Since the gain spectrum depends on the pump wavelength, it is indeed possible to achieve large flat gain using multiple pumps. Thus using 12 pumps with wavelengths lying between 1410 nm and 1510 nm, a total flat gain bandwidth of 100 nm from 1520 nm to 1620 nm (covering the C band and the L band) has been demonstrated. Since Raman fiber amplifiers can operate at any signal-wavelength region, they allow us to expand the operation region of fiber optic communication systems to other bands where EDFAs do not operate. Apart from this, Raman amplifiers can also be used to extend the operation of optical fiber communication systems in C-band. The repeater-less length can be increased by use of Raman amplifier at the terminal. Similarly when the bit rate of a communication channel is increased, then for the system to operate without signal degradation (within a certain bit error rate), the receiver would need more

power. In this case, the additional Raman gain that is realized by propagating an appropriate pump with the signal can be used to increase the transmission bit rate for the same distance between the transmitter and receiver.

Since the gain coefficient depends on the effective area of the fiber, the Raman gain spectrum could be modified by proper fiber designs with appropriate spectral dependence of effective area. Thus, recently novel fiber designs have been proposed that can give flat Raman gain with just a single pump [8.252, 253]. For nice reviews of fiber Raman amplifiers, readers are referred to [8.251, 254, 255].

8.8.10 Nonlinear Effects in Optical Fibers

Consider a light beam having a power of 100 mW propagating through an optical fiber having an effective mode area of $50\,\mu\mathrm{m}^2$. The corresponding optical intensity is $2 \times 10^9\,\mathrm{W/m}^2$. At such high intensities, the nonlinear effects in optical fibers start to influence the propagation of the light beam and can significantly influence the capacity of a WDM optical fiber communication system [8.256]. The most important nonlinear effects that affect optical fiber communication systems include self phase modulation (SPM), cross phase modulation (XPM) and four-wave mixing (FWM). Stimulated Raman scattering (SRS) and stimulated Brillouin scattering (SBS) are also important nonlinear phenomena and earlier we have seen how SRS can be used for optical amplification. In this section, we will discuss mainly SPM, XPM and FWM, which affect pulse propagation through optical fibers.

Self Phase Modulation (SPM)

The lowest-order nonlinearity present in an optical fiber is the third-order nonlinearity. Thus, in an optical fiber,

Table 8.6 Mode effective area of typical commercially available fibers

Fiber type	Effective area ($\mu\mathrm{m}^2$)
Single-mode fiber (SMF) G652	$\approx 85\,\mu\mathrm{m}^2$
Dispersion-shifted fiber (DSF)	$\approx 46\,\mu\mathrm{m}^2$
Nonzero DSF (NZDSF)	$\approx 52\,\mu\mathrm{m}^2$ ($D > 0$), $56\,\mu\mathrm{m}^2$ ($D < 0$) and $73\,\mu\mathrm{m}^2$
Dispersion-compensating fiber (DCF)	$\approx 23\,\mu\mathrm{m}^2$ ($D < 0$)
Photonic-crystal fiber / holey fiber	$\approx 3\,\mu\mathrm{m}^2$

the polarization generated consists of a linear and a non-linear term

$$P = \varepsilon_0 \chi E + \varepsilon_0 \chi^{(3)} E^3 , \tag{8.139}$$

where χ and $\chi^{(3)}$ represent the linear and third-order susceptibility of the medium (silica) and E represents the electric field of the propagating light wave/pulse. The nonlinearity due to $\chi^{(3)}$ results in an intensity-dependent refractive index given by

$$n = n_0 + n_2 I , \tag{8.140}$$

where $n_2 = 3\chi^{(3)}/4c\varepsilon_0 n_0$ and n_0 is the refractive index of the medium at low intensities. It is this intensity-dependent refractive index that gives rise to SPM.

Due to the intensity-dependent refractive index, the propagation constant of a mode becomes intensity dependent and can be written as

$$\beta_{\mathrm{NL}} = \beta + \gamma P \tag{8.141}$$

where

$$\gamma = \frac{k_0 n_2}{\tilde{A}_{\mathrm{eff}}} , \quad \tilde{A}_{\mathrm{eff}} = 2\pi \frac{\left(\int \psi^2(r) r \, \mathrm{d}r \right)^2}{\int \psi^4(r) r \, \mathrm{d}r} \tag{8.142}$$

represent the nonlinear coefficient and the nonlinear mode effective area, respectively, and β is the propagation constant of the mode at low powers. If we assume the mode to be described by a Gaussian function, then $\tilde{A}_{\mathrm{eff}} = \pi w_0^2$, where w_0 is the Gaussian-mode spot size. Note that the nonlinear coefficient γ of the fiber depends on the effective area of the mode; the larger the effective mode area, the smaller the nonlinear effects. Table 8.6 gives the mode effective area of some common fiber types.

If α represents the attenuation coefficient of the optical fiber, then the power propagating through the fiber decreases exponentially as $P(z) = P_0 e^{-\alpha z}$ where P_0 is the input power. In α is the attenuation coefficient. In such a case, the phase shift suffered by an optical beam in propagating through a length L of the optical fiber is given by

$$\Phi = \int_0^L \beta_{\mathrm{NL}} \, \mathrm{d}z = \beta L + \gamma P_0 L_{\mathrm{eff}} , \tag{8.143}$$

where

$$L_{\mathrm{eff}} = \frac{\left(1 - e^{-\alpha L} \right)}{\alpha} \tag{8.144}$$

is called the effective length of the fiber. If $\alpha L \gg 1$ then $L_{\mathrm{eff}} \approx 1/\alpha$ and if $\alpha L \ll 1$ then $L_{\mathrm{eff}} \approx L$. For single-mode fibers operating at 1550 nm, $\alpha \approx 0.25$ dB/km and
Fig. 8.85 An unchirped pulse at the input after propagating through an optical fiber gets chirped due to self phase modulation

thus $L_{\mathrm{eff}} \approx L$ for $L \ll 20$ km and $L_{\mathrm{eff}} \approx 20$ km for $L \gg 20$ km.

Since the propagation constant β_{NL} of the mode depends on the power carried by the mode, the phase Φ of the emergent wave depends on its power and hence this is referred to as *self phase modulation* (SPM).

For a light pulse P_0 in (8.145) becomes time dependent and this leads to an additional time dependent phase apart from $\omega_0 t$. Thus the output pulse is chirped and the instantaneous frequency of the output pulse is given by

$$\omega(t) = \frac{\mathrm{d}}{\mathrm{d}t} \left(\omega_0 t - \gamma P_0 L_{\mathrm{eff}} \right) = \omega_0 - \gamma L_{\mathrm{eff}} \frac{\mathrm{d}P_0}{\mathrm{d}t} . \tag{8.145}$$

The leading edge of the pulse corresponds to the positive values of $\mathrm{d}P_0/\mathrm{d}t$ and the trailing edge to negative values of $\mathrm{d}P_0/\mathrm{d}t$. Thus in the presence of SPM, the leading edge gets downshifted in frequency while the trailing edge gets upshifted in frequency. The frequency at the center of the pulse remains unchanged from ω_0. Figure 8.85 shows an input unchirped and the output chirped pulse generated due to SPM. The output chirped pulse with the same temporal width has a larger frequency spectrum. These new frequencies have been generated by the nonlinear process.

The chirping due to nonlinearity without any corresponding increase in pulse width leads to increased spectral broadening of the pulse. This spectral broadening coupled with the dispersion in the fiber leads to modified dispersive propagation of the pulse in the presence of nonlinearity. In the normal-dispersion region the chirping due to dispersion is to downshift the leading edge and upshift the trailing edge of the pulse.

This is of the same sign as that due to SPM. Thus in the normal-dispersion regime (wavelength less than the zero-dispersion wavelength) the chirping due to dispersion and nonlinearity add. Thus at high powers, where the nonlinear effects are not negligible, the pulse will suffer additional dispersion as compared to the dispersion of the same pulse at low powers. On the other hand, in the anomalous-dispersion region (wavelength greater than the zero-dispersion wavelength), the chirping due to dispersion is opposite to that due to nonlinearity and thus in this wavelength region, nonlinearity and dispersion-induced chirpings can partially or even totally cancel each other. When total cancelation takes place, the pulse neither broadens in time nor in its spectrum and such a pulse is called a *soliton*. Such solitons can hence be used for dispersionless propagation of pulses to realize very high-bit-rate systems.

Assuming only second-order dispersion and $\chi^{(3)}$ nonlinearity, the amplitude $A(z, t)$ of the electric field of an incident pulse can be shown to satisfy the following equation [8.257]:

$$\frac{\partial A}{\partial z} = \mathrm{i}\frac{\beta_2}{2}\frac{\partial^2 A}{\partial T^2} - \mathrm{i}\gamma |A|^2 A \,, \tag{8.146}$$

where $\beta_2 = \mathrm{d}^2\beta/\mathrm{d}\omega^2$ and $T = t - z/v_{\mathrm{g}}$. Equation (8.146) is referred to as the nonlinear Schroedinger equation and describes the propagation of a pulse in a medium possessing second-order dispersion and $\chi^{(3)}$ nonlinearity. The solution of the above equation give us solitons which are described mathematically by:

$$\tilde{A}(z, t) = \sqrt{P_0}\,\mathrm{sech}\left(\sqrt{\frac{P_0\gamma}{|\beta_2|}}\,T\right)\mathrm{e}^{-\mathrm{i}\gamma P_0 z/2} \,. \tag{8.147}$$

where $\tilde{A}(z, t)$ is the normalized electric field defined such that $|\tilde{A}(z, t)|^2$ gives the power carried by the pulse. Equation (8.147)) shows that the peak power required to form a soliton is related to the pulse width and dispersion coefficient D. As an example, for a soliton pulse at 1550 nm with full width at half maximum of $\tau_{\mathrm{f}} = 10$ ps propagating in a fiber with $\gamma = 2.4\,\mathrm{W}^{-1}\mathrm{km}^{-1}$ and $D = 2\,\mathrm{ps/(km\,nm)}$ and the required peak power will be $P_0 = 33$ mW.

A heuristic derivation of the power required to form a soliton by cancelation of chirping due to dispersion and nonlinearity can be found in [8.235].

