring to spherical shapes of the particles [19.10]. Henceforth, this type of light scattering from particles is mostly known as Mie scattering. This name is sometimes also used for extensions to nonspherical particle shapes. For nonabsorbing particles, which are small compared to the wavelength, the Mie scattering gives the same results as Rayleigh scattering. In the general case, however, it shows pro-

Part D | 19.6

nounced differences regarding wavelength dependence, angular dependence, degree of polarization of the scattered radiation as well as scattering cross section per molecule [19.40–42, 77].

Comparison of Rayleigh and Mie Scattering

Wavelength Dependence. Figure 19.16 gives a schematic example of the scattering of light by water molecules as well as water droplets of, say, $10 \mu m$. Whereas molecules or very small particles scatter light mostly according to the inverse fourth power of wave-
Fig. 19.16 Schematic wavelength dependence for light scattering from water molecules and water droplets of, e.g., $10 \mu m$ size
Fig. 19.17 Schematic overview of the angular dependence of light scattering from molecules and very small particles (Rayleigh scattering) to larger particles (Mie scattering)

length, scattering from water droplets is essentially independent of wavelength.

Angular Dependence. Figure 19.17 gives a schematic overview of how the angular dependence of scattering changes with particle size. Molecules scatter unpolarized light nearly isotropically (see also Fig. 19.1) whereas large particles scatter rather asymmetrically in the forward direction. For a given particle size, the scattering also depends on wavelength.

Degree of Polarization. For Rayleigh scattering, and assuming perfectly spherical air molecules, light scattered at an angle of 90° would be perfectly polarized [19.84]. However, air molecules already show an anisotropy, reducing the polarization to only about 94% [19.77, 79]. For larger particles, the degree of polarization varies considerably as a function of scattering angle for fixed size. These patterns, however, strongly depend on size [19.40, 41, 77]. In addition, the degree of polarization at a fixed angle varies as a function of wavelength.

Scattering Cross Section per Molecule:. The enormous differences between incoherent and coherent scattering become apparent when comparing light scattering from isolated molecules to those of the same molecules within a particle, e.g. water molecules within a water droplet or a raindrop [19.77]. For example, the scattering per molecule that belongs to a cloud droplet of $1 \mu m$ is about 10^9 times larger than scattering by an isolated water molecule and still a factor of about 100 larger than a molecules in a 1 mm raindrop.

Single and Multiple Scattering, Optical Mean Free Path and Air Mass

Light from the sun (or moon) has to traverse the atmosphere before reaching the eye of an earthbound observer. It is attenuated by scattering and absorption, depending on the number of scatterers present in the line of sight. If absorption can be neglected, one may use the scattering coefficient

$$\beta_S = N\sigma , \tag{19.35}$$

where N is the number of scatterers per unit volume and σ is the extinction cross section, $1/\beta_S$ defines the scattering mean free path, i. e. the average distance a photon has to travel before being scattered. (If absorption is included, an additional absorption coefficient β_A is introduced and β_S will be replaced by $\beta = \beta_S + \beta_A$.) Using β_S, one may define the optical thickness τ between two

points A and B of the atmosphere as

$$\tau = \int_A^B \beta_S(x)\,dx \,. \tag{19.36}$$

The optical thickness is a measure of the physical thickness in units of the scattering mean free path. For light along a radial path, i. e. coming from the zenith, the amount of air to be traversed is least and one refers to the normal optical thickness, which is also called the optical depth. For a pure molecular atmosphere, this is depicted in Fig. 19.18. In the visible spectral range, its values are small compared with unity, hence, a photon is unlikely to be scattered more than once, i. e. single scattering predominates.

The amount of air to be traversed by light, the so called air mass, depends on the sun's elevation. Air mass (AM) is defined to be unity for the light source in the zenith. It increases for smaller sun elevation angles. As a matter of fact, it is the optical thickness, relative to its zenith value. The exact value depends on the surface pressure. At 5° elevation (85° zenith angle) its value is about 10 and it ultimately reaches a value of about 40 at grazing incidence [19.51, 77, 85, 86], i. e. for the case of sunrise or sunset. In this case, the light must pass about 40 times the amount of air compared to the case of the zenith.

Combining the air mass with the normal optical thickness gives the optical thickness for arbitrary sun elevation. Since AM reaches large values, optical thicknesses may become large compared with unity, i. e. multiple scattering events become likely for low sun elevations.

19.6.2 Mirages

Mirages are due to the propagation of light waves in air that has gradients in the index of refraction [19.44–48, 51]. In general, light which is propagating in clear air (no particles) is partly scattered according to Rayleigh scattering, while the rest propagates undisturbed in the forward direction. The scattered light consists of sideways scattering and forward scattering, the latter being in phase with the incident light. As a consequence, light in clear air is slightly weakened by sideways scattering, the forward-propagating light being the superposition of the incident light and the forward-scattered light. The weakening due to sideways scattering will be discussed below (blue sky). Here, the phenomena associated with the forward-propagating light will be
Fig. 19.18 Normal optical thickness of a purely molecular atmosphere (data from [19.3])

discussed. Scattering effects by particles are neglected here.

In homogeneous media, the forward propagation of light is expressed in terms of the refractive index n (for tables of n [19.3]). n depends on temperature T (in K), pressure p (in mbar) and humidity. Equation (19.37) [19.87] gives an approximation for n of dry air

$$n = 1 + \frac{77.6p}{T} \times 10^{-6} \,. \tag{19.37}$$

For example, $T = 300\,\mathrm{K}$ and $p = 1030\,\mathrm{mbar}$ yields $n \approx 1.000266$. Increasing the air temperature by 40 K (e.g., air directly above the ground which is heated by the sun) gives $n \approx 1.000235$ (for humid air, the numbers only change slightly). These small changes of $\Delta n \approx 3 \times 10^{-5}$ are responsible for all kinds of mirages.

The most simple mirage effect is known from astronomy: if an observer looks at an object in the sky at a certain altitude, the actual position of the object is lower in the sky. This is due to the refraction of light upon propagation in the atmosphere with a gradient in n giving rise to curved light paths.

At the zenith, the deviation is zero, at 45° zenith distance it amounts to 1′ (1 minute of an arc) increasing to more than 38′ at an angle of 90°. This has to be compared with the angular size of the sun or moon, which is about 30′, i. e. half a degree. Since the refraction is only about 28′ at a zenith distance of 89.5°, the sun or the moon in an otherwise undisturbed atmosphere (no inversion layers) will thus be flattened [19.47], see also [19.88–92].

Mirages are images of objects which may be seen in addition to the real objects. They can be seen whenever there are temperature differences in the atmosphere,
Fig. 19.19 Inferior mirage: a palm tree scatters sunlight in all directions. The atmosphere is heated close to the ground. Therefore the index of refraction is smaller there, giving rise to curved light paths. Direct and refracted light can enter the eye of an observer, which is interpreted as an object on top of an inverted image (after [19.48])

which give rise to unusual gradients in the index of refraction. Similarly to astronomical refraction, gradients in n give rise to curved light paths. If warm air is above the ground, n is smaller close to the ground than above it. This leads to inferior mirages like the well-known wet streets on hot summer days. The formation of inferior mirages is illustrated in Fig. 19.19. A prominent feature of a mirage is the so-called vanishing line of the object [19.48]. Light below certain object points has no chance whatsoever to reach the eye of the observer, i. e. parts of the object cannot be seen, irrespective of the direction into which the light is scattered.

In the case of an inversion layer in the atmosphere, the air at a given height is warmer than below, which may give rise to superior mirages. Similarly to inferior mirages, the propagation of light with curved paths in this case can give rise to multiple images on top of the object. In nature, combinations of inferior and superior mirages may occur. Also, heated vertical walls may result in lateral mirages.

The angular size of mirages is usually about 0.5–1.0°. For observations, binoculars and cameras with telephoto lenses are used. The mirages are often distorted and flicker due to local density fluctuations in the air.

Theoretical progress in understanding mirages came with the computer. The propagation of light rays in a given atmosphere, defined by the vertically varying index of refraction $n(z)$, is computed theoretically using ray-tracing methods. The various methods [19.93–96] differ by their choice of geometry and $n(z)$. Such simulations prove very helpful in understanding the general characteristics of mirages, like e.g. so-called mock mirages [19.97, 98].

Recent research has explained many unusual mirage phenomena quantitatively, including long-range mirages like the Novaya–Zemlya effect from atmospheric ducting [19.99–102] and small-scale movements seen within superior mirages when atmospheric gravity (buoyancy) waves are present [19.103, 104].

Superior mirages seen over large distances (70–100 km) can result from fairly complex atmospheric temperature profiles [19.95]. Also, the origin of double inferior mirages as well as unusual horizontal stripes in inferior mirages has been analyzed theoretically [19.96]. Very recently, focus had been on very precise measurements and comparison to modeled astronomical refraction of the setting sun [19.105, 106] and the occurrence of very bright superior mirages [19.107].

In addition to analysis of observations and theoretical models, inferior mirages and superior mirages with multiple images may also be studied quantitatively or as demonstration experiments in the laboratory [19.65, 108–112].

19.6.3 Clear Sky: Blue Color and Polarization

Light scattering in pure gases is due to the electrons in atoms and molecules. As a result, the scattered light intensity varies approximately as $1/\lambda^4$ (Fig. 19.16), i. e., red light is scattered much less than blue light [19.1, 78, 79]. When looking at the daylight sky illuminated by the sun one mostly sees scattered light and, hence, a blue sky (In Sect. 19.6, the qualitative term intensity which is often not properly defined (see [19.113]), does usually mean either radiance, given in W/m^2 sr, or spectrally resolved radiance in W/m^2 sr nm).

The scattered light is strongly polarized at a scattering angle of 90° [19.84]. Concerning the whole sky, the polarization varies and also has neutral points, named after Arago and Babinet [19.44, 46, 51]. In reality, even if very clean air is used, the maximum degree

of polarization is about 94%, see Sect. 19.6.1. The atmosphere usually also contains an appreciable number of particles, which show Mie scattering with different angular polarization dependencies. In addition, there may be contributions of multiply scattered light as well as backscattering from the surface of the Earth. Overall, the degree of polarization typically reaches values around 80%. Obviously, this depends on the concentration of particles and is thus related to the transmission of the atmosphere [19.114]. More details on scattering effects and recent research will be given in Sect. 19.6.7.

19.6.4 Rainbows

Rainbows are due to scattering of sunlight from raindrops in the atmosphere [19.43–48, 51]. The drops are in the size range between $10\,\mu\mathrm{m}$ (white fogbow/cloud bow) and several millimeters. One usually assumes spherical droplets, however, drop shapes may vary depending on size [19.115, 116] or they may even oscillate [19.117]. Drop formation and size distributions have been extensively studied [19.118]. The effect of nonsphericity on rainbow phenomena is discussed, e.g., in [19.119, 120].

The observed bows are mostly due to single scattering events. Hence, the complex problem of light scattering from millions of raindrops in a rain shower can be reduced to the scattering of sunlight from a single raindrop. Since raindrops are large compared to the wavelength of light, geometrical optics already gives a rough description. Figure 19.20 depicts a single raindrop and parallel light rays from the sun.

The rays are characterized by their impact parameter b. Each ray is reflected and refracted upon hitting an interface between air and water. For clarity, only the light paths that give rise to the primary rainbow are sketched. They are defined by refraction into the droplet, internal reflection and refraction back into the air. Similarly higher-order rainbows may be constructed by allowing for multiple internal reflections. The central ray (1) is not deflected by the refractions and exits at a scattering angle of $180°$ with respect to the incident ray. Ray number (2) suffers a scattering angle of about $170°$ and so on. For increasing impact parameter the scattering angle δ decreases until a minimum is reached at an impact parameter of about $0.86\,R$ (ray 7). The flatness of this shallow minimum (Fig. 19.20) at an angle of about $138°$ is responsible for the fact that much more light is scattered into this direction – geometrically along the surface of a cone – than in others, since many incoming light rays of slightly differing impact parameters will emerge in the same output di-
Fig. 19.20 Simple explanation of a rainbow from a single raindrop in terms of geometrical optics. Parallel light rays, characterized by the impact parameter b, are scattered due to refraction, internal reflection and refraction (for clarity other light paths are omitted). The scattering angle δ as a function of b exhibits a shallow minimum, i.e. many incoming light rays with different values of b will be scattered in the same direction

rection. As a consequence, an observer who is looking at a cloud of raindrops that is illuminated from the back by sunlight, will observe a bow of angular size $42°$ (Fig. 19.21).

The rainbow angle, i.e. the minimum of δ in the plot of Fig. 19.20, can be easily calculated (e.g. [19.47, 121]) with geometrical optics by finding the minimum of the scattering angle $\delta(\alpha_{\mathrm{inc}})$ with respect to the angle of incidence α_{inc} of the light rays onto the droplet. Assuming $n_{\mathrm{air}} \approx 1$ one finds for the primary bow

$$\delta(\alpha_{\mathrm{inc}}) = 2\alpha_{\mathrm{inc}} - 4\alpha_{\mathrm{refr}} + \pi, \quad \text{with}$$

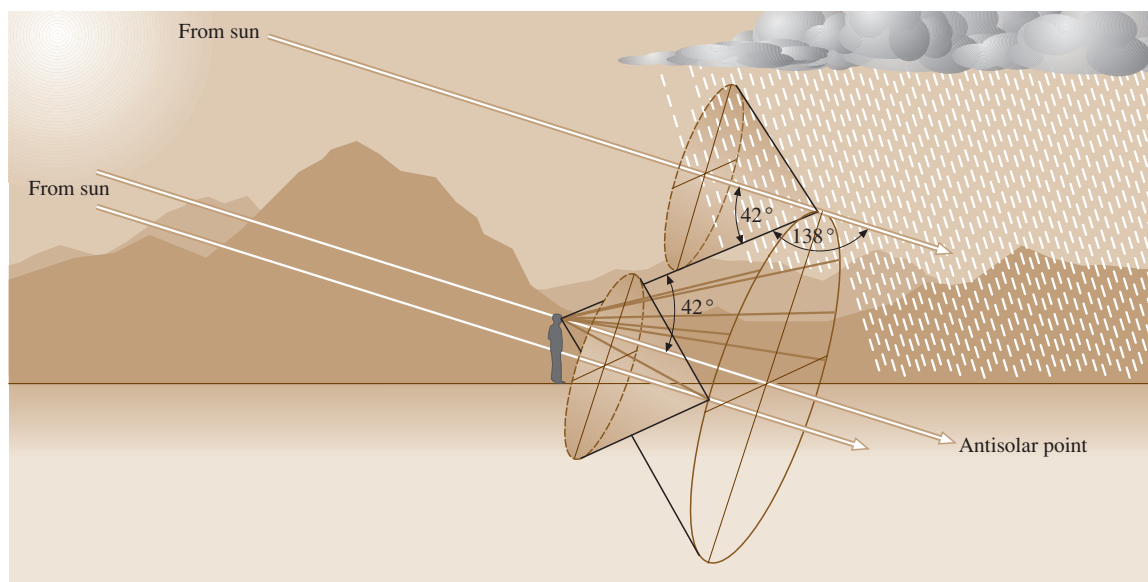
$$\cos\alpha_{\mathrm{inc}} = \sqrt{\frac{n^2 - 1}{3}}. \tag{19.38}$$


Fig. 19.21 Observation of a rainbow. Each raindrop scatters light preferably in a cone of the rainbow angle. Hence, an observer will see more light when looking in the direction of the surface of a cone that is centered in a droplet. The whole rainbow is due to millions of drops, the effect of which is an observable bright feature, geometrically on the surface of another cone centered in the eye of the observer and making an angle of 42° with regard to the antisolar point (after [19.48]). Its surface touches the surfaces of the scattered light cones of each individual droplet

Here α_{refr} denotes the angle of the refracted ray within the raindrop and n is the index of refraction of water. For $n = 1.33$, Snell's law gives a scattering angle of $\delta(\alpha_{\text{inc}}) = 137.5°$. Due to dispersion ($n_{650\,\text{nm}} = 1.331$, $n_{400\,\text{nm}} = 1.343$) the rainbow angles depend on wavelength. Taking into account the finite size of the sun of about $0.5°$ one finds an angular width of about $2.2°$ for the primary bow. The analysis is easily extended to higher-order rainbows [19.47], most of which may, however, only be observed in the laboratory [19.110, 122–125].

Several rainbow features can only be explained by wave optics. Light from the rainbow is appreciably polarized perpendicular to the plane of incidence, since the angle of incidence for the internal reflection is close to the Brewster angle [19.126]. Also, careful measurements showed that the light intensity shows an interference pattern, named after Airy [19.50, 127, 128], which differs markedly from the prediction of geometrical optics (Fig. 19.22).

Until the beginning of the 20th century, wave optics features were computed using Airy's theory, which gives reasonable results for droplet sizes down to $10\,\mu\text{m}$; for smaller sizes, it fails. Improvements came with

Mie theory [19.10, 40, 41], however, its numerical solutions in terms of scattering efficiencies as a function of angle for size distributions of the droplets and finite angular size of the solar disk had to wait for the development of computers. Similarly, Debye developed
Fig. 19.22 Differences between the theories of Descartes and Airy for the scattered light intensity of raindrops

a tool of how to decompose the partial wave amplitudes for scattering of a plane wave into individual contributions of certain types. This later led to the complex angular-momentum theory [19.129]. Application of the mathematics of catastrophe theory to light scattering showed that the rainbow is a manifestation of the so-called fold caustic [19.130].

Here, results of the full electrodynamic treatment, i. e. Mie theory, are presented [19.40, 41, 131–133]. Figure 19.23 depicts results for monochromatic blue light of $\lambda = 450\,\mathrm{nm}$, scattered by a lognormal distribution of water droplets with mean radii ranging from $2\,\mu\mathrm{m}$ to $200\,\mu\mathrm{m}$. The full width at half maximum of the size distribution is 10% of the mean radius.

Obviously, large droplets show Airy rings at the rainbow angles. For other wavelengths, these curves would be slightly shifted due to dispersion. The overlapping of the interference rings for all wavelengths leads to so-called supernumerary arcs (e.g. [19.134, 135]). Decreasing the droplet size leads to a broadening of the rainbows due to diffraction. In this case, the overlapping of all wavelengths leads to a white rainbow, also called a fog bow. If the size becomes too small, no rainbows are observable. The other features in Fig. 19.23 will be discussed in Sect. 19.6.5.

There are many other interesting features of rainbows. For example the first-order rainbow often visually appears brighter at the base of the bow than at the top of the bow. This is due to the fact that, in a rain shower, raindrops are distorted in shape to oblate spheroids. Light reaching an observer from the base of a rainbow traverses a water droplet in the horizontal plane where the droplet cross section is circular. In contrast, light from the top of the rainbow traverses the water droplet in the vertical plane where the droplet cross section is elliptical. Since the scattered light intensity due to the internal reflection is less in the elliptical cross section than that in the circular cross section the base of the rainbow is brighter than the top of the bow (the longer optical path from the top may also lead to increased extinction).

Similar explanations [19.136] are possible for other features such as, e.g., that the supernumeraries of the first-order rainbow often appear most vividly at the top of the bow or that supernumeraries of the second-order rainbow are almost never seen. Also, the effects of the electric fields [19.137] and acoustic forces accompanying thunderstorms can have observable consequences on rainbows [19.117]. Visibility and general brightness of rainbows depend on multiply scattered and absorbed
Fig. 19.23 Angular distribution of blue light scattered by water droplets with mean radii ranging from $2\,\mu\mathrm{m}$ and $8\,\mu\mathrm{m}$ (fog and cloud droplets) to $200\,\mu\mathrm{m}$ (small raindrops) (computation by E. Tränkle)

light [19.138, 139]. Even infrared rainbows have been detected [19.140].

In addition to analysis of observations and theoretical models, rainbow phenomena may also be studied in the laboratory either for quantitative comparison to theory or just as demonstration experiments using either single droplets or cylinders of water or other materials [19.109, 110, 122–124, 136, 141, 142].

Present investigations of rainbow phenomena deal, e.g., with experiments on higher-order rainbows from acoustically levitated water drops [19.143] or cylinders [19.144, 145] and total internal reflection rainbows [19.146] as well as new simulations of rainbows and fogbows [19.147, 148].

19.6.5 Coronas, Iridescence and Glories

The forward and backward scattering of small water droplets can also give rise to very distinct features [19.43, 44, 47, 48, 51]. First, colored concentric rings, called coronas, around the sun or the moon with angular distances up to, e.g., 15° may be observed, when looking through thin clouds. The middle whitish part around the light source is often called an aureole. If, second, colorful clouds are observed at larger distances from the sun (up to 45°), one usually speaks of cloud iridescence. Third, backscattering that leads to colorful concentric rings at angles close to 180° with respect to the light source are called glories. Figure 19.24 gives an

Part D | 19.6
Fig. 19.24 Overview of geometries of light-scattering phenomena from a water droplet

overview of the light-scattering geometries of rainbows, coronas and glories due to water droplets.

Coronas

In its most spectacular form, coronas can be observed as a concentric series of three or four brilliantly colored rings around the sun or moon. In its simplest form, the corona is just represented by the aureole, which is a white disk near the sun or moon bordered by a bluish ring and terminated by a reddish-brown band.

Coronas are easily explained using Mie theory [19.149, 150]. Coronas occur as strong forward-scattering phenomena (Fig. 19.23) for very small nearly monodisperse sizes of typically about $10 \, \mu m$. More simply, coronas are treated as diffraction phenomena by water droplets. The first minimum for light of wavelength λ diffracted by a circular aperture of diameter $2R = D$ is given by

$$D \sin \phi = 1.22\lambda \, . \tag{19.39}$$

For droplets of nearly uniform size, the diffraction angles ϕ obviously depend on wavelength, giving rise to rather pure perceived colors of the coronas. In this case, the average droplet size may be estimated from the angular size of the rings from (19.39). To obtain the approximate angle for the red band of the solar corona, it is customary to use $\lambda = 570 \, nm$ in (19.39) since the positions of the red bands are believed to correspond to the minima for green light [19.151]. (Alternatively to 570 nm, 490 nm has been proposed [19.152].) For example, $2R = 10 \, \mu m$ gives $\phi \approx 4°$. (Note that there will be deviations between the correct Mie theory and diffraction theory for droplets with sizes of $10 \, \mu m$ and below.) A much better way to judge droplet sizes is to fit the col-

ored rings of computer simulations to those of photos of natural observations [19.150].

An aureole may be produced by relatively large particles that tightly compress the rings, or by the presence of a broad particle size distribution that causes the colored rings to overlap.

Simple diffraction theory has problems for drops with sizes only slightly greater than the incident wavelength. In this case, Mie theory must be applied, since the amplitudes of the diffracted and transmitted light are comparable in the forward-scattering direction, leading to interference between the two components that can significantly alter the scattering pattern.

The nature of the cloud particles that cause coronas has been the subject of controversy [19.152, 153]. Observations of some coronas due to very high clouds suggested that not only supercooled spherical cloud droplets, but also ice crystals may be responsible for coronas. However, ice crystals can assume a variety of shapes and orientations that should not give very pure coronal colors. The issue was settled by experiments which simultaneously used polarization LIDAR data as well as photographic evidence of coronas to demonstrate that cirrus clouds composed of hexagonal ice crystals with particle sizes ranging from 12 to $30 \, \mu m$ (which is unusually small for most cirrus clouds) can generate multiple-ringed colored coronas [19.152]. Later the study also included aircraft probes of the particles [19.153]. In one case a weak corona and a halo display (see below) of the hexagonal crystals were observed simultaneously within the same cloud. This is possible, since laboratory experiments indicate a lower limit of about $20 \, \mu m$ for the sizes of ice crystals that can produce halo effects.

Some while ago, it was also noted that coronas need not be spherical. Elliptical coronas have been reported at special times in early summer. They were explained as diffraction phenomena from nonspherical birch and pine pollen grains [19.154–156]. Also, split coronas due to local variations of droplet size or changes between water and ice have been observed [19.157]. Recently, new simulations have been reported [19.158]. Special coronas, called Bishop's rings, can be produced by volcanic ashes, as has been reported after the explosion of Krakatau in 1883.

Iridescence

Cloud iridescence is a brilliant display, which occurs quite often when appropriate thin clouds are close to the sun or moon or if edges of thick clouds happen to

have rather monodisperse droplets. Iridescence is also observed, though more rarely, at much larger angular separation from the sun of up to 45° and it may be easily observed and analyzed within contrails [19.151]. If interpreted using diffraction, like coronas, the drop sizes $2R$ are in the range $2-4\,\mu m$. These sizes are indeed quite rare, though possible near the edges of growing or evaporating clouds.

Whereas, coronas are generally observed at smaller angles for mostly monodisperse droplet populations with sizes of about $10\,\mu m$, iridescence usually occurs at larger angles and requires cloud droplet sizes on the order of a few microns in diameter with broad size distributions. These conditions are often found in the vicinity of the visible cloud margin where there is also a sharp gradient of the drop sizes. Thus, coronas and iridescence appear to require quite different cloud microphysical conditions to be present, and should also be most frequently observed in different angular regions [19.151]. Recent studies deal with coronas and iridescence in mountain wave clouds [19.157] as well as rare iridescence cases in cirrus clouds [19.159, 160].

Glories

The colored rings of glories, sometimes also called spectre of the Brocken are observed in a backscattering geometry, if sunlight illuminates fog or clouds with very small water droplets. Nowadays, observations can be performed easily when flying in airplanes and observing the shadow of the plane on nearby clouds.

Early interpretations could not use Mie theory (since computers were not available), but tried to understand the phenomenon in simpler terms. The assumption of diffraction of reflected light by the droplets (diffraction from circular apertures) did not work, since intensities and angular distances of the pattern are different. However, diffraction from circular rings could explain the phenomenon [19.40, 161]. For this to happen, glories must be due to light entering the raindrops at grazing incidence (this interpretation was later supported by Mie theory [19.162]). Then, the scattered light is more or less exiting at the opposite side of a droplet, i. e. at scattering angles of 180°. In terms of geometrical optics, this is not possible, however, wave theory allows for surface waves at the boundary. In the backward direction, all contributions interfere constructively to produce the glory. These model assumptions were supported by experiments with microscopic water droplets supported by submicroscopic spider webs [19.163]. Later on, this model was further developed very successfully [19.129]. Nowadays, glories are explained by using Mie theory.

Glories are present in Fig. 19.23 as oscillatory structures in the angular range from about 160 to 180° for droplets of 4 and $16\,\mu m$ size. The more uniform the droplet size, the more rings may be observed.

Knowing from coronas that colorful rings may also be produced by fairly monodisperse assemblies of ice crystals and even tree pollen, one may ask whether the glories that are often observed from airplane windows may also be due to ice crystals in high-altitude cirrus clouds.

From the above interpretation of Mie theory, the glory is due to circumferential, i. e., surface-wave ray paths which are unique to spheres. Glories are, hence, produced by spherical scatterers. Based on photographic evidence, it was therefore investigated [19.164] whether glories may be also due to spherical or near-spherical ice crystals? In conclusion it was found that ice grows in amorphous and presumably spherical shapes only at unlikely frigid temperatures. Recent studies have, however, suggested that small near-spherical ice particles (diameters ranging from 9 to $15\,\mu m$) can sometimes, though very rarely, occur near the tops or along the margins of some ice clouds, and these may give rise to observable glories. Very recently, new simulations for glories were reported [19.147, 165, 166].

19.6.6 Halos

Halos are caused by the refraction and/or reflection of sunlight by ice crystals in the atmosphere [19.43–48, 51, 52, 66, 167]. They can already be understood in terms of geometrical optics. Ice crystals that cause good halo displays are usually hexagonal plate or column crystals with sizes in the range of $20-100\,\mu m$ [19.168]. Such crystals form very often, depending on the temperature and the amount of water vapor in the air [19.169]. Good documentation with micrographs can be found in the literature [19.52, 170].

A great number of different halos may be observed in nature and in the laboratory since there is an enormous variety of possible types of ray paths through the crystals and crystals may have different orientations in the air.

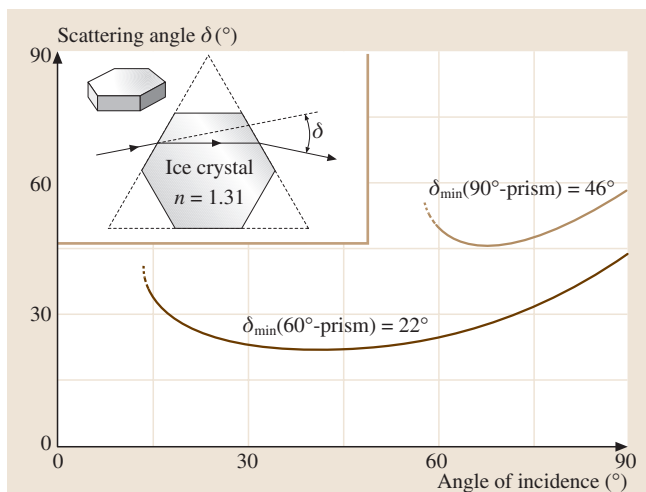
The most simple halos are parhelia, also called sun dogs, which are often observed in cirrus clouds (and sometimes in contrails [19.171]). They are due to oriented plate crystals, i. e. crystals falling with their principal axes vertical. This orientation mode is often possible and is, e.g., similar to movements of leaves (or sky divers), which maximize their air resistance as they fall [19.118]. If light rays from the sun enter a prism face


Fig. 19.25 Ray paths within hexagonal ice crystals ($n = 1.31$) show an angle of minimum deviation of 22°. For clarity, other light paths are omitted

of a crystal and exit an alternate prism face, the situation corresponds to refraction from a 60° prism. The scattering angle as a function of angle of incidence shows a flat minimum (Fig. 19.25) that is at a scattering angle of 22° for ice crystals with $n = 1.31$. Similarly to the explanation of the rainbow, more light is deflected in this direction. Therefore an observer looking at the sun or the moon through a thin cirrus cloud will see more light at an angular distance of 22° from the light source. For randomly oriented crystals, the resulting display will be
Fig. 19.26 A schematic survey of some halos which may be observed (1: 22° halo, 2: parhelia, 3: 46° halo, 4: sun pillar, 5: parhelic circle, 6: circumscribed halo, 7: circumzenithal arc). These displays all depend on sun elevation

a circular halo, centered at the light source, for oriented crystals, light will be deflected to both sides of the light source, giving rise to parhelia. The color of the parhelia, reddish towards the sun and bluish tails at the outside, is due to dispersion, i.e. different minimum deviation angles for the various wavelengths.

Similarly, other halos, often referred to as arcs, are due to other ray paths. A very brief survey of some common halos (today, more than 40 different types are known) is shown in Fig. 19.26. The circumzenith arc (No. 7 in Fig. 19.26) is due to rays which enter the top basal face and exit a prism face of crystals with vertical symmetry axis. For random orientation, ray paths which refer to such a 90° prism lead to circular halos of 46° (No. 3 in Fig. 19.26). Pure reflection halos – not colored, since refraction does not contribute – are e.g. sun pillars (No. 4 in Fig. 19.26). They arise when sunlight is reflected at grazing incidence from the horizontal faces of plate crystals oriented with their axes vertical. Similarly oriented crystals also give rise to the parhelic circle (No. 5 in Fig. 19.26), which is due to reflected sunlight from crystal faces lying in the vertical plane.

Singly oriented column crystals – column crystals with axes horizontal but otherwise unconstrained – give rise to the upper and lower tangent arcs. Much more rarely, column crystals orient with two prism faces horizontal. Crystals having these Parry orientations give rise to Parry arcs. Still other crystal orientation modes are possible. Furthermore, crystals occasionally have pyramidal faces that produce halos at other angular distances, referred to as odd-radius halos.

The modern theory of halos started in the 17th century [19.44, 172]. In recent decades, enormous progress has been made. This is due to computer techniques, the application of more traditional, conceptual mathematics [19.173], experiments which collected atmospheric ice crystals during observation of halo displays in cold climates, and to dedicated observers who have documented many new halos.

Probably the biggest step was made by the introduction of computer simulations which allow the computation of complex halos from many different types of crystal shapes, sizes and orientation. They gave a lot of new information, especially regarding intensity variations within a given halo [19.48, 174, 175]. Various arcs could be directly related to the crystals and the ray paths that were producing them. The theoretical displays could be easily compared with photographs or drawings of real halo displays.

Many excellent displays were documented by Finnish or German observer networks ([19.176], see

also Table 19.4) and scientists in Antarctica [19.52]. Computer simulations were also used to explain old documented displays dating back to the 18th century [19.177]. Analysis of halos also include polarization effects, started by systematic studies in the seventies [19.53, 178]. Halo polarimetric studies should allow the detection and identification of birefringent crystals in extraterrestrial atmospheres [19.179–181]. Very recently, the focus had been on comparison of observations with the simulation of halo polarization profiles, the size and shape of the crystals in the model being based on sampled ice crystals [19.182].

Halo phenomena have also been studied in the laboratory for quantitative comparison to theory and as demonstration experiments using prisms or hexagons made of glass, lucite or other materials [19.43, 66, 109, 110, 112].

19.6.7 The Color of the Sun and Sky

The Color of the Sun

Light scattering in the atmosphere is responsible for the color of the sun or moon, as perceived by earthbound observers. Outside the atmosphere, solar irradiation has a very broad spectrum, ranging from UV to the deep infrared [19.183]. Neglecting processes in the sun's atmosphere, it more or less resembles the emission of a black body of about $5900\,K$. This radiation is interpreted as white by human eyes (the exact color may be computed from spectra according to color metric formulae, see e.g. [19.76]). In the Earth's atmosphere, the radiation is absorbed and scattered. Compared to the outside spectrum, the irradiation curve is lowered and shows characteristic absorption features, mostly from H_2O, CO_2 and oxygen (see Fig. 19.7).

Color changes occur depending on air mass, i.e. sun elevation. Starting with a purely nonabsorbing molecular atmosphere, atmospheric transmission has been computed for air mass $AM = 1$ [19.3]. Therefrom the transmission at arbitrary zenith angles φ and starting at height h of an observer may be computed according

to [19.86, 114]

$$T(\varphi, h) = T(0, h)^{AM(\varphi, h)} \qquad (19.40)$$

Results for the transmission of red ($\lambda = 630\,nm$), green ($\lambda = 530\,nm$) and blue ($\lambda = 430\,nm$) light for a molecular atmosphere and $AM = 1$, ($\varphi = 0°$, zenith), $AM = 10$ ($\varphi \approx 85°$) and $AM = 38$ ($\varphi = 90°$, horizon) are given in Table 19.6.

Whereas the zenith sun is still regarded as white, the sun's spectrum near the horizon is drastically changed in favor of red and green light. Above the horizon, yellow colors may be observed and close to the horizon, red dominates. Since, simultaneously, the radiance of the sun decreases drastically, the brightness also decreases with φ. Naked-eye observations are, however, still not possible in very clear air even if $h = 0$ (sea level). In general, however, haze due to water vapor and aerosols leads to additional weakening.

Aerosols are very important for optical variations within the atmosphere [19.15, 16]. The difference of observations and theoretical spectra, including selective absorption of molecules within the air, is attributed to aerosols [19.114].

Extraordinary color changes of the sun can sometimes occur, if clouds of nearly uniformly sized particles are present in the line of sight. For example, the forest fires in Canada in 1950 ejected large numbers of oil droplets in the air. These were transported over long distances and led to blue sun observations even in Edinburgh [19.74, 184]. Similar events may be due to volcanic eruptions.

Sky Colors

Obviously, sky colors are due to many factors [19.43–49, 51]. A simple qualitative explanation of typical sky colors at sunset can be given according to Fig. 19.27.

Table 19.6 Transmission of a molecular atmosphere ($h = 0$) for sun in zenith ($AM = 1$: $\varphi = 0°$) or close to the horizon ($AM = 10$: $\varphi = 85°$, $AM = 38$: $\varphi = 90°$), $T(\varphi = 0°)$ after [19.3]

λ(nm)	$T(AM = 1)$	$T(AM = 10)$	$T(AM = 38)$
630	0.945	0.625	0.117
530	0.892	0.320	0.013
430	0.764	0.068	0.000036
Fig. 19.27 Geometry for qualitative explanation of sky colors after sunset (see text for details)

The sun has just set, i.e. it is below the horizon. Sunlight still illuminates portions of the atmosphere. The color that an observer perceives in a given direction is due to contributions of scattered and attenuated light along a line of sight in the respective direction. In simple terms, the amount of radiation entering the observers eye depends on, first, the light path through the atmosphere before scattering, second, the height of the scattering event, which determines the density of scatterers, third, the scattering angle, and fourth, the optical thickness along the line of sight, i.e. the attenuation due to scattering and/or absorption. The subtle interplay of these four parameters determines the spectrum of light reaching the eye of an observer and hence the perceived color.

Different locations along the line of sight will contribute to the scattered light with varying intensity as well as spectral composition. The light beam most distant from the Earth will reach the line of sight, nearly unattenuated, and a broad spectrum is available for scattering. Due to the large height, only a small amount of radiation is scattered towards the observer, with blue dominating. This light is further attenuated before reaching the observer. The final spectral composition of the light depends on the optical thickness that must be traversed. However, blue is most strongly attenuated, i.e. overall this light will not contribute much and will not dominate the color. The closer the light passes to the ground, the more its spectrum is shifted towards the red. Although less light will intersect the line of sight compared to the large height rays, it will contribute more, since it interacts at lower heights, i.e. with a much larger density of scatterers. Taking into account the further shift of the scattered light spectrum towards the red due to scattering along the line of sight shows that the sky color will be dominated by yellowish and red colors.