Even if the cancelation between dispersive and nonlinear chirping is not perfect, the nonlinear effects in an optical fiber lead to reduced pulse broadening in the anomalous-dispersion region. Thus the net dispersion suffered by the pulse decreases as the power increases.

This fact needs to be kept in mind while designing dispersion-compensation schemes.

Cross Phase Modulation (XPM)

Consider the simultaneous launching of two or more different light beams of different wavelengths into an optical fiber. In such a case, each individual light wave will lead to a change in the refractive index of the fiber due to the intensity-dependent refractive index. This change in refractive index of the fiber then affects the phase of the other light beam(s); this results in what is referred to as cross phase modulation (XPM). Similar to the case of SPM, the instantaneous frequency of a signal at frequency ω_0 in the presence of XPM is given by

$$\omega(t) = \omega_0 - 2\gamma L_{\mathrm{eff}}\frac{\mathrm{d}P_2}{\mathrm{d}t} \,, \tag{8.148}$$

where P_2 is the power carried by the other wavelength. The part of the signal that is influenced by the leading edge of the pump will be downshifted in frequency (since in the leading edge $\mathrm{d}P_2/\mathrm{d}t > 0$) and the part overlapping with the trailing edge will be up shifted in frequency in frequency (since $\mathrm{d}P_2/\mathrm{d}t < 0$). This leads to a frequency chirping of the signal pulse just like in the case of SPM. Conventional detectors detect the intensity variation of the signal and hence are not affected by phase variations caused by XPM. However, these phase variations get converted to intensity variations due to dispersive effects in the fiber and these intensity variations can cause further bit errors in a fiber optic communication system.

If the two light waves are pulses, then XPM leads to chirping of the pulses. In the presence of finite dispersion (i. e., operation away from the zero-dispersion wavelength), the two pulses will move with different velocities and thus the pulses will walk off from each other. In case the pulses enter the fiber together, then due to walk off each pulse will see only the trailing or the leading edge of the other pulse which will lead to chirping. On the other hand, if the *collision* is complete, i. e., if the pulses start separately and walk through each other and again separate as they propagate through the fiber, then there would be no XPM-induced chirping since the pulses would have interacted with both the leading and the trailing edge of the other pulse. In an actual system, this cancelation will not be perfect since the pulses suffer attenuation and this leads to reduced nonlinear interaction as the pulses walk through each other.

Four-Wave Mixing (FWM)

Consider the incidence of three waves at three frequencies ω_2, ω_3 and ω_4 into an optical fiber. In the presence

of the three waves, the third-order nonlinearity in the fiber leads to the generation of a nonlinear polarization at a frequency ω_1 given by

$$\omega_1 = \omega_3 + \omega_4 - \omega_2 \tag{8.149}$$

This nonlinear polarization can, under some circumstances, lead to the generation of electromagnetic waves at the new frequency ω_1. This phenomenon is referred to as four-wave mixing (FWM). In a dense wavelength division multiplexed (DWDM) system, FWM leads to cross talk among different wavelength channels of the system.

The nonlinear polarization at frequency ω_1 due to the presence of other waves is given by:

$$P_{\mathrm{NL}}^{\omega_1} = \frac{1}{2}\left(p_{\mathrm{nl}}\, \mathrm{e}^{\mathrm{i}(\omega_1 t - \beta_1 z)} + \mathrm{c.c.}\right) \tag{8.150}$$

where

$$p_{\mathrm{nl}} = \frac{3\varepsilon_0}{2}\chi^{(3)} A_2^* A_3 A_4 \psi_2 \psi_3 \psi_4\, \mathrm{e}^{-\mathrm{i}\Delta\beta z}, \tag{8.151}$$

where $\Delta\beta = \beta_3 + \beta_4 - \beta_2 - \beta_1$ and A_i and ψ_i represent the amplitudes and modal field profiles corresponding to modes at frequency ω_i. From the expression for the nonlinear polarization it can be seen that, in general, the velocity of the nonlinear polarization is not equal to the velocity of the electromagnetic wave that it is generating. For efficient generation of the electromagnetic wave at the frequency ω_1, there must be phase matching, i.e., the velocity of the nonlinear polarization (which acts as the source of the radiation at frequency ω_1) and the electromagnetic wave (at frequency ω_1) must be equal. For this to happen we must have $\Delta\beta = 0$. Assuming the frequencies to be closely and equally spaced (i.e., $\omega_1 = \omega_2 - \Delta\omega$, $\omega_3 = \omega_2 - 2\Delta\omega$, $\omega_4 = \omega_2 + \Delta\omega$) and making a Taylor series expansion of all βs about a frequency ω_2, we get

$$\Delta\beta = -\frac{4\pi D\lambda^2}{c}(\Delta\nu)^2, \tag{8.152}$$

where $\Delta\omega = 2\pi\Delta\nu$ represents the frequency spacing between adjacent channels. Thus when the channels lie around the zero-dispersion wavelength of the fiber, $D = 0$ and we have phase matching and thus an efficient FWM. If one wishes to reduce FWM, then one must operate away from the zero-dispersion wavelength. This has led to the development of nonzero-dispersion-shifted fibers (NZ-DSF), wherein a finite but small dispersion (≈ 2 to $8\,\mathrm{ps/(km\,nm)}$) is introduced to reduce FWM effects in an actual fiber optic communication system. On the other hand, if a strong FWM is desired for an application such as all-optical signal processing or wavelength

conversion, then the interacting wavelengths must lie close to the zero-dispersion wavelength.

Assuming that all frequencies have the same attenuation coefficient α and neglecting depletion due to conversion, the power generated at the frequency ω_1 due to mixing of the other three frequencies can be shown to be

$$P_1 = 4\gamma^2 P_2 P_3 P_4 L_{\mathrm{eff}}^2 \eta\, \mathrm{e}^{-\alpha L}, \tag{8.153}$$

where

$$\eta = \frac{\alpha^2}{\alpha^2 + \Delta\beta^2}\left(1 + \frac{4\,\mathrm{e}^{-\alpha L}\sin^2\frac{\Delta\beta L}{2}}{\left(1 - \mathrm{e}^{-\alpha L}\right)^2}\right). \tag{8.154}$$

As evident from (8.153), maximum conversion occurs when $\eta = 1$, i.e. $\Delta\beta = 0$. If we assume all wavelengths to carry the same power P_{in}, then under phase matching, the ratio of the power generated due to FWM to that exiting from the fiber is given by

$$R = \frac{P_{\mathrm{g}}}{P_{\mathrm{out}}} = \frac{P_1(L)}{P_{\mathrm{in}}\, \mathrm{e}^{-\alpha L}} = 4\gamma^2 P_{\mathrm{in}}^2 L_{\mathrm{eff}}^2. \tag{8.155}$$

Thus if in each channel we have an input power of 1 mW, then for $\gamma = 1.73\times 10^{-3}\,\mathrm{m^{-1}W^{-1}}$, $L_{\mathrm{eff}} = 20\,\mathrm{km}$, the FWM generated output will be about 0.5% of the power exiting in the channel. This gives us the level of cross talk among the channels created due to FWM.

Figure 8.86 shows the output spectrum measured at the output of a 25 km-long dispersion-shifted fiber ($D = -0.2\,\mathrm{ps/(km\,nm)}$ at the central channel) when three 3 mW wavelengths are launched simultaneously.
Fig. 8.86 New frequency components generated due to four wave mixing in an optical fiber operating close to the zero-dispersion wavelength. The input consists of the three large-amplitude frequencies (after [8.258])
Fig. 8.87 Spectral broadening by supercontinuum generation (after [8.259])

Notice the generation of nine new frequencies with different amplitudes (with a maximum peak ratio of 1% to the input signals) due to FWM. Newly generated waves will interfere with power present in those channels and lead to cross talk. By choosing a nonzero value of dispersion, the four-wave mixing efficiency can be significantly reduced. The larger the dispersion coefficient, the smaller can be the channel spacing for the same cross talk.

Since dispersion leads to increased bit error rates in fiber optic communication systems, it is important to have low dispersion. On the other hand, lower dispersion leads to cross talk due to FWM. This problem can be resolved by noting that FWM depends on the local dispersion value in the fiber while the pulse spreading at the end of a link depends on the overall dispersion in the fiber link. If one chooses a link made up of positive and negative dispersion coefficients, then by an appropriate choice of the lengths of the positive and negative dispersion fibers, it would be possible to achieve a zero total link dispersion while at the same time maintaining a large local dispersion. This is referred to as dispersion management in fiber optic systems.

Although FWM leads to cross talk among different wavelength channels in an optical fiber communication system, it can be used for various optical processing functions such as wavelength conversion, high-speed time-division multiplexing, pulse compression, and optical amplification [8.260, 261]. For such applications, there is a concerted worldwide effort to develop highly nonlinear fibers with much smaller mode areas and higher nonlinear coefficients. Some of the very novel fibers that have been developed recently include holey fibers, photonic band-gap fibers or photonic crystal fibers which are very interesting since they posses

extremely small mode effective areas ($\approx 2.5\,\mu m^2$ at 1550 nm) and can be designed to have zero dispersion even in the visible region of the spectrum [8.262, 263]. This is expected to revolutionize nonlinear fiber optics by providing new geometries to achieve highly efficient nonlinear optical processing at lower powers.

Supercontinuum Generation

Supercontinuum (SC) generation is the phenomenon in which a nearly continuous spectrally broadened output (bandwidth > 1000 nm) is produced through nonlinear effects on high-peak-power picosecond and femtosecond pulses. Such broadened spectra find applications in spectroscopy, optical coherence tomography, WDM sources for optical communication by slicing the spectrum etc. Supercontinuum generation in an optical fiber is a very convenient technique since the intensity levels can be maintained high over long interaction lengths by choosing small mode areas and the dispersion profile of the fiber can be appropriately designed by varying the transverse refractive-index profile of the fiber. The spectral broadening that takes place in the fiber is attributed to a combination of various third-order effects such as SPM, XPM, FWM, and Raman scattering. Since dispersion plays a significant role in the temporal evolution of the pulse, different dispersion profiles have been used in the literature to achieve broadband SC. Some studies have used dispersion-decreasing fibers, dispersion-flattened fibers, while others have used a constant anomalous-dispersion fiber followed by a normal-dispersion fiber. Figure 8.87 shows the input and output broadened spectra obtained by passing a light pulse through a photonic-crystal fiber [8.259].