The brightness and color of the clear sky has also been investigated for various zenith angles φ [19.185]. For high sun elevations, the zenith sky of a pure Rayleigh atmosphere is blue (as observed for clear air), however, it would turn yellowish after sunset. This is in contrast to the observed blue color. The solution of this puzzle are the Chappuis absorption bands of ozone in the wavelength range between 500 and 700 nm. For high sun elevations, the ozone absorption contribution to sky light is small compared to Rayleigh scattering whereas it dominates for very low sun elevations.

Aerosols within the atmosphere are usually not distributed homogeneously, but in the form of ac-cumulations, carried by the wind, thus undergoing constant qualitative changes, including condensation processes [19.114]. As a consequence, the extinction coefficient for various atmospheric compositions, e.g., for different types of clouds, and low- or high-altitude haze varies considerably [19.76]. For simplicity, let us now assume just a single aerosol layer. Its influence on sky colors is simply to intensify the red and yellow colors in the forward direction. This is due to the fact that the scattering angles are rather small and that aerosol particles show very strong forward scattering, compared to Rayleigh scattering (Fig. 19.17).

Similar qualitative arguments may also be applied to the phenomenon of the so-called blue mountains. During the day, the sky is illuminated by the sun. If the line of sight to a distant mountain is close to the horizon, the radiation entering the eye of an observer is due to two contributions. First, it consists of the light originally scattered by the mountain towards the observer. This light is attenuated due to scattering along the line of sight. Second, the observer will see sunlight that is scattered by the air along the line of sight. This air light will be blue in a Rayleigh atmosphere. Observing a scenery with mountains at various distances will change the amount of the two contributions: the more distant, the smaller the first will be and the more important the second contribution (see the discussion on visibility in Sect. 19.6.8). As a consequence, distant objects will appear to have a faint blue color [19.45, 51]. This scheme can be used to get a measure for the thickness of the atmosphere [19.186].

Very often, one observes that sky light close to the horizon is whitish. This can be understood in a similar way. Since no objects except the sky are observed, the first contribution from the above argument vanishes and only air light has to be considered. Sunlight which is scattered in a length interval close to the observer contributes a large amount of blue light due to Rayleigh scattering at low heights above the ground. Light which is scattered at larger distances from the observer is scattered at larger heights, i.e. contributes smaller amounts of predominantly blue light. In addition this light is attenuated and spectrally modified by additional scattering along the line of sight. As a result, light which originates far from the observer contributes small amounts of multiply scattered mostly red light. All contributions along the line of sight add up to give an overall white color. Since light from distant portions will cease to contribute if scattered out of the line of sight, the overall brightness has a limit [19.45, 51, 77].

Observations from Mauna Loa of the polarization and color ratio during twilight often show deviations from the clear-sky average. These were attributed to cloud or haze shadow effects and the importance of stratospheric dust layers was emphasized [19.187]. Stratospheric dust clouds from volcanic eruptions do strongly affect the degree of polarization of sky light and also shift the positions of neutral points by more than 15° [19.188]. Such investigations strongly profit from the development of LIDAR systems and the respective theories of backscattering from small particles [19.189–192].

Modern experiments simultaneously measure the sky light radiance distribution at three wavelengths, the degree of polarization, and the plane of polarization [19.193]. Recently, the color coordinates of sky light have been investigated, showing that sky light colors have a wide range of chromaticity curves, depending strongly on location. Sometimes difficulties arise in separating luminance changes from chromaticity changes [19.194]. Astonishingly, clear daytime skies show a local maximum of radiance near the astronomical horizon. Its angular width and elevation vary with the solar elevation, azimuth relative to the sun, and aerosol optical depth. This is understood in terms of second-order scattering processes [19.195].

When the sun is seen through thin clouds, it usually has a sharp edge, but occasionally is fuzzy. This is due to certain clouds with ranges of cloud optical thicknesses depending on the cloud particle sizes [19.196].

Present investigations of sky light deal, e.g., with digital imaging of clear-sky polarization [19.197], twilight modeling [19.198] as well as color and luminance asymmetries in clear [19.199] and overcast [19.200] skies. Sky light measurements have also been reported for Mars, based on data from the Viking and Pathfinder missions. The Martian atmosphere has a high dust-particle content resulting in very high sky brightness and the sky colors vary strongly with the angular position of the sun [19.201].

Theoretical modeling of atmospheric extinction greatly profited from computer technology. Nowadays, the transmission of the atmosphere is modeled by extensive databases. The most prominent of these are the HITRAN and LOWTRAN databases [19.76, 202]. In particular, the LOWTRAN program calculates the transmission spectrum for molecular absorption, Rayleigh scattering and aerosol extinction at a moderate resolution of $20\,cm^{-1}$.

19.6.8 Clouds and Visibility

Clouds

Clouds are visible aggregates of water droplets or ice crystals, suspended in the air and grown around condensation nuclei [19.118]. Fog or clouds have droplet sizes around or above $10\,\mu m$, with densities ranging from 10 to 1000 droplets/cm^3. On average we will assume 300 droplets/cm^3 [19.203]. Droplets of $5-10\,\mu m$ radius will then correspond to volume fractions f of about $10^{-7}-10^{-6}$.

Clouds exhibit several optical phenomena, the most obvious being their white color, but certain types of clouds show particular phenomena. Cirrus and cirrustratus clouds may give rise to coronas, iridescence and halos, contrails of aircraft engines are cirrus-like trails of condensed vapor with characteristics similar to cirrus clouds, and cumulonimbus clouds relate to thunderstorms, i. e. lightning. Here, the color of clouds, their absorption and extinction will be briefly discussed. The effect of photon path length distributions within clouds is discussed in the contribution of *U. Platt* and *K. Pfeilsticker* (Sect. 19.5.5).

If illuminated by white light, clouds appear white (lower brightness is often interpreted as grey or dark). Since water droplets are mostly nonabsorbing in the visible, the color must be due to scattering. Scattering of light from monodisperse water droplets of about $10\,\mu m$ shows Ripple structures (Fig. 19.16) [19.40,41], for size distributions this is washed out and scattering is mostly independent of wavelength in the visible spectral range. Although this is a sufficient condition for clouds to be white, it is not necessary [19.204]. As a matter of fact, a suspension of Rayleigh scatterers (such as fat droplets in milk), i. e. selective scatterers, also give a white color due to multiple scattering.

The criterion for multiple scattering to take place is that the optical thickness τ is large compared to unity. A molecular atmosphere had $\tau < 1$, therefore the explanation of the blue sky needs only single scattering events. For clouds, τ for a distance x can be estimated by the following argument: within clouds, the extinction coefficient is more or less constant, hence $\tau = \beta x$. The extinction coefficient β can be estimated from Mie theory calculations. Droplets of about $10\,\mu m$ in diameter have extinction cross sections of about twice the geometrical cross section (this is the extinction paradox, [19.41]), i. e. of the order of $10^{-6}\,cm^2$. For concentrations of 300/cm^3, this leads to extinction

coefficients β of the order of $0.05\,\text{m}^{-1}$. A very simple estimate [19.77] can also be made by starting from $\beta = N\sigma$ and substituting the number density N by the volume fraction $f \approx N\varnothing^3$ and the cross section by approximately the geometrical cross section $\sigma \approx \varnothing^2$ to find

$$\beta \approx f/\varnothing \qquad (19.41)$$

for $f = 10^{-6}$ and 10-μm particles, this also gives the order of $0.1/\text{m}$.

Hence, a cloud of several meters thickness corresponds to the optical thickness of the whole normal atmosphere. The transmission is given by $T = \text{e}^{-\beta x}$ and for $\beta = 0.05\,\text{m}^{-1}$ a distance of 20 m leads to $\tau = 1$ ($T = 1/\text{e}$), $x = 100\,\text{m}$ to $\tau = 5$ ($T \approx 7 \times 10^{-3}$), and $x = 200\,\text{m}$ to $\tau = 10$ ($T \approx 5 \times 10^{-5}$), which is sufficient to obscure the disk of the sun [19.77]. Low transmission automatically leads to high reflection, i.e. thick clouds have a high albedo which explains the bright white color observed from airplanes above clouds. In conclusion, multiple scattering dominates for any cloud that is optically thick and composed of nearly nonabsorbing particles; upon illumination by white light it will look white. The color of clouds may change during sunrise and sunset if spectrally filtered light illuminates the clouds, giving rise to spectacular sceneries.

The very small transmission of sunlight through thick clouds also accounts for the fact that the bases of such clouds are usually very dark. If droplets near the base grow to form raindrops, the extinction coefficient changes. The volume fraction stays about the same, but raindrops have a size of, say, 1 mm, hence β in a rain shower is about a factor 100 smaller than within the clouds. This explains, why it is easily possible to look through very heavy rainfalls.

Visibility

Visibility is a measure of how far one can see through the air. Even in the clearest air – assuming that no aerosol particles are present and that one is not restricted by the Earth's curvature – the horizontal visibility is limited to a few hundred kilometers. This is due to the scattering and absorption of the components of the air (vertically, the atmosphere is optically much thinner, hence we may see the stars at night). In meteorology, visibility refers to the observation of distant dark objects against a bright background, usually the sky. The basis for a theoretical derivation [19.77, 205–209] is the contrast ratio C, giving the normalized difference between the background intensity of the object and the intensity of the air light from the line of sight. One finds for the resulting maximum distance D

$$D = -\ln(C)/\beta, \qquad (19.42)$$

where β is the scattering coefficient. The sensitivity of the human eye has a maximum at $\lambda = 555\,\text{nm}$, therefore one usually evaluates (19.42) for green light. D then just depends on the threshold contrast C, i.e. the lowest visual brightness contrast, a person can see. It is common to assume $C = 0.02$ although it varies from individual to individual. This gives $D = 3.912/\beta$. Values of D for various β are shown in Table 19.7. Obviously, there is an enormous range of distances from several meters in dense fog to several hundred kilometers in very clear air. Hence, the visibility is an indicator of the aerosol and/or water droplet content.

19.6.9 Miscellaneous

There is a great number of other optical phenomena associated with the atmosphere. In the following, these will be very briefly described and references will be given.

Green flashes or green suns are phenomena when either the last rays at sunset or the first rays at sunrise look green or when, at low sun elevations, the upper rim of the sun looks green. In the first case, just a very small portion of the sun is above the horizon, in the second case, the sun's disk is usually highly distorted due to mirage effects. The explanations of these phenomena require refraction and the scattering of the sunlight as well as mirage effects [19.103, 210, 211].

Noctilucent clouds are blue, white or silvery looking clouds within the stratosphere at heights of about 80 km

Table 19.7 Typical values for visibility in molecular atmosphere and examples if aerosols (natural/anthropogenic) and water droplets are present

	β	D	
Molecular atmosphere	$0.013\,\text{km}^{-1}$	300 km	Extremely excellent visibility
Some particles	$0.050\,\text{km}^{-1}$	80 km	Excellent visibility
Many particles	$0.500\,\text{km}^{-1}$	8 km	Poor visibility
Thick fog	$0.050\,\text{m}^{-1}$	80 m	Extremely poor visibility

which can still be illuminated by sunlight 1–2 h after sunset [19.212–214]. They often show wavelike features with wavelengths in the range from 1–100 km.

Interesting colorful phenomena may be observed during eclipses. For example, the colors and brightness of lunar eclipses are directly related to the scattering of sunlight within the Earth's atmosphere [19.215, 216]. Other examples include polarization of sky light [19.217, 218], twilight phenomena [19.219], and illuminance measurements [19.220] during solar eclipses.

Shadows are regions in space that are shielded from light. They give rise to very prominent daily-life phenomena in atmospheric optics such as the crepuscular rays, sometimes called sun beams or shadow beams [19.45, 48, 51, 221] or the fact that mountain shadows are always triangular, irrespective of the contour of the mountain [19.222, 223].

A very personal experience, based on our visual system, is the so-called moon illusion, i.e. the fact that the sun or the moon looks much bigger near the horizon than when it is higher in the sky [19.224, 225]. This phenomenon is not reproduced on photos.

In addition to phenomena with external light sources such as the sun, moon or stars, a number of optical phenomena in the atmosphere produce light. The most well known are auroras, multicolored, diffuse and slowly moving lights, usually seen only in high altitudes against the clear dark night sky. They are due to air molecules and atoms, which are excited by collisions with electrons from the solar wind [19.51, 226, 227]. At times of increased solar activity, they may also be observed at low latitudes. These events are accurately predictable, since the solar wind needs time to reach the Earth (see the websites on space weather in Table 19.4).

Lightning, one of the most common and spectacular natural phenomena, is due to electric charging effects in thunderstorm clouds. The exact microphysical processes that are responsible for the charging are still under dispute [19.228–230]. Recent research has revealed a whole new class of phenomena: lightning-related transient luminous events (TLE), including sprites, blue jets, elves, trolls etc. [19.231]. These TLE extend from the top of thunderclouds at heights of up to 100 km and raise serious questions about possible hazards for aerospace operations. In addition, promising efforts are under way concerning lightning protection by initiation of the discharge using intense femtosecond lasers [19.232].

Meteors are sometimes faint, sometimes brilliant streaks of light with luminous trails in the night sky. Meteor incorporates all phenomena when a cosmic particle enters the atmosphere. Outside the atmosphere, they are called meteoroids and, if they reach ground, meteorites. The visual effects are due to heating of particles in the atmosphere due to frictional forces. Small particles heat up until they evaporate. Thereby, they collide with air molecules and ionize a channel of air. Light is then emitted upon recombination [19.233, 234].

20. Holography and Optical Storage

The term holography is composed of the Greek words *holos* (= whole) and *graphein* (= to record, to write), and thus summarizes the key aspects of its underlying principle: recording the complete wavefront of an object, i. e., its intensity as well as its phase. Interference and diffraction phenomena are employed to record and retrieve the full information, a technique pioneered by Dennis Gabor in 1948. He was honored with the Nobel prize in Physics in 1971, reflecting the general impact of holography on modern physics.

Holography plays an essential role in today's science and industry. Relevant applications making use of its principle have been developed, including three-dimensional (3-D) displays and holographic cameras, interferometers for nondestructive material analysis, archival data storage systems, diffractive optical systems, and embossed display holograms for security features. The success of holography was made possible in particular by the availability of coherent laser-light sources. In the meantime holography has even been performed using microwaves, neutrons, electrons, X-rays, and acoustic waves.

The first part of this chapter is devoted to holography itself. It provides an introduction to the historical development and reviews the principle of wavefront reconstruction. This section also includes an overview of hologram classification, recording/read-out geometries, holographic techniques and recording materials. Special emphasis is given to explaining the principles of some of the most important holographic applications, finishing with a brief insight into a few of the latest discoveries making use of Gabor's principle, such as holographic scattering and neutron diffractive optics.

The second part of this chapter addresses trends in optical storage, focussing on holographic data storage. It highlights different approaches to achieving increased optical storage density. This section also discusses the historical development of optical storage, the need for increased storage densities (and hence storage capacities) and the role of optical storage systems in today's life.

Various approaches to increasing the areal density of optical storage systems are introduced. Next, the advantages of and approaches to volume optical recording that are currently under consideration for future generations of optical storage systems are presented. The state of the art as well as physical and technical attempts to realize holographic data storage are discussed in detail.

20.1 Introduction and History

In May 1948 *Dennis Gabor* (Fig. 20.1) introduced the principle of wavefront reconstruction in the scientific journal Nature [20.1]. In the frame of his one-page contribution "A new microscopic principle" he discussed the high-resolution visualization of microscopic objects and emphasized the impact of his idea for the improvement of electron microscopes. The word *holography*, as his principle was designated shortly thereafter, is a compound of the Greek words ὅλος (*holos* = whole) and γράφειν (*graphein* = to record, to write) and summarizes the key aspects of Gabor's principle: the recording of the complete/overall wavefront from an object, i.e., recording of the object within all three dimensions. Holography is therefore a serious extension of photography, which is limited to the recording of the projected image of three-dimensional objects. In standard photography, the intensities/amplitudes of the wavefront of the object are

Fig. 20.1 *Dennis Gabor* (1900–1979, born in Budapest, Hungary), Nobel Prize Laureate 1971 (from [20.10])

recorded without the appertaining phase information. Photography does not include the depth information, i.e., a look around the object is not possible. In holography, viewing the reconstructed image is identical to the observation of the real wavefront of the object. Within ge-

ometrical limits the object can be observed from various perspectives and it is possible to look behind the object.

Holography uses the interference phenomenon for recording both the amplitude and the phase information. The first holograms were realized by Gabor with the light of a mercury-arc lamp, that hence contained distortions and an extraneous twin image. The further history of holography is punctuated by the development of coherent laser-light sources in the 1960s, the real success of holography being initiated in 1962: *Emmett Leith* and *Juris Upatnieks* read Gabor's paper and "simply out of curiosity" they adapted Gabor's principle to an off-axis geometry that they borrowed from their work on side-reading radar. The result was the first laser transmission hologram of three-dimensional objects (a toy train and bird) [20.2, 12, 13]. At the same time *Yuri N. Denisyuk* combined holography with the findings of *Gabriel Lippmann* on natural color photography [20.14] and produced a white-light reflection hologram [20.3]. For the first time, a hologram could be reconstructed using the light from an ordinary incan-

descent light bulb. In 1965 the patent for the off-axis recording geometry for reflection holograms was issued to *N. Hartmann* [20.4] – a technique that emerged as a standard in holographic recording. The invention was due to at least three teams of co-workers: E. Leith, J. Upatnieks, A. Kozma, J. Marks, and N. Massey (University of Michigan); G. Stroke, A. Labeyrie (University of Michigan) with K. Pennington and L. Lin (Bell Labs); C. Schwartz and N. Hartmann (Batelle Memorial Institute). Table 20.1 gives an overview of the impressive milestones within the first decades of the history of holography. A recent review of the history of holography is given in [20.15]. Nowadays, holography touches many fields of our everyday life including arts, archeology, health and medicine, biotechnology, advertising and communication. Gabor's principle continues to be a topic of research and potentially will open up novel perspectives, e.g., in optical data storage (cf. Sect. 20.5). The impact of this invention was honored with the Nobel prize in 1971 [20.10]. *Dennis Gabor* died on February 8, 1979.

20.2 Principles of Holography

20.2.1 Recording of Holograms and Wavefront Reconstruction

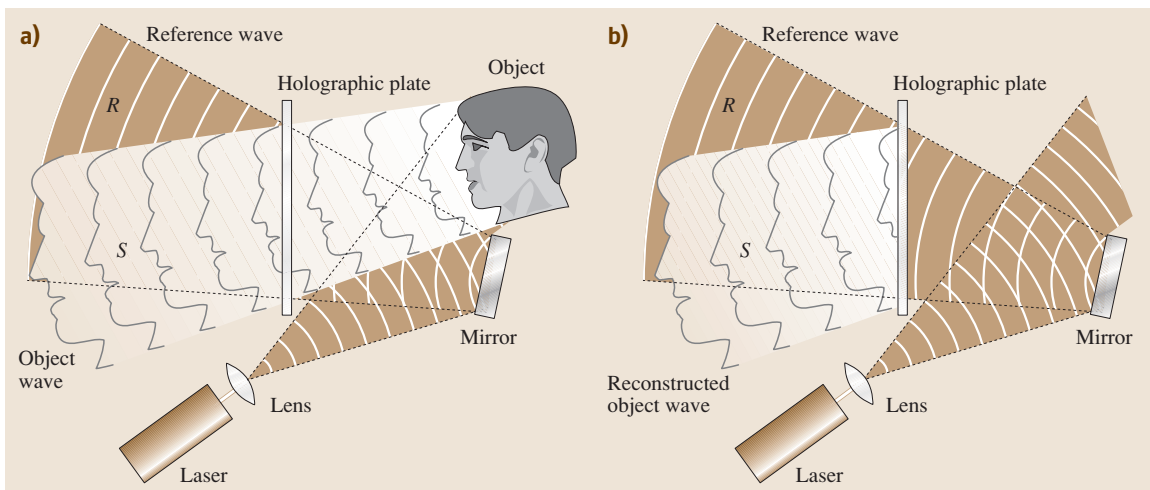
The holographic principle makes use of the interference phenomenon, as interference allows the transfer of the phase information of a wavefront into an intensity pattern. Recording both the amplitude and phase of the wavefront of an object, i. e. recording a hologram, is performed by interference of a reference wave with complex amplitude R and a coherent signal wave S using


Fig. 20.2 (a) Recording a hologram and **(b)** wavefront reconstruction. The intensity pattern from the interfering reference R and signal S waves is recorded by the holographic plate thus representing a hologram. A complete reconstruction of the signal wave S appears by light diffraction if the hologram is exposed to the reference wave only

a holographic plate Fig. 20.2. For the sake of simplicity we do not consider vectorial properties of the waves at the moment. The wavefront of the object is reconstructed by light diffraction if the hologram is exposed only to the reference wave.

The simplest hologram is formed by the interference of two plane waves with non-collinear propagation directions. In this case a pattern with sinusoidally modulated amplitude is recorded on the holographic plate, i. e., an *elementary holographic grating*. Exposure of this grating to the reference wave leads to diffraction along the former direction of the signal wave. Thus the wavefront of the plane signal wave is reconstructed.

More complex wavefronts are reconstructed in an analogous way. Let us consider the reference and signal waves with complex amplitudes R and S. Then the intensity I of the interference pattern can be expressed by

$$I \propto |R+S|^2 = |R|^2 + |S|^2 + R^*S + RS^* , \qquad (20.1)$$

where * denotes the complex conjugate. Exposing a photochromic film (such as a holographic plate) to the interference pattern, the absorption coefficient and hence the transmission T will become spatially modulated. In the case of a linear response of the film to intensity, i. e., $T = T_0 - \Delta TI$, the illumination of the holographic plate with the reference wave results in the reconstructed wave

$$RT = R \left[T_0 - \Delta T(|R|^2 + |S|^2 + R^*S + RS^*) \right] . \qquad (20.2)$$

Here, T_0 is the transmission prior to illumination and ΔT is a parameter that characterizes the photosensitivity of the film. The important term in (20.2) is $\Delta TRR^*S = \Delta T|R|^2S$. The factor $\Delta T|R|^2$ is constant and phase independent, but the signal wave S is completely revealed with *amplitude and phase*. The other terms in (20.2) describe the transmitted reference wave and further diffracted waves. Separation of these particular waves from each other can be established by choosing a proper recording geometry (spatial separation via off-axis geometry, cf. Sect. 20.2.3).

The *amplitude* and *phase* information of the recorded object is stored in each singular point of the holographic plate, representing the particular viewpoint onto the object. Thus the lateral dimension of the holographic plate is the limit for the visual angle onto the recorded object. Reconstruction is even possible by exposure of only a small part of the hologram with the reference wave.

In summary, the holographic principle only requires a source of coherent waves, an object, and a photosensitive medium with sufficient spatial resolution. It is worth noting that there is no restriction on the nature of the radiation or its wavelength and thus any (partially) coherent wave can be applied, such as electrons, neutrons, X-rays, microwaves, photons and acoustic waves. All of these have been utilized for holographic recording within the last decades. As for the variety of waves, the spectrum of photosensitive media for hologram recording is rather broad and ranges from photochromic films, ^{3}He detectors (neutrons) to germanium detectors or avalanche photodiodes (X-rays).

20.2.2 Classification Scheme

The fundamental principle of recording and reconstructing an object wave can be realized in a great deal of variants, predetermined by the available recording materials, the optical setups (geometries) or techniques for recording and read out, etc. Therefore one could classify holograms, e.g., with respect to the recording scheme, the read-out configuration or the hologram properties [20.16]. The classification scheme suggested in this section primarily considers the reconstruction properties of the particular holograms. We note that such properties are closely associated with the geometrical schemes for recording (Sect. 20.2.3) and/or the type of holographic recording medium (Sect. 20.2.5), introduced later in this chapter.

The first step in hologram classification is to distinguish between *phase* or *amplitude*, *thin* or *thick*, *transmission* or *reflection* and *static* or *dynamic holograms* (see Fig. 20.3). Note, that the combination of these particular types yields a precise designation as well as sufficient information about the hologram. Our previous example from Sect. 20.2.1 is a static thick amplitude transmission hologram.

Furthermore, the particular recording and reconstruction properties are considered, which expands the variety of hologram types. Among these are: *rainbow holograms*, *polarization holograms*, *holographic*
Fig. 20.3 Holograms are primarily classified as phase or amplitude, thin or thick, transmission or reflection and static or dynamic holograms

stereograms, *composite holograms*, *multiplexed holograms* (Sect. 20.2.4), *Fresnel holograms*, *Fraunhofer holograms*, *Fourier holograms*, *image-plane holograms*, and *embossed holograms*. The corresponding hologram properties will be presented in the following sections.

Phase and Amplitude Holograms

In Sect. 20.2.1 we assumed that the recording process results in a spatial modulation of the transmission of the holographic plate. The diffracted reference wave is then affected in its amplitude. Thus the hologram commonly is called an *amplitude* or *absorption hologram*. Figure 20.4 shows the microscopic structure of an *amplitude hologram*. In other photosensitive media the refractive index or the thickness is changed upon illumination with light. In this case the phase of the reference wave is affected during diffraction, i. e., reconstruction of the object wave. Therefore this type of hologram is called a *phase hologram*. Usually the latter is more favorable, because the intensity of the reconstructing reference wave is not damped by material absorption, so that holograms with considerable thickness can be recorded.

Thin and Thick Holograms

Taking into account the effective hologram thickness and the amplitude of the absorption or phase modulation, holograms can be classified as *thin* or *thick*. Note, that effective thickness d_{eff} of the hologram has to be distinguished from the thickness of the medium d in which the hologram is recorded. They are related by $d_{eff} \leq d$. The case $d_{eff} = d$ is valid for non-absorbing media and diameters of reference and signal waves much larger than d. A rough rule of thumb defines holograms with a thickness of about the light wavelength or less as thin holograms. However, a sharp boundary does not exist and only the extremal cases are unambiguously defined [20.18]. For thick holograms it is mandatory to fulfill the Bragg condition for reconstruction:

$$s\boldsymbol{K} = \boldsymbol{k}_S - \boldsymbol{k}_R \quad \text{or} \tag{20.3}$$

$$s\lambda = 2\Lambda \sin\theta_B . \tag{20.4}$$

The Bragg condition is a result of energy and momentum conservation. Here, $\boldsymbol{K}$ is the grating vector of the elementary grating, $\boldsymbol{k}_{S,R}$ are the wave vectors of the signal and reference wave, respectively, and s is the diffraction order. Equation (20.4) is a scalar version of (20.3) for the particular case that the grating vector is perpendicular to the surface normal vector $\hat{N}$. Equation (20.4) imposes a strict relation on the wavelength λ, the angle of incidence (Bragg angle θ_B) and the grating spacing
Fig. 20.4 Hologram microstructure of a diffuse object (After [20.17])

$\Lambda = 2\pi/|\boldsymbol{K}|$ to reconstruct the hologram efficiently. At the same time, higher diffraction orders ($s > 1$) are depleted; they are a characteristic property only for thin holograms. The Bragg condition is illustrated by a wavevector diagram in (Fig. 20.5a). The sharpness of the Bragg condition is inversely proportional to the dimensions of the grating. Assuming a symmetric geometry, i. e., $\boldsymbol{K} \perp \hat{N}$, and a grating with thickness d yields an uncertainty of the Bragg condition of $2\pi/d$. This region is indicated by the shaded area in Fig. 20.5. As long as the Bragg mismatch vector $\delta\boldsymbol{k}$ resides within this area, Bragg diffraction can be observed (Fig. 20.5b). The modulus of the mismatch is proportional to the angular and wavelength mismatch ($\Delta\theta$ and $\Delta\lambda$). By this means, an angular accuracy to reconstruct a thick hologram can be in the region of less than $0.001°$, a fact that is utilized for angular and wavelength multiplexing (Sect. 20.2.4).

Transmission and Reflection Holograms

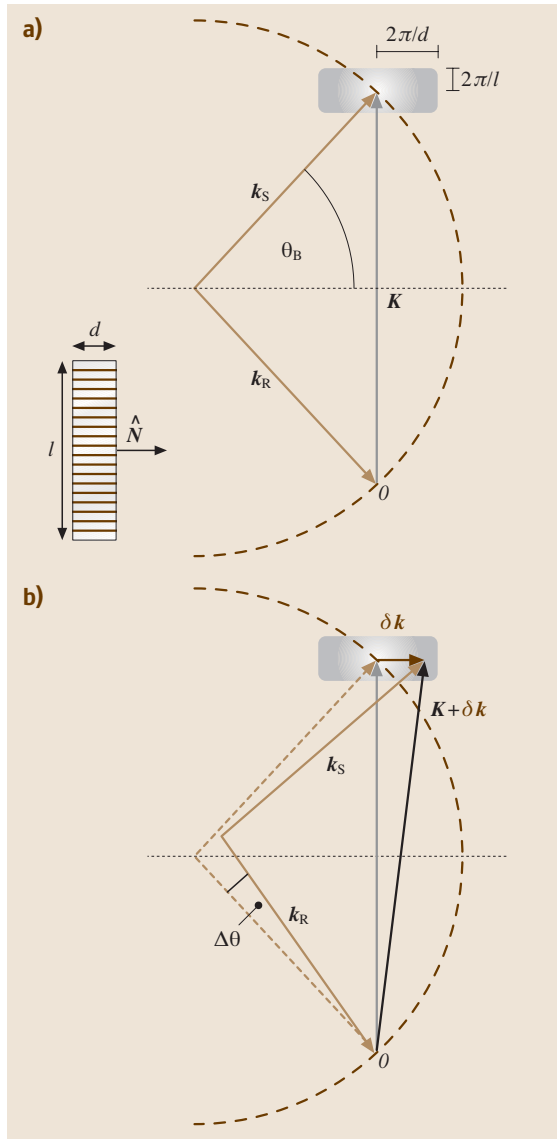
The classification into *transmission* and *reflection holograms* takes the direction of the wave vectors of the reference and reconstructed signal wave with respect to the holographic medium into account. This is schematically illustrated in Fig. 20.6 for two extremal cases. A transmission hologram is characterized by the fact that both reference and signal wave are transmitted through the hologram, i. e., the signal wave is reconstructed by forward diffraction processes. For reflection holograms only the reference wave is transmitted. Thus, the latter is realized if the sign of the dot product between the surface normal vector $\hat{N}$ and the wave vectors $\boldsymbol{k}_R$ and $\boldsymbol{k}_S$, respectively, differ. Reflection holograms require recording media with thicknesses much larger than the grating


Fig. 20.5 Wave vector diagram: energy and momentum conservation in reciprocal space. (**a**) Exact Bragg matching. (**b**) Slight angular mismatch, $|\delta k| < 2\pi/d$. Reconstruction with lower efficiency is still possible as long as the Bragg mismatch vector δk ends within the grey area

Fig. 20.6 Directions of the wave vectors of the reference and signal waves with respect to the holographic recording medium for (**a**) a transmission hologram, and (**b**) a reflection hologram

Static and Dynamic Holograms

Holograms that do not affect the reference and signal waves during recording, e.g., in holographic media that require further (chemical) processing, are called *static holograms*. In contrast an interaction between the recorded hologram and the recording beams leads to *dynamic holograms*: the recording beams themselves coherently diffract from the hologram and thus influence their own light modulation. Obviously, this feedback subsequently leads to changes of the hologram. This nonlinear dynamic interaction can result in an amplification of weak signal beams. As a consequence the contrast ratio of the interference pattern and thus of the hologram is a function of the material thickness. The ratio might be enhanced, e.g., as a function of the propagation coordinate in transmission holograms. Further coupling between the recorded hologram and the incoming interference pattern is shown to result in light amplification [20.19], which has been successfully applied for image [20.20] or signal amplification [20.21].

spacing. Hence they usually represent *thick reflection holograms*. A benefit of a thick reflection hologram or *white-light reflection hologram* is its high wavelength selectivity, which acts as a narrow-band wavelength filter for the reference light and allows reconstruction with white-light sources.

Rainbow Holograms

The invention of *rainbow holograms* stems from *Benton* [20.9, 22], allowing the reconstruction of bright, sharp monochromatic images from transmission holograms with white light. For this purpose the hologram information is reduced by losing the vertical parallax, which is an unimportant feature of holography, as three-dimensional viewing depends essentially on the horizontal parallax. Rainbow holograms are produced by copying a transmission hologram (Sect. 20.2.4) in which the area illuminated by the reference wave is strongly reduced with a horizontal slit. As a result, reconstruction of a rainbow hologram with white light splits the image in the vertical plane to form a continuous (rainbow) spectrum. Thus the reconstructed image can be observed at any part of the spectrum in the corresponding color.

Polarization Holograms

The holographic principle demands reconstruction of the complete object wavefront, usually of its amplitude and phase distribution. However, the object may additionally influence the polarization field of the wavefront, e.g., the electric field vector is influenced by reflection processes on specular surfaces. *Polarization holograms* allow the reconstruction of the polarization field of the signal wave as well and endow the holographic medium with specific recording and reconstruction properties. According to Table 20.2 we distinguish between the materials by their property to record and/or to reconstruct the polarization field. The type I and III media are obviously not suited for recording polarization holograms, although type I is applied to record and reconstruct standard holograms, i. e., phase and amplitude of wavefronts. Type III holograms are of interest, since the reconstructed polarization field is a fingerprint of the material properties and can thus be used to analyze the recording medium.

A sensitivity to light polarization is known in various media, e.g., media with photoinduced dichroism or photoinduced birefringence (type I, type III) [20.23, 24].

Table 20.2 Type I media allow only recording of the light polarization. Type II media allow both recording and reconstructing the polarization field. Type III media superimpose a material-specific polarization field to the reconstructed wavefront

	Record	Reconstruct
Type I	✓	✕
Type II	✓	✓
Type III	✕	✓

Recording and reconstruction of polarization holograms was further shown in photorefractive electro-optic crystals such as iron-doped $LiNbO_3$ [20.25], where the photovoltaic tensor provides the reconstruction of the polarization field (type I, type II and type III). In recent decades further photosensitive materials have been discovered that allow efficient type II recording of the polarization field, among them crystals with a center of inversion [20.26] (Sect. 20.2.5).

Holographic Stereograms and Composite Holograms

Holographic stereograms are recorded by photographing the object from various perspectives in the first step and subsequent holographic recording of the particular photographs at corresponding positions of the stereogram in the second step [20.27, 28]. The advantage of holographic stereograms is that coherent laser light is not required for the primary recording process, and thus it is even possible to record large objects or living subjects. Each hologram reconstructs a two-dimensional photographic image of the object with a particular perspective defined by the spatial position on the stereogram. Obviously, the resolution of the vertical and horizontal parallax depends on the dimension and shape of the particular hologram (slides or frames [20.29]). Modified recording techniques even allow reconstruction with white light [20.30].

Composite holograms are made up from a multitude of single holograms, which – in contrast to holographic stereograms – reconstruct a three-dimensional image of the object from different perspectives [20.31]. This allows one to reconstruct a 360° view of the object at the expense of losing vertical parallax and strong object distortions when the image is viewed with both eyes.

Fresnel Holograms, Fraunhofer Holograms

If the object is placed a short distance from the hologram, the wavefront is described by Fresnel's approximation to the Fresnel–Kirchhoff diffraction integral [20.32]. This type of near-field holograms is called a *Fresnel hologram*. Each particular point of the image is associated with an emerging spherical wave and the hologram resembles the complex wave interference pattern. Thus each particular point of the hologram can be addressed by a reference wave to reconstruct the complete image but is limited to the corresponding perspective. *Fraunhofer holograms* are generated if the Fraunhofer diffraction pattern is recorded, which appears with small objects that are placed in the far-field. In this case the recorded wavefront is proportional to the Fourier trans-

form of the spatial amplitude distribution of the object. Fraunhofer holograms can be applied to inline holography (Sect. 20.2.3), circumventing the usual problem associated with the presence of the conjugate image. As early as 1963 Fraunhofer holography was applied to visualize distributions of aerosol particles [20.33].

Fourier Holograms, Image–Plane Holograms

Recording the Fourier transform of the complex amplitude of the object and reference waves [20.34] yields *Fourier holograms*. Recording can be performed, for example, by using a lens in the optical path. Fourier holograms offer the useful property that the reconstructed image does not move when the hologram is translated in its own plane, owing to a general property of Fourier transforms [20.35]. In *image-plane holograms* the real image of the object instead of the object itself is recorded [20.36–38]. This can be done, for example, by imaging the object onto the holographic medium with a lens. Thus each point of the object directly relates to a single point of the hologram, i. e., the object information is not distributed over the entire hologram. Image-plane holograms are highly sensitive to mechanical defects.

Embossed Holograms

Holograms can be embossed onto various substrate materials by a stamp that carries the inverse hologram as a surface relief. Embossed holograms are usually generated in four steps:

- A hologram is copied to a photoresist (Sect. 20.2.5), so that the fringe pattern appears as a spatial relief structure.
- A metallic stamping master with the inverted relief structure, commonly called the shim, is made by electrolytic processing of the photoresist.
- This metal stamp is embossed onto a substrate, e.g., a thermoplast material, under heat and pressure.
- The embossed hologram results by coating the substrate relief with a thin silver layer and subsequent hardening by electron beams.

The required minimum spatial resolution of 200 lines/mm ensures sufficient quality in reconstructing the signal wave. Nearly any condensed material can be applied as a substrate for the production of embossed holograms, which are profitable in high volumes. Embossed holograms are therefore of interest in commercial industries and as security features (Sect. 20.3.6).

20.2.3 Recording Geometries

Transmission, 90° and Reflection Geometry

Recording geometries are classified according to the directions of the reference and signal beam, and thus of the grating vector, with respect to the surface normal of the medium. Three principal geometries are distinguished: transmission geometry, reflection geometry and 90° geometry, as schematically shown in Fig. 20.7. In the transmission geometry (Fig. 20.7a) the reference and signal waves enter the holographic recording material through the same entrance face. The resulting interference pattern is characterized by the grating vector K, which is perpendicular to this surface normal in the symmetric case ($K \perp \hat{N}$). In order to obtain high diffraction efficiency combined with sharp angular selectivity it is favorable to utilize thick storage media and large Bragg angles.