8.8.11 Microstructured Fibers

A standard optical fiber guides light using the phenomenon of total internal reflection. Recently there
Fig. 8.88a,b Solid core (**a**) and hollow core (**b**) photonic-crystal fibers (Courtesy Blaze Photonics, Bath, UK)

has been intense activity in realization of optical fibers guiding light using Bragg reflections or photonic band-gap effects. Photonic crystals are periodic structures fabricated in an optical material with periodicities comparable to the optical wavelength. These can be one dimensional (like fiber Bragg gratings), two dimensional or three dimensional. Structures with appropriate symmetry and periodicities can exhibit photonic band gaps, which are regions of optical wavelengths where light cannot propagate through the structure, much like the band gaps for electrons in crystals. Thus such structures allow control of light propagation and find applications in semiconductor lasers, light modulators, integrated optical devices, nonlinear devices etc. Microstructured fibers have a periodic arrangement of holes in a silica background material running all along the length of the fiber and can lead to guidance of light using the band-gap effects. Figure 8.88 shows two types of such fibers, one having solid silica core and the other having a air hole at the center. Since confinement can be accomplished using the band-gap effect it is possible to realize optical fibers with air cores; such holey fibers are finding many applications. It is also possible to realize fibers with solid cores with mode effective areas in the region

of $3\,\mu m^2$. Since nonlinear effects depend on the intensity of light such fibers can give rise to very interesting nonlinear effects even at moderate power levels. Microstructured fibers exhibit the very interesting property of being single mode over a very large range of wavelengths. This can be understood from the fact that, due to the presence of holes in the cladding, as the wavelength changes the fraction of light power in the holes changes and this leads to an effective cladding refractive index which becomes highly wavelength dependent and increases with increasing wavelength, leading to an effective V number which results in single-mode operation. Such fibers are also referred to as endlessly single-mode fibers. The dispersion of microstructured fibers can also be controlled by appropriate design and it is possible to achieve zero dispersion in the visible range using silica which is otherwise not possible using conventional fiber designs. Supercontinuum generation which requires control of dispersion and nonlinearity is one such application and devices based on such fibers are now commercially available. With technological inputs, propagation loss in these fibers have been reduced significantly and photonic-crystal fibers with loss values of 0.3 dB/km have been realized recently [8.264].

9. Optical Detectors

Optical detectors are applied in all fields of human activities – from basic research to commercial applications in communication, automotive, medical imaging, homeland security, and other fields. The processes of light interaction with matter described in other chapters of this handbook form the basis for understanding the optical detectors physics and device properties.

This chapter starts with a brief historical sketch of first experiments facilitating development of optical detectors. The overview of photo detector types is followed by the description of the most important figures of merit and different detection regimes.

A detailed description of different types of optical detectors is presented in the following sections. The device structure and physics as well as important materials for fabrication, figures of merit, and brief application notes are given for photoconductors, photodiodes, quantum well photodetectors, semiconductor detectors with intrinsic amplification, charge transfer detectors, photoemissive detectors, and thermal photodetectors. The chapter includes also a brief overview of imaging systems and principles of black and white and color photography.

All photodetectors make use of the effects of the interaction of light with matter. In fact, this interaction occurs via the photoelectric effect, which in most cases is the primary step in the photon detection process.

Among the predictions of Maxwell's theory of electromagnetism, published in 1865, was the existence of electromagnetic waves moving at the speed of light, and the conclusion that light itself was just such a wave. This challenged physicists to experimentally generate and detect electromagnetic radiation. The first successful attempt to generate light was made by Hertz in 1886, who used a high-voltage induction coil to cause a spark discharge between two pieces of brass. Hertz also succeeded in building a receiver capable of detecting the light generated by his emitter.

There were many attempts to explain the effects observed by Hertz, all of which were unsuccessful until 1899, when Thomson established that ultraviolet light caused electrons to be emitted from a metal surface. In 1902, Lenard studied how the energies of the emitted photoelectrons varied with the light intensity. He discovered that there was a well-defined minimum voltage that stopped any electrons emitted from the illuminated cathode from reaching the collector electrode. He also found that this voltage did not depend at all upon the intensity of light. However, Lenard found that the maximum energy of the ejected electrons did depend on the illumination wavelength – the shorter the wavelength, the higher the energies of the ejected electrons.

In 1905 Einstein provided a very simple interpretation of Lenard's results. He just assumed that the incoming radiation should be thought of as quanta of energy $h\nu$, where ν is the frequency and h is Planck's constant. When these photons interact with the metal, they give up some or all of their energy to electrons. An energy that is equal to the product of the metal's work function φ_m and the elementary charge q would be required to release the electrons from their bonds to the metal. The remaining energy would be converted into the kinetic energy of the released electron. Thus, the maximum kinetic energy E_k the emitted electrons could have is

$$E_\mathrm{k} = h\nu - q\varphi_\mathrm{m} \, . \tag{9.1}$$

Thus Einstein's theory makes a very definite quantitative prediction: that there is a minimum frequency of light for a given material that emits electrons for which the quantum of energy is equal to the work function. Incident light below this frequency will not cause photoemission, independent of the intensity of the light. The emission of photoelectrons from solids upon illumination is called now the "photoelectric effect."

The photoelectric effect can be either an external or an intrinsic effect. In the external version of the effect, the electron is ejected completely from the material, while for the case of the intrinsic photoelectric effect, the motion of the electron remains confined within the material. The above experiments on the release of photoelectrons from a metal are typical examples of the external photoelectric effect. The intrinsic photoelectric effect can be exemplified by the processes of photon absorption in semiconductor crystals, chromophores, macromolecular aggregates, etc. In those cases, the work function of (9.1) should be substituted for the activation energy, such as the bandgap energy E_g for semiconductors. The emitted photoelectron participates in creating a qualitatively new state that can be characterized via electronic circuitry.

9.1 Photodetector Types, Detection Regimes, and General Figures of Merit

9.1.1 Types of Photodetectors

Photodetectors can be classified according to the methods used to detect the photons and to record information into, for example, photovoltaic detectors, photoconductors, photoemissive detectors, thermal detectors, charge transfer devices, and photographic detectors.

Photovoltaic Detector

The photovoltaic effect is the generation of a potential across an active region of the detector. For the photovoltaic effect to occur, the different types of photogenerated charge carriers must be separated by an energy barrier. These detectors employ the intrinsic photoelectric effect. For example, when the photon flux irradiates the p–n junction of a semiconductor detector, nonequilibrium electron–hole (e–h) pairs are formed if the photon energy exceeds the forbidden gap energy E_g (Fig. 9.1). Due to the electric field that exists across the junction (the built-in electric field), electrons are swept from the P region to the N region, and holes from the N region to the P region. This process results in a positively charged P region and a negatively charged N region in the semiconductor, creating a potential difference across the contacts.

Photoconductive Detectors

Photoconductive detectors also employ the intrinsic photoelectric effect. In a photoconductive detector, the conductivity σ changes upon illumination if the photon energy is larger than the detector band gap E_g (Fig. 9.2). The change in conductivity depends on the particular detector and its properties, and in the simplest case of either p-type or n-type semiconductors, it can be described by

$$\Delta\sigma = \Delta nq\mu \,, \tag{9.2}$$

in which q is the elementary charge, Δn is the number of nonequilibrium carriers photoexcited over the band gap, and μ is the carrier mobility.

Photoemissive Detectors

Photoemissive detectors make use of the external photoelectric effect. For example, if a photocathode and anode are placed in a vacuum chamber and an external voltage is applied, then the photocurrent is proportional to the number of incident photons if their energies $h\nu$ are higher than the electron affinity ψ of the photocathode

(Fig. 9.3). The other example of a photoemissive detector – the photomultiplier tube (PMT) – will be discussed later in this chapter.

Thermal Detectors

Unlike most of the other types of photodetector, thermal detectors do not produce nonequilibrium carriers per se; instead they use the energy of the absorbed light to heat the substrate. In some secondary steps, the dissipated energy causes some other physical parameter to change, thus providing the light-detecting functionality.

Charge Transfer Devices

Charge transfer devices normally operate by storing the nonequilibrium charge created by the incident light in the potential well of a metal–insulator–semiconductor (MIS) capacitor (Fig. 9.4), and then transferring the stored charge across the semiconductor substrate towards readout electronics.

Photography

Photography is a process based on chemical changes initiated by the absorption of a photon by a silver halide microcrystal or a dye molecule attached to that microcrystal incorporated into the photographic emulsion. These changes accumulate and amplify during the exposure of photographic film to light, forming a latent image. The image becomes visible after further chemical processing.

9.1.2 Sources of Noise

Noise performance is one of the most important characteristics of a photodetector, since it determines the detector's sensitivity. The noise associated with a detector can be divided into two main groups.

1. Photon noise:

- Noise due to an optical signal
- Noise due to background radiation

2. Detector-generated noise:

- Johnson noise
- Shot noise
- Generation–recombination noise
- $1/f$ noise
- Temperature fluctuations
- Microphonics
Fig. 9.1 Photovoltaic effect. The contact of p-type and n-type semiconductors creates a barrier with a built-in potential V_{bi}, which facilitates the separation of photogenerated carriers

Photon Noise

Assuming that the photon flux follows Poisson statistics, the noise σ_N for an incident optical photon flux Φ containing $\bar{N}$ photons received over a given period of time Δt can be expressed in units of number of photons per second by

$$\sigma_N = \sqrt{\bar{N}} = \sqrt{\Phi \Delta t} \, . \tag{9.3}$$

We will see later that the relative strengths of different sources of photon noise determine the regimes in which the detector can be operated.

Johnson Noise

Johnson or Nyquist noise is caused by the thermal motion of charge carriers in a resistive element. This is a white source noise. In general, the Johnson noise power transferred through a circuit with an effective frequency bandwidth Δf is described by [9.1]:

$$P_J = kT \Delta f \, , \tag{9.4}$$

where k is the Boltzmann constant and T is the absolute temperature.
Fig. 9.2 Photoconductive detector. Upon illumination, non-equilibrium carriers are created increasing the conductivity of the detector
Fig. 9.3 A schematic of a simple photoemissive detector

The Johnson noise voltage V_J (or current i_J) is the voltage (current) that causes the noise power given by (9.4) to be transferred between two equal noise-producing resistors R. Alternatively, the Johnson noise voltage (current) can be calculated from statistical mechanics using the expression for the noise power spectrum of a classical system at equilibrium [9.2]

$$V_J = \sqrt{4kTR\Delta f} \quad \text{and} \quad i_J = \sqrt{\frac{4kT\Delta f}{R}} \, . \tag{9.5}$$

Shot Noise

The shot noise generated in a detector is due to the discrete (stochastic) nature of photoelectron generation. The variance of the shot noise current is

$$i_{sh}^2 = \frac{q^2}{\Delta t^2} \overline{(n - \bar{n})^2} = \frac{q^2 \bar{n}}{\Delta t^2} = 2qI\Delta f \, , \tag{9.6}$$
Fig. 9.4 An example of a charge transfer sensor. Each active pixel of the sensor is a capacitor consisting of a electrode (poly-Si or semitransparent metal film) at the top, then an insulating layer of thickness x_i, and a semiconductor layer underneath. Light penetrates the semiconductor bulk through the semitransparent electrode and generates nonequilibrium carriers in the semiconductor bulk. By applying a gate voltage V_G, the nonequilibrium carriers can be separated and stored in the potential well underneath each electrode separately

in which q is the elementary charge, n and $\bar{n}$ are the immediate and average numbers of photoexcited carriers produced in a time period Δt, the photon statistics are assumed to be Poissonian (meaning that $\overline{(n-\bar{n})^2} = \bar{n}$), and the mean photocurrent is $I = \bar{n}q/\Delta t = 2\bar{n}q\Delta f$. Finally, the shot noise for the detector is

$$i_{\mathrm{sh}} = \sqrt{2qI\Delta f} \,. \tag{9.7}$$

The shot noise is a white source noise and the expression (9.7) can be integrated over the whole bandwidth of interest Δf to get the total shot noise of the detector. This equation is usually applied only to photon detectors that contain a potential barrier, such as photovoltaic detectors.

Generation–Recombination Noise
The generation–recombination noise is an analog of the shot noise that is applicable to the photoconductor. This type of noise is caused by fluctuations in the generation and recombination of current carriers (due to photons, thermal generation, etc.), and it is expressed by [9.2]

$$i_{\mathrm{G-R}} = 2I\left(\frac{\tau\Delta f}{n\left[1+(2\pi f\tau)^2\right]}\right)^{1/2} \,, \tag{9.8}$$

where the mean current I is due to all sources of current carriers, τ is the carrier lifetime, n is the total number of free carriers, and f is the frequency at which the noise is measured. This type of noise is not a white noise source, since there is a clear frequency dependence. It can be shown that the total generation–recombination shot noise contribution for the photoconductor depends on the photoconductive gain G (which is the number of electrons generated per initial photogenerated electron), and this type of noise can be approximated by

$$i_{\mathrm{G-R}} = 2\sqrt{qIG\Delta f} \tag{9.9}$$

for the white noise limit case $\left[(2\pi f\tau)^2 \ll 1\right]$. In the opposite case $\Delta f\tau \to \infty$, the generation–recombination shot noise contribution approaches the limit

$$i_{\mathrm{G-R}} = \frac{qIG}{\tau} \,. \tag{9.10}$$

1/f Noise
This noise is also known as flicker noise. The power spectrum of this noise falls rapidly with frequency (according to $1/f$). The origin of this noise is not well understood, but is often attributed to imperfect ohmic contacts or to surface-state traps and dislocations [9.1].

The $1/f$ noise component does not present a fundamental limit to sensitivity. The $1/f$ noise can be reduced to negligible levels using current device technology.

Temperature Fluctuations
In thermal detectors, any fluctuations in the temperature of the detection element that are not due to a change in the signal will produce additional noise in the output signal. The temperature fluctuations can be expressed using the analogy with the shot generation–recombination current (9.8), in which the carrier lifetime is substituted by the heat relaxation time constant $\tau_{\mathrm{H}} = \Theta/K$, where K stands for the thermal conductance and Θ is the heat capacity:

$$T_{\mathrm{rms}} = 2\left(\frac{Kk\bar{T}^2\Delta f}{K^2+(2\pi f\Theta)^2}\right)^{1/2} \,, \tag{9.11}$$

In (9.11) we used the notation $\bar{T}$ for the average temperature of the detector.

Microphonic Noise
The microphonic noise is caused by the mechanical displacement of wiring and other components of the detector. Mechanical vibrations in the detector may cause capacitance changes in detection elements, which is the main reason for microphonic noise.

9.1.3 Detection Regimes

Common problems encountered with any type of optical detector include deciding how best to terminate the photodetector with a suitable load resistor and finding the optimum tradeoff between the bandwidth and signal-to-noise ratio.

If we consider the equivalent circuit of a photodetector terminated with a load resistor R_{L}, then the output voltage $V = IR_{\mathrm{L}}$ has a bandwidth ($-3\,\mathrm{dB}$ high-frequency cutoff) given by

$$\Delta f = \frac{1}{2\pi R_{\mathrm{L}}C} \,, \tag{9.12}$$

where C is a stray capacitance across the photodetector.

Two main noise contributions are added to the signal. One is the Johnson noise (9.5) of the load resistance $R = R_{\mathrm{L}}$; the other is the shot noise ((9.7) in the case of a photovoltaic detector or (9.8) in the case of a photoconductor). To calculate the shot noise (generation–recombination) current, one should take into account the total photocurrent under illumination, which is the sum of the signal current I_{p} and the dark

current I_{dark}:

$$I_{\text{light}} = I_{\text{p}} + I_{\text{dark}} . \tag{9.13}$$

Since the Johnson noise and shot noise are statistically independent, the resulting quadratic mean value of the noise current for the most general case of a photodetector with an intrinsic gain G is

$$i_{\text{n}}^2 = 2q(I_{\text{p}} + I_{\text{dark}})\Delta f G^2 F + \frac{4kT\Delta f}{R_{\text{L}}} . \tag{9.14}$$

For detectors with no intrinsic amplification, the gain $G = 1$ and the excess noise factor $F = 1$.

From (9.12) and (9.14) it can be seen that bandwidth and noise optimization imposes opposite requirements on the value of R_{L}. The largest possible R_{L} is required to minimize the noise current; on the other hand, the smallest possible R_{L} must be used in order to maximize Δf.

It is generally accepted that the best possible detector sensitivity is achieved when the shot noise is greater than the Johnson noise, i. e.,

$$2q(I_{\text{p}} + I_{\text{dark}})\Delta f G^2 F \geq \frac{4kT\Delta f}{R_L} , \tag{9.15}$$

which implies a certain limiting condition on the minimum value of the load resistor. Using (9.14), the signal-to-noise ratio of the detector is calculated as the ratio of the average signal photocurrent $I = I_{\text{p}}G$ to the total noise current i_{n}

$$\frac{S}{N} = \frac{I}{i_{\text{n}}}$$
$$= \frac{I_{\text{p}}G}{\left(2q\left(I_{\text{p}} + I_{\text{dark}}\right)\Delta f G^2 F + \frac{4kT\Delta f}{R_{\text{L}}}\right)^{1/2}} . \tag{9.16}$$

Analyzing (9.16), two detection regimes can be defined, according to whether the signal I_{p} is larger or smaller than the value

$$I_0 = I_{\text{dark}} + \frac{2kT}{qR_{\text{L}}FG^2} . \tag{9.17}$$

Assuming $I_{\text{p}} \gg I_0$ and $F = 1$, we obtain

$$\frac{S}{N} = \left(\frac{I_{\text{p}}}{2q\Delta f}\right)^{1/2} , \tag{9.18}$$

where the S/N value is called the *quantum noise limit* of detection. This limit cannot be overcome by any detection system. In fact, (9.18) is a direct consequence of the quantum nature of light and Poissonian photon statistics.

In the small signal regime, $I_{\text{p}} \ll I_0$, the signal-to-noise ratio is

$$\frac{S}{N} = \frac{I_{\text{p}}}{(2qI_0\Delta f)^{1/2}} , \tag{9.19}$$

which is the *thermal noise limit* of detection.

9.1.4 Figures of Merit

Certain figures of merit are used to compare the performances of detectors of the same type. One such figure – the signal-to-noise ratio – was introduced in the previous section. Here we will consider other important figures of merit that are generally applicable to almost all photodetectors.

Responsivity

The responsivity $\mathfrak{R}$ is the ratio of the detector output (in amperes or volts) to the intensity of the input optical flux Φ_{p} (in watts). For example, the spectral photocurrent responsivity $\mathfrak{R}_{\text{I}}(\lambda, f)$ of the detector at a given wavelength is

$$\mathfrak{R}_{\text{I}}(\lambda, f) = \frac{I_{\text{p}}}{\Phi_{\text{p}}(\lambda)} , \tag{9.20}$$

where I_{p} is the measured photocurrent. The blackbody responsivity $\mathfrak{R}(T, f)$ is the detector output divided by the incident radiant power from a blackbody source of temperature T modulated at a frequency f that produces the observed output [9.3]

$$\mathfrak{R}_{\text{I}}(T, f) = \frac{I_{\text{p}}}{\int_0^{\alpha}\int_{\lambda}\Phi_{\text{p}}(\lambda)\,\mathrm{d}\lambda}$$
$$= \frac{I_{\text{p}}}{A_{\text{source}}\sigma_{\text{SB}}T^4 A_{\text{det}}/\pi L^2} , \tag{9.21}$$

in which α is a solid angle at which the detector is seen from the source site, A_{source} and A_{det} are the source and detector areas, respectively, L is the distance between the source and detector, and $\sigma_{\text{SB}} = 5.67032 \times 10^{-12}\,\text{Wcm}^{-2}\,\text{K}^{-4}$ is the Stefan–Boltzmann constant. Note that the blackbody responsivity is a measure of the response of the detector to the incident radiation, integrated over all wavelengths.

Quantum Efficiency

The quantum efficiency η is the probability that a photoelectron is produced when a photon is incident on the detector. For an incident optical power Φ_{p}, which produces a photocurrent $I_{\text{p}} = \mathfrak{R}_{\text{I}}\Phi_{\text{p}}$, the quantum efficiency

is calculated from

$$\eta = \frac{\left(\frac{I_p}{q}\right)}{\left(\frac{\Phi_p}{h\nu}\right)} = \frac{h\nu}{q}\mathfrak{R}_I \, , \tag{9.22}$$

where q is the elementary charge, h is the Planck constant and ν is the photon frequency.