In reflection geometry (Fig. 20.7b) the beams enter the holographic material from opposite faces of the medium, so that in the symmetric case the grating vector is parallel to the surface normal ($K \parallel \hat{N}$). Note, that the Bragg condition in the form of (20.4) is only valid for the particular case of transmission geometry in the symmetric case ($K \perp \hat{N}$) [20.39]. The reflection geometry provides optimal Bragg selectivity for wavelength multiplexing (Sect. 20.2.4), especially for $\theta_B = 0°$. The thickness of the holographic recording medium enhances the selectivity. The angular range that can be used in the different geometries is reduced by the refractive indices of the storage medium. This reduction can be important for materials with high refractive indices.

In the 90° geometry (Fig. 20.7c) the two beams enter the holographic recording medium via two mutually orthogonal faces. Usually $\theta_B = 0$ is chosen, so that the angle between the grating vector and the surface normal is 45°. In this geometry the storage medium has a cubic shape. The highest angular selectivity is realized, and in addition the medium is thick enough to obtain efficient gratings with a high selectivity due to the beam diameters.

Inline Off–Axis Geometries

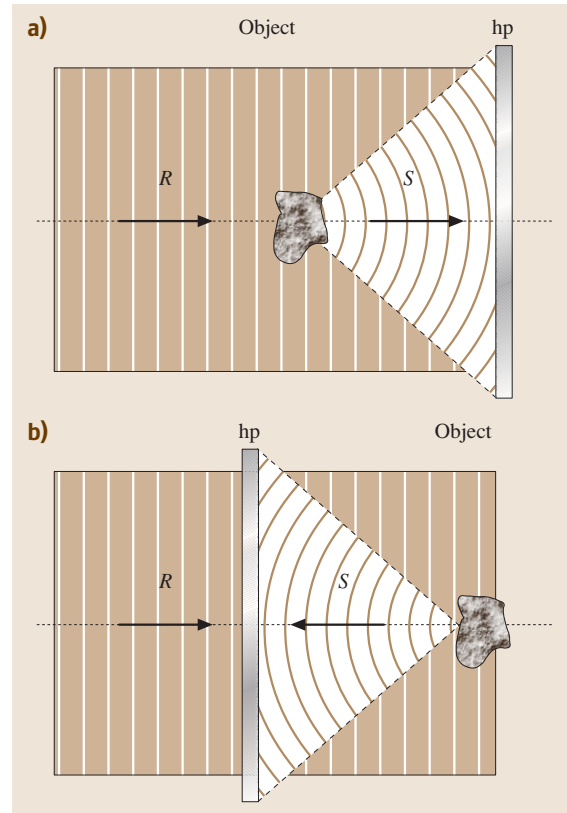
A recording geometry is designated as *inline* if the wave vectors of the reference and signal wave are collinear (Fig. 20.8). The inline transmission geometry (or *Gabor geometry*) was introduced by Gabor when recording his first holograms [20.1]. The requirements on the coherence length of the recording waves and the spatial resolution of the holographic medium are low. These obvious advantages are accompanied by the
Fig. 20.7 Principal geometries for hologram recording. (**a**) Transmission geometry: reference and signal beams penetrate the holographic recording medium through the same entrance face. In the symmetric case, the grating vector is perpendicular to the surface normal $\hat{N}$ of the medium. (**b**) Reflection geometry: reference and signal beams enter the holographic recording medium through opposite entrance faces. In the symmetric case, the grating vector is parallel to the surface normal. (**c**) 90° geometry: reference and signal beams enter the holographic recording medium through two mutually orthogonal entrance faces, usually with a crossing angle of 90° and $\theta_B = 0$. The grating vector encloses an angle of 45° with the surfaces of the medium


Fig. 20.8 (**a**) Inline transmission geometry (or Gabor geometry), (**b**) Inline reflection geometry (or Lippmann–Bragg geometry or Denisyuk geometry). hp: holographic plate

disadvantage that the image and reference waves are reconstructed in the same propagation direction, leading to an overlap of various images. The inline geometry is still popular for recording of white-light reflection holograms (*Lippmann–Bragg geometry* or *Denisyuk geometry*), because only a few optical components – at least a laser and a lens for beam expansion – are required in addition to a transparent thick holographic medium.

The *off-axis geometry* introduced by Leith and Upatnieks was enabled after coherent laser systems became available. It spatially separates reference and signal beam, both in recording and reconstruction. An off-axis transmission geometry is sketched in Fig. 20.2 and can be applied to the recording of reflection holograms as well.

360° Geometry, Edge–Lit Geometry

The recording of a hologram in a 360° geometry was first demonstrated in 1965 [20.40] and allows one to

reconstruct the complete object information from any perspective [20.41] (also called *full-view holograms*). For recording and reconstruction, a cylindrical holographic film that surrounds the object is used. The expanded reference wave propagates along the symmetry axis, thus illuminating both the film and the object. *Edge-lit holograms* [20.42] are recorded with an expanded reference wave entering at one edge of the holographic medium, thus illuminating the entire photosensitive area. An advantage of this geometry is the opportunity to reconstruct the image using a point source, e.g., a laser diode, integrated at the hologram edge. Thus a space-consuming expansion of the reconstruction wave is superfluous and edge-lit holograms are well-suited for compact, portable holographic displays.

20.2.4 Holography Techniques

Hologram Multiplexing

The Bragg condition is of utmost importance in holography as it allows the superimposition of a multitude of holograms in the same volume element of the holographic medium. The number (#) of holograms superimposed in the same volume element of the holographic recording material is limited by the decrease of the efficiency of the particular hologram, $\eta \sim 1/\#^2$ [20.43]. Figure 20.9a shows schematically the concept of *hologram multiplexing* using the example of *angular multiplexing* [20.44, 45]. Each recorded grating vector occupies a certain volume in the reciprocal space that is inversely proportional to the corresponding grating dimensions (see Sect. 20.2.2). This is equivalent to saying that Bragg diffraction will occur as long as the mismatch is confined within this volume. Three elementary holographic gratings characterized by their grating vectors $K_{1,2,3}$ are recorded (multiplexed) within the same volume element. The recording waves embrace the same angle, i. e., the grating spacing is constant, but vary in their Bragg angle $\theta_{1,2,3}$. The definition of Bragg angle is adopted from [20.39]. The holograms are reconstructed, completely unaffected from each other, if the angular mismatch $\Delta\theta_B$ for reconstruction of the particular hologram exceeds a certain value $|\delta k|$, which is represented by the shaded area.

In an analogous way the Bragg condition allows *wavelength multiplexing* [20.45–47]. Here holograms are recorded with different writing wavelengths (cf. Fig. 20.9b). Other techniques tune the phases of the reference wave separately for each hologram (*phase-coded multiplexing* [20.48]) or shift the spatial position of the interfering beams slightly with respect to the pre-

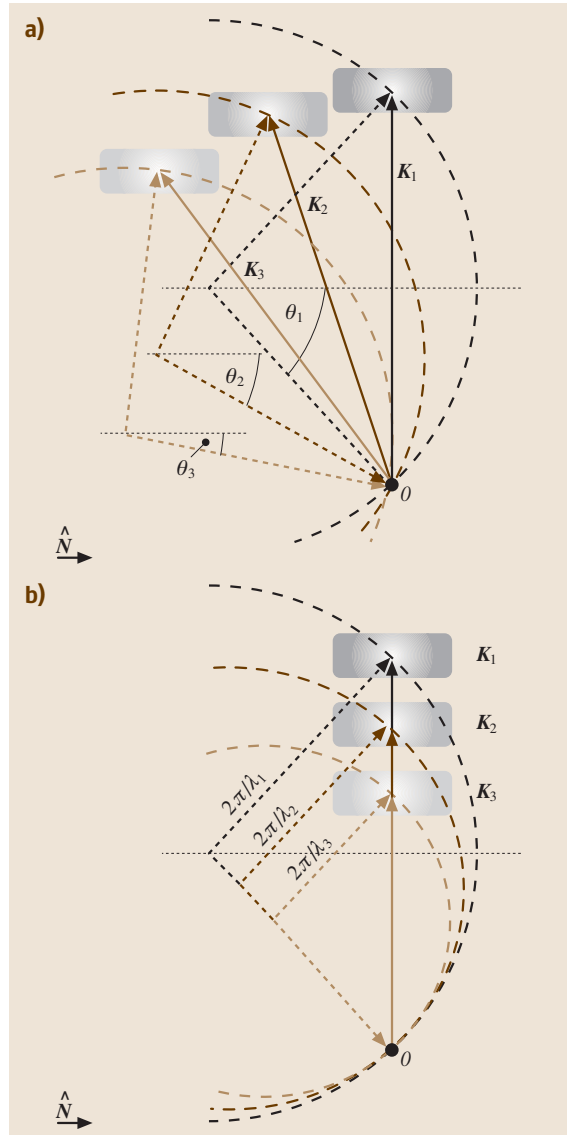
viously recorded hologram (*shift multiplexing* [20.49]), i. e., phase and spatial shift are further Bragg selective measures. As early as 1962 *Denisyuk* [20.3, 50] and *van Heerden* [20.51] discussed the possibility of using the high selectivity of the Bragg condition for volume data storage in order to obtain extremely high data storage


Fig. 20.9 The *shaded area*, proportional to $(dl)^{-1}$ (see Sect. 20.2.2), represents the region in reciprocal space, that is occupied by a particular recorded grating. Thus, grating vectors with overlapping areas would produce cross-talk. **(a)** Angular multiplexing. **(b)** Wavelength multiplexing

densities. The high Bragg selectivity further provides a high diffraction efficiency [20.39, 52], the suppression of the conjugated image [20.53], the reconstruction of holograms with white light [20.37, 54] and the recording of multicolor holograms (*color holography*) [20.55, 56].

A second class of multiplexing methods takes the recording geometry and the properties of the recording material into account and is not based on the Bragg selectivity. Such *fractal methods* [20.57] can therefore be applied to thin holograms as well. As an example holograms can be recorded within different volume elements of the holographic medium without affecting each other (*spatial multiplexing* [20.58, 59]). Other methods include *out-of-plane angular multiplexing* [20.60–62], *peristrophic multiplexing* [20.63] and *out-of-plane shift multiplexing* [20.64]. In addition, the combination of different multiplexing techniques greatly enhances the number of superimposed holograms and has successfully been shown to have a high impact on holographic data storage [20.62, 65–71].

Copying Holograms

White-light reflection holograms are usually produced by a direct copy from a transmission hologram, called the transmission *master hologram*. In the copying process the real image is generated from the master and can thus be used as a signal wave to record a copy in reflection geometry. As a result the initial virtual image of the master is reconstructed from the copy. This process offers some unique advantages: (a) a multitude of identical white-light reflection holograms can be fabricated without the presence of the original object, (b) the reconstructed object of the master hologram can be placed before, in, and behind the plane of the hologram copy, (c) the copying process does not require the high mechanical stability of the optical setup in a *contact copy*, i. e. the master and hologram copy are next to each other, and (d) the contrast ratio between the signal and reference wave can be adjusted and thus optimized. However, interference due to reflected waves between the master and copy, mechanical deformations of the master or copy and the presence of higher diffraction orders by reconstructing the master may result in unwanted image distortions, such as *Talbot* fringes.

Digital Holography

An interference pattern of wavefronts can be recorded digitally by using computer-addressable photosensitive detectors with sufficient spatial resolution, such as charge-coupled devices (CCDs). This opens up the field of *digital holography*, sometimes also called *tele-vision (TV) holography* or *electro-holography* [20.72]. The recording geometry for digital holography is limited by the low spatial resolution of the photosensitive digital array. Recording in the off-axis geometry with a standard array resolution of about 100 lines/mm limits the maximum angle between the reference and signal waves to a few degrees. Thus, only small objects at large distances can be recorded [20.73] encouraging the development of concepts to overcome this limitations, such as *phase-shifting digital holography* [20.74].

Digital holography further allows the reconstruction of digitally recorded fringe patterns by optoelectronic devices, i. e., by sending the information of the fringe pattern to a computer-addressable array such as a spatial light modulator (SLM). The SLM pixels manipulate the phase or amplitude of transmitted (or reflected) waves and hence it is possible to reconstruct the spatial distribution of the phase or amplitude of the signal wave. Such digital holograms offer several advantages, as the fringe pattern sent to the SLM can be manipulated digitally and actively. This allows, e.g., the suppression of the annoying twin and conjugate images by digital filtering or switching between different fringe patterns. The latter is useful for active optics or real-time holographic displays. Digital holograms are finally limited by the spatial resolution and the particular modulation depth of the phase or amplitude of the computer-addressable array. The field of applications for digital holograms is of increasing importance for *computer-generated* or *synthetic fringe patterns* and will be presented in more detail in Sect. 20.3.5.

20.2.5 Holographic Recording Materials

Holographic recording with high contrast of the reconstructed waves requires a photosensitive recording material with an optical resolution down to a light wavelength of $\approx 0.2\,\mu\text{m}$ ($= 5000\,\text{lines/mm}$), i. e., more than a factor of 5–10 better than photographic films. Besides the optical resolution a linear photosensitive response (linear transfer characteristic), low noise from background scattering, the possibilities to reuse the holographic recording material as well as to record phase and/or amplitude holograms are key characteristics of a recording material. The properties of holographic recording materials have been of interest from the beginning of holography and a first review appeared as early as 1977 [20.75, 76]. At present the variety of holographic recording materials basically can be classified into reversible and irreversible media, see Table 20.3.

Table 20.3 Some of the common reversible and irreversible holographic recording materials. Still, photographic emulsions and hardened dichromated gelatin [20.6] are the most convenient and widely used materials for display holograms, whereas photoresists are ideal for the production of nickel masters for embossed holograms (cf. Sect. 20.2.2). Photochromic materials keep their importance for holographic interferometry (cf. Sect. 20.3.3) and high storage densities in holographic data storage is based on thick volume phase holograms recorded in photorefractive crystals (Sect. 5.9.3)

Reversible media	Irreversible media	
	(+) chemical processing	(−) chemical processing
Electro-optic crystals[a]	Photographic emulsions[a,b]	Photopolymers[a]
Photochromic crystals[b]	Dichromated gelatin[a]	Chalkogenide glasses[a,b]

Photo-thermoplastics[a]		
Photodichroism[b]		

[a] Recording of phase holograms

[b] Recording of amplitude holograms

In recent years the variety of holographic recording media has been extended to new classes of materials. The search for alternatives was in particular triggered by the development of applications such as holographic data storage (Sect. 20.5). At present there is pronounced scientific interest in reversible high-efficient materials with fast response or long-term properties. In the course of this research a new class of materials became apparent, characterized by their unique photosensitive behavior, despite the fact that the physical origin for their photosensitivity is completely different [20.77–80]. These are centrosymmetric crystals, so that the linear electro-optic effect is forbidden by symmetry. Photorefraction and photochromism were discovered, e.g., in centrosymmetric molecular crystals [20.81] where the photosensitivity originates from photoinduced generation of long-lived metastable electronic states. Here, the unique properties

are: highly efficient recording of polarization holograms, a photoreversible recording process, and the possibility to tune the spectral range of photosensitivity and the storage time over a wide range simply by material design. Further promising candidates from this new group of holographic recording materials are photorefractive garnets, e.g. $Gd_3Ga_5O_{12}$ [20.82] (Fig. 20.10). Another novel, fascinating type of holographic materials is a composite of liquid crystals and polymers, so-called polymer-dispersed liquid crystals. The initial stage is a homogeneous solution, that is a mixture of mesogenic molecules and photosensitive monomers. Upon holographic exposure, a photopolymerization reaction takes place more rapidly in the bright regions of the optical interference pattern and consequently the monomers diffuse to these regions while the liquid-crystalline molecules congregate in the dark regions [20.83]. The

Fig. 20.10 Representatives of novel photorefractive materials: Na$_2$[Fe(CN)$_5$NO] × 2H$_2$O(Na$_2$[NP]), (courtesy of Theo Woike, Institute of Mineralogy and Geochemistry, University of Cologne, Germany), CdF$_2$: Ga, Y (courtesy of Institute of Crystallography of Russian Academy of Sciences, Moscow, Russia), Gd$_3$Ga$_5$O$_{12}$: Ca (GGG:Ca, courtesy of László Kovács, Research Institute for Solid State Physics and Optics, Hungarian Academy of Sciences, Budapest, Hungary), Tb$_3$Ga$_5$O$_{12}$: Ce (TGG:Ce, courtesy of Lothar Ackermann, FEE, Idar-Oberstein, Germany), and a polymer-dispersed liquid crystal (PDLC) between glass substrates

advantages over other holographic media are the large amplitudes of the light-induced change of the refrac-tive index, and the ability to tune this amplitude using external electric fields [20.84, 85].

20.3 Applications of Holography

From the beginning, Gabor's principle of wavefront re-construction primarily was applied in the field of wave optics. Gabor himself emphasized the possibility to en-hance the optical resolution in electron microscopy by holography, which was finally demonstrated, but not un-til 1990 [20.86]. It is therefore not surprising that the first dominant applications of holography were in the field of *high-resolution three-dimensional displays*. This ini-tiated the entry of holography into the fields of arts and commerce, accompanied by great interest from the film industry and the military. The first museum for holog-raphy opened its doors already in 1976 in New York City.

Holographic interferometry developed as a fur-ther key application for holography, as was already recognized in 1965 [20.5]. The technique allows the vi-sualization of object deformations and movements with a resolution down to the order of the light wavelength – even in real time. Holographic interferometry has had a great impact in *object recognition*, which has only re-cently attracted interest since it was adapted to work with digital holography [20.87].

Wavefront reconstruction with computer-generated holograms has driven the important field of *diffractive optics* in applied holography. Today it is possible to generate any phase and intensity wavefront distribution using synthetic holograms. In this way, beams can be deflected, focused or shaped with high precision and velocity, which is a basic property for a lot of other common optical applications, such as optical switches and filters in optical telecommunication.

During recent decades holography has been ap-plied with microwaves, neutrons, electrons [20.88–91], X-rays [20.92–94], and acoustic waves. The latter, e.g., finds its applications in nondestructive material testing, in medicine for diagnostic purposes, in ultrasound mi-croscopy, in seismology or in underwater positioning. In contrast, microwave holography has had its impact in understanding the important microwave techniques such as radar, doppler radar, antennae with synthetic apertures, etc. [20.95].

At present the field of applications is still grow-ing and new discoveries in the field of holography are currently being recognized, such as second-harmonic holography [20.96–99], holographic creation of photonic crystals [20.84, 100, 101] or self-adaptive intra-cavity holography in lasers [20.102, 103], which mean that holography remains an exciting field in optics. In the following we present some selected impressive applications – beyond the field of science – to give an insight into this broad spectrum of applied holography: holographic data storage, holography in archaeology, holographic interferometry, holography in medicine and biology, applications of computer-generated holograms, holograms as security features, holographic scattering for material analysis, atomic-resolution holography and neutron optics.

20.3.1 Holographic Data Storage

The application of holography for optical data storage was introduced by *van Heerden* in 1963 [20.51]. He dis-cussed the recording of multiple holograms within the same volume element, which was successfully demon-strated by *Leith* using a photographic plate as the storage medium three years later [20.45]. High-density record-ing using the angular multiplexing technique was not applied to holographic data storage until 1973 [20.104].

Today, after 40 years, a holographic data storage system is still not commercially available. Most of the technological components that are necessary for such a system, such as, e.g., the laser, camera, and two-dimensional liquid-crystal display (SLM), were available in the past, with breakthroughs in specifica-tion and cost being achieved in recent years. However, the search for a holographic storage material fulfill-ing all the application requirements is still in progress, since holographic storage demands unique specifica-tions such as high light sensitivity and nearly no light absorption. Today we find a multitude of development platforms that have been built in the last four decades. They prove the principles and demonstrate the differ-ent ways to store a large amount of data at a sufficient high rate [20.105–108]. An insight into holographic data storage is given in [20.109, 110] and Sect. 20.5.

20.3.2 Holography in Archaeology

Holography is ideal for archival recording not only of digital data but also of any valuable or fragile,

analogue three-dimensional objects, such as museum artifacts. The technique is of increasing significance in the field of archaeology, as it allows the production of true replicas of the original for distribution throughout the world [20.111, 112]. In particular color holography is applied to achieve optimum results, as shown in Fig. 20.11 [20.113, 114]. Besides presentation or display purposes, objects can seldom be studied in places remote from the museum and this makes it possible to compare and even to assembly pieces excavated from different places in the world.

20.3.3 Holographic Interferometry

The principle of *holographic interferometry* with its broad variety of applications is already a key topic of several books [20.115–118]. The technique was first discovered in 1965 [20.5, 119–123] and is also referred to as *hologram interferometry* or *holometry*. In the following we introduce three of the basic inventions of *holographic interferometry*: double-exposure, real-time, and time-average interferometry.

Double–Exposure Interferometry

The technique of *double-exposure interferometry* is applied to visualize and/or to determine object deformations or dilatations down to the scale of the light wavelength [20.124–127]. The object is holographically recorded twice, before and after the object deformation or dilatation. Thus the hologram reconstructs two signal waves at the same time and a fringe pattern results by signal wave interference. The fringe pattern is correlated to the phase differences of the object wavefronts between the two exposures. Holographic interferometry is advantageous when compared with non-holographic techniques, since it allows the visualization of changes in the object's wavefront arising at two different times. The *heterodyne technique* was the first automated analysis in holographic interferometry with sufficiently high precision [20.128–130]. Two reference waves of slightly different frequencies are used for hologram recording. In this way, each pixel of the reconstructed image is time-dependent and can be monitored by photodiodes. As a result the resolution in the object's wavefront distortion is less than 1 nm. However, the analysis of the fringe pattern is ambiguous when the scale of object deformation exceeds the light wavelength because of the phase-shift periodicity of modulo 2π in the fringe pattern. This problem is solved in part by the *phase-shift technique*. Here, two reference waves of the same wavelength but at different recording angles are used

Fig. 20.11 Hologram of a plate of clay with cuneiform writings exhibited in a museum in Nicosia (Cyprus). As the hologram reconstructs the three-dimensional object information it is possible to decipher the cuneiform writings, which contain important information in their relief structure. (Photo courtesy of G. von Bally, Laboratory of Biophysics, University of Münster, Germany)

for recording and reconstruction [20.131–133]. Thus the intensity of the fringe pattern is a function of both the object's wavefront distortion and the phase difference between the two reference waves. Impressing an external phase shift on one of the reference beams during reconstruction, the intensity of any object point oscillates modulo 2π as a function of the external phase shift. The phase distortion of the object wavefront is then equal to the phase difference between the reference and reconstruction waves, both of which are automatically determined with high precision.

Real–Time Interferometry

The optical principle of *real-time interferometry* [20.134] is equivalent to double-exposure interferometry, but allows the determination of the kinetics of phase distortion of the object's wavefront. The hologram is recorded only once in a holographic recording material and is reconstructed within the same optical setup. Thus, the reconstructed signal wave interferes with the object wave itself and any distortion of the object's wavefront is immediately visualized by a corresponding fringe pattern in the reconstructed image. In this way, deformations or dilatations of the object can be

investigated with respect to the holographically recorded object wave in real time, i. e., the reconstructed signal wave of the hologram acts as the initial measure.

Time–Average Interferometry

Linear or harmonic oscillations are visualized with *time-average interferometry* [20.136, 137], as shown for a violin at various frequencies in Fig. 20.12. The key idea is that the contrast of the hologram is reduced by moving objects, i. e., the recorded amplitude of the phase or amplitude modulation decreases due to movement of the interference pattern during the recording process. This feature is a disadvantage in holography as it requires extremely high mechanical stability of the optical setup (less than $\lambda/10$) during holographic recording. However, in the case of linear or harmonic oscillations, the intensity of the reconstructed image is shown to follow a Bessel function, so that it is a function of the phase amplitude of the periodic object deformation. Thus it is possible to visualize amplitudes of oscillating membranes with high precision. In order to overcome the problem of the mechanical stability of the optical setup due to mechanical coupling with the oscillating objects, *real-time time-average interferometry* is commonly applied, including a phase-shift technique for the reference beam [20.138, 139]. A hologram of the unexcited object is recorded and the method of real-time interferometry is used to visualize the oscillation amplitudes. Stroboscopic reconstruction [20.140–142] with the same frequency as the object oscillation can also be applied to visualize object deformations restricted to single frequencies.

20.3.4 Holography in Medicine and Biology

The fields of medicine and biology have impressively demonstrated how different holographic inventions, such as holographic interferometry and digital holography, can be applied together to give powerful results, and how the life sciences already make extensive use of holography.

Endoscopic holography was the first important medical application of holography. This method combines the advantages of endoscopic intra-cavity observation with holography, and thus offers the physician new in situ diagnostic capabilities. Recording of a hologram with the use of a single fiber for both the signal and the reference beam was demonstrated as early as 1976 [20.143]. Further improvements used fiber bundles [20.144] and gradient-index optical imaging systems [20.145] or even combined with an articulated arm [20.146]. The problem
Fig. 20.12 Reconstructed double-exposed hologram of resonant eigenmodes of a violin at **(a)** 465 Hz, **(b)** 600 Hz, and **(c)** 820 Hz. The *brightest areas* indicate oscillation nodes. (After [20.135])

of the cumbersome equipment of conventional holography was overcome by migrating from analog to digital recording [20.147] using numerical reconstruction, enabling morphology studies of cavities and tissues even at the cellular level.

Holography is applied as a nondestructive optical technique to image the properties of biological objects and tissues and to detect abnormalities such as tumors. In medicine, holographic interferometry in its different variants is the method of choice to perform in situ and even in vivo detection of tissue. Phase-shifting holographic interferometry was demonstrated to work for breast-cancer detection [20.148] by using mild pressure stressing of the breast and pulsed laser light. Pulsed digital holography has also been employed as a noninvasive technique to measure the elasticity of biological tissues, e.g., a human hand, pig tissue or human tumors in gel, by exciting them by short-shock mechanical pulses prior to recording phase-difference maps [20.149, 150].

Imaging an object located below the flesh of a human being, i. e., recording a hologram through a living person, has been performed by using a low-intensity continuous-wave laser [20.151] and the principle of first-arriving light [20.152]. Digital holography has been applied as a gating method, which allows a rapid succession of holograms to be made, thus increasing the signal-to-noise ratio.

True three-dimensional representation (*holographic display*) is another facet of the use of holography in cardiology, where the third dimension might be an electric potential, time or any other variable of interest [20.153]. Standard medical imaging techniques such as magnetic resonance imaging or computerized tomography provide two-dimensional transect images of the organ

or object to be examined. Employing digital holography a three-dimensional hologram can be obtained, which considerably facilitates the interpretation of the data [20.154, 155]. Utilizing a photorefractive film in conjunction with digital Fourier holography, it has been demonstrated that abnormalities detected in mammography, which usually vary in size, can be picked out according to their size and then visualized with high resolution down to about $10 \, \mu m$ [20.156].

Digital holographic microscopy is a useful noninvasive method for the visualization of transparent objects, e.g., living cells or tumors with high accuracy. In contrast to phase-contrast microscopy it provides a full-field, high-resolution amplitude measurement and even detects the quantitative distribution of the optical path length created by the specimen. Therefore information on the morphology and the refractive-index pattern can be gained, which allows sub-wavelength axial accuracy [20.157, 158].

20.3.5 Diffractive Optics with Computer–Generated Holograms

Since the early days of holography the generation of holograms by means of simply computing the interference pattern has attracted attention [20.159–162] and is still one of the fastest developing topics in holography. The main advantage is that the object only has to be known in mathematical terms and does not need to exist physically. Starting with one-bit holograms drawn by plotters, which were photographically reduced and recorded on a film, computer-generated holograms (CGHs) have developed greatly with increasing computing power and the availability of high-resolution eight-bit spatial light modulators (SLM) with refresh rates of up to 1 kHz [20.163, 164].

Various applications making use of CGHs have been realized, in particular as device for beam steering and manipulation, i.e., as computer-generated holographic optical elements. CGHs are employed as so-called *laser tweezers*, i.e., tools for micromanipulation of particles in both physics [20.165, 166] and life sciences [20.167], using the principle of optical trapping [20.168]. Another fascinating application is the realization of non-diffracting beams by means of CGH [20.169]. Contrary to standard Gaussian beams, a fundamental Bessel beam does not undergo diffraction, i.e., the transverse optical intensity distribution does not change during propagation [20.170]. Optical phase singularities can be created with CGHs, calculated by the interference between a plane wave and superposition of the TEM_{10} and

TEM_{01} Gauss–Hermite optical-resonator modes (hybrid doughnut mode) [20.171]. Moreover, CGHs are utilized for quality control of optical systems, e.g., for the characterization of aberrations. In particular, the assembly and adjustment of multicomponent optical systems can be monitored [20.172].

20.3.6 Security Aspects of Holography

A valuable, practical and widespread application of holography is its use for authentication or security devices. Holograms on credit cards, banknotes and identity documents are state of the art today, see e.g. [20.173, 174]. However, the impact of holography as a security feature becomes much more impressive, e.g., in optical data transmission. Data must not only be transferred in a fast but also a secure way, which is realized using *holographic encryption*. Benefits of this technique over others are that optical processing provides the maximum number of degrees of freedom and that optical encryption is ideal for information stored in holographic media. One promising approach is to process data using a double-random phase encryption technique [20.175] and record them as a digital hologram [20.176]. Sophisticated geometries and elaborate techniques such as phase-shifting interferometry [20.177] allow fast and secure encryption/decryption using electronic, optoelectronic or even all-optical approaches. The latter is inexpensive in time, whereas pure electronic decryption requires a huge computer load. Further possibilities are orthogonal phase-coded multiplexing with a random phase mask in the reference-beam path [20.178], fabrication of CGHs using incoherent multiplexing (synthetic double-exposure) by electron-beam lithography [20.179], or encrypted optical storage in a photorefractive crystal using angular multiplexing [20.180]. Besides its other advantages over standard methods holography provides the unique possibility of watermarking three-dimensional objects [20.181], again employing phase-shifting interferometry and digital holography.

20.3.7 Holographic Scattering for Material Analysis

Light scattering in holographic recording materials is a disadvantage for wavefront reconstruction as it generates a serious scattering background in the reconstructed image and thus strongly affects the signal-to-noise ratio. Scattering in holographic recording materials with nonlinear response to intensity shows up as a bright intensity
Fig. 20.13 Far-field nonlinear holographic light scattering as observed in various recording materials in the steady state. (**a**) Holographic scattering ring in $Na_2[Fe(CN)_5NO] \times 2H_2O$: the scattered light is orthogonally polarized to the incident pump beam polarization. The diameter of the ring depends on the birefringence [20.189], (**b**) photoinduced light scattering in $Sr_{0.61}Ba_{0.39}Nb_2O_6 : Ce$: the scattering lobe is directed antiparallel to the orientation of the polar c-axis [20.183], (**c**) beam fanning in $LiTaO_3 : Fe$: the two scattering lobes are directed parallel to the polar c-axis [20.190]. One lobe shows higher intensity which indicates the orientation of the spontaneous polarization

distribution with a characteristic shape. The scattering appears over a wide apex angle and is a function of the exposure. At present such scattering phenomena have gained considerable interest in the scientific field of optical nonlinearities [20.182]: besides investigations of their physical origin, *holographic scattering* phenomena are useful for material analysis [20.183]. It has been demonstrated that holographic scattering can be applied as a nondestructive contact-free optical method, e.g., to investigate phase transitions [20.184, 185] and ferroelectric properties [20.186, 187]. Figure 20.13 shows the example of a far-field steady-state scattering pattern observed in three different holographic recording materials. The diameter of the ring in Fig. 20.13a allows the determination of the birefringence [20.188]. Photoinduced light scattering in $Sr_{0.61}Ba_{0.39}Nb_2O_6 : Ce$ (SBN:Ce, Fig. 20.13b) and $LiTaO_3$ (Fig. 20.13c) can be used to determine the direction of the polar c-axis. In SBN:Ce, the scattering lobe is oriented in a direction antiparallel to the polar axis.

20.3.8 Atomic–Resolution Holography

The key technique for the determination of atomic and molecular structures, in particular for investigations of crystallographic structures, has been diffraction for a long time. However, this method is not a true physical solution, as it only yields information about the intensi-

ties and not about the amplitudes of the diffracted waves. Holography, on the other hand, is known to overcome this obstacle by recording the interference pattern of the reference and object waves. However, its spatial resolution is limited by the wavelength of radiation and also by the resolution of the recording medium. The first limitation is lifted simply by using electrons, high-energy electromagnetic waves (X-rays, γ-rays) or neutrons with wavelengths in the range of Å for holographic recording. To overcome the second limitation *Szöke* proposed a scheme to study the atomic order of solids by employing atomic-resolution holography [20.191], an idea that was first experimentally demonstrated by using electrons [20.192]. In this experiment a 3-D reconstruction of the relative positions of atoms was performed by evaluating the angular distributions of the scattering intensities. The intensity patterns are formed by interference between electrons that are emitted from a source atom and reach the detector either directly (reference wave) or after scattering from neighboring atoms (object wave). This is called the inside-source concept, where a point-like source is produced inside the investigated material. The inverse scheme exchanges the role of the source and detector (inside detector), i. e., the interference pattern of the incident and scattered waves is investigated using a point-like detector in the material (see [20.193, 194] and Fig. 1 in [20.195]).

Several experimental approaches for atomic-resolution holography have been demonstrated, employing electrons, positrons [20.196, 197], X-rays, γ-rays, and neutrons, each of them characterized by its specific interaction with matter. Therefore, electrons and positrons are mostly used for investigating the structure of surfaces because of their low penetration depth. X-rays are sensitive to the electronic properties, whereas with neutrons the nuclear structure is probed.

Various mechanisms of electron emission from a localized atomic source have been utilized, e.g., Kikuchi scattering [20.192], the photoelectric effect [20.198–200], low-energy electron diffraction [20.196, 201, 202] or Auger-electron diffraction [20.203]. Atomic-resolution X-ray holography was first performed by using fluorescent X-radiation [20.204], later by employing a multi-energy inverse mode [20.195] or a combination of these [20.205, 206]; γ-ray holography was experimentally demonstrated using the example of an ^{57}Fe film in the inverse scheme [20.207]. Only recently an advanced γ-ray holography technique has been developed that allows the distinction between atoms of the same kind that occupy inequivalent crystallographic sites, a task where X-rays and neutrons

failed. Here, coherent effects in the Mößbauer nuclear absorption are utilized, which provide local spectroscopic information [20.208]. The latest development is atomic-resolution neutron holography, suggested by *Cser* et al. [20.194] and subsequently realized in both experimental schemes, the *inside source* [20.209, 210] and *inside detector* arrangement [20.211].

Still there is a steady improvement of the evaluation techniques, e.g., complex γ- or X-ray holography to remove the disturbing twin image without making measurements too time consuming [20.212, 213].

20.3.9 Neutron Diffractive Optics

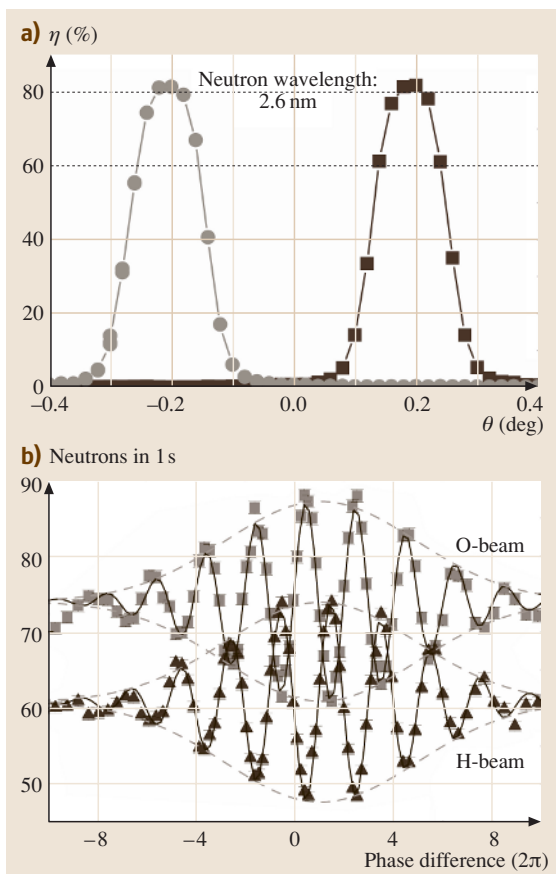
In 1990 it was demonstrated that a holographically recorded refractive-index pattern could be reconstructed not only with light but also with cold neutrons [20.214]. Obviously, the illumination induced refractive-index changes for both light and neutrons. In analogy to light optics this phenomenon was called the *photo-neutron-refractive effect* [20.215]. The efficient diffraction of cold neutrons from light-induced gratings was a huge step in the development of neutron diffractive optics by means of optical holography, as such methods were not previously possible. For thermal neutrons (with wavelengths in the sub-nanometer range) single crystals are usually used as diffractive optics, for ultra-cold neutrons (with wavelengths of about 5 nm and more) mechanically ruled gratings are used. The method of preparing gratings by means of light optical holography closed the gap between these two approaches. Nowadays, mirrors and beam splitters can be produced, culminating in the successful setup of an interferometer for cold neutrons [20.216, 217]. In Fig. 20.14a the angular dependence of the diffraction efficiency for a holographically prepared volume grating that acts almost like a mirror is shown. Figure 20.14b depicts the results of an interferometric measurement utilizing three holographically prepared thick diffraction gratings as beam splitters and a mirror. The interferometer may be regarded as one of the most useful neutron optical devices as it provides information about the wave function, i. e., *amplitude and phase*, in contrast to standard scattering or diffraction techniques where only the intensity is measured. The


Fig. 20.14 (a) Diffraction efficiency for neutrons with 2.6 nm wavelength. **(b)** Interference fringes obtained by introducing a phase difference between two partially coherent neutron beams. *Squares* and *triangles* show the measured intensity of the output beams as a function of the phase shift. Wavelength 2 nm

principal future application of such an instrument could be the investigation of mesoscopic structures and their kinetics in the fields of condensed-matter physics and engineering, chemistry, and biology. A recent review on neutron optics with gratings employing the photo-neutron-refractive effect and light optical holography is given in [20.218].