Noise Equivalent Power

The noise equivalent power (NEP) of the detector is the optical power incident on the detector Φ_p required to produce an output signal equal to the noise output. Sometimes the NEP is specified for a bandwidth of 1 Hz. It can also be defined as being the value of the optical input power needed to produce a signal-to-noise ratio of one. Since the current signal output is $I_p = \mathfrak{R}_I\Phi_p$, the signal-to-noise ratio is

$$\frac{S}{N} = \frac{\mathfrak{R}_I\Phi_p}{i_n} \, , \tag{9.23}$$

where the rms noise output current i_n is given by (9.14). Placing the left-hand side of (9.23) to unity, we obtain

$$NEP = \frac{i_n}{\mathfrak{R}_I} \, . \tag{9.24}$$

In cases when the thermal noise dominates over all other noise sources, the system signal-to-noise ratio is described by (9.19). The noise equivalent power in this case defines the value S_0, known as the device sensitivity

$$S_0 = NEP = \frac{2}{\mathfrak{R}_I}\sqrt{\frac{kT\Delta f}{R_L}} = \frac{2h\nu}{\eta q}\sqrt{\frac{kT\Delta f}{R_L}} \, . \tag{9.25}$$

This equation is valid for a photovoltaic device or photoconductor with no intrinsic gain ($G = 1$ and $F = 1$).

In the specific case of photon-limited performance, the system's signal-to-noise ratio is described by (9.18). This mode of operation is typical of photomultiplier tubes, microchannels and some detectors with intrinsic multiplication in the visible and near-infrared spectral ranges. Photon-limited performance is also typical of photovoltaic, photoconductive and some thermal detectors in the infrared spectral range. As mentioned above, the ultimate performance of the detector is reached when the detector noise and amplifier noise are low compared to the photon noise. The photon noise is fundamental,

in the sense that it arises not from any imperfection in the detector or its associated electronics, but rather from the detection process itself, as a result of the discrete nature of the electromagnetic field. The radiation falling on the detector is a combination of that from the target (signal) Φ^S (in number of incident photons per second) and that from the background Φ^B (also in number of incident photons per second). An infrared photon detector that achieves background-limited performance is called a "*background-limited infrared photodetector*" (BLIP). The noise equivalent power is then obtained for the BLIP case from (9.24) and (9.18), using the expression (9.22) for the quantum efficiency η, and by noting that the radiant flux $\Phi_p^{B,S} = \Phi^{B,S}h\nu$

$$NEP_{BLIP} = h\nu\sqrt{\frac{2\Phi^B\Delta f}{\eta}} = \sqrt{\frac{2h\nu\Phi_p^B\Delta f}{\eta}} \, . \tag{9.26}$$

Detectivity

The detectivity D of a detector is the reciprocal of the noise equivalent power:

$$D = \frac{1}{NEP} \, . \tag{9.27}$$

A more useful figure of merit is the specific detectivity D^* ("dee-star"), which does not depend on the detector area A_{det} and bandwidth Δf

$$D* = D\sqrt{A_{det}\Delta f} = \frac{\sqrt{A_{det}\Delta f}}{NEP} \, . \tag{9.28}$$

D^* may be used to directly compare detectors of different sizes whose performances have been measured over different bandwidths. The relationship between the spectral D^* and the blackbody D^* is [9.2]:

$$D^*(T, f) = \frac{\int_0^\infty D^*(\lambda, f)\Phi(T, \lambda)\,d\lambda}{\int_0^\infty \Phi(T, \lambda)\,d\lambda} \, . \tag{9.29}$$

For the BLIP case, any shot noise-limited detector will have an D^* given by

$$D^*_{BLIP}(\lambda, f) = \frac{\sqrt{A_{det}\Delta f}}{NEP_{BLIP}(\lambda, f)} = \frac{1}{h\nu}\sqrt{\frac{\eta A_{det}}{2\Phi^B}} \, . \tag{9.30}$$

9.2 Semiconductor Photoconductors

A photoconductor is a light-sensitive resistor that, at its simplest, can consist of a slab of semiconductor with ohmic contacts on opposite sides (Fig. 9.2). The intrinsic photoelectric effect is the dominant mechanism that creates nonequilibrium carriers in the conduction band of an intrinsic photoconductor. In an extrinsic photoconductor, the excitation of shallow impurity levels is involved. The long-wavelength cutoff for this simple case is given by

$$\lambda_c = \frac{hc}{E_g} , \qquad (9.31)$$

where E_g is the semiconductor bandgap and c is the speed of light. The conductivity of an unilluminated intrinsic semiconductor device is

$$\sigma_0 = n_0 \mu_n q + p_0 \mu_p q , \qquad (9.32)$$

where n_0, p_0, μ_n, and μ_p are the equilibrium concentrations of free electrons and holes and their mobilities, respectively, and q is the elementary charge. The reciprocal value is called the resistivity and is defined as

$$\rho_0 = \left(n_0 \mu_n q + p_0 \mu_p q \right)^{-1} . \qquad (9.33)$$

Under illumination, nonequilibrium carriers are created at a concentration of

$$\Delta n = \Delta p = \frac{\eta_{ex} \Phi \tau}{A_{det} W} , \qquad (9.34)$$

where η_{ex} is the external quantum efficiency, defined above as the probability that a photoelectron is produced when a photon is incident on the detector; Φ is the photon flux in photons per unit time; τ is the carrier lifetime; A_{det} and W are the detector's active area and thickness. Using (9.32) and (9.34), we can obtain the relative change in conductivity of the illuminated photoconductor

$$\frac{d\sigma}{\sigma} = \frac{q \left(\mu_n + \mu_p \right) \eta_{ex} \Phi \tau}{\sigma A_{det} W} . \qquad (9.35)$$

The light-driven change in photoconductor resistance R_{det} is described by

$$dR_{det} = -R_{det} \frac{q \left(\mu_n + \mu_p \right) \eta_{ex} \Phi \tau}{\sigma A_{det} W} . \qquad (9.36)$$

For an extrinsic semiconductor, the sum $\left(\mu_n + \mu_p \right)$ should be replaced with the mobility of the available carrier.

9.2.1 Photoconductors – Figures of Merit

Responsivity
If the load resistor R_L is connected in series with the photoconductor and the two resistors are biased with a DC voltage V_0, then the light-induced voltage drop across a uniformly illuminated photoconductor can be expressed as

$$dV = \frac{V_0 R_L R_{det}}{(R_L + R_{det})^2} \frac{q \lambda \eta_{ex} \tau \left(\mu_n + \mu_p \right)}{\sigma hc A_{det} W} \Phi_p , \qquad (9.37)$$

where Φ_p is the input radiant flux (in watts), λ is the wavelength, h is Planck's constant, and c is the speed of light. The voltage and current spectral responsivities are obtained from (9.37)

$$\Re_V = \frac{dV}{\Phi_p}$$
$$= \frac{Iq\lambda\eta_{ex}\tau \left(\mu_n + \mu_p \right)}{\sigma hc A_{det} W} \frac{R_L R_{det}}{R_L + R_{det}} \, [V/W] , \qquad (9.38)$$

$$\Re_I = \frac{Iq\lambda\eta_{ex}\tau \left(\mu_n + \mu_p \right)}{\sigma hc A_{det} W} \, [A/W] , \qquad (9.39)$$

where $I = \frac{V_0}{R_L + R_{det}}$ is the total DC current through the detector.

Photoconductive Gain
Analyzing the expression (9.39) for the photocurrent responsivity, the photoconductive gain of the intrinsic detector can be defined as

$$G = \frac{I \tau \left(\mu_n + \mu_p \right)}{\sigma A_{det} W} . \qquad (9.40)$$

A similar expression for an extrinsic photoconductor containing carriers with a mobility value μ is

$$G = \frac{\tau \mu E}{d} = \frac{\tau}{t} , \qquad (9.41)$$

where $E = I/\sigma A_{det} W$ is the electric field across the detector, d is the spacing between the electrodes, and $t = d/\mu E$ is the total carrier transit time between the two electrodes, assuming that the electric field is far from saturation.

Noise
1/f Noise. The $1/f$ dependence holds for the noise power. The noise current/voltage varies as $1/\sqrt{f}$. This

noise is always present in photoconductors since they operate at bias current. The empirical equation obtained for the mean square noise current is [9.3]

$$\overline{i_{1/f}^2} = \frac{\text{const} \cdot I^2 \Delta f}{f^\beta} \, , \tag{9.42}$$

where const is a proportionality constant, Δf and f are the bandwidth and frequency respectively, and β is a constant close to 1.

Johnson Noise. For a semiconductor with an internal resistance of R_{det}, the Johnson noise mean square current is expressed by the right-hand side of (9.5).

Generation–Recombination Noise. The mean square generation–recombination noise current due to photon and thermal excitations of the semiconductor is given by [9.4]

$$\overline{i_{\text{G--R}}^2} = 4q \left(q\eta_{\text{ex}} \Phi A_{\text{det}} G^2 + q G_{\text{th}} G^2 \right) \, , \tag{9.43}$$

where Φ is the incident photon flux, G is the gain, and G_{th} is the thermal generation rate.

Noise Equivalent Power (NEP)
The signal-to-noise ratio for the conductor can be obtained via (9.5) and (9.43) as

$$\frac{\text{S}}{\text{N}} = \frac{\mathfrak{R}_{\text{I}} \Phi_{\text{p}}}{i_{\text{n}}} = \frac{\mathfrak{R}_{\text{I}} h\nu \Phi}{\sqrt{\overline{i_{\text{J}}^2} + \overline{i_{\text{G--R}}^2}}} \, , \tag{9.44}$$

where $\mathfrak{R}_{\text{I}}$ is the current responsivity given by (9.39), and $\Phi_{\text{p}} = h\nu\Phi$ is the incident radiant power. The related figure of merit – NEP – can be obtained from (9.44) by setting $\frac{\text{S}}{\text{N}} = 1$.