20.4 Summary and Outlook

There is no doubt that holography is an important field in optics and one of the key inventions of the 20th century.

It is stressed that the idea of Dennis Gabor could not have its full impact until the development of light sources with

sufficient coherence – nearly 20 years after discovery. Obviously, Gabor was quite ahead of his time when inventing holography.

Holography offers a multitude of applications in various fields of our life. Now, new developments are making use of the wavefront reconstruction principle. As it will probably have an increasing influence on our life, the history of holography will continue to be an exciting journey.

20.5 Optical Data Storage

After the correction of vision with glasses, contact lenses or reshaping of the cornea, and after the recording of still and moving images on film or electronic cameras, the most pervasive application of optics in our daily life is optical data storage: the storage and retrieval of data using optics close to the diffraction limit and a miniature solid-state laser, all realized at very affordable prices.

The distribution of audio information on a removable disk – sound stored as modulations in a flat surface – has had a long and successful track record. At first, analog signals were imprinted on shellac and then later vinyl platters. However, recently sound has been almost exclusively distributed as and replayed from digitally encoded data, molded into the surface of compact polymer disks. This migration was driven by consumer demand for higher fidelity, i. e., higher bandwidth in recording, replication and playback, which in turn required dramatic increases in the amount of stored information. At first the diameter of the disk was increased, but this soon reached its practical limit. With a mechanical stylus, higher areal storage density increased the susceptibility to wear and tear, which forced a transition from mechanical detection to a noncontact optical scheme.

In the form of the read-only compact disk (CD), optical data storage became the dominant distribution vehicle for music (CD) and later for computer software with the CD read-only memory (CD-ROM) [20.225, 226]. With the ferocious appetite of consumers for ever more information at ever higher data rates, the CD and the CD-ROM have undergone a metamorphosis into the digital versatile disk (DVD) [20.227]. The DVD standard offers higher areal density per layer, and with as many as four layers of prerecorded information, can provide sufficient read-out bandwidth and capacity for the distribution of several hours worth of high-quality compressed video. Since its introduction into the market, DVD devices have reportedly experienced the fastest growth of quarterly sales and market penetration of any consumer electronics technology ever, as of the last quarter of 2002. But with the advent of high-definition television (HDTV), even higher data rates and capacity will be needed, requiring yet another increase in areal density. Such increases have motivated several proposed next-generation formats, including the BluRay® optical disk format. Table 20.4 compares the pertinent characteristics of the CD, DVD and the proposed BluRay formats, highlighting the significant technical progress that has been made.

In addition to this distribution of prerecorded content on removable and interchangeable media, the desire of consumers to record information by and for themselves has been an important economic and technical driver. The wax-coated drum of Edison, with analog information engraved with a vibrating needle, has given way to the CD and DVD *burner*, with carefully modulated and interleaved digital data imprinted with a flashing laser beam. Recordable optical disks rely on using high

Table 20.4 Comparison between CD, DVD, and the proposed BluRay format [20.219–224]

	CD	DVD	BluRay
Capacity (single layer)	0.65 GB	4.7 GB	23.3, 25, or 27 GB
Laser wavelength	780 nm	650 nm	405 nm
Numerical aperture	0.45	0.6	0.85
Track density	16 000 /in.	34 000 /in.	79 000 /in.
Minimum length pit ($\sim 2-3$ bits)	0.833–0.972 µm	0.4–0.44 µm	0.138–0.16 µm
Areal density (user)	0.39 Gb/sq.in.	2.77 Gb/sq.in.	13.7, 14.7, or 15.9 Gb/sq.in.
Reference velocity	1.2 m/s	3.49–3.84 m/s	4.55–5.28 m/s
Data rate	1.47 Mb/s	11.08 Mb/s	36 Mb/s

laser power to write marks that low laser power can still read. The high laser power must modify the local optical properties of the recording medium to provide a significant change of signal; conversely, the low read-out power must *not* affect the properties of the media so as to protect any recorded data. Processes such as ablation of a dye layer are irreversible and thus are well suited for *write-once, read-many times* (WORM) applications. The prevalent implementation of this technique is the CD-R: WORM media with a form factor and functionality nearly identical to a CD or CD-ROM once it has been recorded. Other recording processes – foremost the change between amorphous and crystalline structure in a thin metal, semiconductor or alloy film – can be reversible and allow erasable or rewritable (R/W) media. For these types of media, the thermal characteristics are as important as the optical parameters. One has to ensure that, after short transient heating with the tightly focussed laser, each very small spot will cool fast enough to quench the film rapidly into an amorphous phase. On the other hand, the same R/W medium must cool slowly after a large area is uniformly illuminated, allowing recrystallization of the film and erasure of previously recorded data. The issues of optical, thermal and device engineering for WORM and R/W recording are extremely complex and go beyond the scope of this brief summary. Details can be found, for example, in [20.226].

In addition to the pervasive 120 mm-diameter CD/DVD disk, many other disk diameters have been used. One early niche application was the laser disk, used for the distribution of high-quality prerecorded movies before DVD-level areal densities and data compression were available. For high-end data storage applications, diameters of 5.25″, 12″ and up to 14″ have been commonly used to increase the capacity per platter up to 200 GB. Smaller disks for small-form-factor, portable consumer electronics devices are becoming increasingly popular. Examples are MP3 players, digital still and digital video cameras using optical disk media with diameters as small as 1″.

The facts that the optical recording media are removable, have high storage capacity and a relatively low price also make them a prime candidate for massive data warehouses. Jukeboxes for home audio and video applications allow a home user to have all the multimedia content that they own at their fingertips. In a similar fashion, commercial data libraries and warehouses use data silos with robotics and industrial-strength CD-R recorders and CD-ROM players to provide massive amounts of near-line storage at low cost.

Optical read out of cheaply replicated, injection-molded CDs, CD-ROMs, and the rapidly emerging DVD disks has clearly come to dominate multimedia content and software distribution. On the other hand, general-purpose read–write information storage is still the exclusive domain of magnetic recording. Magnetic recording in the form of hard disk drives delivers higher areal densities, higher data rates and faster access times than optical storage, while supporting millions of write/erase cycles and many years of retention time at very competitive cost. To obtain these high performance characteristics, the removability offered by the once ubiquitous floppy disk had to be sacrificed. Thus the key advantages of optical recording are clearly the removability and interchangeability of the media, as well as the parallel replication of prerecorded disks in seconds via injection molding. Optical recording on WORM media, typically in the form of burning a CD-R, plays an important role as inexpensive backup for data stored on magnetic disks, and is trying to compete with magnetic tapes for archival data storage in large libraries. Attempts to bring a commercially viable optical tape technology to market have not succeeded to date [20.228].

In 1997, 2000 and again in 2003, the National Storage Industry Consortium (NSIC) convened meetings of 50 leading industry experts to develop three comprehensive optical disk storage roadmaps [20.219–221]. These roadmaps summarized the anticipated component, system and market development. While the overall trends were predicted correctly, technical and economic challenges considerably slowed down the actual pace of development.

Key drivers for future developments were expected to be the rapid expansion of the Internet and the emergence of HDTV, with both calling for higher bandwidth and storage capacity. The Internet has expanded, but high-speed broadband service to the home is not yet pervasive. Standards issues, broadcaster resistance and concern about copyright management have delayed the advent of HDTV. At the same time, the pervasive use of computers and storage in consumer electronics devices (and eventually common household appliances) is requiring more storage in smaller form factors. Thus all of these requirements are still driving optical data storage to reach ever higher storage densities [20.219–221].

The remainder of this article highlights different approaches towards achieving this goal of increased optical storage density, either by increasing the density at the surface of an optical recording material, or by utilizing the unique capability of optics to access the volume of suitable media.

20.6 Approaches to Increased Areal Density

For many years, the demands for better data storage have been met by evolutionary advances: increases in the areal density and other performance specifications of magnetic and optical recording devices. The areal density of hard disks has been growing continuously through more than seven orders of magnitude over the last 50 years, but during the last five years the growth accelerated to a compounded annual growth rate of slightly more than 100%. Optical storage, with a much shorter track record, has increased in storage density by a factor of five from the original CD standard to the DVD format, and another factor of five to the proposed next-generation BluRay format (Table 20.4). The reason for this dramatic difference between the increase of aerial densities for magnetic and optical recording is that optical data storage has specialized on applications that require removability of the optical recording media. Since high-performance magnetic recording does not support removability, hard drives need not work with the media of previous generations. Thus the only standards to satisfy are those on data input/output and form factor, which has encouraged strong technical competition and resulted in tremendous progress. Optical storage, however, is dominated by removable, interchangeable media with backward compatibility. This compatibility facilitates the introduction of each new generation of technology in the market, due to the large existing base of recorded material, but forces a time-consuming standards process for each higher-density generation.
Fig. 20.15 Conventional optical storage uses a tightly focussed laser beam to access individual bits in a single layer

Still, optical storage has substantial potential as a storage technology. While the limits of magnetic recording are still being debated [20.229], the limits of conventional optical recording are well understood [20.219–221]. Current optical storage technology is already working close to the optical diffraction limit. However, significant future increases in density are possible by taking advantage of the wavelength and/or numerical-aperture dependence of the diffraction limit, or by going beyond it with near-field techniques. In addition, if the signal/noise ratio is sufficient then gray-scale techniques allow the storage of more than one bit per location [20.230].

The diameter of the diffraction-limited spot is directly proportional to the laser wavelength λ and inversely proportional to the numerical aperture (NA) of the imaging lens (Fig. 20.15). The area A of the spot is then proportional to the square of these parameters [20.231]

$$A \sim \left(\frac{\lambda}{\mathrm{NA}}\right)^2 , \qquad (20.5)$$

and the resulting maximum areal density is simply the inverse of this area times b, the number of bits per spot,

$$\mathcal{D} \sim b \left(\frac{\mathrm{NA}}{\lambda}\right)^2 . \qquad (20.6)$$

As described in Table 20.4, the differences in capacity and data rate between the CD, DVD and BluRay formats is a clear consequence of reducing the diffraction-limited spot size of the focus at the medium. Other factors were also involved in the density improvement found in the newer standards – such as stronger modulation coding, signal processing, error correction, and more aggressive tolerancing – but it is unclear how much more improvement could be extracted from these areas in future optical disk standards.

20.6.1 Short–Wavelength Lasers

Early optical storage products used infrared wavelengths between 830 nm and 780 nm, simply because these were the only diode lasers available with the reliability, optical power, quantities and cost that the industry required for a consumer product. As the development from CD to DVD to BluRay highlights, the obvious path to further increases in storage density has been the development of suitable short-wavelength lasers. While blue lasers have been used in laboratories around the world for

high-density recording studies, they have yet to show up in consumers products. Instead of leapfrogging from 800 nm to 400 nm lasers (using GaN) and thus immediately quadrupling the storage density, the development has been gradual. Magneto-optical (MO) drives employ visible wavelengths of 650–685 nm, while DVDs rely on 635–650 nm lasers [20.219]. Continued advances to even shorter wavelength have been made with novel diode laser materials and concepts. Progress with prototypes of green ZnSe lasers at 490 nm has been substantial and blue GaN lasers with wavelength as short as 375 nm have been explored [20.219]. The NSIC roadmaps predicted the general availability of optical storage products with these short-wavelength lasers around 2002 [20.219, 220]. That this has not occurred reflects both technical difficulties in fabricating cheap, long-lifetime blue lasers as well as economic reality: HDTV and broadband Internet, the applications that were to drive the need for this technology, are penetrating the market much more slowly than expected. However, other promising evolutionary approaches might provide significant improvements in areal storage density while the performance, lifetime, and cost of blue laser diodes slowly improve.

20.6.2 Increased Numerical Aperture

Instead of reducing the laser wavelength, a corresponding increase in numerical aperture can achieve the same increase in areal density. The increase in density when making the transition from CD to DVD was partially due to an increase in NA. There are, however, practical limits to the increase in NA, such as manufacturing tolerances for diffraction-limited optics. The key issue here is depth of focus, δ, which is directly proportional to the wavelength, but inversely proportional to the square of the numerical aperture [20.231]:

$$\delta \sim \frac{\lambda}{NA^2} \, . \tag{20.7}$$

To maximize density, the data layer of the media should be as close as possible to the focus of a diffraction-limited read-out beam. Inevitably, manufacturing tolerances on the drive and media make a fast focusing servo essential. For ultimate performance, even dual-stage servos with multiple lenses are being considered. Obviously, these issues become more difficult as the optical depth of focus decreases. Smaller depth of focus requires that the thickness of the cover layer over the recorded data (which takes up some of the working distance of the optics and forces correction for spheri-
Fig. 20.16 A solid-immersion lens (SIL) can increase the effective NA beyond 1.0, further increasing density but requiring evanescent coupling between the SIL and disk

cal aberration) decreases, and indeed the BluRay format calls for a cover layer only 100 μm thick [20.224].

Although the maximum NA in air is 1.0, microscopists have long improved their resolution beyond this by using oil-immersion objective lenses. Rather than coating optical disks with oil, however, numerical apertures greater than 1 can similarly be attained by bringing a solid-immersion lens into close proximity of the disk media [20.232], as shown in Fig. 20.16. If the gap between the bottom of the lens and the media is smaller than the light wavelength, then evanescent coupling of light across this gap illuminates a subwavelength-diameter spot on the media. Similar to the read–write head in magnetic recording, it is possible to fly a solid immersion lens on an air bearing over the media [20.232]. This approach to high storage density, while pursued aggressively for several years, has yet to deliver a successful commercial storage product. In addition, because of the susceptibility of this tiny air gap to external contaminants on the disk, such near-field approaches would seemingly have to sacrifice media removability: one of the very advantages that optical storage has historically had to offer.

20.6.3 Magnetic Super–resolution

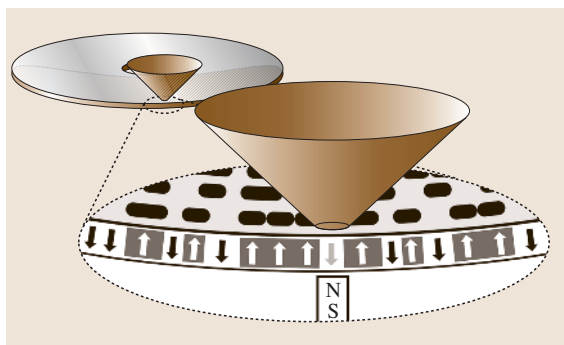
In magnetooptic recording, another interesting effect can be utilized to increase the resolution. In this technology, bits are stored by heating a magnetic film locally with a laser in the presence of an externally applied magnetic field (Fig. 20.17). In the portions of the film that exceed the Curie temperature, the local magnetization will orient with the applied field. This magnetization change is then sensed optically by detecting the slight rotation of the polarization due to the Faraday effect [20.231]. Here,


Fig. 20.17 Magneto-optical storage uses a tightly focussed laser beam to record bits, using local heating of a magnetic film above its Curie temperature in the presence of an external magnetic field

Fig. 20.18 Magnetic super-resolution uses two layers, with the heat from the laser spot transferring just the bits of interest from the bottom storage layer into the top read-out layer

thermal diffusion processes rather than optics can dominate the resolution. A short exposure with a laser beam of nonuniform spatial profile, such as a simple Gaussian beam, can produce a temperature distribution that exceeds the Curie temperature only for a brief time, and only in the very center of the beam. Subsequent heat diffusion away from the spot quickly brings the temperature below the Curie point, resulting in magnetic reversal in an area of sub-optical-wavelength dimensions, including marks as small as 100 nm [20.233].

However, such marks must still be optically detected. With dozens of such marks within the diameter of each focussed spot, deconvolving each mark individually from the aggregate optical signal would be quite challenging. An elegant technique called magnetic super-resolution (MSR) can overcome this read-out problem using the highly nonlinear behavior of thermal diffusion [20.233]. The MSR technique adds a magneto-optic read-out layer above the magnetic storage layer. For read out of a particular sub-wavelength spot, this top layer is briefly heated with a laser just as in the recording process described above: the power density in the center of the beam barely exceeds the Curie temperature. As above, the magnetization of the hot spot orients

with the applied field, which in this case is the field due to the recorded bit in the lower layer. The surrounding area of the upper layer does not reach the Curie point and is not affected. After the magnetization at that location has been *revealed*, the read-out layer contains only the sub-resolution spot with reversed magnetization surrounded by a magnetically homogeneous background (Fig. 20.18). This sub-resolution spot can then be optically detected with sufficient signal/noise ratio, despite the much larger diameter of the focussed laser beam. Magnetic super resolution is, therefore, a near-field technique, where the aperture is created in close proximity to the recording layer by illuminating a cover layer with a suitable laser.

Taking advantage of similar magnetic multilayer techniques that have been recently introduced to increase the areal density of conventional magnetic recording, further increases in optical storage density are possible by introducing additional layers for magnetic amplification (magnetically amplified magneto-optic system or MAMMOS [20.234]).

20.7 Volumetric Optical Recording

Both magnetic and conventional optical data storage technologies, where individual bits are stored as distinct magnetic or optical changes on the surface of a recording medium, are approaching physical limits beyond which individual bits may be too small or too difficult to store and retrieve. Storing information throughout the

volume of a medium – not just on its surface – offers an intriguing high-capacity alternative.

Three-dimensional optical storage literally opens up another dimension to increase the capacity of storage media. In principle, a volume element with the dimensions of the wavelength should suffice to store one

bit. The volumetric density that can be achieved in the diffraction limit would then scale with $1/\lambda^3$. Trade-offs between density and data rate make it possible, at least in principle, to forgo some of this density to obtain blistering data rates. Some of the techniques that have been proposed do not require mechanical motion, enabling access times in the range of tens of microseconds, albeit to a small storage volume with moderate capacity.

20.7.1 Volumetric Addressing Techniques

Several approaches for volumetric optical data storage have been explored. These can be distinguished by the method used to address the stored data. Some of the techniques simply extend the multilayer nature of conventional optical storage already begun with the two-layer DVD standard, while others take advantage of the 3-D character of optics. The techniques described here are:

- Adjusting focus to access data on a particular layer;
- Using an interferometer (sensing differences in path length) to address a layer;
- Addressing a particular point, line, or plane in a medium by intersecting two laser beams;
- Using material with extremely narrow spectral sensitivities to address data; and
- Addressing data by the spacing and direction of interference fringes, known as K-vector or holographic addressing

20.7.2 Addressing by Depth of Focus

Depth of focus, a phenomenon familiar to anyone that has used a microscope, is already an integral part of the current DVD standard. To increase the capacity per disk over the single-layer limit of 4.7 GB per disk [20.235], the standard can double this capacity with two data layers, or quadruple it with a two-sided, two-layer-per-side option (the disk must be flipped to access data with a single objective, or a second optical pick-up is required to address both sides of such a data carrier simultaneously).

Using depth of focus has the clear advantage of being similar to existing CD and DVD technology, and it could possibly be compatible with the large installed base of optical storage devices. As shown in Fig. 20.19, the key disadvantage is that the individual layers must be widely separated to avoid crosstalk errors on read out, or tracking problems with the focus servo. The required diffraction-limited performance is difficult to accom-
Fig. 20.19 The effective optical areal density can be increased by using depth of focus to access multiple bit layers within a disk

plish over a sizable depth range, limiting the maximum number of layers.

One way to improve this is to use fluorescence for read out: since the light from a mark is now incoherent, the effects of interference and scattered light can be reduced and a higher signal-to-noise ratio (SNR) obtained. These reduced noise effects trade off with the omnidirectional output of the fluorescence from the illuminated voxel (volumetric pixel).

Multilayer fluorescent disks (MFD) employ media with many (10 to possibly as many as 100) layers [20.236]. Each layer contains pits or grooves filled with fluorescent material, which absorbs the incident laser light and re-emits incoherent red-shifted fluorescent light. Portions of the disk manufacturing process are similar to CD/DVD fabrication: a mastering process (here for each individual layer) followed by replication via hot embossing or stamping. The pits are filled with fluorescent dyes – which require appropriate absorption/emission spectra, high conversion efficiency, short time response, and high saturation levels – and then the layer substrates are bonded together. Such ROM media fluorescent dyes are under development, as well as WORM media based on thermal bleaching and multiphoton processes for red and green light [20.236]. Reversible photochromic material have been demonstrated in the lab.

MFD drives are similar to CD/DVD drives with differences in the optical head: dichroic mirrors and filters to separate the fluorescent signal light from the excitation light, optics for spherical aberration correction, and a more sensitive detector. Tracking and focusing tech-

niques are similar to other optical disks, with additional electronics and possibly data encoding needed to find and maintain focus on the different layers. A ROM system with more than 20 layers has been demonstrated at CD density (650 nm-wavelength semiconductor laser, 1 mW in the reading spot, three-spot tracking, astigmatic focusing) [20.236]. The SNR for the experimental disk was better than 30 dB (1.5 MHz bandwidth) [20.236].

In addition, optical cards with 10-layer media and 1 micron-sized marks have been demonstrated. CCD read out was used, image processing was applied to read data. This could lead to MFD-ROM systems with 10–20 layers at DVD density (approximately 50–100 GB per disk), and optical ROM cards with 1 GB capacity, followed later by WORM versions of these devices [20.236]. As with CDs and DVDs, the advent of blue lasers would be expected to support an increase in capacity by a factor of four, although this would require the dye chemistry to be re-engineered to these wavelengths.

20.7.3 Two–Photon Absorption for Addressing of a Bit Cell

Another means of limiting the interaction volume of the addressing beam in the medium is by using two-photon absorption, which scales with the square of the beam intensity. This effectively shortens and narrows the focus volume where the intensity is sufficient for writing. These approaches often require femtosecond lasers with high peak intensities, but could enable media with hundreds of layers allowing capacities approaching 1 terabyte per disk. Here the media is initially homogeneous (not layered), with two-photon effects used to either initiate or quench fluorescence at each voxel [20.238,239]. Confocal microscopy has been used to detect extremely small marks in initial studies, but it is unclear whether such an approach would work on a rapidly spinning disk.

Further gains in depth resolution can be realized by crossing two laser beams of the same or different wavelength, using two-photon absorption to initiate a change of the media's optical properties only in the commonly illuminated volume [20.237, 240], as shown in Fig. 20.20. Here just one volume element within a larger block of recording media can be selected for recording or read out without affecting adjacent volume elements, thus avoiding inter-track and inter-layer interference. Extensions of this technique use columns or sheets of light to address a large number of volume elements in parallel, although these extensions make diffraction-
Fig. 20.20 Orthogonal beams can write and read data in parallel into a three-dimensional volume, using two-photon fluorescence at the intersection of the beams (After [20.237])

limited performance for sub-micron-sized marks more difficult to obtain.

Even so, effective areal densities greater than $100 \, \mathrm{Gb/in}^2$ would appear achievable by using many layers with relatively large marks (i.e., greater than $1 \, \mu\mathrm{m}$). Once written, the marks (or columns or pages) may be nondestructively read by the two-photon fluorescence. Demonstrated capabilities include the recording and reading of media with more than 100 data layers, recording tracks of $2 \times 2 \, \mu\mathrm{m}^2$ data marks, and the construction of several proof-of-principle portable read-out systems [20.237, 240, 241].

This two-photon 3-D optical storage technology seeks to provide disk drive systems with high capacity (100–500 GB/disk) and high data rates (1–10 Gb/s) using inexpensive, easily manufactured, and long-lived plastic media. The drive technologies are potentially backward compatible with conventional DVD media. The media will be removable and offers the possibility of wide wavelength and mechanical tolerances in drives for near-line/online servers.

Efficient two-photon absorption recording requires moderate average laser power (50 mW) but high peak intensity at the focused spot (on the order of $\mathrm{GW/cm}^2$), necessitating the use of a pulsed laser source for recording. Suitable diode-pumped solid-state pulsed lasers are available, albeit at a significant price and size disadvantage as compared to semiconductor laser diodes. These laser requirements remain the largest risk to this approach.

20.7.4 Interferometry

Taking advantage of a relatively short coherence length and variable path difference between two laser beams,

one can obtain constructive interference somewhere along the path of a collimated laser beam to address volume elements throughout the depth of the media [20.242]. While similar to the conventional depth of focus approach, it is different enough to be not easily compatible with CD or DVD. Interferometric optical storage would have the advantage of diffraction-limited performance throughout thick media, and that it is similar to optical coherence domain reflectometry, widely explored as a method for imaging through thick biological samples [20.243]. While simple in concept, it does require interferometric stability and has not been explored in detail for data storage.

20.7.5 Persistent Spectral Hole Burning (PSHB)

Spectral hole burning uses media that can support dopants with extremely selective spectral response (Fig. 20.21). Accessing this narrow spectral response requires a tunable narrow-band laser, which tends to be a complex and expensive light source. Thus high storage densities and storage volumes are essential to amortize the cost of this light source over a large storage capacity. Unfortunately, these very high densities are currently only possible at cryogenic temperatures, adding additional complexity and cost. However, the latency and the data transfer rates that could theoretically be achieved by this technique are superior, allowing spectral hole burning to play in the memory as well as in the storage arena.

Several groups have been pursuing variations of spectral hole burning for data storage and memory applications [20.244, 245]. PSHB can alternatively be
Fig. 20.21 After illumination with a narrow-band laser at ω_L, a persistent and very narrow spectral hole has been *burned* into the absorption spectrum

addressed using time-domain interference techniques, in which holograms laid down in frequency spectrum allow time sequences to be replayed as *photon echoes* [20.246, 247]. Both time- and spectral-access alternatives support spatial multiplexing across numerous locations, and would support the prospect of combining this technique with the spatial holographic techniques to be described below. Crosstalk and distortions between spectral channels, and photon flux are typically the important limiting factors. Time-domain access relieves the requirement for laser tunability, although the laser source does still need to be narrow band and extremely stable. It can also enable content addressability (accessing data by its correlation or similarity with search data). However, efficient time-domain addressing schemes are yet to be developed and random access to data is difficult to provide, with *first-in first-out* (FIFO) being the standard.

Tunable solid-state narrow-band lasers are currently being developed both for these PSHB applications as well as for telecommunications applications. Depending on the choice of PSHB medium, the required frequency tuning range spans either 10 GHz (0.25 Å at about 750 nm), 200 GHz (15 Å at 1500 nm) or 2 THz (30 Å at 650 nm). None of these tuning ranges is extremely difficult – although mode hopping can be problematic – but opto-mechanical approaches would sacrifice one of the key features of spectrally sensitive storage: rapid random access.

20.7.6 Holographic Storage

Holographic data storage is a volumetric approach which, although conceived decades ago, has made recent progress toward practicality with the appearance of lower-cost enabling technologies, significant results from long-standing research efforts, and progress in holographic recording materials [20.248, 249].

A hologram preserves both the phase and amplitude of an optical wavefront of interest – called the object beam – by recording the optical interference pattern between it and a second coherent optical beam (the reference beam). Figure 20.22a shows this process. The reference beam is designed to be simple to reproduce at a later stage, such as a simple collimated plane wave. These interference fringes are recorded if the two beams have been overlapped within a suitable photosensitive media. The bright and dark variations of the interference pattern create chemical and/or physical changes in the media, preserving a replica of the interference pattern as a change in absorption, refractive index or thickness.
Fig. 20.22 How to record and read data using holograms. (**a**) Holographic storage of a single data bit. The spherical wave from a single pixel interferes with a coherent plane wave in the reference beam. The resulting interference pattern changes the refractive properties of the photosensitive medium. (**b**) The hologram is read out using the original reference beam, which is diffracted by the stored interference pattern to reconstruct the original spherical wavefront. An image of this beam can be formed on a single detector pixel, resulting in the retrieval of a single bit. (**c**) The hologram can also be read out by illuminating it with a counter-propagating (or *phase-conjugate*) reference beam, which reconstructs a phase-conjugate copy of the original object beam. This beam returns to its original point of origin, where the bit value can be read without requiring a high-quality imaging system [20.251–255]. (**d**) A third way to retrieve data involves illuminating it with a diverging object beam, which reconstructs the original plane-wave reference beam. This beam can be focused onto a detector and provides an optical measurement of the correlation between the stored data and the illuminating object beam [20.250, 256]. This technique can allow one to search the stored data according to its content, rather than according to its address [20.257–259]. (After [20.260])

When the recording is illuminated by a read-out beam that is similar to the original reference beam, some of the light is diffracted to reconstruct a weak copy of the object beam (Fig. 20.22b). If the object beam originally came from a 3-D object, then the reconstructed hologram makes a virtual image of the 3-D object reappear [20.250]. Interestingly, a backward-propagating or phase-conjugate reference wave, illuminating the stored grating from the back side, reconstructs an object wave that also propagates backward toward its original source (Fig. 20.22c), creating a real but pseudoscopic image.

Although holography was conceived in the late 1940s, it was not considered a potential storage technol-ogy until the development of the laser in the 1960s. The resulting rapid development of holography for display-ing 3-D images led researchers to realize that holograms could also store data at a volumetric density of as much as $1/\lambda^3$ [20.261]. In contrast to conventional data stor-age, where each bit of data is assigned to a particular location within the storage volume or upon the storage surface, holographic storage distributes data throughout a volume in a delocalized way. Data are transferred to and from the storage material as 2-D images composed of thousands of pixels, with each pixel representing a sin-gle bit of information. No one location in the crystal is responsible for storing that one bit; each is distributed
Fig. 20.23 Data are imprinted onto the object beam by shining the light through a pixelated input device called a spatial light modulator. A pair of lenses image the data through the storage material onto a pixelated detector array, such as a charge-coupled device (CCD). A reference beam intersects the object beam in the storage material, allowing the holograms to be stored and retrieved later. (After [20.260])

throughout the associated recorded interference fringes. The direction and spacing of those particular fringes ensures that light arrives at a particular photodetector (within the large detector array) only when a particular read-out beam is incident.

The $1/\lambda^3$ theoretical density limit can thus be intuitively understood as a crosstalk limit forced by diffraction. Given that each reconstructed object beam must pass through an aperture A to reach a detector array, then two sets of fringes that differ in direction by less than $\lambda/\sqrt{A}$ will be indistinguishable due to diffraction. Given that the contributions of the fringe spacings will be integrated over a thickness of L, two sets of fringes that differ in spacing by less than λ/L cannot be individually reconstructed. So roughly L/λ data pages of A/λ^2 pixels each can be holographically stored within a volume $V = AL$. While this simple argument ignores the role of the bulk index of refraction (as well as real-world media and noise issues), $1/\lambda^3$ would be impressive density performance, corresponding (for green light) to the storage of 1 terabyte of data in a cubic centimeter.

Since each data page is retrieved by an array of photodetectors in parallel (Fig. 20.23), rather than bit-by-bit, the holographic scheme promises fast read-out rates as well as high density [20.249, 260, 262–265], because laser beams can potentially be moved rapidly without inertia, unlike the actuators in disk drives. With the inherent parallelism of its page-wise storage and retrieval, a very large compound data rate could be reached by

having a large number of relatively slow (and therefore cheap) parallel channels. If a thousand holograms, each containing a million pixels, could be retrieved every second, for instance, then the output data rate would reach 1 Gb/s.

Despite this attractive potential and fairly impressive early progress [20.266, 267], holographic storage has been – for nearly four decades – an intriguing but elusive alternative to conventional data storage techniques. With the recent availability of relatively low-cost components, such as liquid-crystal displays as input devices and camera chips from electronic cameras and camcorders for detector arrays, interest in commercializing holographic storage efforts was rekindled. Recently, largely as part of an effort that was sponsored by the United States Defense Advanced Research Projects Agency (DARPA), members of the holographic data storage systems (HDSS) consortium were able to demonstrate impressive performance with experimental platforms: at the IBM Almaden Research Center a data density of $250\,\text{Gb/in}^2$ was achieved [20.268]; at Stanford University a data rate of $10\,\text{Gb/s}$ was reached for the read out of holographic data [20.269], and a team at the Rockwell Science Center demonstrated access times on the order of 10 microseconds [20.270]. Each of these demonstrations were the product of extensive studies of recording physics, systems trade-offs, signal processing, and coding techniques. These experiments also showed that it will be difficult, but not impossible, to obtain a combination of all three desirable performance characteristics in one hardware platform.

A rather unique feature of holographic data storage is associative retrieval, or content-addressable data storage [20.258]. If a partial or search data pattern is imprinted on the object beam, illuminating the stored holograms reconstructs all of the reference beams, each weighted by the similarity between the search pattern and the content of their particular data page. By determining, for example, which reference beam has the highest intensity, the closest match to the search pattern can be found without initially knowing its address.

20.7.7 Holographic Multiplexing

If a hologram is recorded in a thin material – as on many credit cards – the read-out beam can differ in angle or wavelength from the reference beam used for recording the image; the scene will still appear. However, if the hologram is recorded in a thick material, the reconstructed object beam will only appear when the read-out beam is nearly identical to the original reference beam.

For any read-out beam, some of the incident optical power is diffracted by the recorded hologram to create a diffracted wavefront. In a thick hologram, this diffracted wavefront accumulates energy from throughout the thickness of the storage material. The Bragg condition applies when the diffracted wavefront is momentum matched to the read-out beam and grating. For holographic media that record an exact copy of the interference fringes, this occurs when the read-out beam is identical in wavelength and incidence angle to the original recording beam. Away from this condition, the discrepancy between the wavefront that would be momentum matched (to the read-out light and the grating) and the wavefront that can actually propagate (the closest solution of the wave equation) represents a phase error. Thus the wavefront diffracted by the front portion of the hologram, after propagating through most of the thick material, finds itself out-of-phase with the wavefront diffracted by the rear portions of the hologram. The integration of this phase error over the thickness of the volume hologram creates Bragg selectivity: the hologram disappears as the angle or wavelength is tuned away from the Bragg condition.

As the material becomes thicker, accessing a stored volume hologram requires tight tolerances on the stability and repeatability of the wavelength and the angle provided by the laser and read-out optics. However, Bragg selectivity also opens up a tremendous opportunity: a small storage volume can now store multiple superimposed holograms, each distributed throughout the entire volume yet selectively accessible with its original reference beam. Any particular data page can then be read out independently by illuminating the stored gratings with the reference wave that was used to store that particular page. The theoretical limits for the storage density of this technique are around tens of terabits per cubic centimeter [20.248, 249].

Several different techniques [20.271] have been developed to define a set of suitable reference beams. It has already been implied that tuning the incidence angle [20.272, 273] or wavelength [20.274] will multiplex holograms. The former has been used much more than the latter, simply because rotating a mirror through large angles has been easier to implement than rapidly – and widely – tunable lasers.

Instead of recording one hologram per incidence angle, it is possible to use all the incidence angles for each hologram, imposing a unique phase on each of these beamlets individually. The number of holograms that can be superimposed depends on the number of orthogonal phase codes. Such phase-code multiplexing [20.275, 276] is widely investigated because spatial light modulators could be used to apply these phases rapidly without mechanical motion. One issue is the need for low phase error (both random and deterministic [20.277, 278]) in these devices; another is the impact of grating degeneracy on any phase codes arranged in a 2-D pattern, a consideration that is unfortunately often overlooked.

Another improvement upon angle multiplexing actually exploits this grating degeneracy. Although holographic data pages do not disappear when changing the incidence angle out of plane, they are displaced on the detector array as the diffracted beam moves to remain in the plane formed by the incident beam and the grating vector. Once the data page slides completely off the detector array, the same Bragg angle can be used to store a second hologram. This is referred to as fractal multiplexing, because one backs off from $(A/\lambda)^2$ pixels per page to some fractal dimension (say, $(A/\lambda)^{2-x}$), allowing an increase in the number of stored pages to $(L/\lambda) \times (A/\lambda)^x$ [20.279]. Using a combination of angle and fractal multiplexing, as many as 10 000 holograms have been stored in a 1 cm^3 volume [20.280, 281]. Techniques analogous to angle and fractal multiplexing, called shift and peristrophic multiplexing, have been developed for multiplexing holograms in thin disks and are described later.

20.7.8 Media

Media for holographic storage has long been one of the primary focus points for researchers in this field. There are two major classes of holographic storage media: write-once media, typically to be used as thin (0.2–2 mm) disks and accessed through disk rotation or translation; and read–write media, typically kept stationary and accessed by beam steering.

20.7.9 Write–Once Read–Many

A material that permanently stores volume holograms must generally support some irreversible photochemical reaction or photophysical process, triggered by the bright regions of the optical interference pattern, that then leads to changes in index of refraction or absorption. For example, a photopolymer material (as its name would suggest) polymerizes in response to optical illumination: material diffuses from darker to brighter regions so that short monomer chains can bind together to form long molecular chains [20.282–286]. Because this diffusion process can be phototriggered,

sensitivities can be made high enough to support holographic recording with single short pulses [20.287]. While high sensitivity is desirable in a commercial application, so that holograms can be rapidly recorded with a cheap, low-power laser, high sensitivity can also cause problems. For instance, some of the media volume may be inadvertently affected by partial exposure as nearby spots are recorded, forcing either a reduction in sensitivity or in areal density (e.g. guard bands). In contrast to photopolymers, the illuminated molecules in a so-called direct-write or photochromic material undergo a local change in their absorption or index of refraction, driven by photochemistry or photoinduced molecular reconfiguration. Examples include photoaddressable polymers [20.288], and binding of absorbers to polymer hosts (such as phenanthraquinone (PQ) to polymethylmethacrylate (PMMA) [20.289]).

Both types of materials are inexpensive to make in bulk, but both can have problems reproducing the object beam faithfully. Photopolymers tend to shrink during recording, distorting the reconstructed pixelated images [20.290]. Direct-write media respond both to the rapid variations of the interference pattern encoded with data and to long-range brightness variations across the illuminated spot. Such effects also distort the reconstructed data pages. These problems can be minimized by careful system design, such as signal-processing techniques that can compensate for shifted and distorted data pages [20.291, 292], and optical illumination systems that deliver beams with extremely uniform brightness [20.293].

Although problems with shrinkage, scattering and dynamic range remain, recent developments in these write-once materials have overcome previous difficulties with poor optical quality and excessive absorption and led to fairly thick samples (0.5–1 mm). Together with recently developed multiplexing techniques that use peristrophic beam rotation [20.294], spherical [20.295] or randomly speckled [20.296] reference beams to increase the number of holograms that can be superimposed in thin media, these developments have brought write-once read-many holographic storage systems to the stage where several commercialization efforts are underway.

20.7.10 Read–Write

In contrast to the organic WORM media, most erasable holographic materials tend to be inorganic photorefractive crystals doped with transition metals or rare-earth ions [20.297–300]. These crystals are often available in centimeter-thick samples and include lithium niobate, strontium barium niobate, and barium titanate, doped with iron, cerium, manganese or other dopants.

For details on these materials please see Sect. 20.5 on photorefractive crystals by Buse and Krätzig. Before discussing the important issue of volatility in photorefractive crystals, we describe some alternative read–write holographic storage media. These include photorefractive polymers [20.301–304], bacteriorhodopsin [20.305–307], and the DX center in semiconductor materials [20.308]. These materials are difficult to obtain in the thicknesses that would be required for competitive capacities, and also have their own idiosyncrasies. While photorefractive polymers can achieve large index changes very rapidly and provide many avenues for tuning through constituent substitutions, they require large voltages to create the orientational analogue of the electro-optic effect and tend to have fairly short dark lifetimes (seconds to minutes) [20.301–304]. Bacteriorhodopsin can be tuned by genetic and chemical modifications [20.305, 307] and does not require an external electric field. However, volatility and dynamic range are serious issues [20.306, 307], and the required operating wavelengths tend to be tightly tied to the protein's innate photocycle [20.305–307]. Essentially, bacteriorhodopsin acts much like a write-once direct-write saturable material, where readout fills in the holograms. By completing the photocycle with a second wavelength, holograms are erased and new ones can be written in the photosensitive molecules reset to their initial state. Finally, at low temperatures (< 150 K), the persistent photoconductivity exhibited by the DX center in semiconductors offers an opportunity for writing strong phase holograms [20.308]. Photoexcited electrons persist in the conduction band without decaying, leading to large index changes. This DX-center material also acts as a saturable material. Here, raising the temperature erases the holograms, since the photoelectrons now have enough thermal energy to make it back to the original ground state [20.308].

20.7.11 Nonvolatile Read–Write Storage

Unfortunately, the ability of a photorefractive material to erase through charge re-excitation also results in the undesired erasure of stored holograms during any subsequent optical exposure. This means that holograms erase while other holograms are being recorded, and worse still, while any of the holograms superimposed within that same volume are being read out. In addit-

ion, there is gradual erasure in the dark through thermal excitation [20.309, 310].

These erasure effects can be counteracted during recording by carefully scheduled the sequence of exposures, to ensure that the final diffraction efficiencies will be equal [20.256, 311]. The first holograms are recorded to somewhat higher diffraction efficiencies with longer exposures, so that as subsequent holograms are recorded and these first ones decay, all final diffraction efficiencies are equal [20.311]. As a result of the recording schedule, the effect of erasure is mitigated at some small cost in effective recording rate. (Recording schedules are also used in write-once media, to compensate for changes in sensitivity as a function of recording exposure [20.312]. This can include any pre-exposure required before the material begins to change its index of refraction.)

The more crucial issue is erasure of the stored holograms during read out. With some photorefractive crystals, stored holograms can be fixed – made semi-permanent and resistant to erasure during read out – by separate thermal [20.313–317] or electronic [20.318, 319] processes. Unfortunately, these fixing processes affect all the stored holograms within a volume simultaneously, only preserve a fraction of the original grating strength, and tend to be slow and cumbersome. For instance, it is not clear how to thermally fix holograms in one sub-volume while not affecting holograms in any of the immediately neighboring sub-volumes.

Another proposed solution to the volatility problem is periodic copying and refreshing of the pixelated data pages [20.320]. Here the data pages are read out periodically and rewritten into the memory. Most of the experimentally demonstrated schemes have involved methods to reinforce the original hologram, but copying the data page into a separate storage location should also work. The problems with all of these is their complexity, the possibility of loss of data fidelity in all the copying and re-copying, and the reduced performance from having the system inaccessible to user-generated read and write commands during the refresh operations.

A third approach to nonvolatile holographic storage is to read the hologram with a wavelength different to that used for recording [20.321, 322]. The idea is that if the absorption at this new read-out wavelength is much lower, the erasure will take place much more slowly. The systems problem with this is that not all of the spatial frequencies in the hologram will be Bragg-matched simultaneously, and there will be a trade-off between how much of the page will be visible, whether the pixels in the page will land where they are supposed to, and how hard one can push towards the theoretical density limit

of $1/\lambda^3$ [20.321, 322]. These systems issues grow worse as the ratio between the two wavelengths grows larger; but given the broad absorption spectra in these crystals, significant changes in absorption require large ($\sim 50\%$) changes in wavelength.

A fourth method for achieving nonvolatile storage in photorefractive materials is by recording at a wavelength of light which is only absorbed by the crystal in the presence of an additional gating beam of different wavelength [20.323–327]. This additional beam is present only during recording and is switched off while the information is read out, allowing the data to be retrieved without erasure. The recorded interference fringes thus remain Bragg-matched to the read-out wavelength, and both read-out and diffracted wavefronts experience low absorption losses.

Conventional photorefractive materials can be optimized for this gated, two-color recording process by changing the way in which they are fabricated or by adding multiple dopants. For instance, the two-color response of lithium niobate can be enhanced by changing the ratio of lithium to niobium in the compound [20.324], or by doping it with both manganese and iron atoms [20.325]. Gated, two-color photorefractive materials have received much attention in the past few years, leading to improvements in both the sensitivity and dynamic range of the materials (increasing both the speed with which data can be written and the capacity) [20.324, 325, 327]. Further improvements, however, will be needed before prototypes can be built.

20.7.12 Phase-Conjugate Read Out for Read–Write Systems

Recent experimental demonstrations of holographic data storage have concentrated on demonstrating high density and fast read out. High areal density can be achieved in holographic data storage by carefully balancing inter-pixel crosstalk (introduced by the small aperture through which each data page is focused) against the loss of signal associated with recording multiple holograms. For instance, an equivalent areal density of $394\,\mathrm{bits}/\mu\mathrm{m}^2$ ($80\times$ larger than single-layer DVD) was recently demonstrated [20.268]. (The equivalent volumetric density was 1.1% of $1/\lambda^3$). Conversely, fast read-out rates can be attained by reading out large data pages in rapid succession. An optical read-out rate of $10\,\mathrm{Gbits/s}$ at moderate density ($\sim 10\,\mathrm{bits}/\mu\mathrm{m}^2$) was recently demonstrated, and a full system read-out rate of $1\,\mathrm{Gbit}$ shown (including the camera and decoding hardware) [20.328]. Both of the demonstrations reached these specifications by com-

bining large *megapixel* data pages of 1024×1024 pixels with the short focal length optics needed for high density.

However, extending read–write holographic storage to high capacity without sacrificing fast access means that this same high density must be achieved at many storage locations without moving the storage media. The demands this would impose upon optical imaging performance are quite severe – thus the further improvements in capacity that could be achieved by simply designing better lenses would be limited to commercially uninteresting values. However, several researchers have long proposed bypassing these imaging constraints with phase-conjugate read out [20.251–254], as shown in Fig. 20.24. Once a hologram is recorded, the wavefront reconstructed by a phase-conjugate read-out beam will retrace the path of the incoming object beam in reverse, canceling out any accumulated phase errors from lens aberrations or material imperfections. This allows data pages to be retrieved with high fidelity using image confinement in fiber-type media [20.251, 252], an inexpensive lens, or even without imaging lenses for an extremely compact system [20.253, 254]. However, many pairs of phase-conjugate reference beams are needed to read the many different holograms recorded within the same volume – and maintaining these beams over long periods of time would be impossible from a practical point of view.

One solution to this problem is to separate the phase-conjugation and hologram storage processes into two successive steps with a *buffer* hologram [20.255]. Holograms can then easily be multiplexed at a large number of separate storage locations using only one SLM and one detector array. With gated, two-color media, the long-term storage material does not absorb the information-bearing beam until the gating light is present [20.255]. With the phase-conjugate read-out, total internal reflection could be used to confine the image-bearing beam within a small cross section without sacrificing the ability to retrieve this image at the detector array [20.251, 252, 255]. Such a system only requires a single pair of phase-conjugate beams, generated either by carefully alignment or with a self-pumped phase-conjugate mirror [20.255].

A second proposed solution to phase-conjugate read out is to attain high capacity from multiple compact modules, each created by attaching an SLM, a detector array, and the storage media directly to a pair of beam splitters [20.253]. The phase-conjugate readout allows the whole system to remain extremely compact, and density can be further augmented by increasing the page size. It has been shown that phase-conjugate read
Fig. 20.24 By adding a counter-propagating readout beam, a phase-conjugate object beam can be reconstructed which retraces the original path of the object beam in reverse. Proper placement of a polarizing beam splitter and detector array can allow high-fidelity data retrieval without expensive imaging optics

out can retrieve pages with pixel pitches as small as $1\,\mu\text{m}$ [20.329]. This approach has the advantage that the object beam need not be confined with total internal reflection because it is never allowed to propagate far from the SLM. But it does require inexpensive components, since the capacity per set of components is relatively low. Both the compact and buffer-enable phase-conjugate systems still require a low-power and convenient method for supplying thousands of unique reference beams to hundreds or thousands of spatial locations, using either micromechanical mirrors, liquid-crystal beam steerers, individually addressable lasers, or wavelength-tunable lasers.

The successful use of phase-conjugation in holographic storage should enable compact and affordable high-capacity systems, with only a moderate increase in the overall system complexity. Obviously, such systems still await a recording material that supports both read–write access and nonvolatile storage [20.325, 326, 330]. Even so, there remain other serious issues that must be addressed before commercialization. Thermal stability must be good lest the interference patterns change spacing and orientation as the media expands or contracts with temperature. Good mechanical and laser stability are also required (the media and interference fringes must not move during exposures, and motion afterwards can cause the reconstructed optical signals to veer away from their assigned detector pixels). Fortunately, the stability during recording will become easier to attain as exposure times decrease through improvements in material sensitivity and increases in available laser power.

Despite all of the techniques for removing and suppressing volatility, it is unlikely that any read–write holographic storage material will be truly nonvolatile: most likely the data will slowly fade over several months or years due to thermal effects (slow excitation from electron traps, diffusion of compensating ions) or through residual absorption. So while blocks of read–write media may be removable from the read–write head (which enables something like a petabyte jukebox), the media will probably need to remain within the jukebox so that data can be periodically refreshed.

20.7.13 Write–Once Systems Using Spinning Disks

In contrast to read–write holographic systems, progress in write-once materials research (especially photopolymers [20.285, 286, 331]) has brought write-once systems to the stage where prototypes for the first holographic storage products are being developed.

Beyond the problems of perfecting the media (in characteristics such as dynamic range, scatter, sensitivity, shelf-life before and after recording, and thermal expansion properties) are the systems engineering issues of building robust holographic data storage devices around a spinning disk format. What makes this even more challenging is that the obvious application areas (low-cost data archiving, possible next-generation distribution format for data and multimedia) call for inexpensive and robust disk readers (as well as cheap media). The first systems problem is the interplay between high rotation speed (needed for low latency) and the need for a high-power, compact pulsed laser to read and write with single pulses. And then there are the difficulties of getting the pulse to the right spot (tracking, focusing, synchronizing pulses to disk rotation), and getting the reconstructed data page to the detector array (compensating for tracking, tilt, disk jitter). *Zhou* et al. have demonstrated tracking for low-density holographic disks [20.332]. They showed both tracking and tilt compensation: the former by measuring the data page rotation to synchronize the beam shutter (on a continuous wave (CW) laser), and the latter by tuning the reference beam angle so that data pages landed squarely on the pixelated detector array [20.332].

To reach high density, the reference beam must cover a wide spread of incidence angles, so good antireflection coatings are essential to keep power from being lost in Fresnel reflections (and this increases media cost). To get the best density while suppressing aberrations

in the imaging system, the object beam should enter the holographic disk media at normal incidence. As this must be done with a short-working-distance optical system, the delivery of writing and reading beams around these imaging optics (without increasing the scatter into them) is further complicated. Although a read-only transmission-geometry head can avoid passing the reference beam past input optics, transmission geometry implies that the read head is split into two parts on either side of the rotating disk (and both sides must be carefully aligned).

Several novel multiplexing methods have been developed to allow holograms to be superimposed very densely, even in thin disks. High density can be reached with peristrophic multiplexing, at the cost of a fairly complicated read head that rotates the reference beam around the normal to the disk surface [20.294]. In contrast, by using either a spherical [20.295] or a randomly speckled [20.296] reference beam, the motion of the spinning disk can allow the reference beam to reconstruct stored holograms selectively with an extremely simple read heads. If this shift multiplexing is done with a spherical reference beam, then holograms can be packed densely along one line (i. e., along the track), but only sparsely along the orthogonal direction (tracks must be widely spaced) [20.295]. Speckle-shift, or correlation, multiplexing using a random phase plate or diffuser [20.296] can allow dense packing in both radial and along-track dimensions, but this advantage does not come for free. Essentially, the size of the random speckles determines the disk motion needed to make each hologram disappear through destructive interference [20.296]. This should be small to maximize density, but not as small as the innate disk wobble and jitter of an inexpensive disk and spindle. On the other hand, the destructive interference depends on the number of random speckles that are spatially integrated as the reconstructed hologram transits the thickness of the disk. So while smaller speckle lead to better inter-page crosstalk SNR, they also make the read-out conditions so selective that holograms might not be reliably found with inexpensive components. Another consideration is any noise from gratings and index changes recorded into the highly sensitive WORM recording media by the speckle pattern itself.

These systems difficulties do not prevent one from building systems that can write and read holograms on spinning disks – several working demonstrations have been shown [20.332, 333]. For instance, Orlov et al., working at Stanford on the final systems demonstrator for the DARPA-sponsored holographic data storage

systems (HDSS) program, built a system capable of
10 Gbit/s optical read out, and 1 Gbit/s end-to-end elec-
tronic read out, at greater than DVD areal densities
on a disk spinning at > 300 rpm [20.328]. The spindle
was so accurate that holograms could be incrementally
recorded over several rotations (i. e., the accuracy and
repeatability were at interferometric levels). However,
any commercial product will need to use much smaller
and cheaper components, without sacrificing the high
density, the fast read-out rate, and the ability to robustly
write and read holograms on the fly.

An alternate approach to wavelength multiplexing is
to use micro-holograms [20.335,336]. Here each micro-
hologram occupies a few square microns of surface area,
and can either extend throughout the thickness of the
disk or exist in one of several thick layers. Multiple bits
of data are written at each micro-hologram by means
of reflection gratings, which can be read out by active
wavelength multiplexing (laser light scanned across the
appropriate spectral band) [20.335], wavelength mul-
tiplexing (white light in, colored light out containing
data) [20.336] or by angle multiplexing [20.335]. The
beams are confined either by the focussed beam itself
within a thin film [20.335], or by a micro-fiber within
the material [20.336].

20.7.14 Content–Addressable Storage

With a conventional memory or data storage device,
a user must supply an address at which the desired data
is located. In volume holographic data storage, this im-
plies that the data – which were once imprinted on an
object beam and stored within the volume – can be read

out later by illuminating the volume with the correct
addressing reference beam (Figs. 20.15a and 20.15b).
However, this hologram can also be illuminated by
the object beam (Fig. 20.15d), reconstructing all of the
angle-multiplexed reference beams that were used to
record data pages into the volume (Fig. 20.25). The
amount of power diffracted into each output beam is
proportional to the similarity between the input data
page being displayed on the spatial light modulator and
the stored data page. The set of output beams can be
focused onto a detector array, so that each beam forms
its own correlation peak. The stored pages that match
the input page can be identified by setting a threshold
on the detected optical signal. If the patterns that make
up these pages correspond to the various data fields of
a database, and if each stored page represents a data
record, then this optical correlation process can be used
to compare an entire digital database against the search
argument simultaneously.

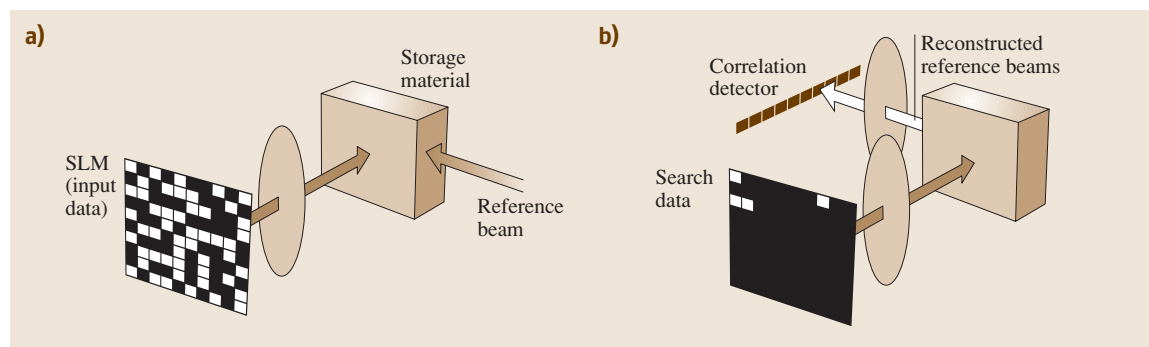
This search parallelism gives content-addressable
holographic data storage an inherent speed advantage
over a conventional serial search. This is particularly true
for searches on complex queries through large databases,
where an index for every possible search query becomes
untenable. For example, it would take a conventional
software-based search ≈ 40 s to go through one million
records, each containing 1 kB of data, if this gigabyte of
data has to be pulled off a hard drive for each search.
Connecting a gigabyte of dynamic random-access mem-
ory (DRAM) to a 1 GHz microprocessor could reduce
this search time to ≈ 1 s. In comparison, an appro-
priately designed holographic system could search the
same records in about 1 millisecond. Spatial light mod-


Fig. 20.25 (a) After multiple holograms are stored, each with a structured data page modulated onto the object beam
and the reference beam introduced at a unique angle, then **(b)** illuminating the stored holograms with a new data-bearing
object beam (the search data page) will reconstruct all of those reference beams in parallel. The optical power in each is
proportional to the 2-D cross-correlation between the search page and the associated stored page, making it possible to
search an entire database with a single optical exposure. (After [20.258, 334])

ulators capable of 10 kHz frame rates (e.g., one search every 100 µs) are also becoming commercially available, although the potential performance speed of such a holographic content-addressable memory depends on having sufficient hologram output power (diffraction efficiency times read-out power) as well as on the requisite modulator speed.

The key to the massive parallelism is to arrange multiple storage volumes, which can each store around 1000 holograms, along the path of the data-bearing object beam [20.334]. As the optically encoded search beam passes through each sub-volume, a small amount of power diffracts from the holograms that are significantly similar to the search information [20.258, 334]. By using one photodetector per hologram, millions of analog similarity metrics could be measured simultaneously. Exact matches to a query [20.257–259], or records that are just similar to a query [20.258, 334, 337] could be identified.

However, since the detected analog result of each correlation is subject to random noise, it is possible that database records which sufficiently match the search argument may be overlooked in favor of records that *almost* sufficiently match it. Fortunately, a hybrid system can combine the speed advantage of the holographic content-addressable memory with the digital precision of serial electronics [20.258, 334]. By passing both matching and near-matching records from the holographic front-end to a subsequent electronic processor, the probability of overlooking even one matching record can be made arbitrarily low ($< 10^{-12}$) while retaining much of the speed advantage [20.258]. Given sufficient signal-to-noise ratio and a spatial light modulator of merely 1 kHz frame rate, a database of 1 million one-kilobyte records could be searched in less than 0.5% of the time required by a 1 GHz microprocessor connected to 10 GB of DRAM.

If the ability to search thousands or millions of holograms in parallel can be demonstrated and a suitable nonvolatile holographic recording media developed, volume holographic content-addressable data storage could be an attractive method for rapidly searching vast databases with complex queries.

20.8 Conclusion

The evolutionary approaches that are based on current technologies and have the potential to be forward compatible – such as the use of depth of focus – have the lowest risks in terms of media, storage device and cost. However, the benefits for potential density gains are also limited, especially if the key features of optical data storage – removability and interchangeability – are to be retained. And the window of opportunity for becoming a viable storage technology is closing.

On the other hand, the revolutionary approaches promise much higher densities at substantially higher risk. Some of this risk arises because laboratory development tends to demonstrate features individually, avoiding effects which only show up when performance is pushed across-the-board. For instance, as density and data rates increase, maintaining an acceptable signal-to-noise ratio and accessing each desired record without crosstalk become severe concerns that cannot be considered independently. However, some of the more exotic techniques have additional attributes that may make them advantageous for niche applications.

These revolutionary approaches are several years away from product prototypes. Issues here are mainly the need for better media, and the relatively high complexity and cost of the drive. Applications that take advantage of some of the unique properties will in all likelihood be targeted by first product designs. Whether revolutionary optical storage technologies will be able to become mainstream, or whether conventional optical disk storage will continue to evolve, will depend on both technical feasibility and commercial viability. The demand is there, but the jury is still out on the best approach to meet the ferocious appetite of the information age.

21. Laser Safety

After a short introduction on current applications of lasers at the beginning of this chapter, Sect. 21.1 gives some historical remarks on laser safety.

In Sect. 21.2 biological interactions and the effects of laser radiation on human tissue are described. Absorption, penetration and transmission of optical radiation are dealt with in detail. The wavelength–dependent transmission through the eye from the cornea to the retina and the role of the pigment epithelium as a selectively absorbing layer are illustrated quantitatively. The optical gain as a result of the focusing capability of the eye is demonstrated together with the increase of irradiance on the retina relative to the power density of the laser beam in front of the eye. State–of–the–art descriptions of photochemical, photothermal and photoionizing effects on biological tissue in general are given and the effects of laser radiation, especially on the various parts of the eye, are described. Retinal and non–retinal injuries of the eye are analyzed and illustrated. In addition, injuries to the skin are shown.

The topic of Sect. 21.3 is maximum permissible exposure. Its relevance to the prevention of short– and long–term effects is described and some remarks on safety or reduction factors are made. The relationship between radiant exposure and irradiance is derived and its general perspective to maximum power values and exposure duration is demonstrated. For the eye, the influence of physiological factors such as eye movements is discussed in more detail for the case of a continuous wave exposure from a point–source. In addition, the concept of an angular subtense to describe the irradiation from an extended optical source is analyzed. Furthermore, recently achieved results are described which show that the strong belief in aversion responses and especially in the blink reflex as a reliable physiological reaction is no longer valid, since no more than about 20% of people perform a blink reflex and even less avert the head.

International standards and regulations on laser safety worldwide are summarized in Sect. 21.4.

Laser classes are described in Sect. 21.5 of this chapter according to the classification scheme of the international standard IEC 60825–1. The meanings of accessible emission limits and time base are explained. A comprehensive description of the various laser classes is given and valuable hints about dealing with each laser class are also described. It is shown how the nominal ocular hazard distance might be calculated from given data.

In Sect. 21.6 protective measures are described. As is usually the case technical and engineering measures rank more highly than administrative and personal protective measures. The protective measures are assigned to the respective laser classes. In addition the role of a laser safety officer is described.

In Sect. 21.7 special recommendations for the most hazardous situations are given and common unsafe procedures are listed. Finally a special topic deals with laser pointers.

Lasers are used in various applications in industry, science, and medicine, for materials processing, distance measurement, alignment, industrial and medical heat treatment etc. In addition, there is increasing public use in the entertainment field and for simple laser pointers.

The laser is often hidden in a protective enclosure and the laser beam is not visible like in an optical fiber communication system, compact disc (CD) player, laser printer, to name but a few. In other applications, such as diagnostic devices, laser endoscopes, or devices for cutting, welding and soldering, the laser beam irradiates a target either to measure levels of some substance or to treat a material. The objective is to deliver enough energy to heat or even vaporize the respective material, while the construction of the laser product and the mode of operation ensure that no harmful laser radiation can escape from the laser device or laser product. In some cases so much optical radiation, i.e. laser radiation and/or secondary and collateral optical radiation, can be scattered or produced during material processing procedures, that adverse health effects cannot be completely excluded.

Normally, lasers used in industrial applications are not a source of special health concern under normal operating conditions, but the situation may be completely different during maintenance or service, where the laser beam is freely accessible and a potentially hazardous situation might arise if the necessary safety measures are not in place.

Special care has to be taken in research and development laboratories, where the open beam is accessible and intrabeam viewing (direct viewing into the beam) may involuntarily happen.

Since there are a large number of devices where lasers are incorporated and since the wavelengths cover the whole optical spectrum, and the power ranges from few micro- or milliwatts to petawatts, various hazardous situations have to be considered in laser safety. In addition not only continuous wave (CW) lasers but also pulsed ones are in use, even in the femtosecond range, i.e. a few mW/cm^2 as well as power densities such as $10^{21}\,W/cm^2$ are achieved in special cases.

21.1 Historical Remarks

Due to the fact that the first laser, which had originally been named an optical maser by Th. Maiman in 1960, emitted a red beam at 694.3 nm in a pulsed mode [21.1] and the first He–Ne lasers emitted in the near-infrared [21.2] or at 632.8 nm, experience was limited to a few special laser types and their corresponding wavelengths in the beginning of the laser era.

Initially, only common-sense safety guidelines could be developed based on a qualitative understanding of the interactions. There was no quantitative understanding at that time.

A dramatic change was observed when ion lasers, such as the argon-ion laser, became commercially available in 1966 and output powers of a few watts became available in science, medicine and entertainment in the subsequent years.

The recommended corneal exposure levels, mainly given for the ruby-laser wavelength varied at that time between $6.8 \times 10^{-4}\,mW/cm^2$ to $1\,mW/cm^2$, i.e. a factor of about 1 500 [21.3]. Less-conservative laser safety factors were used as more biological data became available; this tendency toward an increase in the recommended safe exposure levels was quite different to that for other physical or chemical agents.

The increasing number of laser users, the spread of laser applications into new fields, and the lack of ade-

quate measures for protection resulted in an increasing number of accidents in these early years. Damage to the eyes was noted relatively often, whereas injuries to the skin, such as burning or even charring, occurred very seldom, since powerful infrared lasers such as the Nd:YAG or CO_2 laser at $1.064\,\mu m$ and $10.6\,\mu m$, respectively, were not as widespread at that time.

The increasing number of laser accidents prompted the establishment of a conference dealing with the topic of laser accidents and how to prevent them; laser safety has been regarded as an integral part of laser application development since then.

The fact that there has never been a single organization that had the competence or legislative power to establish an applicable system of safety procedures, rules and protective measures worldwide, to be respected by all laser users irrespective of their geographic location or national affiliation, resulted in many different systems of regulations and recommendations.

One of the first supranational recommendations was published in 1982 by the World Health Organization (WHO) as the *Environmental Health Criteria* [21.4].

Since optical radiation is normally defined in the wavelength range from 100 nm to 1 mm the same is true for laser radiation, i.e. a very large range of laser wavelengths has to be taken into account. In addition,

lasers might be used as a continuous-wave emitter or in a pulsed mode with pulse durations from milliseconds to a few femtoseconds. Simultaneously there exists a huge range of power and/or energy densities that can be achieved with the various laser types. This fact clearly shows that it is not possible to allocate a laser to either a safe or to an unsafe group of products.

Therefore more than two so-called laser classes have been used from the very beginning in international, regional and national standards. Today laser products are categorized into as many as seven different laser classes in order to take account of the various parameters of emitted radiation and the associated hazard level.

In order to protect against adverse health effects of exposure to laser radiation, so-called exposure limits (ELs) or maximum permissible exposure values (MPEs) have been introduced, based on the best available scientific and experimental knowledge and have been adapted whenever new experience justified a change of the former values.

21.2 Biological Interactions and Effects

21.2.1 Fundamental Interactions

Laser radiation might hit every site on the surface of a human being. Due to their anatomical and optical characteristics, the eyes are most vulnerable to laser radiation from about 400 nm to about 1400 nm, i. e. covering the visible and the near-infrared regions of the optical spectrum, where optical radiation is transmitted from the cornea to the retina Fig. 21.1.

The eye is divided into two parts: the front or anterior chamber, which is bounded by the cornea, the iris, and the lens; and the back or posterior eye ball, which is bounded by the retina and contains the gel-like vitreous humour (vitreous body). If we look in the direction of the laser beam shown in Fig. 21.1 into the eye with an ophthalmoscope we will see an image of the ocular fundus. It looks reddish, but the prominent retinal vessels can be clearly seen. Other distinctive features are the whitish optic disc (blind spot), and the fovea. The fovea is a small depression in the retinal surface that may be more highly pigmented than the surrounding retina and is the area of most acute vision. The fovea is the center of the macula. The macula is responsible for detailed and color vision.

The retina consists of several layers of nerve cells (horizontal, bipolar, amacrine and ganglion cells) that cover the photosensitive rods and cones; i. e. light falling on the retinal surface has to pass through the different layers of cells before it reaches the photoreceptors. Underneath the layer of rods and cones is a layer called the retinal pigment epithelium (RPE), which contains a brownish black pigment called retinal melanin, and beneath this is a layer of fine blood vessels, the choriocapillaris. The final absorbing layer is the choroid, which contains both pigmented cells and blood vessels. The outside of the eye ball is called the sclera Fig. 21.1.

The eyes and the skin are the organs that are most susceptible to potential damage from laser radiation. The degree of interaction between laser radiation and biological tissue is determined mainly by its optical characteristics. Only the laser radiation that is transmitted through the respective surface and not reflected can interact with the tissue structures. Since the tissue consists of various substructures and components such as vessels, cells, membranes, and proteins, the inhomogeneous materials mainly demonstrate Mie scattering, since the components and areas are larger than the respective laser wavelength.

Some of the photons are scattered hundreds or even thousands of times per centimeter, but the most important fundamental interaction is absorption. Only in this case is the energy carried by the photons transformed into other kinds of energy, namely the excitation of
Fig. 21.1 Schematic drawing of the human eye with the standardized pupil diameter

atoms and the vibration of molecules. This increases the heat content of the respective tissue volume.

Normally the interaction of laser radiation with biological tissue can be described as a function of the irradiance, given in units of W/m^2 or radiant exposure in J/m^2.

Irradiance and radiant exposure correspond to the power and energy density and describe the power of a laser beam at a given position in space at a given time; the exposure duration is one of the most relevant quantities describing the extent of a biological effect.

Comparing the interaction of laser radiation and organic material with inorganic material, the main difference is given by the fact that specific processes may happen in a living tissue as a result of the time course of the interaction where destructive and repair processes have to be taken into account, i.e. the result of laser irradiation is not only dependent on the physical parameters of the laser beam but on biological capabilities and characteristics as well.

The reflection from a light-colored surface is normally much larger than from a dark-pigmented one, especially in the visible part of the optical spectrum. Between 400 nm and 1400 nm a lot of photons are backscattered from the biological tissue, i.e. generalized reflection coefficients as large as about 50% are possible. In the case that only absorption takes place

the power density or irradiance $E(z)$ decreases exponentially according to the Lambert–Beer law

$$E(z) = E_0 \exp(-\alpha z) , \qquad (21.1)$$

where α is the absorption coefficient of the respective medium given in cm^{-1}, E_0 is the irradiance just below the tissue surface (incident irradiance), and z denotes the optical axis (direction of the laser beam).

From (21.1) the depth of penetration z_0 can be derived as

$$z_0 = \frac{1}{\alpha} , \qquad (21.2)$$

i.e. the laser beam penetrates a less-absorptive tissue more than a translucent or opaque material. In human tissue the absorption is determined by the components of the corresponding structures.

Absorption and Penetration Depth of Water

Since many parts of the human body contain a lot of water, the wavelength dependence of absorption in water, which is shown in Fig. 21.2, determines the absorption characteristics of tissue with a high water content.

In this graph the increase of absorption in the ultraviolet due to the excitation of the constituent atoms can be clearly seen. In addition the infrared spectrum is a fingerprint of the fundamental valence vibrations at about $6 \mu m$ and $3 \mu m$, and of the respective overtones (second harmonics and above) at shorter wavelength. The decreased strength of absorption of the harmonics, which normally decreases by a factor of about 10 between orders of harmonics, can be seen in Fig. 21.2.

In addition to the absorption coefficient of water, that of hemoglobin is shown in Fig. 21.2. The absorption of the red chromophore of blood fills the gap in the water absorption to a certain extent, i.e. in human tissue both components normally have to be considered in calculations.

With respect to (21.2) the penetration depth in water, where the irradiance decreases to $1/e$ of the amount at the surface, might be calculated from Fig. 21.2 and is shown in Fig. 21.3.

Transmission and Absorption of the Human Eye

Since the human eye has a thickness of about 25 mm between the surface of the cornea and the retina, and since the ocular media, especially the anterior chamber and the vitreous body (cf. Fig. 21.1) might be considered from optical data to be like water, it can be seen from Fig. 21.3 that optical radiation between UV-A and about 1500 nm reaches the retina. Due to the fact that the
Fig. 21.2 Absorption of water and hemoglobin as a function of wavelength

cornea and the lens show some absorption in the ultraviolet the range of ocular transmission is given, as shown in Fig. 21.4, as 400–1400 nm.

In addition to the ocular transmission, Fig. 21.4 shows the wavelength-dependent absorption of the retinal pigment epithelium, which is anatomically located between the retina and the choroid. To estimate the most hazardous wavelength region both curves for transmission T and absorption A in Fig. 21.4 have to be multiplied to give the actual percentage of optical radiation that is absorbed in the most sensitive layer of the human eye [21.6]. The product TA may be thought of as the action spectrum for retinal injury.

Since the eyes are the doors to the brain, function as the gateway to the optical environment, and possess the capability to focus optical radiation onto a relatively small spot on the retina, which in correct vision is located in the fovea Fig. 21.1, the irradiance is increased by a factor of about 500,000. This optical gain is equivalent to the quotient of the area of the beam at the front of the eye to the small spot on the retina. Since the pupil limits the extension of the beam Fig. 21.1 the ratio is given by

$$\left(\frac{\text{largest diameter of the pupil}}{\text{smallest spot on the retina}} \right)^2$$

$$\approx \left(\frac{7\,\text{mm}}{10\,\mu\text{m}} \right)^2 \approx 500\,000 \tag{21.3}$$

Due to the special characteristics of a laser beam, namely that it is:

- monochromatic,
- coherent (capable of interference), and
- directional (laser generally radiate in a narrow beam),

a 60 W laser with a 4 mm-diameter beam produces about $480\,000\,\text{mW/cm}^2$ on a surface 1.0 m away, whereas a conventional 60 W light bulb (with a theoretical efficiency of 100%) produces only about $0.5\,\text{mW/cm}^2$ at the same distance. For comparison the irradiance of the sun is about $100\,\text{mW/cm}^2$.

Laser radiation is distinguished from most other known kinds of radiation by its beam collimation. Considering the capability of the human eye to focus the beam onto the retina, a laser beam with a power density of about $1\,\text{mW/cm}^2$ in the plane of the pupil or at the cornea might be transformed into an irradiance of up to $500\,\text{W/cm}^2$ due to the optical gain in irradiance from the cornea to the retina. This characteristic has to be taken into account in the wavelength region of 400–1400 nm.
Fig. 21.3 Depth of penetration in water as function of wavelength (cf. some often used laser lines)
Fig. 21.4 Transmission T of the eye from the cornea to the retina and absorption A of the retinal pigment epithelium (RPE) as a function of wavelength λ_0 [21.5]

Due to the fact that the transmission is nonzero in this wavelength region, it is often called the *retinal hazard region*, but wavelengths outside this band should not be described as *eye-safe*, since other parts of the eye are vulnerable to shorter or longer wavelengths and adverse health effects may happen there.
Fig. 21.5 Penetration depth of water, hemoglobin and melanin as a function of wavelength

The most likely effect of intercepting a laser beam with the eye is a thermal burn that destroys the retinal tissue. Since retinal tissue does not regenerate, the damage is permanent.

In addition to the absorption of water, other chromophores have important characteristics for eye and skin. Figure 21.5 compares the penetration depth of water, hemoglobin and melanin.

Photochemical, Photothermal and Photoionizing Effects

In general the irradiance or radiant exposure can result in a large spectrum of biological effects, which can be divided into photochemical, photothermal and photoionizing effects.

The irradiance or power density is the radiant power incident per unit area upon a surface expressed in watts per square meter (W/m^2) and the radiant exposure or energy density is the time integral of the irradiance, expressed in joules per square meter (J/m^2). In some cases the radiance is used to describe the respective bioeffect. The radiance is the radiant flux or power output per unit solid angle per unit area, expressed in watts per square meter per steradian ($Wm^{-2}sr^{-1}$).

The irradiance E is given as

$$E = \frac{dP}{dA} \quad \text{in } W/m^2 \tag{21.4}$$

and the radiant exposure H

$$H = \int_0^t E(t) \cdot dt \quad \text{in } J/m^2 \tag{21.5}$$

where dP is the power expressed in watts [W], dA is the surface in square meters [m^2], and t is the time or duration of the exposure, expressed in seconds [s].