In the case of a photon-limited conductor, the noise equivalent power is determined by the generation–recombination noise current, and it can be expressed using (9.26) and (9.24)

$$\text{NEP} = \frac{\sqrt{\overline{i_{\text{G--R}}^2}}}{\mathfrak{R}_{\text{I}}} = h\nu \sqrt{\frac{2\Phi^{\text{S,B}} \Delta f}{\eta_{\text{ex}}}} \, , \tag{9.45}$$

where $\Phi_{\text{S,B}}$ is the input signal/background photon flux per unit time on the detector. In the case where the Johnson noise is dominant,

$$\text{NEP} = \frac{\sqrt{\overline{i_{\text{J}}^2}}}{\mathfrak{R}_{\text{I}}} = \frac{h\nu}{q\eta_{\text{ex}} G} \sqrt{2kT \Delta f \left(\frac{1}{R_{\text{det}}} + \frac{1}{R_{\text{L}}} \right)} \, . \tag{9.46}$$

Detectivity
The specific detectivity for the photon-limited conductor is determined by the expression

$$D^*(\lambda, f) = \frac{1}{h\nu} \sqrt{\frac{\eta_{\text{ex}} A_{\text{det}}}{2\Phi^{\text{S,B}}}} \, . \tag{9.47}$$

For the Johnson noise limited conductor, the corresponding specific detectivity is

$$D^*(\lambda, f) = \frac{q\eta_{\text{ex}} G}{h\nu} \sqrt{\frac{A_{\text{det}}}{2kT} \left(\frac{R_{\text{L}} R_{\text{det}}}{R_{\text{L}} + R_{\text{det}}} \right)} \, . \tag{9.48}$$

9.2.2 Photoconductors: Materials and Examples

Lead–Salt-Based Compound Photoconductors
PbS, PbSe, and PbTe cells are the most common examples of semiconductor-based photoconductors. They are sensitive to infrared radiation, have high quantum efficiencies, fast time responses, and can operate at room temperature. Cooled lead salt photoconductors have detectivities that are close to the background limit.

Lead-salt-based photodetectors are manufactured through either chemical deposition or the evaporation of thin ($\approx 1\,\mu\text{m}$) polycrystalline layers of lead salts. The layers are usually sensitized by the controlled introduction of oxygen. It was found that the conductivity of the film changes from n-type to p-type with increasing exposure to oxygen at 300 K.

By controlling parameters such as the dopants used, the deposition temperature, the passivation coating used, and the film thickness, performance characteristics such as resistance, responsivity, time response, spectral response range, noise, and signal-to-noise ratio can be tailored over a wide range. The wavelengths of peak response for different lead salt photodetectors can be tuned within the range of $\approx 2.4\,\mu\text{m}$ to $> 5\,\mu\text{m}$. The spectral response can be extended into infrared by cooling the detector due to the positive temperature coefficient of the energy gap [9.5].

Mercury Cadmium Telluride (MCT) Photoconductors
MCT photoconductors ($\text{Hg}_{1-x}\text{Cd}_x\text{Te}$) that operate over different spectral regions can be created simply by tuning the Cd/Hg ratio. The photoconductive $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ detector is a good intrinsic detector and can achieve background-limited sensitivities at operating temperatures substantially higher than extrinsic detectors.

$Hg_{1-x}Cd_x$Te photoconductors are typically fabricated from n-type material with an excess concentration of ionized donors of about $10^{14}\,cm^{-3}$ [9.1]. This large intrinsic carrier concentration is the result of excess mercury atoms that exceed the stoichiometry and reside interstitially in the lattice. For a typical $Hg_{1-x}Cd_x$Te detector with a square optically active area and a thickness of $10\,\mu m$, the resistance is rather small ($\approx 200\,\Omega$). The disadvantage of such a low-resistance detector is that high currents can flow with relatively low voltage, which produces high dissipation power and limits the detector to applications in the low voltage range.

Selenium Photoconductors

Amorphous selenium (α-Se) is widely used to build the photoconductor arrays used in direct conversion systems for γ-radiation detection.

9.3 Semiconductor Photodiodes

Semiconductor photodiodes are the most popular photodetectors; they are capable of operating in both photovoltaic and photoconductive modes.

9.3.1 Semiconductor Photodiode Principles

p–n Diode in Thermal Equilibrium

Semiconductor photodiodes can be considered to be a variation on regular p–n junction diodes. The p–n junction is obtained by joining together oppositely doped semiconductors. Once in contact, thermodynamic equilibrium is attained by lining up the Fermi levels across the whole structure. Electrons from the n-type semiconductor diffuse into the p region and holes from the p-type semiconductor into the n region, and so a surplus is created of negative electric charge in the p region and a surplus of positive charge in the n region. This creates an electric field that sweeps mobile charges out of the junction region, creating a so-called "space-charge region" depleted of mobile carriers (Fig. 9.5).

Using the band model, the requirement to line up the Fermi levels of n-type and p-type semiconductor species results in a built-in potential V_{bi}, which for the thermal equilibrium case is given by [9.6]

$$V_{bi} = \frac{1}{q}\left(E_i^p - E_i^n\right) = \frac{kT}{q}\ln\frac{N_A N_D}{n_i^2}, \qquad (9.49)$$

where E_i^p and E_i^n are the intrinsic levels in the neutral p and n regions, N_A and N_D are the acceptor and donor dopant concentrations, and n_i is the intrinsic carrier density, which is obtained using the values for the energy bandgap E_g and the effective densities of states N_V and N_C in the valance band and conduction bands, respectively

$$n_i = \sqrt{N_V N_C}\exp\left(-\frac{E_g}{2kT}\right), \qquad (9.50)$$

$$N_V = 2\left(\frac{2\pi m_p kT}{h^2}\right)^{3/2} \text{ and}$$

$$N_C = 2\delta\left(\frac{2\pi m_n kT}{h^2}\right)^{3/2}. \qquad (9.51)$$

The effective masses of the electrons m_n and holes m_p as well as the conduction band degeneracy factor δ (the number of equivalent minima in the conduction band) are specific to each semiconductor.

The space-charge region (depletion region) extends from the junction into the n and p regions. For the simplest case of a two-sided abrupt junction, the width $w = w_n + w_p$ (Fig. 9.5) of the depletion region is found from the requirement that the electric field at the boundary of the space-charge region is zero, and that the potential difference equals the built-in voltage

$$w = w_n + w_p = \sqrt{\frac{2\varepsilon\varepsilon_0\left(N_A + N_D\right)}{qN_A N_D}V_{bi}}, \qquad (9.52)$$

where ε_0 is the vacuum permittivity, ε is the semiconductor dielectric constant, and w_n and w_p are the space-charge region widths of the n-type and p-type regions of the semiconductor, separated by the junction.

p–n Diode with External Bias

For a forward bias V, the voltage across the junction will decrease from the equilibrium value V_{bi} to $(V_{bi} - V)$, and the width of the space-charge region will shrink correspondingly. For the reverse bias condition, the voltage across the junction will increase to the value $(V_{bi} + V)$, causing an expansion of the space-charge region. The width of the space-charge region (depletion region) for an external bias V is given by

$$w = \sqrt{\frac{2\varepsilon\varepsilon_0\left(N_A + N_D\right)}{qN_A N_D}\left(V_{bi} \mp V\right)}, \qquad (9.53)$$
Fig. 9.5a–c An abrupt p–n junction in thermal equilibrium.**(a)** Space-charge distribution: *small circles* show mobile electrons and holes, *large circles* indicate ionized donors and acceptors; **(b)** energy band diagram; **(c)** electric field distribution

in which the $\mp$ signs are for the forward- and reverse-bias conditions, respectively.

The total current density J for the ideal photodiode is expressed by the Shockley equation (curve 1 in Fig. 9.6) [9.6]

$$J = J_S \left[\exp\left(\frac{qV}{kT}\right) - 1 \right]$$
$$\equiv q \left(\frac{n_{p0} D_n}{L_n} + \frac{p_{n0} D_p}{L_p} \right) \left[\exp\left(\frac{qV}{T}\right) - 1 \right],$$
$$(9.54)$$

where J_s is the so-called saturation current density, n_{p0} and p_{n0} are the minority carrier concentrations at equilibrium in the p and n regions, respectively, and the carrier diffusion constants D_n and D_p are given by the Einstein relationship

$$D_n = \frac{kT}{q} \mu_n \quad \text{and} \quad D_p = \frac{kT}{q} \mu_p ,$$
$$(9.55)$$

in which μ_n and μ_p are the carrier mobilities. The carrier diffusion lengths L_n and L_p are

$$L_n = \sqrt{D_n \tau_n} \quad \text{and} \quad L_p = \sqrt{D_p \tau_p}$$
$$(9.56)$$

where τ_n and τ_p describe the electron and hole lifetimes. The equilibrium concentration of minority carriers is
Fig. 9.6 I–V characteristics of an ideal photodiode in the dark (1) and under illumination (2)

determined from $p_{n0} = (n_i^2 / n_{n0}) \approx (n_i^2 / N_D)$ for the n-type semiconductor and $n_{p0} = (n_i^2 / p_{p0}) \approx (n_i^2 / N_A)$ for the p-type semiconductor.

Equation (9.54) was obtained for an ideal photodiode with an abrupt junction, using the Boltzmann approximation for carrier concentrations throughout the space-charge layer, assuming that the minority carrier densities are small compared to those of the majority carrier (a low injection assumption), and assuming no generation–recombination current in the space-charge area, which imposes a related requirement on the constant electron and hole currents through the depletion layer.

Using (9.53), one can obtain an expression for the depletion layer capacitance per unit area, which is one of the main parameters that determines the time response of the semiconductor photodiode. For a two-sided abrupt junction,

$$C_j = \frac{\varepsilon\varepsilon_0}{w} = \sqrt{\frac{\varepsilon\varepsilon_0 q N_A N_D}{2 (N_A + N_D)(V_{bi} \mp V)}} . \qquad (9.57)$$

p–n Diode Under Illumination

To derive the total photocurrent generated in the bulk of a p–n semiconductor diode, assuming a very shallow p layer on top of the n-type substrate and neglecting the thermally generated current, one must separately consider the photocurrent generated in the space-charge region (of width w) the photocurrent from the neutral region of the bulk of the semiconductor.

Case 1 – Front-Illuminated Photodiode. First consider the situation where light penetrates the photodiode bulk from the p side and the surface p^+ layer is much thinner than the light absorption length $1/\alpha (\delta \ll 1/\alpha$; α is the absorption coefficient) (Fig. 9.7, panel a). This case is typical of so-called front-illuminated photodiodes. Also assume that the crystal thickness is much larger than

the light penetration depth, meaning that all light quanta are absorbed during a single passage inside the crystal. We will also neglect the effects of surface carrier recombination to simplify our considerations.