Values of $E(t)$, E and/or H come from measurements, or may be calculated from data provided by the manufacturer of the laser product.

Irradiances up to $1\,W/cm^2$ normally result in reversible processes such as photostimulation or photochemical reactions in the skin, especially for exposure durations longer than 1 s. However, there exist photochemical reactions at higher irradiances that may also result in permanent damage. Photochemical reactions generally follow the law of Bunsen and Roscoe, and for exposure durations of the order of $1-3$ h or less (where repair mechanisms come into play), the threshold expressed as a radiant exposure is constant over a wide range of exposure durations.

At higher irradiances between about $10\,W/cm^2$ and $10^5\,W/cm^2$ in the millisecond regime up to a few seconds the biological tissue becomes heated and denaturation, i. e. coagulation of proteins, results in cell necrosis (cell death). If a temperature level of $100\,°C$ is achieved, vaporization of cell substances such as water happens.

At even higher irradiances up to about $10^{10}\,W/cm^2$ and exposure durations as short as microseconds and somewhat shorter, as in the case of Q-switched pulses, so-called nonthermal effects are initiated. These result in the ablation of superficial layers of the tissue caused by mechanical disruption, where only a minimal temperature rise can be measured in the circumference of the irradiated area and the respective necrotic zones extend only some micrometers, i. e. are comparable to the cell dimensions.

In the case of very short exposure durations at power densities/irradiances up to $10^{12}\,W/cm^2$ so-called optical breakdown happens. The electrical field amplitudes might have values of $1-100\,MV/cm$, which is comparable to the atomic or intramolecular Coulomb field, and therefore a microplasma is created, resulting in an ionizing effect. The rapid expansion of this plasma results in a shockwave and has the capability to destroy even the hardest substances in the human body.

If a photoacoustic effect occurs in the eye a shockwave in the retinal tissue is induced that causes a rupture of the tissue. This damage is permanent, as with a retinal burn. Acoustic damage is actually more destructive than a thermal burn. Acoustic damage usually affects a greater area of the retina, and the threshold energy for this effect is substantially lower. Table 21.1 summarizes these various effects.

All these effects are used in various medical treatments for the benefit of patients. In this case the application of laser radiation is under medical super-

Table 21.1 Effects of laser radiation on biological tissue

Effect		
Photochemical	**Photothermal**	**Photoionizing**
Biostimulation	Hyperthermia	Ablation
	Coagulation	Disruption
	Carbonization	Fragmentation
	Vaporization	
$t = 10$–1000 s	$t = 1$ ms–1 s	$t = 10$ ps–10 µs
$\leq$ 100 mW	1–100 W	
$\leq$ 50 mW/cm^2	1–100 W/cm^2	

vision and control, whereas involuntary exposure can result in a hazardous situation and/or damage of the respective tissue. This can be very dramatic if the eyes are involved and therefore maximum permissible exposure limits have been established, based on the best available knowledge of these effects as a function of irradiance, radiant exposure, exposure duration, wavelength, size of the irradiated area etc.

21.2.2 Effects of Laser Radiation on the Eye and Skin

Since laser radiation might be generated at nearly every wavelength in the range between 100 nm and 1 mm, various effects have to be considered as a result of acute or chronic exposure. Table 21.2 gives an overview of the various processes and effects that might predominantly happen in these wavelength regions in the eyes or skin, since these organs are the most susceptible to damage by laser radiation.

The anatomical and physiological characteristics of the eye result in the most dangerous wavelength region of 400–1400 nm, where transmission of laser radiation from the cornea to the retina occurs, as can be seen in Fig. 21.4.

In this case most of the optical energy is absorbed by the photopigments (chromophores) of the retinal pigment epithelium, which has a layer thickness of about 10 µm, whereas not more than about 15% of the incident

Table 21.2 Effects of laser radiation as a function of wavelength region in the eye and skin

Wavelength region (nm)	Eye	Skin
UV-C: 100 nm to 280 nm	Photokeratitis (corneal inflammation; cornea surface absorbs all) Photoconjunctivitis	Erythema (reddening of the skin) Pre-carcinoma
UV-B: 280 nm to 315 nm	Photokeratitis Photoconjunctivitis Cataractogenesis (cataract formation)	Increased pigmentation Enhanced skinphotoaging (accelerated skin aging) Erythema Oedema Pre-carcinoma Carcinoma (skin cancer)
UV-A: 315 nm to 400 nm	Cataract formation (lens is principal absorber)	Acute pigmentation Enhanced skinphotoaging Skin burns Carcinoma (skin cancer)
VIS: 400 nm to 700 nm	Photochemical and photothermal damage to the retina	Photosensitive reactions (photosensitization) Skin burns (reddening of skin, blisters, charring)
IR-A: 700 nm to 1400 nm	Cataract formation from heating proteins in the lens Photothermal retinal damage	Skin burns (reddening of skin, blisters, charring, damage to underlying organs)
IR-B: 1400 nm to 3000 nm	Cataract formation (corneal or lenticular opacities) Photothermal damage (burns) to the cornea	Oedema of the skin Skin burns
IR-C: 3000 nm to 1 mm	Photothermal damage of the cornea	Skin burns

laser radiation is absorbed in the chromophores located in the cones and/or rods. As a result thermal damage is initiated in the RPE, but extends to the receptor cells in the retina and may, in addition, destroy the neuroretina, which contains horizontal, bipolar and amacrine cells and finally projects onto the ganglion cells. Hazardous irradiation in the human eye can extend as far as the choroid.

Retinal Injuries

Photothermal damage might appear as a minimal lesion, where only a few receptor cells are destroyed, but at higher optical energy values much larger, permanent destruction may happen. A mild burn on the retina appears yellow or grey, and a white patch is produced at greater power. A lesion which is only visible as a slight discoloration is a threshold lesion. If a victim is looking directly into the beam (intrabeam viewing), he might receive a foveal burn, i. e. his center of vision is destroyed. If this region is damaged, the effect may appear initially as a blurred white spot obscuring the central area of vision; however, within two or more weeks, it may change to a black spot. Ultimately, the victim may cease to be aware of this blind spot (scotoma) during normal vision. However, it can be revealed immediately on looking at an empty visual scene such as a blank sheet of white paper. Figure 21.6 shows two examples of retinal injuries from a visible laser beam.

A burn in the peripheral retina may only cause a small scotoma, which may not be detected subjectively or even during a systematic eye examination.

Photoacoustic retinal damage may be associated with an audible pop at the time of exposure. Visual disorientation due to retinal damage may not be apparent to the victim until considerable thermal damage has occurred. Hole burning and bleeding might also happen with sufficiently high power levels, i. e. in addition to field defects, hemorrhage and debris projected into the vitreous humor can permanently impair vision.

This kind of injury will be clearly noticed by the victim, whereas smaller retinal lesions might not even be recognized and can barely be found in a routine ophthalmoscopic inspection.

Exposure to a visible laser beam can be detected by the bright color flash of the emitted wavelength and an afterimage of its complementary color, e.g., a green 532 nm laser light would normally produce a green flash followed by a red afterimage.

Since laser radiation at wavelengths above about 700 nm is invisible to the human eye, near-infrared radiation has to be regarded as particularly hazardous and might result in serious injuries. Exposure to the Q-switched Nd:YAG laser beam (1064 nm) is especially hazardous and may initially go undetected because the beam is invisible and the retina lacks pain sensory nerves. At these longer wavelengths photothermal effects still dominate for exposure durations in excess of 10 s, which is important when using near-infrared lasers in the CW mode.

The real extension of a retinal injury is very often not apparent directly after the laser irradiation, but several hours later. This is related to time-dependent processes that are incurred with thermal damage such that inflammation and repair processes have to be taken into account.

At lower irradiance values chronic injuries may result from laser radiation in the wavelength region of 400–600 nm, when the respective exposure duration is long enough, i. e. several seconds or more [21.7]. The explanation of such effects is given by a photochemically initiated process, which is not connected to a measurable temperature increase of the tissue. However a small temperature rise in the retina appears to be synergistic with the photochemical effect. Photoretinitis is one of these special radiation-induced effects, which may even result in blindness, i. e. due to the photochemical processes the respective photoreceptors are no longer able to fulfill their normal functions.
Fig. 21.6a,b Photothermal retinal lesions from a visible laser beam; **(a)** small lesion of about 150 μm, **(b)** lesion diameter about 500 μm (different magnifications)

Damaging effects can also be the direct result of specific molecular absorption of a given light. Rather than releasing the energy, however, the species undergoes a chemical reaction that is unique to its excited state. This is what is known as the photochemical effect.

Non-retinal Injuries

In addition to retinal injuries, hazards are also possible in the ultraviolet and the mid- and far-infrared spectrum to the anterior parts of the eye, i. e. the cornea, conjunctiva and the lens.

Similar to the photochemically induced, so-called athermal retinal injuries, photokeratitis and photoconjunctivitis, which are inflammations of the cornea and the conjunctiva, respectively, are both wavelength dependent and can be described by their respective action spectra. This is a characteristic of all photochemical effects, which show a relatively strong wavelength dependence and a maximum sensitivity.

In the UV-A part of the spectrum, the intensities or exposure durations required to produce photokeratitis or erythema are much greater than for so-called actinic UV radiation (UV-B and UV-C). The cornea and the skin are nearly as sensitive in the actinic UV region, but corneal damage is more painful.

In addition to these photochemical effects, lenticular cataracts may be formed by ultraviolet [21.8] and infrared radiation.

Exposure to the invisible carbon-dioxide laser beam (10 600 nm) can be detected by a burning pain at the site of exposure on the cornea or conjunctiva. A corneal burn may be manifested as a surface irregularity or a white opacity Fig. 21.8. If the lesion is minor, i. e. restricted to the outer cellular layer, then it will heal and disappear within about 48 hours. Deeper burns may cause permanent damage.

Fig. 21.7 Damage of the eye with a Nd:YAG laser (deep coagulation of the anterior parts; illumination with and scattering of an aimed He–Ne laser beam)
Fig. 21.8 Damage of the eye with a CO_2 laser with the mode pattern visible on the cornea

Figure 21.7 shows an example of a 1 s exposure with a 100 W Nd:YAG laser (1.064 μm) of an animal eye in a laboratory trial, where it can be seen that even the anterior parts of the eye are destroyed by coagulation. Retinal damage was not the goal of this special investigation, but has certainly happened due to the high transmission at this wavelength and the focusing capabilities of the eye. In Fig. 21.8 the damaging capability of a short exposure (about 0.5 s) of a 60 W CO_2 laser of the cornea is illustrated, where even the mode pattern of the laser beam can be seen.

Injuries to the Skin

In contrast to eye injuries any damage to the skin is of minor importance as far as skin burns are concerned, although even third-degree burns might not be completely excluded at higher laser power levels. Injury to the skin normally results from temperatures exceeding 45–60 °C, but this value is also time dependent.

Special care has to be taken if ultraviolet radiation is present, since erythema (skin reddening resulting from vasodilatation), oedema (swelling) and even carcinoma might result from acute (short-term) or chronic (long-term) exposure, respectively.

Ultraviolet radiation may not only arise from UV lasers, such as e.g. excimer lasers, but from so-called secondary optical radiation, which comes from various material processing applications like cutting and welding with high-power Nd:YAG or CO_2 lasers. Concerning its biological effect, it is not important whether it is a coherent or incoherent radiation which interacts with biological tissue, but this characteristic clearly determines the smallest spot on the retina.

Exposure of the skin to high-power laser beams (1 W or more) can cause burns. At the sub-five-watt level, the heat from the laser beam will cause a flinch reaction before any serious damage occurs. The sensation is similar to touching any hot object, you tend to pull your hand away or drop it before any major damage occurs. With
Fig. 21.9 Surface reactions (*top*) and penetration depth (*below*) of various laser beams (*left* to *right*: CO_2, Nd:YAG, and argon-ion laser), beam diameter: about 4 mm, tissue: liver

higher-power lasers, a burn can occur even though the flinch reaction may rapidly pull the affected skin out of the beam. These burns can be quite painful as the affected skin can be cooked, and forms a hard lesion that takes considerable time to heal.

Figure 21.9 shows examples of tissue reactions and penetration depth achieved with an argon-ion laser, a CO_2 and a Nd:YAG laser. As can clearly be seen

the penetration depth is largest for near-infrared wavelengths, as might be explained from Figs. 21.4 and 21.5, whereas due to the high absorption in water or hemoglobin the penetration depth is low with the CO_2 (10.6 µm) and argon-ion (450–515 nm) lasers.

In addition to incoherent optical radiation other secondary effects have to be taken into account when lasers are applied. To name but a few, the respective hazards might arise from electrical currents and high voltages, electromagnetic high-frequency fields, optical pump radiation, X-rays, explosive atmospheres, inflammable materials, toxic and infectious or even carcinogenic liquids or solid materials.

The various so-called secondary physical and chemical agents associated with laser products and applications must be regarded in the risk assessment or analysis and shall be restricted to a given limit of exposure or dose.

21.3 Maximum Permissible Exposure

21.3.1 Threshold values and ED-50

In order to protect human beings from any hazardous laser radiation, maximum permissible exposure (MPE) values have been established. The MPEs represent that level of laser radiation to which, under normal circumstances, persons may be exposed without suffering adverse effects. The MPE levels represent the maximum level to which the eye or skin can be exposed without consequential injury immediately or after a long time and are related to the wavelength of the radiation, the pulse duration or exposure duration, the tissue at risk and, for visible and near-infrared radiation at 400–1400 nm, the size of the retinal image.

Whereas these MPEs were very conservative at the beginning many values were increased in later years due to improved investigation methods and more-sophisticated models taking into account the various effects as a function of wavelength and exposure duration.

Since in many cases there is no distinct threshold value for humans the MPEs have been derived from experimental results on different animal species. Therefore a certain degree of uncertainty exists as far as extrapo-

lations from animal experiments to effects in humans have to be made. However all currently available scientific knowledge indicates that the respective exposure limits (ELs) provide a safe level of protection against known biological laser radiation effects.

By agreement, the MPEs have mainly been established at 1/10 of the so-called ED-50 value (effective dose 50%), which is the value of irradiance or radiant exposure where an ophthalmoscopically visible lesion exists in 50% of the irradiated cases. The ED-50 is also often referred as the *threshold*. Since the slope of the probit curve is relatively steep it might be expected that at 10% of the ED-50 no harmful effects can be found and therefore the MPE values include a safety or reduction factor.

Not only individual susceptibility but biological and biophysical variables affect the data and therefore it is not possible to define a single safety or reduction factor between the threshold of an injury (observed effect) and the exposure limit.

As has been shown in different laboratory studies microscopically visible injuries usually appeared at between 25% and 50% of ED-50, but never at values less than 10% [21.9]. A safety or reduction factor of about 2

in the UV and 5–10 in the visible part of the spectrum is used for most corneal and retinal effects [21.9].

MPE values should be used as guides in the control of exposures, and should not be regarded as precisely defined dividing lines between safe and dangerous levels. In any case, exposure to laser radiation should be as low as possible.

The extent of injury varies considerably with wavelength and therefore it is necessary to adjust the exposure limits and the MPEs for different wavelengths, but in a simple manner, i.e. by correction factors given as straight lines (potential functions or constants) in a logarithmic illustration. For example, this factor increases from 1 to 5 as the wavelength increases from 700 nm to 1050 nm. As a consequence of the increased absorption of laser radiation in the ocular media (Fig. 21.4) another factor has been introduced in the MPEs, which increases from 1 to 8 in the wavelength region between 1150 nm and 1200 nm.

At exposure durations exceeding about 10 s the difference between the ocular exposure limits for shorter wavelengths, i.e. below about 500 nm, and longer ones, increases with greater exposure durations since short-wavelength visible laser radiation causes predominantly photochemical retinal injuries, i.e. the MPEs are much lower for longer exposure durations at shorter wavelengths.

Since exposure limits are based on experimental results and on understanding of the possible photochemical, photothermal, photomechanical and photoionizing interactions with biological tissues that should not cause adverse effects, it can easily be understood that there was and still is a lack of accurate data for some wavelengths, exposure durations, beam parameters and so on. Therefore worst-case exposure conditions have been assumed.

In addition, new and improved data have shown that some of the earlier exposure limits had over-conservative safety factors and revised exposure limits have been recommended.

One could certainly follow the contours of the experimentally achieved bioeffect threshold curves, as far as they exist, resulting in more gradual exposure limit curves, but up to now step functions and simple mathematical functions have been used for the MPE values.

MPE values were derived to preclude not only acute effects but delayed adverse effects too. Since to date only limited data are available for chronic, long-term, exposures, delayed effects might not be completely excluded. Until now no MPE values have been given for extremely long exposures, i.e. more than eight hours.

On the other hand intrabeam exposure situations seldom last more than 100 s. However, situations where long-term scattered or diffusely reflected laser radiation is present should be included in a risk analysis, especially in the case of occupational exposure.

21.3.2 MPE Values for the Eye

MPE values are given for the cornea and for the skin. The values for the cornea have been derived for worst-case situations, i.e. a pupil diameter of 7 mm and a stable image of the respective laser beam on the retina. Since these conditions might happen very seldom, e.g. with an anesthetized eye, the MPE values for the eye implicitly include an additional safety factor.

The pupillary aperture averages the radiant exposure and the irradiance. For many years a 7 mm aperture, corresponding to the dark-adapted, maximal, dilated pupil, has been standard. This is equivalent to a worst-case situation. The risk does not decrease proportionally with decreasing pupillary area when a point source is viewed [21.10]. In the visible and near-infrared region, since laser radiation is focused on the retina, it does not matter whether the laser beam is 1 mm or 2 mm in diameter when it enters the pupil. Ultimately all the optical power/energy is concentrated into approximately the same spot on the retina.

Based on diffraction theory a retinal image diameter of about 3–6 μm would be expected, but the human eye is not such a good optical device and therefore a minimal image size of about 25 μm has been chosen for safety considerations, although somewhat smaller spots have been reported.

Point Sources and Eye Movements

In the case of CW exposure, physiological factors have to be taken into account whenever exposure situations are analyzed. Pupillary activity (pupillary reflex), eye movements (saccades, micro-saccades, drift, tremor), breathing, heart beat, blood flow and other bodily movements are the physiological factors that influence the exposure duration, being greatest for point sources and least for large, extended sources. On the other hand the person's visual task is also governed by visual fixations, i.e. there are periods when the retina fixes an object only on the fovea. The fixation time is normally about 200–400 ms, but depending on the level of processing or cognition, longer times might not be excluded. The eye movement studies of *Ness* et al. [21.10] clearly showed that the retinal image can remain remarkably still for a few seconds. It turned out in investigations that cor-

rection factors for eye movements were only important for viewing conditions longer than 10 s [21.9].

It has been shown that the expected image diameter of about 25 μm, which is equivalent to an angular subtense (visual angle) α of 1.5 mrad for an object of 150 μm at a distance of 100 mm, which is taken as a very conservative minimal distance of accommodation, and is given by the focal length of 17 mm, is blurred due to eye movements to a diameter of about 50 μm within an exposure duration of 250 ms for unrestrained head viewing, to 75 μm for 10 s, and that it is rare to achieve an illuminated zone as small as 135 μm for 100 s [21.10].

As is stated in a revision of the laser guidelines given by the International Commission on Non-ionizing Radiation Protection (ICNIRP) [21.11] the earlier recommendations of the exposure limits have not been changed as far as exposure durations between 1 ns and 10 s are regarded, but due to the fact that the image is blurred by physiological reactions like various eye and body movements, the safety factor is further increased. On the other hand the MPEs for longer exposure duration, i.e. longer than 10 s, have been increased, especially from 2001.

The accumulated radiant exposure in the retinal image area directly predicts the extent and position of photochemical retinal injury such as photoretinitis, i.e. fixation and eye movement studies have permitted the determination of the so-called *blue-light hazard* exposure limits. It is important to note that thermal retinal injury thresholds decrease for increasing retinal image or spot size due to radial heat flow during and after exposure.

Due to the influence of eye movements, the photothermal exposure limit is given as a constant irradiance of 1 mW/cm^2 for point sources (i.e. $\alpha \leq 1.5$ mrad) in the visible part of the spectrum for exposure durations longer than 10 s. For longer exposure durations the photochemical exposure limit becomes the important part, especially below 500 nm.

It has been shown by modeling the exposure situation for longer exposure durations, taking into account experimentally achieved data relating to eye movements, that thermal damage of the retina is not possible with a laser beam power of 0.4 mW at the 632.8 nm wavelength of a He–Ne laser, which is equivalent to an irradiance of 1 mW/cm^2 through a 7 mm pupil [21.12].

With the same model and a higher absorption in the green–blue part of the spectrum (cf. Fig. 21.4) it can be shown that a beam power of 5 mW can be sufficient to increase the retinal temperature by about 18 K, and can therefore result in protein denaturation, i.e. coagulation

of the area on the retina. It should be taken into account that most of the thermal denaturation of proteins (coagulation) occurs after the pulse, which means that the geometry of the retinal exposure influences the lesion size. Radial heat flow is responsible for a relatively strong dependence of retinal injury on retinal image or spot size [21.13].

In addition long-term irradiation with wavelengths shorter than about 500 nm can result in predominant photochemical damage of the retina. This is the main reason that exposure limits are lower for shorter wavelengths for longer exposures.

Extended Sources

In order to take into account that there is a difference concerning the image size and the dynamics of the thermal processes, an additional factor has been included in the MPE values. This is important for extended optical sources. Such cases might happen when diffuse surface reflections, transmission through a diffusing translucent material or e.g. laser-diode arrays have to be treated in safety considerations. Due to the optical imaging relationships for extended sources in the 400–1400 nm wavelength region the correction factor increases from 1 for point sources and collimated beams up to 100/1.5 for a maximum angular subtense of 100 mrad, equivalent to a retinal image diameter of 1.7 mm. If the extension of the respective source is larger than 10 mm no further increase of the MPE values occurs.

For collimated beams (focus or "focal point" at infinity) and point sources the angular subtense, i.e. the visual angle subtended by a circular source at a distance of e.g. 100 mm at the eye is denoted by α. If the value of α is greater than $\alpha_{min} = 1.5$ mrad, so-called extended-source conditions apply. The angle α should not be confused with the beam divergence, which is a characteristic of the laser. The beam divergence is the far-field plane angle of the cone defined by the beam diameter, and the beam diameter at a point in space is the diameter of the smallest circle that contains a certain amount of the total laser power (or energy). For the purpose of standards dealing with laser safety the percentage is taken to be 63%. In the case of a Gaussian beam, 63% corresponds to a diameter where the irradiance (radiant exposure) falls to $1/e$ of its central peak value. It should be borne in mind that the beam diameter is very often taken in textbooks at the point where the intensity, i.e. the power density, falls to $1/e^2$. In this case the amount of power/energy passing through an aperture with such a diameter would be about 86%. The relationship between both diameters is

simply a factor of $\sqrt{2}$ in the case of a Gaussian beam (TEM_{00} or fundamental mode), i. e. the diameter corresponding to a decrease to $1/e^2$ of the maximum value is larger by this factor compared to the diameter used in safety standards.

The consideration of image size in the exposure limits is done by applying another correction factor, which is related to the angular subtense. This simplifies the MPE values, since the point-source exposure limits simply have to be multiplied by this factor to yield the linearly increased extended-source exposure limits, i. e. limits applicable to extended sources are based on the intrabeam viewing exposure limits modified by a correction factor α/α_{min}.

For biological effects, the irradiance or radiant exposure on the retina is important. These two quantities are directly proportional to the radiance or integrated radiance of the optical source, which are inherent characteristics of the source. This means that the energy entering the eye increases as the square of the diameter of the retinal image when an extended source is viewed [21.5]. Because of heat dissipation by the choroidal blood flow this image-size dependence fails above about 100 mrad, which is equivalent to an image size of 1.7 mm.

For visual angles subtending the source that exceed 100 mrad the exposure limits increase as the square of the angle or can be expressed as a constant radiance.

Based on many years of experience in laser safety it is important to recognize that almost all hazardous ocular exposure conditions occur for intrabeam point-source or collimated-beam conditions. Extended sources very seldom pose a realistic hazard, but nevertheless should be treated with care, in order not to exceed the respective MPEs.

21.3.3 MPEs given as Radiant Exposure and Irradiance

As an example the MPE values for the radiant exposure H_{MPE} and the irradiance E_{MPE} are given for the wavelength region 400–700 nm as [21.11]

$$H_{MPE} = 18t^{0.75}C_E \text{ in J/m}^2 \qquad (21.6)$$

and

$$E_{MPE} = \frac{H_{MPE}}{t} = 18t^{-0.25}C_E \text{ in W/m}^2 , \quad (21.7)$$

where $C_E = \alpha/\alpha_{min}$ for $\alpha_{min} = 1.5$ mrad $\leq \alpha \leq \alpha_{max} = 100$ mrad and t is the exposure duration.

Because the thermal injury threshold, expressed as the radiant power entering the eye, decreases as the exposure duration raised to the -0.25 power, moderate increases in the exposed retinal area will compensate for the increased risk for longer viewing duration. A reduction of e.g. only 44% results in a tenfold increase in the exposure duration. On the other hand doubling the optical power and therefore the irradiance requires that the exposure duration is decreased by a factor of 16, i. e. only 6.25% of the former value are allowed, in order to stay below the MPE-value.

From (21.6) and (21.7) the maximum optical power P_{MPE} can be calculated as

$$P_{MPE} = E_{MPE}A = E_{MPE}\frac{\pi}{4}d_p^2 \approx 0.7t^{-0.25} \text{ in mW} ,$$
$$(21.8)$$

where the diameter d_p of the pupil has to be taken as 7 mm according to IEC 60825-1 [21.14] and t is measured in seconds.

Table 21.3 shows some examples of maximum power and the corresponding maximum exposure duration $t \approx 0.23/P^4$ derived from (21.8).

A pupil size of 7 mm is certainly unrealistically large for longer exposure durations since the pupillary reflex, which decreases the pupil diameter with a velocity of some millimeters per second and starts after a latency period of 0.3–1 s, limits the incident optical power in the case of beams with a somewhat larger diameter. In addition, it is conservatively assumed that the retinal thermal injury threshold varies inversely with the retinal spot size.

For photochemically induced retinal injury such a relationship does not exist, but the threshold values are wavelength- and dose (i. e. radiant exposure)-dependent, i. e. the photochemical thresholds expressed as irradiances decrease inversely with lengthening exposure duration.

Outside the retinal hazard region, i. e. below 400 nm and above 1400 nm, the source size is not important

Table 21.3 Maximum power P_{MPE} and exposure duration t (examples given for point sources and collimated beams, i. e. $C_E = 1$)

P_{MPE}/mW	0.39	0.5	0.6	0.7	1.0	2.0	4.0	5.0
t/ms	10 000	3 700	1 800	1 000	250	15	1	0.37

Table 21.4 Laser classes according to IEC 60825-1 and additional advice for safety

Class 1

The accessible laser radiation is non-hazardous under all reasonable foreseeable conditions. These conditions are kept during the intended use. Class 1 lasers do not emit harmful levels of radiation.

Although neither photochemical nor photothermal damage is possible it might not be excluded that glare, dazzling and reduction in color vision due to afterimages might happen, especially when the emitted power is close to the upper limit of this laser class.

Class 1M

The accessible laser radiation is restricted to the wavelength region between 302.5 nm and 4000 nm, since this is the preferred range, where optical instruments are used.

The accessible laser radiation does not pose any hazard for the eyes as far as the beam diameter is not decreased by optical instruments like eye-loupes, lenses, or telescopes.

As long as no optical instrument that decreases the beam diameter is used the hazard is similar to the one in class 1. However, the use of optically collecting instruments might result in hazards comparable to those for classes 3R or 3B.

The optical power is limited to class 3B.

Class 2

The accessible laser radiation is restricted to the visible part of the optical spectrum, i. e. 400 nm to 700 nm. The laser radiation is non-hazardous for short-term exposure (up to 0.25 s), even for the eyes.

Additional radiation outside the visible spectrum has to fulfill the conditions of class 1.

Since the eyes are not in danger as far as accidental and short-term exposure is regarded, laser products of class 2 may be applied without any additional protective measures if it is ensured that neither a deliberate intrabeam viewing of more than 0.25 s nor a repeated intrabeam viewing into a specular reflected laser beam could happen.

However, it should be taken into account that neither the blink reflex nor aversion responses limit the exposure duration to 0.25 s, as is stated in IEC 60825-1, since these physiological reactions do not occur to a high enough degree. It has been shown in a recent study that the frequency of the blink reflex is less than about 20% and aversion responses occur even less frequent [21.15–18].

These findings do not state that class 2 laser are no longer safe, but that users of such lasers should be instructed to perform active protective reactions, i. e. close the eyes actively and avert the head in the case of intrabeam viewing. These measures can increase the safety of laser class 2 sufficiently and prevent a violation of the MPE values.

It is believed that it is possible to stare long enough into a class 2 laser to cause damage to the eye.

In the case of continuous-wave (CW) operation, i. e. for emission durations longer than 0.25 s, the optical power is limited to 1 mW, as far as collimated beams or point sources are considered. For extended sources the power might be increased by a correction factor depending on the angular subtense up to a maximum of about 66.7 mW.

Class 2M

The accessible laser radiation is restricted to the visible optical spectrum (400–700 nm) and does not pose any hazard to the eyes as long as the beam diameter is not decreased by optical instruments such as eye-loupes, lenses, or telescopes.

Additional radiation outside the visible spectrum has to fulfill the conditions of class 1M.

As long as no optical instruments that decrease the beam diameter are used the hazard is similar to that in class 2. Therefore the same recommendations are valid for this class. In addition the use of optical collecting instruments might result in hazards comparable to those for classes 3R or 3B.

The optical power is limited to class 3B.

Table 21.4 (cont.)

Class 3R

The accessible laser radiation is between 302.5 nm and 10^6 nm (1 mm) and might be hazardous for the eyes.

Laser products belonging to this class are potentially dangerous, but the risk of eye damage is less than for class 3B due to the fact that the AELs are restricted to a much lower level.

The optical power or energy is a maximum of five times the accessible emission limit (AEL) of class 2 between 400 nm and 700 nm and five times the AEL of class 1 for all other wavelengths.

In the case of CW operation the optical power is limited to 5 mW for collimated beams and point sources between 400 nm and 700 nm.

Due to the fact that the maximum power is not large compared to class 3B minor protective measures and safety requirements have to be fulfilled. However, anyhow laser belonging to this class should be treated with care since a fivefold exceeding of the MPE could result in minimal but nevertheless persistent defects on the retina. This is especially important to consider since aversion responses including the blink reflex might not limit the exposure duration as required in the visible part of the optical spectrum.

Class 3A

In the former edition of the international standard IEC 60825-1 this class was used for laser products that did not pose a hazard either for short-term exposure up to 0.25 s in the visible part of the spectrum or for long-term exposure at all other wavelengths, as long as no optical instruments capable of reducing the beam diameter were used.

This laser class is not hazardous when viewed momentarily with the naked eye, but poses severe eye hazards when viewed through optical instruments (e.g., microscopes and binoculars).

This special class has a double limit; first a power ceiling of 5 mW in the visible part of the optical spectrum and simultaneously a 25 W/m^2 limit, to restrict the power entering a 7 mm pupil to 1 mW. This particular class has resulted in quite a lot of trouble, mainly due to the fact that some standards never incorporated these double limits. In addition instead of class 3A these laser products are labeled class IIIA, IIIa or 3a, which resulted in many mistakes. Moreover, due to national regulations many imported laser products have been classified incorrectly, e.g. a class IIIA laser product according to the ANSI standard has to be classified as a 3B product wherever the EN 60825-1 standard is applied and the manufacturer requirements according to this standard have to be fulfilled. In addition the user has to be familiar with the different demands concerning class 3B instead of class IIIA, which should not be confused with class 3A. In some cases there was a difference in labeling for class IIIA, i. e. if the power density did not exceed 2.5 mW/cm^2 a *caution* label was used and if $E > 2.5$ mW/cm^2 a *danger* label was used.

The misunderstanding arising from this situation has been overcome with the introduction of the new class 3R, where reduced requirements have to be fulfilled, but a certain risk, although not very high, does exist, especially for worst-case conditions, such as the adjustment and alignment of the beam in intrabeam viewing and accommodation of the eyes.

Voluntarily staring into the beam would increase the risk of retinal eye damage; therefore care has to be taken when the MPE values are exceeded.

Class 3B

The accessible laser radiation is hazardous for the eyes and often even for the skin. Intrabeam viewing is especially dangerous.

The classification of laser products into this class is based on the conditions that a reflection of a beam from a perfect diffuse reflector might be safely viewed from a distance of 13 cm for a 10 s period. However, diffuse reflection seldom exists and instead partially direct reflections should be considered in a risk assessment, especially when the maximum power of 500 mW in this laser class is used.

Even active aversion responses including active closure of the eyes are not sufficient to protect against laser radiation from such a laser.

In addition to the fact that the MPE values of the eye are exceeded the same is true in general for the skin too.

Table 21.4 (cont.)

Class 4
The accessible laser radiation is very dangerous for the eyes and dangerous for the skin. Even diffuse scattered laser radiation might be hazardous.
In addition this laser radiation can result in fire and explosion.
Lasers belonging to this class are regarded as high-power lasers, where the power or energy exceeds the AELs of class 3B.
The laser radiation of class 4 laser products is so intense that damage can be expected for all kinds of exposure of the eyes or the skin.
Special care has to be taken concerning fire and explosion hazards.

and therefore the exposure limits are given without a correction factor based on the angular subtense.

In addition to alterations in the exposure limits for exposure duration above 10 s, exposure limits for pulse durations between 1 ns and 100 fs are recommended in the revised exposure limit guidelines [21.9]. The main reasons for this are that the corresponding data have not appeared to be consistent until recently and that the underlying damage mechanisms for sub-nanosecond laser-induced injury have not been well understood.

The development of exposure limits for very short laser pulses has been very difficult because of the different mechanisms involved. It was found that the damage produced by nonlinear effects does not follow the same relationship with wavelength, pulse duration, and retinal image size as thresholds from thermochemical (photothermal) and thermoacoustic injury or damage mechanisms [21.19, 20]. In addition self-focusing of the ocular media further concentrates incident laser energy and increases the retinal radiant exposure.

For many years the ICNIRP has published guidelines on limits of exposure to laser radiation [21.9, 11], which have become part of various laser-safety standards. In the ICNIRP guidelines recommendations are given that have been accepted in various standards, concerning the treatment of single-pulse laser exposure and exposure of the eye to any continuous-wave laser [21.11].

Aversion Responses Including the Blink Reflex; Active Protective Reactions

For exposure of the eye to a CW laser an aversion response time of 0.25 s is recommended as an adequate hazard criterion, if purposeful staring into a visible laser beam is neither intended nor anticipated. A maximum exposure duration of 10 s is recommended for hazard analysis for either unintended or purposeful viewing

conditions for ocular exposures of the eyes in the near-infrared. These two recommendations are based on expected natural behavior.

There was a strong belief in aversion responses and especially in the blink reflex as a reliable physiological reaction if a bright light is viewed. A laser source certainly represents a very bright light. For example a 1 mW laser has a luminance (brightness) that exceeds even the luminance of the sun at noon. However, as has been shown in recent investigations, a class 2 laser is not sufficient to stimulate more than about 20% of people to perform a blink reflex [21.21, 22]. Aversion responses such as head and body movements are even less frequent and therefore active protective measures such as those given in the adapted recommendations for class 2 and 2M (Table 21.4) are strongly recommended to prevent any hazard that might result from omission of the expected natural physiological behavior and prolonged exposure.

Non-Visible Laser Radiation and Repetitively Pulsed Lasers

A duration of 10 s is regarded as a sufficient for near-infrared exposure situations, since in this case eye movements will provide a natural physiological exposure limitation and thus eliminate the need to consider exposure durations greater than 10 s. Unusual situations, where even longer exposure durations have to be taken into account, should be treated in a special hazard analysis.

In the case of repetitive laser exposures UV and non-UV lasers are treated differently. For UV lasers the exposure dose is additive regardless of the repetition rate, whereas for visible and infrared laser the exposure limit per pulse for repetitively pulsed intrabeam viewing must be reduced by a correction factor of $N^{-0.25}$, where N is the number of pulses, i. e. the product of the

pulse repetition frequency (PRF) and the total exposure duration (e.g. 0.25 s or 10 s).

The thermal repetitive-pulse exposure obeys what is referred to as the additivity rule where the net effect is modified by the described correction factor [21.11]. This reduces the exposure limit for a single pulse in a train of pulses. However, if multiple pulses exist within a shorter duration than a wavelength-dependent minimal time, e.g. 18 µs for 400–1050 nm, the pulses are treated like a single pulse.

Although there is some lack of knowledge in special exposure situations, current knowledge of bioeffects from the last 40 years seems to be sufficient to establish guidelines for exposure limits. There is no special need for separate MPEs for the general population compared to occupational exposure as is the case for electromagnetic fields with frequencies below 300 GHz. Exposure limit values or maximum exposure limits are limits on exposure to laser radiation that are based directly on established health effects and biological considerations. Compliance with these limits will ensure that people exposed to artificial sources of laser radiation are protected against all known adverse health effects.

Exposure levels below the MPE should not result in adverse health effects, since the exposure limits incorporate the knowledge of scientific research and practical experience, based upon the best available information.

21.4 International Standards and Regulations

In the USA, the manufacturer of a laser product has to fulfill the legal requirements given in the Food and Drug Administration/Center for Devices and Radiological Health (FDA/CDRH) regulation 21CFR1040.10 [21.23], i. e. by the federal government, while the establishment of standards for laser users is left to the individual states.

The federal government of the USA has established requirements covering the manufacture in or import into the USA of any product containing lasers. These regulations provide for product classification and require certain product features and labels in accordance with the product class. The categories utilized are classes I, IIa, II, IIIa, IIIb, and IV, corresponding to increasing levels of hazard.

Standards exist on an international, regional and national basis. As far as laser safety is regarded the International Electrotechnical Commission (IEC) published a first standard in 1984. This standard IEC 825 [21.24] has been updated or amended several times and has been valid in its current edition since 2001 as IEC 60825-1 [21.14]. A second edition of this international laser safety standard will be published in 2007.

Since many national standard organizations are members of the IEC this standard is accepted as a horizontal product safety standard by many countries around the world. Due to various agreements this international standard is transferred into regional ones, such as the European standard EN 60825-1, which is published by the Commission Européenne Normalisation Electrotechnique (CENELEC) for its member states. All national standards based on regional ones such as the European Normalization (EN) standards must only be translated into the language of the respective country, i. e. alterations or modifications are not allowed. This results in national editions of the fundamental laser safety standard such as DIN EN 60825-1 in Germany, BS EN 60825-1 in the UK, and AF EN 60825-1 in France.

One important disparity between the CDRH requirements and the IEC standard reflects the fact that the IEC is not an enforcement body but only publishes standards written by expert committees. Implementation and enforcement depend on the laws and regulations of the individual nations.

The European standard EN 60825-1, which is equivalent today to IEC 60825-1, applies throughout the European Union (EU) and the European Free Trade Association (EFTA) countries and became increasingly important as it is referred to as a harmonized standard in the official journal of the EU under the *Low-Voltage Directive*.

However, in addition to the international standard IEC 60825 other standardizing organizations have developed their own standards dealing with laser products and laser safety. For a long time the standard ANSI Z136.1 [21.25, 26], which is edited by the American National Standards Institute (ANSI), has been a competitor on a standardization market place. The ANSI standard provides guidance for the safe use of lasers and laser systems for four laser classes, i. e. 1, 2, 3 and 4, where the medium-power lasers are divided into two subclasses, 3a and 3b. For the purpose of the ANSI standard, laser products which have been classi-

fied earlier than 2000 as class IIa under the federal laser product performance standard should be treated the same as class 1. Due to a *laser notice* [21.27] published by the CDRH/FDA there is now a relatively wide-reaching agreement between IEC 60825-1 and ANSI Z136.1. In addition ANSI Z136.1 includes an appendix where harmonization with the IEC 60825-1 is described in more detail and some differences are stressed.

Since standards are being developed as a market-regulating or supporting element in many cases, national and/or regional divergence is sometimes economically explainable, but for laser safety in general, a consistent and widely agreed level should exist. This is currently the case.

In addition to the general product safety standard IEC 60825-1 other safety requirements are specified in other relevant standards, e.g. for medical lasers [21.28], information technology or machinery [21.29].

For the safety of optical-fiber communication systems the standard IEC 60825-2 [21.30] provides guidance concerning products that enable laser radiation including light-emitting diode (LED) radiation for communications applications. Another part of IEC 60825 describes laser guards [21.31]. IEC 60825-12 is one of the youngest standards of the IEC 60825 series and describes the safety with free-space optical communication systems [21.32]. In total, 15 parts of IEC 60825 are currently published or exist as drafts.

21.5 Laser Hazard Categories and Laser Classes

Three aspects of the use of lasers need to be taken into account in the evaluation of the possible hazards and in the application of control measures:

- the capability of the laser or laser system to injure people. This includes any consideration of human access to the main exit port or any subsidiary port,
- the environment in which the laser is used, and
- the level of training of the personnel who operate the laser or who may be exposed to its radiation.

The practical means for evaluation and control of laser radiation hazards is to classify laser products according to their relative hazard potential, and then to specify appropriate controls for each class. The use of the classification system will, in most cases, preclude any requirement for radiometric measurements by the user. In many cases it is therefore unnecessary to make use of the MPEs directly. The experience from laser use in industrial, scientific and medical applications has permitted the development of a system of laser hazard categories.

Laser products are assigned, therefore, to different laser classes. This should aid the user in hazard evaluation of the laser and provide the necessary information concerning protective and control measures. Thus the classification of laser products is based on the increasing degree of hazard or risk posed by the laser product. Currently there exist seven classes, namely 1, 1M, 2, 2M, 3R, 3B, and 4 in IEC 60825-1. In addition, the laser class 3A exists, but new laser products are no longer classified into this special category.

One of the main objects of the international standard IEC 60825-1 is to protect persons from laser radiation in the wavelength range 180 nm to 1 mm by indicating safe working levels of laser radiation and by introducing a system of classification of lasers and laser products according to their degree of hazard. In addition, requirements for both user and manufacturer to establish procedures and supply information are laid down so that proper precautions can be adopted. To ensure adequate warning to individuals of hazards associated with accessible radiation from laser products, signs, labels and instructions have to be used.

The increasing classification number applies not only to an increasing hazard, i. e. the capability to cause an injury, but to more protective measures as well, which form the requirements to be specified by the manufacturer and used by the user. The manufacturer is required to perform the classification and to label the laser product accordingly.

21.5.1 Accessible Emission Limits

The classification of laser products is based on so-called accessible emission limits (AEL), i. e. maximal power or energy values. The respective values are given in tables for the different laser classes in the product standard IEC 60825-1.

The determination and derivation of the AELs, although generally based upon the MPEs, necessitated a risk analysis and determination of reasonably foreseeable exposure conditions.

A main characteristic of the AELs is that the respective MPEs, which are valid for the time base of 30 000 s or 100 s, are not exceeded for laser class 1. The

AELs of class 1 are simply derived by multiplication of the respective MPEs by the area of the averaging aperture as specified, e.g. 7 mm in the case of visible laser radiation. The time base of 30 000 s is used when intentional or deliberate and long-term exposure is intended, whereas 100 s is used when unintentional exposure is expected. However, in the case of ultraviolet radiation 30 000 s always has to be used, since this shorter optical radiation shows dose-related effects.

The classification of a laser product has to be done by the manufacturer for normal use and maintenance under reasonable, foreseeable so-called single-fault conditions.

Maintenance implies tasks which are necessary to ensure routine performance of the laser, i.e. maintenance might be done by the laser user. This includes tasks such as cleaning and replenishing of expendables. Beam access is usually not required. This should not be confused with service, which is performed less frequently and usually requires beam access, e.g. to replace resonator mirrors or to repair components of the laser product.

The AEL for class 2 is derived by assuming an exposure duration of 0.25 s, i.e. the time base for class 2, and multiplying the MPE for 0.25 s for visible laser radiation by the area of a 7 mm aperture.

21.5.2 Description of the Laser Classes

The classes can be described as in Table 21.4. Besides the definitions in IEC 60825-1 some additional advice is given in order to improve the safety of working with lasers considering the latest findings, particularly for low-power lasers.

The maximum power of a laser product belonging to class 1M or 2M is limited to the AEL of class 3B. When the exposure with optical instruments is unlikely, the use of class 1M and 2M lasers does represent a small risk, but if it is reasonably foreseeable that optical instruments might be used, controls and restrictions are required.

One of the main reasons to alter the former classification system has been that LED products have been included in the scope of the international standard IEC 60825-1 whenever the word laser is used. The newly defined measurement conditions for classes 1M and 2M had the effect that fewer LED products were classified at unrealistically high levels, e.g. 3B. In the meantime is was decided to remove LEDs from the scope of IEC 60825-1 in the second edition, which will be published in 2007 and to treat most of them as lamps according to the Commission International de l'Eclairage

(CIE) standard S009 [21.33]. An international dual-logo standard IEC 62471/CIE S009:2002 currently exists as a first edition (2006-07) on photobiological safety of lamps and lamp systems [21.34].

Risk Analysis
In order to perform a risk analysis and to classify a laser product the characteristics of the laser itself and its applications must be known. This means that the following data in particular should be available:

- wavelength,
- mode of operation [continuous wave (CW), single pulsed, Q-switched, repetitively pulsed (scanning), mode locked, very short pulses (femtosecond laser)],
- optical power (W) or optical energy (J or J/pulse),
- pulse duration,
- pulse repetition frequency (PRF),
- beam diameter,
- beam divergence,
- mode profile.

It is worth mentioning that for safety calculations the beam diameter and the beam divergence are taken at the $1/e$ decrease of the irradiance and not at $1/e^2$, which means that the corresponding values according to the standard are a factor of $\sqrt{2}$ less.

Beam divergence and Nominal Ocular Hazard Distance
The beam produced by a laser does spread according to its divergence, which is the rate at which the beam spreads. The laser radiation covers a continually larger area as it travels away from the laser product. This angle is measured in radians or milliradians and is usually very small compared to the beam from other light sources. A typical divergence value for a laser is 1 milliradian (1 mrad). This means that the beam spreads such that its spot increases in diameter at a rate of 1 mm for every 1 m (1000 mm) from the laser.

Because the beam spreads at a fixed and measurable angle, the diameter of the beam can be determined at any desired distance from the laser. To approximate the beam size (diameter D) for long distances z one can use a linear equation:

$$D = (\text{divergence angle}) \cdot (\text{range}) + a = \Theta z + a ,$$
(21.9)

where z is the distance (range), θ is the divergence angle, and a is the diameter of the beam at the aperture of the laser product.

When estimating the situation near the laser aperture, i. e. in the so-called near field the following equation has to be used:

$$D = [(\Theta z)^2 + (a)^2]^{1/2} . \tag{21.10}$$

From (21.9) the nominal ocular hazard distance (NOHD) can be calculated as

$$z = \text{NOHD} \geq \frac{1}{\Theta} \left[\sqrt{D^2} - a \right] \tag{21.11}$$

and together with (21.8)

$$\text{NOHD} \geq \frac{1}{\Theta} \left[\sqrt{\frac{4P}{\pi E_{\text{MPE}}}} - a \right] \tag{21.12}$$

is obtained. This equation might be used to estimate the safe distance from a given laser source with a given optical power and beam divergence for the respective MPE value.

21.6 Protective Measures

The majority of injuries involve the eye and, to a lesser extent, the skin. The injuries occur mainly during alignment procedures, or because protective eyewear is either inappropriate or not used.

In order to reduce the possibility of injury by minimizing unnecessary accessible radiation and to give improved control of the laser radiation hazards through protective features and provide safe usage of laser products by specifying user control measures IEC 60825-1 has been published.

Laser products require certain built-in safety features, depending on the class to which they have been assigned by the manufacturer.

Usually technical and engineering protective measures shall be applied to protect against hazardous laser radiation. The trivial and most effective solution is total enclosure of the laser (encapsulation) and of all accessible beam paths. If this is not possible partial beam enclosure or restricted access to beam paths, and administrative controls have to be applied whenever possible instead of using personal protective equipment (PPE) such as laser eye protectors (laser safety goggles).

The safest laser products rely upon engineered safety features. Technical measures might be divided into such measures that are part of the laser product itself or that have to be installed as a consequence of the degree of hazard of the respective laser product. For example safety interlocks can isolate the laser if anyone enters an area of high risk.

21.6.1 Technical and Engineering Measures

Table 21.5 gives an overview of technical and engineering measures as a function of the laser class and degree of hazard, whereas Table 21.6 gives some information concerning administrative measures. Protective housings with interlocks, service access panel with interlocks, master switch, key control, viewing portals/display screens, safe collecting optics, and enclosed or encapsulated open beam paths are all types of engineering controls. In addition a remote interlock connector, beam-stop attenuator, activation warning systems, a controlled area where the nominal hazard zone (NHZ) has to be determined are required. Equipment labels and area posting are required or recommended for class 3B and class 4 lasers.

For more-specific and detailed information on manufacturing requirements the standard is obligatory. The warning labels for class 2, 3R (in the wavelength range 400–1400 nm) or 4 read as follows according to IEC 60825-1:

> LASER RADIATION
> DO NOT STARE INTO BEAM
> CLASS 2 LASER PRODUCT

> LASER RADIATION
> AVOID DIRECT EYE EXPOSURE
> CLASS 3R LASER PRODUCT

or

> LASER RADIATION
> AVOID EYE OR SKIN EXPOSURE TO
> DIRECT OR SCATTERED RADIATION
> CLASS 4 LASER PRODUCT

The laser hazard symbol, the safety alert symbol and information carried by the sign are different in IEC 60825-1 and ANSI Z136.1.

21.6.2 Administrative Measures

Administrative measures are an important backup for technical measures and controls. Administrative controls might be given by written standard operating procedures (SOP), maintenance and service procedures,

Table 21.5 Technical and engineering measures

Measure	1	1M	2	2M	3R	3B	4
Walls					Matt, light, diffuse reflecting		
Shielding					High absorption for the laser wavelength and effective against secondary radiation		
Nominal ocular hazard distance (NOHD)					Labeling of the boundaries/limits		
Beam warning; emission warning					Optical or acoustical at the entrance; on top of the laser product; only for non-visible radiation	Optical or acoustical at the entrance, on top of the laser product	
Emergency switch	Dependent on the product specific risk analysis						
Protective housing	Class 1 should be the goal						
Safety interlock					Designed to prevent removal of the panel; reliable implementation		
Remote control	Necessary if class 3B or 4 are embedded					At the door contact or connection of an emergency stop	
Key-switch, key control						Limited subgroup of people; remove key when laser is not used	
Viewing optics				Install laser filter; AEL of class 1/1M must not be exceeded			
Scanning	Scan failure shall not cause laser product to exceed its classification						
Class label	Required wording		Warning label/hazard symbol and required wording on explanatory label				
Aperture label					Specified wording required		
User information	Operation manuals must specify product classification and contain instructions for safe use						

Table 21.6 Administrative measures for the different laser classes. These are examples according to accident insurance at the workplace in Germany only; different regulations may be valid at other countries, institutions etc.

Measure	1	1M	2	2M	3R	3B	4
Advice	Required when a laser class 3R, 3B or 4 is embedded				Registration of the laser product		
LSO (laser safety officer)	In general not required				Required*; written appointment		
NOHD NHZ (nominal hazard zone)	In general not required, labeling necessary if the beam belongs to class 2 or 2M and passes the working place				Determination of the boundaries/limits; eventually for a limited duration; movable shielding during maintenance; the area must be posted with appropriate warning signs		
Laser protective filters	Not required as long as intrabeam viewing is not mandatory				Required** if engineering and administrative procedures are not practicable; ambient luminance should eventually be increased		
Special training	Not required	Required; written confirmation; at least annually					
Beam paths		Block the beam at the end of its path; avoid specular reflections					

* According to IEC 60825-1 an LSO is not required for class 3R laser products for visible emission
**According to IEC 60825-1 eye protection is not required for class 3R; ANSI Z136.1 requires an LSO for embedded class 3a too if service is performed

output emission limitations, education and training, authorized personnel, controlled access and a limit on the number of spectators to name but a few. Lights and notices should warn people when they approach a laser hazard zone.

Laser Safety Officer

According to IEC 60825-1 the presence of a laser safety officer (LSO) is not required when working with lasers classified less than class 3B. But since class 3R has been part of the former class 3B up to 2001 the requirement is still valid according to the regulations applicable in Germany as far as occupational laser safety is concerned [21.35, 36]. This is especially justified since the MPEs might be exceeded working with class 3R lasers and the LSO is a person who is aware of the safe working practices with these laser products. The special responsibility of the LSO may be regulated according to national regulations. In some countries the LSO is an adviser or consultant only, in others it is a certified person, i. e. one who is knowledgeable in the evaluation and control of laser hazards and has responsibility for oversight of the control of laser hazards.

Training and Education

Training and education is certainly one of the most important things which has to be done in advance of using certain lasers. Operation of class 1M and class 2M laser products where there is a possibility to use optical instruments, class 3R, class 3B and class 4 laser products, can represent a hazard not only to the user but also to other people over a considerable distance. Because of this hazard potential, only persons who have received training to an appropriate level should be placed in control of such systems. The training, which may be given by the manufacturer or supplier of the laser product, the laser safety officer, or by an approved external organization, should include, but is not limited to:

- Familiarization with system operating procedures
- the proper use of hazard control procedures, warning signs, etc.
- the need for personnel protection
- accident reporting procedures
- bioeffects of the laser beam upon the eye and the skin

21.6.3 Personal Protective Equipment

Last but not least, protective equipment may be used to prevent hazardous situations or even damage to the eyes.

This PPE should be in compliance with the respective standards. In Europe PPE have to meet the essential safety requirements stated in a directive of the European Economic Community (EEC)/EU and must be labeled with a conformité Européenne (CE) mark.

Concerning the adequate PPE, i. e. laser safety goggles, one has to determine wavelength and maximum viewing duration. The maximum irradiance or radiant exposure is calculated and from this data an adequate level of protection is chosen.

In general the following should be considered when specifying suitable protective eyewear:

- Wavelength of operation
- radiant exposure or irradiance
- MPE value(s)
- level of protection/optical density of eyewear at laser output wavelength
- visible-light transmission requirements
- resistance or radiant exposure or irradiance, at which damage to eyewear occurs
- need for prescription glasses
- comfort and ventilation
- degradation or modification of absorbing media, even if temporary or transient,
- strength of materials (resistance to shock),
- peripheral vision requirement
- any relevant national regulations.

Protective eyewear should be comfortable to wear, provide as wide a field of view as possible, maintain a close fit while still providing adequate ventilation to avoid problems of misting up and provide adequate visual transmittance. Care should be taken to avoid, as far as possible, the use of flat reflecting surfaces which might cause hazardous specular reflections. It is important that the frame and any side-pieces should give equivalent protection to that afforded by the lens(es)/filters. In addition all laser eye-protectors shall be clearly labeled with information adequate to ensure the proper choice of eyewear with particular lasers.

21.6.4 Beyond Optical Hazards

In some laser applications, mainly with class 4 laser products, in addition to optical hazards, control measures can be necessary for electrical and fire hazards, X-rays, noise, and airborne contaminants.

Most lasers utilize high voltages that can be lethal. Some lasers require hazardous or toxic substances to operate (i. e., chemical dye, excimer lasers). The solvents used in dye lasers are flammable. High-voltage

pulses or flash lamps may cause ignition. Flammable materials may be ignited by direct beams or specular reflections from high-power continuous wave (CW) infrared lasers.

21.6.5 Future Regulations

The current edition of the international standard IEC 60825-1 includes a detailed user's guide to administrative regulations and controls. However, guidelines for users in standards are only informative and not normative, since it is the right of the various countries to set local regulations according to the given laws, decrees and regulations etc.

In the European Union a *Directive of the European Parliament and of the Council on the minimum health and safety requirements regarding the exposure of workers to the risks arising from physical agents (artificial optical radiation)* has been published as the 19th directive within the remit of article 16(1) of directive 89/391/EEC [21.37]. Member states of the European Union shall bring into force the laws, regulations and administrative provisions necessary to comply with the Directive 2006/25/EC by 27 April 2010.

It is one of the main goals under the treaty of the council of the EU, by means of directives, to adopt minimum requirements for encouraging improvements, especially in the working environment, to guarantee a better level of protection of the health and safety of workers. This will be done by the introduction of minimum health and safety requirements regarding the exposure of workers to the risks caused by physical agents; in this case by artificial optical radiation, which includes laser radiation.

The directive lays down minimum requirements, thus giving member states of the EU the option of maintaining or adopting more-stringent provisions for the protection of workers, in particular the fixing of lower exposure limit values. Adherence to the exposure limit values should provide a high level of protection as regards the health effects that may result from exposure to optical radiation.

Since the exposure limits in the European directive are in agreement with the given values in the ICNIRP guidelines it might be expected that there is no strong influence as far as current regional laser safety regulations in Europe are affected. In order to facilitate implementation of the Directive 2006/25/EC the Commision shall draw up a practical guide to the articles dealing with the determination of exposure and assessment of risks as well as provisions aimed at avoiding or reducing risks.

Laser safety is treated in several textbooks, handbooks and publications of various institutions. In addition to the international, regional and national standards, more-detailed information on laser safety in general can be found in a recent publication [21.38], but nevertheless even more historical texts should be regarded as a source of information, especially if background knowledge is needed [21.39, 40]. Laser safety is dealt with on many Internet web-sites, but many of these need a thorough update.

21.7 Special Recommendations

Up to now the number of accidents is low relative to the number of applications of lasers worldwide. However, nevertheless there is a risk, especially during situations such as beam alignment and working with high-power lasers, where even reflected beams might be hazardous.

The most dangerous situations and causes of ocular beam accidents besides exposure during alignment are misaligned optics, lack of training, improper restoration, intentional intrabeam viewing, use of multiple wavelengths, and last but not least when PPE are not utilized.

Laser types such as ruby, argon ion, krypton ion, dye, He:Cd, SHG–Nd:YAG (second-harmonic generated, so-called green-lasers at 532 nm), He:Ne and many diode lasers (semiconductor lasers) all belong to lasers whose beam will be focused on the retina due to the fact that the ocular media are transparent. The same is true for Nd:YAG too, but in this case the beam is non-visible, which enhances the risk. This is especially true for Q-switched Nd:YAG lasers, which have caused a lot of ocular incidents. In nearly all cases eye protection normally available was not worn in ocular incidents.

However, even with laser safety goggles one cannot be sure of being adequately protected, since there exist a lot of eye protectors that do not guarantee the resistance against a laser beam stated in the European standard EN 207 [21.41], rather they are rated according to optical density only. This is an important characteristic of safety goggles, but might not be sufficient for high-power laser radiation. The European standard

ensures not only a specified safety level for the laser eye-protector but resistance against damaging laser radiation of 10 s.

In addition to laser eye-protectors laser adjustment eye-protectors are used, especially during adjustments. Laser adjustment eye-protectors according to the relevant European standard [21.42] reduce the incident laser radiation to a value according to class 2 conditions, i. e. the safety is based on short-term exposure, and the blink reflex has been chosen as an argument. Due to the new findings laser adjustment eye-protectors should be used with care in order not to trust in this expected physiological reaction, but to perform active protective reactions (e.g. close the eyes and turn the head away) in case of intrabeam viewing with this kind of goggles.

Laser Pointers

It is not possible to close this chapter without the following remarks on the special topic of laser pointers.

On the subject of laser pointers ICNIRP states that "based upon current medical knowledge a 5 mW laser is incapable of producing a permanent retinal thermal injury for a momentary (0.25 s) exposure under ideal optical conditions of exposure" [21.43]. In addition it is said: "Although an unintentional momentary intrabeam viewing will not produce a permanent retinal injury, it is theoretically possible to produce retinal photocoagulation in an eye with perfectly clear ocular media by staring at a collimated 5 mW laser beam for more than 10 s" [21.43, 44]. According to the ICNIRP one is assured that "in adults, the pupillary, blink, and aversion responses terminate accidental laser pointer exposures in less than 0.25 s". This clearly says that there is no realistic risk for permanent eye damage from a laser pointer, but at least on that score the statement is wrong as has been shown in lab and field trials with more than 1500 volunteers [21.22], since the frequency of aversion responses including the blink reflex is less than 20%. It cannot be denied that physiological eye movements exist as have been described above, but nonetheless one should avoid shining a laser pointer into anyone's eye and it should be common sense not to stare into the beam of a laser pointer. Any person engaging in a trial to find out whether there is a risk or not could end up with a small but permanent eye injury. This is especially worthy of note since laser pointers are mass-produced devices where quality control is not a particular feature, which is supported by the fact that specimens with

a power of more than 10 mW have been found. It is therefore wise that some countries have restricted the sale or use of laser pointers above class 2 in order to increase safety against retinal injury. In addition even green class 1 laser pointers could do the job, since the photopic brightness is much higher compared to red laser-diode pointers.

Hazardous Situations

The following list contains some reasons for hazardous situations and common unsafe practices that are causes of preventable laser accidents:

- High retinal irradiance results when the beam is focused by the lens of the eye to create an extremely high retinal hazard risk for visible and near-infrared lasers
- low beam divergence resulting in a large intrabeam hazard distance
- not wearing protective eyewear during alignment procedures
- not wearing protective eyewear in the laser control area
- available eye protection not used
- wearing the wrong eyewear
- misaligned optics and upwardly directed beams
- equipment malfunction
- improper methods of handling high voltage
- intentional exposure of unprotected personnel
- bypassing of interlocks, door and laser housing
- insertion of reflective materials into beam paths
- lack of pre-planning
- turning on power supply accidentally
- operating unfamiliar equipment
- lack of protection from non-beam hazards
- high irradiance at the focal point of an external lens creating greater skin hazard risk

In order to prevent laser accidents it is highly recommended to use the lowest possible or practical power, especially during alignments. It is recommended that the plane of the laser beam be above or below the level of a seated or standing person.

Perhaps the most important recommendation is never to aim a laser beam at a person, especially not at a person's eye. As quickly as it takes to blink – spontaneously or voluntarily – a laser beam can severely damage the eye. Though these injuries are relatively rare, they are permanent and can be avoided.

About the Authors

Andreas Assion   Chapter C.12

Femtolasers Produktions GmbH
Vienna, Austria
andreas.assion@femtolasers.com

Andreas Assion joined Femtolasers in January of 2005. Prior to joining Femtolasers, he worked with ultrafast lasers on the observation and control of quantum optical phenomena in atoms and molecules. He earned his diploma and doctorate studying molecular dynamical effects, including coherent control of complex molecules. After a post-doctoral position with the German Space Agency, he completed his Habilitation 2004.

Thomas E. Bauer   Chapter A.5, Sect. 5.7

JENOPTIK Polymer Systems GmbH
Coating Department
Triptis, Germany
thomas.bauer@jenoptik-ps.de

Thomas Bauer is a physicist working at Jenoptik Polymer Systems GmbH (former WAHL optoparts) as head of coating department. His main areas of interest are plastic optics in general and coating of plastic optics in particular.

Thomas Baumert   Chapter C.12

Universität Kassel
Institut für Physik
Kassel, Germany
baumert@physik.uni-kassel.de

Professor Baumert received is Ph.D. with Prof. Gerber, University of Freiburg, Germany in 1992. Further positions in his carreer were: 1992–1993, post doc with Prof. Zewail, Caltech, Pasadena; 1993–1997, "Habilitation", University of Würzburg, Germany; 1998–1999, head of LIDAR group, DLR Oberpfaffenhofen, Germany; 1999 Full Professor of Experimental Physics at University of Kassel, Germany. His research area: Femtosecond spectroscopy and ultrafast laser control of matter. Awards: Gödecke thesis award (1992), Heisenberg-Scholarship of DFG (1997–1998), Philip-Morris-Award (2000).

Dietrich Bertram   Chapter C.10

Philips Lighting
Aachen, Germany
dietrich.bertram@philips.com

Prior to joining the CTO office at Philips Lighting as technical officer solid-state lighting, Dietrich Bertram headed a project on LED light sources at Philips Research. His background education is physics, where he obtained a masters degree at Marburg University in epitaxy of III-V materials and a Ph.D. from the Max-Planck Institute of Solid State Research, Stuttgart, Germany.

Klaus Bonrad   Chapter A.5, Sects. 5.9.2, 5.10

Schott Spezialglas AG
Division Luminescence Technology
Mainz, Germany
klaus.bonrad@schott.com

Klaus Bonrad studied chemistry in Darmstadt and received his Ph.D. in Mainz at the Max-Planck-Institute of Polymer Research for synthesis and characterisation of electrooptical macrocycles. After a post-doc position at Virginia Polytechnic Institute and State University in Blacksburg/USA he worked for IBM and SCHOTT Spezialglas AG in the field of organic light emitting diodes developing large area displays in Mainz.

Matthias Born   Chapter C.10

Philips Research Laboratories Aachen
Aachen, Germany
matthias.born@philips.com

Matthias Born is a physicist and joined Philips Research Aachen, Germany, in 1992. He is leading several projects about plasma physics and diagnostics of gas discharges with a major topic on mercury-free lamps for general and automotive lighting applications. He is also working as a professor for physics at the Heinrich-Heine-University of Düsseldorf.

Annette Borsutzky

Technische Universität Kaiserslautern
Fachbereich Physik
Kaiserslautern, Germany
borsu@uni-kl.de

Chapter C.11, Sect. 11.9

Annette Borsutzky studied physics in Bielefeld and Hannover, Germany, where she received in 1992 her Dr. rer. nat. working on nonlinear frequency mixing in crystals and gases. Joining the university of Kaiserslautern studies of optical parametric oscillators, diode-pumped solid state lasers as well as the characterization of new nonlinear and laser active materials are at the center of her work.

Hans Brand

Friedrich-Alexander-University of
Erlangen-Nürnberg LHFT
Department of Electrical, Electronic
and Communication Engineering
Erlangen, Germany
hans@lhft.eei.uni-erlangen.de

Chapter C.11, Sect. 11.4

Hans Brand received the degrees Dipl.-Ing. in 1956, Dr.-Ing in 1962 and Dr.-Ing. habil. in 1962 at the RWTH Aachen, Germany. In 1969 he became professor at the Chair for Microwave Engineering at the FAU Erlangen, Germany. His main fields of research are microwaves, millimeter wave and terahertz components and systems as well as gas laser and infrared laser technology. In 1996 he became Fellow of the IEEE. He is emeritus since 1998.

Robert P. Breault

Breault Research Organization, Inc.
Tucson, AZ, USA
bbreault@breault.com

Chapter B.7

Robert P. Breault is the Chairman and founder of the Breault Research Organization. He works on stray light analysis and suppression. He is the author of the APART stray light analysis program, used to analyze the Hubble telescope and many others. He received the B.S. in mathematics from Yale University, and his M.S. and Ph.D. in optical sciences from the University of Arizona. He is a fellow of SPIE and founder and Co-chairman of the Arizona Optics Industry Association.

Matthias Brinkmann

University of Applied Sciences Darmstadt
Mathematics and Natural Sciences
Darmstadt, Germany
brinkmann@fh-darmstadt.de

Chapter A.5, Sects. 5.1, 5.1.9, 5.10

Dr. Brinkmann is a professor of optical engineering at the University of Applied Sciences Darmstadt, Germany. He obtained his Ph.D. degree in Physics from the Ruhr-Universität Bochum, Germany in 1997 for his work on high-temperature superconductors. Prior to joining the University of Applied Sciences Darmstadt, he worked as a staff scientist and research manager at Schott Glas corporate research in Mainz, Germany. His main scientific focus covered thermal material properties of glass and microstructured optical glass for photonic applications. His current research activities include integrated waveguide optics and diffractive microoptics for various Photonic applications.

Uwe Brinkmann

Bovenden, Germany
ubri@arcor.de

Chapter C.11, Sect. 11.7

Uwe Brinkmann obtained his education in physics at the universities Munich, Heidelberg, Hannover, and worked in laser research at the Universität Cologne before joining Lambda Physik, Göttingen, as Head of Research and Development. Since 1988 self-employed, he edited the German periodical Laser und Optoelektronik over 20 years and is a contributing editor to Laser Focus World since 1987.

Robert Brunner

Carl Zeiss AG
Central Research and Technology
Jena, Germany
r.brunner@zeiss.de

Chapter B.8, Sect. 8.1

Robert Brunner graduated from the University of Ulm in 1994 and received his Ph.D. degree in the field of near-field optical microscopy. Since 1998 he works at the Research Center of Carl Zeiss, where he is the responsible Lab Manager for microstructured optics. His current research interests are hybrid diffractive/refractive optics, subwavelength structures, refractive microoptics, and high resolution optics.

Geoffrey W. Burr

IBM Almaden Research Center
San Jose, CA
burr@almaden.ibm.com

Chapter D.20

Geoffrey W. Burr received his B.S. in Electrical Engineering (EE) and B.A. in Greek Classics from the State University of New York at Buffalo in 1991. That year Eta Kappa Nu selected him as the Alton B. Zerby Outstanding EE Senior in the U.S. He received his M.S. and Ph.D. in Electrical Engineering from the California Institute of Technology in 1993 and 1996, respectively, under the supervision of Professor Demetri Psaltis. Since that time, Dr. Burr has worked at the IBM Almaden Research Center in San Jose, California, where he is currently a Research Staff Member. He has worked extensively in holographic data storage, volume holography, signal processing and systems tradeoffs in data storage, and optical information processing. Dr. Burr's current research interests also include nanophotonics, numerical modeling for design optimization, and phase-change nonvolatile memory. He is a member of SPIE, OSA, IEEE, Eta Kappa Nu, and Tau Beta Pi.

Karsten Buse

University of Bonn
Institute of Physics
Bonn, Germany
kbuse@uni-bonn.de

Chapter A.5, Sects. 5.9.3

Karsten Buse received his Ph.D. from the University of Osnabrück, Germany. Since 2000 he is holding the Heinrich Hertz professorship for physics at the University of Bonn. His research focus is on nonlinear-optical and photosensitive dielectric materials like nonlinear and photorefractive crystals. He authored and co-authored more than 150 publications and more than 20 patents in this field.

Carol Click

Schott North America
Regional Research and Development
Duryea, PA, USA
carol.click@us.schott.com

Chapter A.5, Sects. 5.1.2, 5.1.3, 5.10

Dr. Click received her Ph.D. from the University of Missouri – Rolla in ceramic engineering focused in contamination in phosphate laser glasses. She is now involved in the research and development necessary to commercialize Schott's inorganic low-temperature reactive bonding technology for producing light-weighted Zerodur optics and precision optical components.

Mark J. Davis

Schott North America
Regional Research and Development
Duryea, PA, USA
mark.davis@us.schott.com

Chapter A.5, Sects. 5.5, 5.10

Mark Davis earned his Ph.D. in Geology from Yale University in 1996, focusing on the kinetics of nucleation in glass-forming melts and related topics. Since then, his research has centred on the development of new glass-ceramic materials for a range of applications, in addition to continued efforts towards a more fundamental understanding of crystallization processes.

Wolfgang Demtröder

TU Kaiserslautern
Department of Physics
Kaiserslautern, Germany
demtroed@physik.uni-kl.de

Chapter D.13, Sects. 13.1, 13.2

Wolfgang Demtröder studied Physics, Mathematics and Science of Music at the Universities of Münster, Tübingen and Bonn. He received his Ph.D. in 1961 with Prof. Paul in Bonn. He was research assistant in Freiburg, visiting fellow at JILA in Boulder, Colorado and since 1970 he is Professor of Physics at the University of Kaiserslautern, and visiting Professor at the Universities at Stanford (USA), Kobe (Japan), New South Wales in Sydney (Australia) and at the Technical University in Lausanne (Switzerland). His fields of research are high resolution laser spectroscopy of molecules and metal-clusters, time resolved spectroscopy, spectroscopy of collision processes. He received the Max Born Prize in 1994 and the Heisenberg Medal 2001.

Henrik Ehlers   Chapter A.6

Laser Zentrum Hannover e.V.
Department of Thin Film Technology
Hannover, Germany
h.ehlers@lzh.de

Henrik Ehlers is working in the field of optical thin films. He studied physics in Hannover, Germany, and is currently head of the Process Development Group in the department of Thin Film Technology at the Laser Zentrum Hannover. The focus of the group is on R&D in modern deposition processes, in situ process monitoring, and advanced process automation.

Rainer Engelbrecht   Chapter C.11, Sect. 11.4

Friedrich–Alexander–University of
Erlangen–Nürnberg
Department of Electrical, Electronic and
Communication Engineering
Erlangen, Germany
rainer@lhft.eei.uni–erlangen.de

Rainer Engelbrecht studied electrical engineering at the University of Erlangen-Nürnberg and received his diploma and Dr. degree in 1995 and 2001, respectively. The doctoral thesis was on gas analysis in CO_2 lasers by diode laser spectroscopy. His current research fields are nonlinear fiber optics, Raman fiber lasers and low-noise photo receivers.

Martin Fally   Chapter D.20, Sect. 20.1

University of Vienna
Faculty of Physics, Department for
Experimental Physics
Vienna, Austria
martin.fally@univie.ac.at

Martin Fally earned both his Ph.D. in physics (1996) and his habilitation in solid-state physics (2003) from the Vienna University, Austria. Since then he is Associate Professor at the Department for Experimental Physics. In 2003–2004 he held a Mercator Visiting- Professorship at the University of Osnabrück, Germany. He authored or co-authored more than 40 publications in the fields of structural phase transitions (experimental and theoretical), quasi one-dimensional systems (theoretical), neutron-scattering, neutron-diffraction, photorefractive materials, holographic scattering (experimental and theoretical). In 2001 he was awarded the Prize of the City of Vienna for research in natural sciences.

Yun–Hsing Fan   Chapter A.5, Sects. 5.3, 5.10

University of Central Florida
College of Optics and Photonics
Orlando, USA
yfan@mail.ucf.edu
Ms. Yun-Hsing Fan is currently a Ph.D. candidate at the School of Optics/CREOL, University of Central Florida. Her current research is to develop novel electronic liquid crystal (LC) lenses and fast-response infrared phase modulators for optical communications. Her future work will focus on polarization-independent LC lens and fast switching polymer-network LC modulators for far-infrared and visible regions.

Enrico Geißler   Chapter B.8, Sect. 8.2

Carl Zeiss AG
Central Research and Technology
Jena, Germany
e.geissler@zeiss.de

Enrico Geißler completed his studies of electrical engineering at the University of Applied Sciences Jena, Germany, in 1998. Since graduation he has been at the Research Center of Carl Zeiss, where he is currently Senior Scientist for Digital Visualization Systems. His current research interests are spatial light modulators and MEMS.

Ajoy Ghatak   Chapter B.8, Sect. 8.7

Indian Institute of Technology Delhi
Physics Department
New Delhi, India
ajoykghatak@yahoo.com

Ajoy Ghatak has published more than 170 research papers in international journals and is the co-author (with Professor Thyagarajan) of six books. He is a Fellow of the Optical Society of America (OSA) and is the recipient of the 2003 OSA Esther Hoffman Beller award, the International Commission for Optics Galileo Galilei award and the CSIR S.S. Bhatnagar award. His areas of interests are fiber optics and quantum mechanics.