The e–h pairs generated in the space-charge region of the p–n junction by light absorption are separated by the electric field, giving rise to a drift photocurrent J_{dr}. Those carriers that are generated in the neutral, undepleted part of the semiconductor bulk ($x > w$) may also reach the space-charge region via the diffusion mechanism if the diffusion distance is shorter then the carrier diffusion depth L_n or L_p. This current is treated as the diffusion current J_{diff}.

The electron–hole photogeneration rate $G(x)$ in the semiconductor bulk at a distance x from the surface is determined from

$$G(x) = \frac{\partial \Phi(x)}{\partial x} \, dx = \Phi_0 \alpha \exp(-\alpha x) \,, \qquad (9.58)$$

in which Φ_0 is the incident optical photon flux per unit area, α is the absorption coefficient, and $\Phi(x) = \Phi_0 \exp(-\alpha x)$ (in accord with the Beer–Lambert law) is the photon flux inside the semiconductor bulk at a distance x from the photodiode surface. The drift current is then

$$J_{dr} = -q \int_0^w G(x)\,dx = q\Phi_0 \left[1 - \exp(-\alpha w)\right] \,.$$
$$\qquad (9.59)$$

For $x > w$, the minority carrier density p_n in the semiconductor bulk is determined by the one-dimensional diffusion equation

$$D_p \frac{\partial^2 p_n}{\partial x^2} - \frac{p_n - p_{n0}}{\tau_p} + G(x) = 0 \,. \qquad (9.60)$$

Since the sample thickness was assumed to be much thicker than $1/\alpha$, the boundary condition at $x = \infty$ is $p_n = p_{n0}$. The boundary condition at $x = w$ is also $p_n = p_{n0}$ because the electric field in the depletion region sweeps away nonequilibrium carriers effectively. Hence, the solution to (9.60) for $x > w$ is given by

$$p_n = p_{n0} - A \exp(-\alpha w) \exp\left\{\frac{w - x}{L_p}\right\}$$
$$+ A \exp(-\alpha x) \,, \qquad (9.61)$$

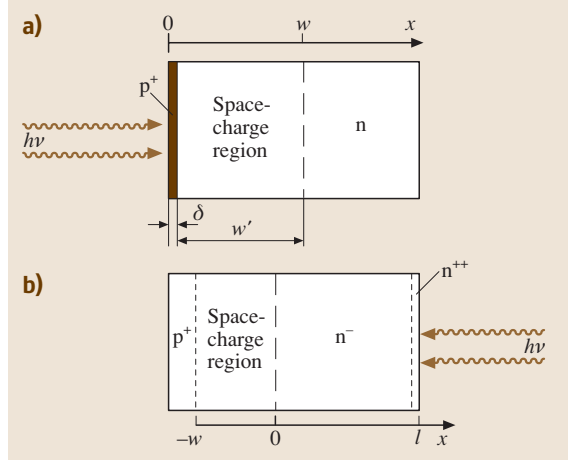
$$A = \frac{\Phi_0}{D_p} \frac{\alpha L_p^2}{\left(1 - \alpha^2 L_p^2\right)} \,. \qquad (9.62)$$


Fig. 9.7 (a) Operation of a front-illuminated p/n junction photodiode. The junction depth δ is very small, so $w \approx w'$. The drift photocurrent originates in the space-charge region and the diffusion current comes from the undepleted n region; **(b)** Back-illuminated photodiode operation. The carrier injection occurs from the back surface of the diode, assuming that the photocurrent only contains the diffusion component

The diffusion current density is then

$$J_{diff} = -qD_p \left(\frac{\partial p_n}{\partial x}\right)_{x=w}$$
$$= q\Phi_0 \frac{\alpha L_p}{1 + \alpha L_p} \exp(-\alpha w) \,. \qquad (9.63)$$

Combining (9.59) and (9.63) yields the total photocurrent density

$$J_p = J_{dr} + J_{diff} = q\Phi_0 \left(1 - \frac{\exp(-\alpha w)}{1 + \alpha L_p}\right) \,, \qquad (9.64)$$

which shows that the photocurrent J_p is proportional to the incident photon flux Φ_0.

If the thermally generated current (9.54) is not negligible, then the total photodiode current is

$$J_{total} = q \left(\frac{n_{p0} D_n}{L_n} + \frac{p_{n0} D_p}{L_p}\right)$$
$$\times \left[\exp\left(\frac{qV}{kT}\right) - 1\right] + J_p \qquad (9.65)$$

and the corresponding typical current–voltage ($I - V$) characteristic of the photodiode under illumination is shown in Fig. 9.6, curve 2.

If the external leads of the photodetector are shorted, the voltage across the junction is maintained at the built-in potential level and photocurrent will flow. This current

is called the *short circuit current* (J_{sc}) and it can be approximated from (9.65) by putting $V = 0$

$$J_{sc} \cong J_p \ . \tag{9.66}$$

On the other hand, if the leads are open, the voltage across the junction will drop to such a value that the flow of photogenerated carriers is compensated for by an increase in the diffusion current given by (9.54). This voltage change appears as an output voltage on the device leads and is called the *open circuit voltage* (V_{oc}), which, ignoring the change of the depletion width under illumination, can be calculated from (9.65) by placing $J_{total} = 0$:

$$V_{oc} = \frac{kT}{q} \ln \left(\frac{\Phi_0 \left(\exp(-\alpha w)/(1 + \alpha L_p^{-1}) \right)}{(n_{p0} D_n)/L_n + (p_{n0} D_p)/L_p} \right) \ . \tag{9.67}$$

Case 2 – Back-Illuminated Photodiode. In this case, the junction is created on one side of the semiconductor crystal and light penetrates from the other side of the structure. It is interesting to consider the situation when light is absorbed mostly in the neutral region of the semiconductor. To further simplify the description, assume that absorption occurs within a very thin surface layer of the photodiode's backside (absorption coefficient $\alpha \to \infty$). This means that the carrier surface photogeneration rate is described by the δ function

$$G(x) = \Phi_0 \alpha \exp\left[-\alpha \left(l - x \right) \right] \delta(x - l) \ , \tag{9.68}$$
Fig. 9.8 (a) Biased p–i–n photodiode and **(b)** electric field distribution at reverse bias conditions. The depletion width w and the maximum field strength E_m depend on the magnitude of the reverse bias applied. The slope of the electric field distribution in each region depends on the donor/acceptor concentration

where l is the distance between the edge of the depletion region and the surface to which light penetrates (Fig. 9.7, panel b). We will also account for the surface recombination events, which may be important in back-illuminated diodes with extended diffusion regions.

Since the excess carriers are extracted at the edge of the depletion region, the boundary condition at $x = 0$ is $p_n = p_{n0}$. The other boundary condition is obtained from the diffusion current at the surface

$$J_{diff} \mid_{x=c} \equiv qD_p \left(\frac{\partial p_n}{\partial x} \right)_{x=l}$$
$$= q\Phi_0 - qS_r \left[p_n(l) - p_{n0} \right] \ , \tag{9.69}$$

where S_r is the surface recombination rate in cm/s and $p_n(l)$ is the minority carrier concentration at the surface. For the boundary conditions chosen, the solution to the diffusion equation is

$$p_n = p_{n0}$$
$$+ \frac{\Phi_0 \left(1 - \frac{S_r}{D_p} \alpha \delta(x-l) L_p^2 \right) \sinh(x/L_p)}{(D_p/L_p) \cosh\left(l/L_p \right) + S_r \sinh\left(l/L_p \right)}$$
$$+ \frac{\Phi_0 \alpha \delta(x-l) L_p^2}{D_p} \ . \tag{9.70}$$

The photocurrent in this case contains the diffusion component only and is calculated as

$$J_p = J_{diff} \mid_{x=0} = qD_p \left(\frac{\partial p_n}{\partial x} \right)_{x=0}$$
$$= \frac{q\Phi_0}{\cosh(\frac{l}{L_p}) + \frac{S_r L_p}{D_p} \sinh(\frac{l}{L_p})} \ . \tag{9.71}$$

p–i–n Photodiode

The efficiency of the transfer of nonequilibrium carriers into the external circuit is much higher in the space-charge region than in the neutral region of the semiconductor. The width w of the space-charge region increases as $(\sqrt{N_{A,D}})^{-1}$ as the donor/acceptor concentrations $N_{A,D}$ decrease; see (9.53). The space-charge layer width will be maximized if an intrinsic layer is inserted between the p-type and n-type layers, resulting in a *p–i–n* structure like that shown in Fig. 9.8. In practice, an intrinsic layer is often substituted for a low-implant concentration layer. The behavior of such a *p–i–n* photodiode is described by the same equations as presented above; however, those equations can be simplified in some cases because the dopant concentrations on different sides of the junction are significantly different.

Part B | 9.3

9.3.2 Photodiodes – Figures of Merit

Quantum Efficiency and Responsivity

The external quantum efficiency of the photodiode is defined as the ratio of the number of carriers producing photocurrent to the number of incident photons Φ_0. Using this definition and (9.64), we obtain for the front-illuminated photodiode

$$\eta_{ex} = \frac{(J_p/q)}{\Phi_0} = 1 - \frac{\exp(-\alpha w)}{1 + \alpha L_p} \, . \tag{9.72}$$

Note that the right-hand side of (9.72) is valid for a relatively large value of αw when light is completely absorbed during the first passage through the semiconductor bulk and nothing is reflected from the backside of the die.

For the case of a back-illuminated photodiode, as described above, the external quantum efficiency is obtained from (9.71):

$$\eta_{ex} = \frac{(J_p/q)}{\Phi_0} = \left[\cosh(\frac{l}{L_p}) + \frac{S_r L_p}{D_p} \sinh(\frac{l}{L_p}) \right]^{-1} . \tag{9.73}$$

The internal quantum efficiency is defined as the ratio of the number of electron–hole pairs generated by the light to the number of photons absorbed in the semiconductor bulk:

$$\eta_{in} = \frac{\eta_{ex}}{(1 - R_F)} = \frac{(J_p/q)}{\Phi_0(1 - R_F)} \, , \tag{9.74}$$

where R_F is the reflection coefficient of the light incident surface.