Alexander Goushcha   Chapter B.9

SEMICOA
Costa Mesa, CA, USA
ogoushcha@semicoa.com

Dr. Alexander Goushcha (aka Gushcha) is a Chief Scientist and CTO at SEMICOA, a California-based manufacturer of high-reliability silicon transistors and optoelectronics. He obtained his Ph.D. degree in Physics from the Institute for Physics, Ukrainian Academy of Sciences in Kyiv (Ukraine). He has been working in the fields of semiconductor physics and technology, biophysics and molecular electronics, and nonlinear optics at the Institute for Physics, Kyiv, Ukraine, MPI Strahlenchemie, Mülheim a.d. Ruhr, Germany, and UC Riverside, CA. Dr. Goushcha is the author of about 100 technical papers in referred journals and holds 10 patents and patent applications.

Daniel Grischkowsky   Chapter D.17

Oklahoma State University
Electrical and Computer Engineering
Stillwater, OK, USA
grischd@ceat.okstate.edu

Daniel R. Grischkowsky is a Regents Professor and the Bellmon Professor of Optoelectronics at Oklahoma State University. He received his B.S. from Oregon State University in 1962 and his Ph.D. degree in physics from Columbia University in 1968. In 1969 he joined the IBM Watson Research Center, Yorktown Heights, New York, where he developed and experimentally verified the adiabatic following model in 1972. In 1982 his research group developed the optical-fiber pulse compressor, and later in 1989 developed the technique of THz time-domain spectroscopy (THz-TDS). In 1993 he relocated to Oklahoma State University to pursue THz-TDS applications. He is a fellow of The American Physical Society (APS), The Institute of Electrical and Electronics Engineers (IEEE) and The Optical Society of America (OSA). He was awarded the Boris Pregel Award (1985) by the New York Academy of Sciences for the development of the optical fiber pulse compressor, the R.W. Wood Prize (1989) from OSA for distinguished contributions to the field of optical pulse compression, particularly for pioneering work on the use of optical fibers for generating ultrashort pulses of light, and the William F. Meggers Award (2003) from OSA for seminal contributions to the development and application of THz time-domain spectroscopy.

Richard Haglund   Chapter A.1

Vanderbilt University
Department of Physics and Astronomy
Nashville, TN, USA
richard.haglund@vanderbilt.edu

Professor Halund earned his Ph.D. in experimental nuclear physics from the University of North Carolina, Chapel Hill. He was staff member, Los Alamos National Laboratory from 1975 to 1984. Since 1984 he is Professor of Physics at Vanderbilt University. He was Alexander von Humboldt awardee in 2003. His current research activities are in nonlinear optics in metal and metal-oxide nanoparticles; size and dimensional effects in metal-insulator transitions; and ultrafast mid-infrared laser processing of polymers and organic materials.

Stefan Hansmann   Chapter C.11, Sect. 11.3

AI Technologies GmbH
Darmstadt, Germany
shansmann@al-technologies.de

Stefan Hansmann received his Ph.D. from the Technical University of Darmstadt for his work on simulation and realization of DFB laser diodes. He worked 10 years in the field of optoelectronics at the research center of Deutsche Telekom and become the head of a research group focusing on the application of photonic technologies in telecommunication. Thereafter he served as a technical manager in several companies of III/V semiconductor industry and is now the chief technical officer of AL Technologies GmbH in Darmstadt, commercializing high speed InP based semiconductor laser technology.

Authors

Joseph Hayden

Schott North America
Regional Research and Development
Duryea, PA, USA
joe.hayden@us.schott.com

Chapter A.5, Sects. 5.1, 5.4, 5.10

Dr. Joseph Hayden has a B.S. in Physics from Saint Joseph's University and a Ph.D. in Chemical Physics from Brown University. He joined the Schott Group in 1985, where he has worked in glass composition and process development with emphasis on laser, nonlinear and technical glasses. He is presently an Executive Scientist at Schott's North American Regional R&D site in Duryea, Pennsylvania.

Joachim Hein

Friedrich-Schiller University Jena
Institute for Optics and Quantum
Electronics
Jena, Germany
jhein@ioq.uni-jena.de

Chapter C.11, Sect. 11.13

Dr. Joachim Hein is a scientist at the faculty of physics of the University of Jena since many years. He is working on femtosecond-lasers, new laser materials for broad-band amplification and applications of ultra-high peak power light sources. He is an expert for diode-pumped high-energy laser systems as well as solid-state laser design and modelling.

Stefan W. Hell

Max Planck Institute
for Biophysical Chemistry
Göttingen, Germany
hell@nanoscopy.de

Chapter D.16

Stefan W. Hell is credited with having both conceived and validated the first viable concept for breaking Abbe's diffraction-limited resolution barrier in a light-focusing microscope. He leads the Department of NanoBiophotonics at the Max Planck Institute for Biophysical Chemistry as well as the High-Resolution Optical Microscopy division at the German Cancer Research Center (DKFZ) in Heidelberg.

Jürgen Helmcke

Physikalisch-Technische Bundesanstalt
(PTB) Braunschweig
Former Head Quantum Optics and Length
Unit (retired)
Braunschweig, Germany
juergen.helmcke@ptb.de

Chapter C.11, Sect. 11.14

Until his retirement at the end of 2003, Dr. Jürgen Helmcke headed the department "Quantum Optics and Length Unit" at the Physikalisch-Technische Bundesanstalt in Braunschweig, Germany. His main interests are in the fields of precision laser spectroscopy, laser cooling, optical and atom interferometry, and optical frequency measurements. From 1977 to 1978 he spent a year as NATO scholar with Dr. John L. Hall at the Joint Institute of Astrophysics in Boulder, CO. In 1999, together with F. Riehle, H. Schnatz, and T. Trebst, J. Helmcke received the Helmholtz Price of Metrology for the paper "Atom interferometer in the time domain for precision measurements".

Hartmut Hillmer

University of Kassel
Institute of Nanostructure Technologies
and Analytics (INA)
Kassel, Germany
hillmer@ina.uni-kassel.de

Chapter C.11, Sect. 11.3

Professor Hillmer received his doctor and habilitation degrees from Stuttgart and Darmstadt University, respectively. He worked 10 years in telecommunication industry (German Telekom and NTT Japan) on design, implementation and characterization of fast and tunable semiconductor lasers. As a full professor at Kassel University since 1999, he deals with optical MEMS and nanotechnology and is a coordinator in the Hess Nano Network (nnh-9). He published more than 200 papers, holds 14 patents and received the European Grand Prix of Innovation Awards 2006

Günter Huber

Universität Hamburg
Institut für Laser-Physik
Department Physik
Hamburg, Germany
huber@physnet.uni-hamburg.de

Chapter C.11, Sect. 11.2

Guenter Huber is Professor of Physics at the Institute of Laser-Physics, University of Hamburg, Germany. His research on solid-state lasers includes the growth, development and optical spectroscopy of laser materials, new diode-pumped lasers in the near infrared and visible spectral region, as well as up-conversion lasers. He is Fellow of the Optical Society of America and received the Quantum Electronics and Optics Prize of the European Physical Society in 2003.

Mirco Imlau

University of Osnabrück
Department of Physics
Osnabrück, Germany
mimlau@uos.de

Chapter D.20, Sect. 20.1

Dr. Imlau studied physics at the University of Cologne, where he received his
Ph.D. for work on centrosymmetric photorefractive crystals. Since 2002 he is Junior-Professor at the University of Osnabrück and team leader of the photonics work group. His research is focused on the field of condensed matter and optics, in particular on nonlinearities of optical materials (optical damage, nonlinear light scattering, photoswitchable compounds, unconventional photorefractive materials, space charge waves). Having his expertise in holography, he authored more than 40 publications in refereed journals, 4 book articles, and 8 international patents.

Kuon Inoue

Chitose Institute of Science and Technology
Department of Photonics
Chitose, Japan
inoue@guppy.chitose.ac.jp

Chapter B.8, Sect. 8.6

Kuon Inoue received his Ph.D. from the University of Tokyo, Japan in 1970. Since 1967, he worked at the Department of Physics, Shizuoka University. In 1984, he joined the faculty of the Research Institute for Electronic Sciences, Hokkaido University. After retirement in 2001, he is now a guest Professor at Chitose Institute of Science and Technology and is a Fellow of the Toyota Physics and Chemistry Research Institute. He has worked in solid-state physics, laser spectroscopy in solids, and photonic crystals.

Thomas Jüstel

University of Applied Sciences Münster
Steinfurt, Germany
tj@fh-muenster.de

Chapter C.10

Thomas Jüstel received his Ph.D. in coordination chemistry in 1995 in the group of Prof. Dr. K. Wieghardt. He worked on luminescent materials for light sources and emissive displays in the Philips Research Laboratories Aachen, Germany from September 1995 to February 2004. In March 2004 he became a Professor for Inorganic Chemistry at the University for Applied Sciences in Münster, Germany. His present research deals with phosphors for LEDs and luminescent nanoparticles.

Jeffrey L. Kaiser

Spectra-Physics
Division of Newport Corporation
Mountain View, CA, USA
jeff.kaiser@spectra-physics.com

Chapter C.11, Sect. 11.5

Jeffrey Kaiser is a product manager in the Spectra-Physics division of Newport Corporation. He has held a variety of positions in marketing, product development, engineering, and manufacturing for gas lasers. He holds several patents in gas-laser technology. He received his M.S. in Applied Physics from Stanford University and B. S. in Physics from Purdue University.

Ferenc Krausz

Max–Planck–Institut für Quantenoptik
Garching, Germany
ferenc.krausz@mpq.mpg.de

Chapter A.4, Sect. 4.2

Ferenc Krausz was awarded his M.S. in Electrical Engineering at Budapest University of Technology in 1985, his Ph.D. in Quantum Electronics at Vienna University of Technology in 1991, and his "Habilitation" degree in the same field at the same university in 1993. He joined the Department of Electrical Engineering as Associate Professor in 1998 and became Full Professor in the same department in 1999. In 2003 he was appointed as Director of Max Planck Institute of Quantum Optics in Garching, Germany, and since October 2004 he has also been Professor of Physics and Chair of Experimental Physics at Ludwig Maximilian's University of Munich. His research has included nonlinear light-matter interactions, ultrashort light pulse generation from the infrared to the X-ray spectral range, and studies of ultrafast microscopic processes. By using chirped multilayer mirrors, his group made intense light pulses comprising merely a few wave cycles available for a wide range of applications and utilized them for pushing the frontiers of ultrafast science into the attosecond regime. His most recent research focuses on attosecond physics: the control and real-time observation of the atomic-scale motion of electrons. He co-founded Femtolasers GmbH, a Vienna-based company specializing in cutting-edge femtosecond laser sources.

Eckhard Krätzig

University of Osnabrück
Physics Department
Osnabrück, Germany
eckhard.kraetzig@uos.de

Chapter A.5, Sects. 5.9.3

Eckhard Krätzig received his Ph. D. degree in physics from the Johann Wolfgang Goethe University of Frankfurt/Main, Germany in 1968. Then he joined the Philips Research Laboratories Hamburg, where he headed the Solid State Physics Group. Since 1980 he has been a Professor of Applied Physics at the University of Osnabrück. During the last years his research interests were focused on photorefractive effects and light-induced charge-transport phenomena.

Stefan Kück

Physikalisch–Technische Bundesanstalt
Optics Division
Braunschweig, Germany
stefan.kueck@ptb.de

Chapter C.11, Sect. 11.2

Dr. Kück is working group leader for laser radiometry at the Physikalisch-Technische Bundesanstalt, the German National Metrology Institute. He obtained his Ph.D. in 1994 and habilitated in 2001 in the field of solid-state lasers. His main research topic is the development of new methods, procedures and standards for the high-precision measurement of laser power and laser pulse energy.

Anne L'Huillier

University of Lund
Department of Physics
Lund, Sweden
anne.lhuillier@fysik.lth.se

Chapter A.4, Sect. 4.2

Anne L'Huillier defended her Ph.D. thesis in Paris in 1986. She worked at the Commissariat à l'Energie Atomique in Saclay, France, until 1995 and then moved to Lund University, Sweden, where she became professor in 1997. Her current research is on the generation of high-order harmonics of laser light in gases and its application to attosecond science. In 2003, she got the Julius Springer prize for Applied Physics together with F. Krausz. She became member of the Royal Swedish Academy of Sciences in 2004.

Bruno Lengeler

Aachen University (RWTH)
II. Physikalisches Institut
Aachen, Germany
lengeler@physik.rwth–aachen.de

Chapter D.18

Bruno Lengeler is emeritus professor of physics and former head of a physics institute at Aachen university. He is a solid-state physicist who has worked for many years on spectroscopy and imaging with synchrotron radiation, in particular on the development of parabolic refractive X-ray lenses. He was Director of Research at the European Synchrotron Radiation Facility.

Martin Letz   Chapter A.5, Sects. 5.1.1, 5.1.4, 5.1.6, 5.1.7, 5.10

Schott Glas
Materials Science, Central Research
Mainz, Germany
martin.letz@schott.com

Dr. Martin Letz studied physics at the universities of Braunschweig, Stuttgart (Germany) and Tartu (Estonia) and finished his Ph.D. in 1995 at Stuttgart University in the field of theoretical solid state physics with a work on magnetic polarons. In the following he worked as a post-doctoral fellow at Queen's University, Kingston (Canada) and at the University of Mainz (Germany). During this time he performed investigations on statistical physics of strongly correlated quantum-mechanical systems of strongly correlated classical systems, light scattering and on the dynamics of the glass transition in molecular fluids. In 2001 Martin Letz joined the central research of Schott Glass.

Gerd Leuchs   Chapters A.2, A.3

University of Erlangen–Nuremberg
Institute of Optics, Information and
Photonics
Erlangen, Germany
leuchs@physik.uni–erlangen.de

Gerd Leuchs studied physics and mathematics at Cologne and received his Ph,D. in 1978. After research years in USA, he headed the German gravitational wave detection group, then became technical director at Nanomach AG, Switzerland. Since 1994 he has been Professor of Physics at the University of Erlangen, since 2003 also director of the Max Planck research group of optics, information and photonics.

Norbert Lindlein   Chapters A.2, A.3

Friedrich–Alexander University of
Erlangen–Nürnberg
Max–Planck Research Group
Institute of Optics Information and
Photonics
Erlangen, Germany
norbert.lindlein@optik.physik.
uni–erlangen.de

Norbert Lindlein received in 1996 his Ph.D. from the Friedrich-Alexander University Erlangen-Nürnberg (Germany). In 2002 he finished his habilitation in physics and is a member of the Physics Faculty of the University of Erlangen-Nürnberg since. His research interests include the simulation and design of optical systems, diffractive optics, microoptics and optical measurement techniques using interferometry or Shack-Hartmann wavefront sensors.

Stefano Longhi   Chapter C.11, Sect. 11.1

University of Politecnico di Milano
Department of Physics
Milano, Italy
longhi@fisi.polimi.it

Stefano Longhi is Associate Professor of Physics of Matter at the Polytechnic Institute of Milan. He has authored more than 100 papers in the fields of laser physics, photonics, nonlinear and quantum optics. Professor Longhi is Fellow of the Institute of Physics and member of the J. Physics-B editorial board. In 2003 he was awarded with the Fresnel Prize of the European Physical Society.

Ralf Malz   Chapter C.11, Sect. 11.6

LASOS Lasertechnik GmbH
Research and Development
Jena, Germany
ralf.malz@lasos.com

Ralf Malz studied physics at the Friedrich-Schiller-Universität Jena 1984-1989 and received his Ph.D. in1993 at the same university. Then he worked at Carl-Zeiss-Jena and later LASOS in the field of CO_2 waveguide and slab lasers. His current work is on argon-ion, HeNe lasers, diode-laser modules and fiber coupling.

Wolfgang Mannstadt   Chapter A.5, Sects. 5.1.4, 5.8, 5.10

Schott AG
Research and Technology Development
Mainz, Germany
wolfgang.mannstadt@schott.com

Dr. Wolfgang Mannstadt studied physics and received his Ph.D. from the Philipps University in Marburg. His main research field is the materials simulation with ab initio DFT methods. He received a Feodor-Lynen fellowship from the Humboldt Foundation and worked as a research assistent in the group of Prof. A.J. Freeman at the Northwestern University in Evanston. His current work in the R&D department at Schott is focuses on the simulation of materials properties with DFT and nanostructured optical materials.

Authors

Gerd Marowsky

Laser–Laboratorium Göttingen e.V.
Göttingen, Germany
gmarows@gwdg.de
Chapter C.11, Sect. 11.7

Dr. Gerd Marowsky graduated in 1969 from the University of Göttingen, Germany in the fields of experimental and theoretical physics and mineralogy, and is currently director of Laser-Laboratorium Göttingen. He has made numerous scientific contributions to the general field of lasers and high-field interactions. Current research interests include quantum electronics in general, lasers, laser applications in environmental research, nonlinear optics, nonlinear inorganic and organic materials, and applications of short-duration ultraviolet laser pulses. Dr. Marowsky is well know in Canada as the Sector-Coordinator in Materials–Physical Technologies, a Science and Technology Agreement that supports numerous collaborations between Canadian and German scientists. Gerd Marowsky is also professor at the University of Göttingen, Germany and holds adjunct professor positions in Electrical and Computer Engineering at both Rice University, Houston and the University of Toronto.

Dietrich Martin

Carl Zeiss AG
Corporate Research and Technology
Microstructured Optics Research
Jena, Germany
d.martin@zeiss.de

Chapter B.8, Sect. 8.4

Dietrich Martin received the B.Sc. (University of Technology, Dresden) in 1992, the M.Sc. (University of Oldenburg) in 1997. He earned his Ph. D. from the University of Kassel in 2002 working on optical properties of alkali metal clusters. He joined the Corporate R&D Department of Carl Zeiss and is engaged in research on microstructured and variable optical components.

Bernhard Messerschmidt

GRINTECH GmbH
Research and Development, Management
Jena, Germany
messerschmidt@grintech.de

Chapter B.8, Sect. 8.3

Bernhard Messerschmidt studied physics at the Jena University, Germany and graduated with a Ph.D. in 1998 from the Fraunhofer Institute of Applied Optics in Jena on modelling and optimization of ion exchange processes in glass for the generation of GRIN lenses. From 1994 to 1995, he was a research fellow at the Institute of Optics, University of Rochester, New York. In 1999, he established the company Grintech as a co-founder and is currently one of the principal managers of Grintech and responsible for research and development.

Katsumi Midorikawa

RIKEN
Laser Technology Laboratory
Saitama, Japan
kmidori@riken.jp

Chapter C.11, Sect. 11.12

Dr. Katsumi Midorikawa is a director and chief scientist of the Laser Technology Laboratory at RIKEN. He received his Ph. D. degree from Keio University in Electrical Engineering. His research interests currently focus on ultrashort high-intensity laser – matter interaction and its application, including the generation of coherent X-ray and femotosecond laser processing.

Gerard J. Milburn

The University of Queensland
Center for Quantum Computer Technology
School of Physical Sciences
St. Lucia, QLD, Australia
milburn@physics.uq.edu.au

Chapter D.14

Milburn's research is largely in the fields of quantum optics, quantum measurement and control, and quantum computing and has published more than 200 papers and three books. He is a Fellow of the Australian Academy of Science and The American Physical Society. He is currently an Australian Research Council Federation Fellow at The University of Queensland.

Kazuo Ohtaka Chapter B.8, Sect. 8.6

Chiba University
Center for Frontier Science
Photonic Crystals
Chiba, Japan
ohtaka@cfs.chiba-u.ac.jp

In 1965 Dr. Kazuo Ohtaka graduated from Department of Applied Physics, University of Tokyo where he was assistant professor since 1967. Since 1998 he was Professor of Department of Applied Physics of Chiba University and since 2000 he is Professor of the Center for Frontier Science, Chiba University. In 2000 he obtained the Best Papers Award of the Physical Society of Japan. He is currently working in the field of photonic crystals, their fundamentals and applications.

Motoichi Ohtsu Chapter D.15

Department of Electronics Engineering
The University of Tokyo
Tokyo, Japan
ohtsu@ee.t.u-tokyo.ac.jp

Dr. Ohtsu is a Professor of the University of Tokyo. As a founder of nanophotonics, he is a director of several national projects for nanophotonic devices, storage and fabrication. He has authored more than 400 technical papers and 50 books. He holds 100 patents. He is a fellow of the Optical Society of America and has been awarded more than ten prizes from academic institutions including the I. Koga gold metal from URSI. He was also awarded the Medal with Purple Ribbon from the Japanese Government.

Roger A. Paquin Chapter A.5, Sects. 5.9.4, 5.10

Advanced Materials Consultant
Oro Valley, AZ, USA
materials.man@att.net

Roger Paquin is an independent materials consultant specializing in materials and processes for dimensionally stable components for optical and precision instrument systems, with emphasis on Be, SiC and composites for mirrors and structures. He has published over 50 papers and book chapters and teaches short courses on the subject. Mr. Paquin is a Fellow of SPIE, The International Society for Optical Engineering.

Klaus Pfeilsticker Chapter D.19, Sect. 19.1

Universität Heidelberg
Institut für Umweltphysik
Fakultät für Physik
und Astronomie
Heidelberg, Germany
klaus.pfeilsticker@iup.uni-heidelberg.de

Dr. Klaus Pfeilsticker is a professor of physics at the University of Heidelberg since 2004. Before he worked at the Max-Planck-Institut für Kernphysik, Heidelberg, the Alfred Wegner Institut, Bremerhaven, the Research Center, Jülich and at the National Oceanic and Atmospheric Administration (NOAA), Boulder. His main research interests are the photochemistry and the radiative transfer of the atmosphere. His recent research focuses on the photochemistry, budget and trend of reactive halogen species in the upper troposphere and stratosphere, the spectral solar irradiance and its variability, and photon path length distribution of solar photons in clear and cloudy skies.

Ulrich Platt Chapter D.19, Sect. 19.1

Universität Heidelberg
Institut für Umweltphysik
Fakultät für Physik
und Astronomie
Heidelberg, Germany
ulrich.platt@iup.uni-heidelberg.de

Dr. Ulrich Platt is a professor of physics at the University of Heidelberg since 1989, before he worked at the research Center Jülich and at the University of California, Riverside. His main interests are atmospheric chemistry of free radicals and spectroscopic measurements of atmospheric constituents. He is the co-inventor of the DOAS technique. His current research centres on reactive halogen species in the troposphere and their role in the tropospheric chemistry as well as on remote sensing of trace gas distributions in the atmosphere.

Markus Pollnau Chapter C.11, Sect. 11.2.4

University of Twente
MESA+ Institute for Nanotechnology
Enschede, The Netherlands
m.pollnau@ewi.utwente.nl

Markus Pollnau obtained his Diploma and Ph.D. in physics from the Universities of Hamburg, Germany, and Bern, Switzerland, respectively. Following research at the University of Southampton, UK, and the Swiss Federal Institute of Technlogy, Lausanne, Switzerland, he was appointed full professor at the University of Twente, The Netherlands, in 2004. Currently, he works on light generation in integrated dielectric structures. He has co-authored over 200 international publications.

Authors

Steffen Reichel

SCHOTT Glas
Service Division Research
and Technology Development
Mainz, Germany
steffen.reichel@schott.com

Chapter A.5, Sects. 5.1.1, 5.1.6, 5.1.7, 5.1.8, 5.10

Dr. Reichel is an electrical engineer with extensive experience in optics and electromagnetics. He got his Ph.D. in Er-doped fiber amplifiers and worked on several topics in electromagnetics, wave and laser optics, optical fibers/waveguides, and geometrical optics. He is Senior Member of the IEEE and worked for Lucent Technologies and is now manager of the Physical Science Group at Schott.

Hans–Dieter Reidenbach

University of Applied Sciences Cologne
Institute of Communications Engineering
Institute of Applied Optics and Electronics
Cologne, Germany
hans.reidenbach@fh–koeln.de

Chapter D.21

Dr. Reidenbach is Professor at the University of Applied Sciences Cologne and head of the research laboratory Medical Technology. He obtained the Dr.-Ing. degree from the University of Erlangen. His scientific work resulted in new applications of laser beams, incoherent optical radiation and high frequency currents in operative endoscopy, transanal surgery and interstitial thermotherapy. Currently his research is on optical irradiation and psychophysical behaviour.

Hongwen Ren

University of Central Florida
College of Optics and Photonics
Orlando, FL, USA
hren@mail.ucf.edu

Chapter A.5, Sects. 5.9, 5.10

Dr. Hongwen Ren received his Ph.D. degree from Changchun Institute of Optics, Fine Mechanics and Physics, Chinese Academy of Sciences in 1998. After that, he was faculty member of the North Liquid Crystal R&D Center, Chinese Academy of Sciences as an assistant professor. In August 2001, he joined the College of Optics & Photonics, University of Central Florida (UCF) as a research Scholar. Dr. Ren's current research interests and projects are liquid crystal/polymer dispersions, nanoliquid crystal device, and adaptive e-lens.

Detlev Ristau

Laser Zentrum Hannover e.V.
Department of Thin Film Technology
Hannover, Germany
d.ristau@lzh.de

Chapter A.6

Detlev Ristau is a physicist with an extensive research background in optical thin film technology. He received his Ph.D. from the University of Hannover in 1988 and authored more than 200 technical papers. Current research activities include the development and precise control of ion processes as well as the measurement of the power handling capability and losses of optical components.

Simone Ritter

Schott AG
Division Research and Technology
Development
Material Development
Mainz, Germany
simone.ritter@schott.com

Chapter A.5, Sects. 5.3, 5.10

Dr. Simone Ritter studied Chemistry in Leipzig and Tübingen and received her Ph.D. 1994 for syntheses, characterization, structures and reactivity of complexes with rhenium-nitrogen-multi-bonds. For the last 7 years, she worked as scientific referent for coloured and optical glasses at Schott. Her research involves development and characterization of glasses with new optical properties.

Evgeny Saldin

Deutsches Elektronen Synchrotron (DESY)
Hamburg, Germany
evgueni.saldin@desy.de

Chapter C.11, Sect. 11.11

Dr. Evgeny Saldin is an expert in the field of physics of charged particle beams, accelerators, and free electron lasers. He has authored a book on free electron lasers and more than a hundred papers in peer-reviewed.

Roland Sauerbrey

Forschungszentrum
Dresden–Rossendorf e.V.
Dresden, Germany
r.sauerbrey@fzd.de

Chapter C.11, Sect. 11.13

Roland Sauerbrey is the Scientific Director of the Forschungszentrum Dresden-Rossendorf and a professor at the Technical University of Dresden. After receiving his Ph.D. in physics from the University of Würzburg in 1981 he worked as a professor at Rice University in Houston, Texas. In 1994 he moved to the Friedrich-Schiller-University in Jena where he stayed until 2006 as a professor of physics. During the last 20 years he has been actively involved in the emerging field of relativistic light – matter interaction and the development of ultrashort pulse, ultrahigh-intensity lasers. He is a fellow of the Optical Society of America and the Institute of Physics.

Evgeny Schneidmiller

Deutsches Elektronen Synchrotron (DESY)
Hamburg, Germany
evgeny.schneidmiller@desy.de

Chapter C.11, Sect. 11.11

Evgeny Schneidmiller is an expert in the field of physics of charged particle beams, accelerators, and free electron lasers. He has authored a book on free electron lasers and more than a hundred papers in peer-reviewed journals.

Bianca Schreder

Schott Glas
Division Research and Technology
Development
Material Development
Mainz, Germany
bianca.schreder@schott.com

Chapter A.5, Sects. 5.1.5, 5.6, 5.10

Dr. Bianca Schreder studied Chemistry in Würzburg and received her Ph.D. from the Department of Physical Chemistry for her work on Laser Spectroscopy on II–VI-Semiconductor Nanostructures. She is now working in the Research and Development Department at Schott Glas, Mainz. Her work involves investigation and development of glass systems with special optical properties.

Christian G. Schroer

Dresden University of Technology
Institute of Structural Physics
Dresden, Germany
schroer@physik.tu–dresden.de

Chapter D.18

Christian G. Schroer made his doctoral studies in mathematical physics at the Research Centre Jülich (doctoral degree University of Cologne in 1995). After a visit as postdoctoral fellow to the University of Maryland, he worked as a research and teaching assiociate at Aachen University in the field of X-ray optics and microscopy. After his Habilitation in 2004, he was a staff scientist at DESY in Hamburg until he responded to a call to the chair of Structural Physics of Condensed Matter at Dresden University of Technology in early 2006.

Markus W. Sigrist

ETH Zurich, Institute of Quantum
Electronics
Department of Physics
Zurich, Switzerland
sigrist@iqe.phys.ethz.ch

Chapter C.11, Sect. 11.10

Markus W. Sigrist is Professor of Physics at ETH Zurich (Switzerland) and Adjunct Professor at Rice University in Houston (USA). His current research involves development and implementation of tunable mid-infrared laser sources and sensitive detection schemes for spectroscopic trace gas analyses in environmental, industrial and medical applications. He published 2 books and over 150 papers. He is Fellow of OSA and Topical Editor of Applied Optics.

Glenn T. Sincerbox

University of Arizona
Optical Sciences
Tucson, AZ, USA
sinbox@cox.net

Chapter D.20, Sect. 20.2

Glenn Sincerbox is currently a Professor Emeritus of the College of Optical Sciences of the University of Arizona where he was a Professor of Optical Sciences and the Director of the Optical Data Storage Center; a Center that performed leading-edge research on advanced optical storage materials, systems and techniques. Prior to that, Mr. Sincerbox was with IBM Research for 34 years holding numerous technical and management positions. He has published over 50 technical papers and presented over 60 papers. He holds 40 US Patents and has 70 patent publications. His research was primarily in the field of optical storage with emphasis on holographic storage. He is a fellow of the OSA and has been active for over 15 years in the International Commission for Optics holding positions as vice president and treasurer.

Elisabeth Soergel

University of Bonn
Institute of Physics
Bonn, Germany
soergel@uni-bonn.de

Chapter B.8, Sect. 8.5

Elisabeth Soergel studied physics at the Ludwig-Maximilian-University in Munich. She received her Diploma and Ph.D. from the Max-Planck Institute for Quantum Optics in Garching in the field of scanning probe microscopy. After a postdoc stay at the IBM research laboratory in Rüschlikon, Switzerland, she joined the University of Bonn in 2000 with the main research field on visualization of ferroelectric domains by scanning probe techniques.

Steffen Steinberg

LASOS Lasertechnik GmbH
Jena, Germany
steffen.steinberg@lasos.com

Chapter C.11

Steffen Steinberg studied physics and received his doctoral degree at Friedrich-Schiller-University Jena, with a work on manipulation of laser light with integrated optical devices. Later his work concentrated on different applications of gas and solid-state laser technology especially laser display technology and fiber optical devices. Currently he is working as Sales Manager at LASOS in Jena, Germany.

Sune Svanberg

Lund University
Division of Atomic Physics
Lund, Sweden
sune.svanberg@fysik.lth.se

Chapter D.13, Sect. 13.3

Sune Svanberg made his Ph.D. in Physics at Göteborg University in 1972. He became professor and head of the Atomic Physics Division, Lund University, in 1980. He is also Director of the Lund Laser Centre, a European Large Scale Infrastructure. He is fellow of the American Physical Society and the Optical Society of America, member of 5 academies and three-fold honorary doctor. His present research fields include basic atomic laser spectroscopy and applications of laser spectroscopy to environmental and medical research.

Orazio Svelto

Politecnico di Milano
Department of Physics
Milan, Italy
orazio.svelto@fisi.polimi.it

Chapter C.11, Sect. 11.1

Orazio Svelto is Professor of Quantum Electronics at the Politecnico di Milano and the Director of the Milan Section at the Institute of Photonics and Nanotechnologies (IFN), Milan, Italy, belonging to the Italian National Research Council (CNR). His current research activities include ultrashort-pulse generation and applications, physics of laser resonators and techniques of mode selection, laser applications in biology and biomedicine, and physics of solid-state lasers, also including the generation of femtosecond laser pulses, down to the record value of 3.8 fs recently established by the group, and to the applications of these ultrashort pulses. He is the author of Principles of Lasers (1998). Professor Svelto is Fellow of the Optical Society of America and the Institute of Electrical and Electronics Engineers, and a member of several Italian academies including the "Accademia dei Lincei". He was the recipient of the Italgas Prize for research and technology innovation, the Quantum Electronics Prize of the European Physical Society and the Charles H. Townes Award of the Optical Society of America.

Bernd Tabbert

Semicoa
Engineering Department
Costa Mesa, CA, USA
btabbert@semicoa.com

Chapter B.9

Bernd Tabbert received his Ph.D. from the University of Heidelberg, Germany in 1994. For several more years his research focused on optical studies of impurity atoms and bubbles in cryogenic liquids including a project at the University of California, Los Angeles. He is now working as an engineering manager for a semiconductor manufacturer developing sensors for medical X-ray applications.

K. Thyagarajan

Indian Institute of Technology Delhi
Physics Department
New Delhi, India
ktrajan@physics.iitd.ernet.in

Chapter B.8, Sect. 8.7

Professor Thyagarajan has published more than 125 research publications and is the co-author (with Professor Ajoy Ghatak) of six books. He has held visiting positions at Thomson-CSF, France and the University of Florida. He is a Fellow of the Optical Soceity of America and was awarded the title of "Officier dans l'ordre des Palmes Académiques" by the French Government in 2003. His current research interests are optical fiber amplifiers and guided wave nonlinear optics.

Mary G. Turner

Engineering Synthesis Design, Inc.
Tucson, AZ, USA
mary.t@engsynthesis.com

Chapter B.7

Dr. Turner has been involved with the development of optical software and conducted training on optical design and optical software for the previous 12 years. She wrote a chapter on "Optical Aberrations" in The Optics Encyclopedia and on "Reflecting and Catadioptric Objectives" in the Optical Engineer's Desk Reference. She is a fellow of SPIE and a member of SID and OSA.

Giuseppe Della Valle

Polytechnic Institute of Milan
Department of Physics
Milan, Italy
giuseppe.dellavalle@polimi.it

Chapter C.11, Sect. 11.1

Dr. Giuseppe Della Valle received his Ph.D. in Physics from the Polytechnic Institute of Milan, Italy, in 2005. He is currently Assistant Professor of Physics at the Physics Department of the same Institute.. His research activity is mainly devoted to solid-state lasers and optical devices based on doped glass substrates operating in the near infrared for telecom and metrological applications.

Michael Vollmer

University of Applied Sciences
Brandenburg
Department of Physics
Brandenburg, Germany
vollmer@fh–brandenburg.de

Chapter D.19, Sect. 19.2

Michael Vollmer studied physics in Heidelberg where he received his Ph.D. and habilitation, working on optical spectroscopy of metal clusters. Presently he is Professor of Experimental Physics working in the fields of infrared thermal imaging, spectroscopy, atmospheric optics, and didactics of physics. He is author of two books and member of the editorial boards of several journals.

Silke Wolff

SCHOTT Spezialglas AG
Department of Research & Technology
Development, Material Development
Optical Glasses
Mainz, Germany
silke.wolff@schott.com

Chapter A.5, Sects. 5.2, 5.10

Dr. Silke Wolff, laureate of R&D award, is an expert in glass development with an origin in analytical chemistry. Her main areas of research are innovative optical glasses, including market and customer-related material development, application, optimization of production processes and patent protection. Actual topics are exceptional optical properties, suitability for reheat hot forming and/or precision moulding and environmental compatibility.

Matthias Wollenhaupt   Chapter C.12

Universität Kassel
Institut für Physik
Kassel, Germany
wollenhaupt@physik.uni–kassel.de

Matthias Wollenhaupt did research in high-resolution laser spectroscopy with applications to aerospace and atmospheric chemistry. His current research in femtosecond laser spectroscopy is focused on pulse-shaping techniques for the design of tailored femtosecond laser pulses as a tool to control ultrafast light-induced processes. His scientific interests range from basic research, such as quantum control of molecular dynamics to applications of non-linear optics and materials processing.

Shin–Tson Wu   Chapter A.5, Sects. 5.9, 5.9.1, 5.10

University of Central Florida
College of Optics and Photonics
Orlando, FL, USA
swu@mail.ucf.edu

Dr. Wu is a Fellow of the IEEE, SID and OSA. He is a recipient of the IEEE Outstanding Engineer Award, SID Special Recognition Award, ERSO (Taiwan) Special Achievement Award, Hughes Team Achievement Award, and Hughes Annual Outstanding Paper Award. Professor Wu has co-authored 2 books: "Reflective Liquid Crystal Displays" (2001), and "Optics and Nonlinear Optics of Liquid Crystals" (1993), 4 book chapters, over 200 journal papers, and 18 issued patents.

Helen Wächter   Chapter C.11, Sect. 11.10

ETH Zurich, Institute of Quantum Electronics
Department of Physics
Zurich, Switzerland
waechter@phys.ethz.ch

Helen Wächter is a Ph.D. student at the Institute of Quantum Electronics of ETH Zurich after receiving her physics diploma from ETH in 2003. Her main research interests are in the field of IR laser spectroscopy and trace-gas monitoring. This includes the development of new coherent light sources by difference frequency generation (DFG) and new sensitive detection schemes. Her emphasis is on isotope-selective trace-gas analysis.

Mikhail Yurkov   Chapter C.11, Sect. 11.11

Deutsches Elektronen Synchrotron (DESY)
Hamburg, Germany
mikhail.yurkov@desy.de

Dr. Mikhail Yurkov is an expert in the field of physics of charged particle beams, accelerators, and free electron lasers. He has authored a book on free electron lasers and more than a hundred papers in peer-reviewed journals.

Aleksei Zheltikov   Chapter A.4, Sect. 4.1

M.V. Lomonosov Moscow State University
Physics Department
Moscow, Russia
zheltikov@phys.msu.ru

Aleksei Zheltikov's current research is related to nonlinear-optical processes in photonic-crystal fibers and nanostructures.