The photodiode current responsivity is the ratio of the total output photocurrent I_p (in amperes) to the incident optical power Φ_p (in watts):

$$R_I = \frac{I_p}{\Phi_p} = \frac{\eta_{ex} q}{h\nu} = \frac{\eta_{ex} q \lambda}{hc} \approx \frac{\eta_{ex} \lambda [\mu m]}{1.24} [\text{A/W}] \, , \tag{9.75}$$

where ν is the photon frequency, c is the speed of light in a vacuum, and λ is the wavelength in micrometers.

Carrier Collection Efficiency Function

The internal quantum efficiency $\eta_{in}(\lambda)$ of an ideal photodiode for the case $\alpha w \gg 1$, when all penetrating quanta of light are absorbed by the crystal (of thickness h), and all nonequilibrium carriers participate in the photocurrent, can be calculated using a simple expression

$$\eta_{in}(\lambda) = 1 - \exp\left[-\alpha(\lambda) h\right]$$

$$\equiv \int_0^h dx \, \alpha(\lambda) \exp\left[-\alpha(\lambda) x\right] \tag{9.76}$$

in which x is the photodiode penetration depth starting from the surface. In a real (nonideal) structure, not all of the photogenerated nonequilibrium carriers are collected by the external circuit and participate in the current. This effect is accounted for by the carrier collection efficiency function $P(x)$ [9.7]

$$\eta_{in}(\lambda) = \int_0^h dx \, P(x)\alpha(\lambda) \exp\left[-\alpha(\lambda)x\right] . \tag{9.77}$$

When $\alpha w \gg 1$, the light passes through the photodiode crystal more than once and the expression for the quantum efficiency needs to be modified. When two passages occur, we obtain [9.8]

$$\eta_{in}(\lambda) = \int_0^h dx \, P(x)\alpha(\lambda) \exp\left[-\alpha(\lambda)x\right]$$

$$+ R_B \exp\left[-\alpha(\lambda)h\right]$$

$$\times \int_0^h dx \, P(h - x)\alpha(\lambda) \exp\left[-\alpha(\lambda)x\right] , \tag{9.78}$$

in which the first term on the right-hand side describes the number of carriers collected into the external circuit due to the first passage of radiation inside the crystal, while the second term describes the corresponding number for the radiation reflected back into the crystal from the rear surface of the die (R_B is the die backside reflection coefficient). The backside reflection is considered to be specular reflection here. Assuming that the quantum efficiency $\eta_{in}(\lambda)$ is known from experiment, the carrier collection efficiency function can be retrieved from (9.78) [9.9]. Note that, usually, $P(x) = 1$ inside
Fig. 9.9 Simplified equivalent circuit of the photodiode

the depletion region, except for the thin surface layer of the photodiode. The expression (9.78) can be easily extended to the case of multiple passages of light inside the semiconductor photodiode bulk.

Shunt Resistance, Series Resistance, and Forward Characteristics

The photodiode equivalent circuit can be thought of as a source of current with a source (or shunt) resistance R_{sh} connected in parallel to it, and a series (or forward) resistance R_s (Fig. 9.9). For the ideal photodiode, $R_{sh} = \infty$ and $R_s = 0$. The photodiode shunt resistance is defined as the dynamic resistance at the origin, and it can be calculated from (9.54)

$$R_{sh} = \frac{\partial V}{\partial I}\Big|_{V=0} = \frac{kT}{qJ_sA_j} \tag{9.79}$$

where A_j is the junction area and J_s is the saturation current density. The shunt resistance is an important characteristic of any photodiode, since it defines the thermal noise current.

The series resistance R_s of a photodiode is defined as the sum of the total resistance R_{cont} of the ohmic contacts and the resistance of the undepleted semiconductor bulk. In the most general case, the series resistance can be expressed as

$$R_s = \frac{1}{A_j}\int_{x_1}^{x_2} \rho(x)\,dx + R_{cont}, \tag{9.80}$$

where $\rho(x)$ is the semiconductor bulk resistivity, x_1 is the depletion layer edge and x_2 is the semiconductor bulk boundary. For a planar structure with a shallow abrupt junction like that shown in Fig. 9.5, the series resistance can be calculated as

$$R_s \approx \frac{d-w}{A_j}\rho + R_{cont}, \tag{9.81}$$

where d is the substrate thickness, w is the space-charge region width given by (9.53), and ρ is the substrate resistivity, which is $\rho_n = (n\mu_n q)^{-1}$ for the n-type substrate and $\rho_p = (p\mu_p q)^{-1}$ for the p-type substrate.

As it is evident from the Shockley equation (9.54), the junction resistance for the ideal semiconductor diode $R_j = (\partial V/\partial I)$ approaches zero as the forward voltage increases. However, (9.54) does not account for the generation and recombination of carriers in the depletion region, high-injection conditions, imperfect ohmic contacts. These three factors can significantly alter the forward current, even for a relatively small forward bias.

The major recombination–generation process in the depletion region is the capture of the injected carriers, which adds the recombination current J_{rec} to the Shockley equation. It can be shown that this current is proportional to the intrinsic carrier density n_i, the trap density N_T, the carrier capture cross-section σ_{capt}, and the carrier thermal velocity $v_{th} = \sqrt{(3kT/m^*)}$ (with m^* representing for the carrier effective mass) [9.6]

$$J_{rec} \approx \frac{qw}{2}\sigma_{capt}v_{th}N_T n_i \exp\left(\frac{qV}{2kT}\right). \tag{9.82}$$

Combining (9.82) and (9.54), the forward current J_f for the p–n structure can be approximated for $p_{n_0} \gg n_{p_0}$ and $V_f > (kT/q)$ by

$$J_f \approx q\sqrt{\frac{D_p}{\tau_p}}\frac{n_i^2}{N_D}\exp\left(\frac{qV_f}{kT}\right)$$
$$+ \frac{qw}{2}\sigma_{capt}v_{th}N_T n_i \exp\left(\frac{qV_f}{2kT}\right). \tag{9.83}$$

In general, the experimental forward current can be fitted by the dependence

$$J_f \propto \exp\left(\frac{qV_f}{\gamma kT}\right), \tag{9.84}$$

where γ is an ideality factor that equals 2 when the recombination current dominates and is closer to 1 when the diffusion current becomes dominant. Equation (9.84), which relates the forward current and voltage, is used to estimate how close the photodiode properties are to those of an ideal photodiode.

Breakdown Voltage

As follows from the Shockley equation, the reverse bias current saturates at high voltages if the diffusion of minority carriers into the space-charge region is the only mechanism that builds up the reverse dark current. An additional increase in the reverse dark current occurs due to the generation of carriers in the space-charge region, which may result from the thermal generation of carriers in either the semiconductor substrate itself or within various defects in the semiconductor volume. The latter effect depends on the defects/impurity concentration, while the former can be expressed via the thermal generation rate G_{th} as

$$G_{th} = \beta n_0 p_0 = \beta n_i^2 = \frac{n_i}{\tau_G}, \tag{9.85}$$

in which $\beta = (n_i\tau_G)^{-1}$ is a proportionality constant, τ_G is the carrier generation lifetime, and $n_i^2 = n_0 p_0$ is the

thermal equilibrium intrinsic carrier concentration, with n_0 and p_0 describing the equilibrium concentrations of electrons and holes. The generation current density within a space-charge region of width w is

$$J_G = qwG_{th} . \tag{9.86}$$

A further increase in the photodiode reverse bias beyond the value at which w extends through the whole semiconductor bulk (the reach-through regime) results in an electric field high enough to cause electrical breakdown, and the reverse bias current increases dramatically. The two mechanisms that are generally considered to be involved are the Zener and avalanche breakdown mechanisms.

Zener Breakdown. This mechanism involves the interaction of the electric field with covalently bound electrons. At a large reverse bias, the conduction band of the n-type region is shifted to well below the top of the valance band of the p-type region of the semiconductor diode. The occupied energy levels in the conduction band of the p-side of the semiconductor line up with the unoccupied energy levels in the conduction band of the n-side, and a strong electric field facilitates the tunneling of the valence electrons through the potential barrier from the p-side towards the n-side of the semiconductor. The barrier height is equal to the semiconductor bandgap E_g, and the tunneling probability ϑ can be found from the expression for tunneling through a triangular barrier [9.10]

$$\vartheta \approx \exp\left(-\frac{8\pi\sqrt{2m}E_g^{3/2}}{3qhE}\right) , \tag{9.87}$$

where m is the mass of an electron, h is Planck's constant, and E is the electric field. The tunneling current density can be estimated as

$$J_{tunn} = qn_Z v_d \vartheta , \tag{9.88}$$

in which n_Z and v_d are the density and the drift velocity of the valance electrons arriving at the Zener barrier, respectively.

Avalanche Breakdown. Avalanche breakdown occurs when the electric field is high enough to trigger multiplication processes during collisions of carriers accelerated by the field with atoms of the substrate. The probability of multiplication depends not only on the value of the electric field but also on the carrier ionization rate and the extent of the avalanche region. The avalanche

process can be characterized by the multiplication factor M, which in the case of one type of carrier can be written as [9.11, 12]

$$M_{n,p} = \exp\left(\int_0^L \alpha_{n,p}(x)\,dx\right) , \tag{9.89}$$

where L is the width of the multiplication region, $\alpha_{n,p}(x)$ is the electron/hole ionization rate, which depends on the coordinate x inside the multiplication region. For a simple case of equal ionization rates $\alpha_n = \alpha_p$, the condition for avalanche breakdown can be deduced as $M \to \infty$:

$$\int_0^L \alpha_{n,p}(x)\,dx = 1 . \tag{9.90}$$

Since the ionization rate is a function of the electric field, which varies inside the space-charge region, the breakdown voltage V_B is not easy to calculate precisely. However, the following empirical formula was shown to be valid for different semiconductors [9.13]

$$V_B \approx 60 \left(\frac{E_g(in\ eV)}{1.1}\right)^{3/2} \left(\frac{N_B(in\ cm^{-3})}{10^{16}}\right)^{-3/4} , \tag{9.91}$$

where N_B is the background dopant concentration on the lightly doped side.

More details on avalanche breakdown will be presented below in the section on avalanche photodiodes.

Noise Current

1/f Noise. The noise current/voltage for this type of noise varies as $1/\sqrt{f}$. The experimentally measured relationship for the mean square noise current is [9.4]

$$\overline{i_{1/f}^2} = \frac{\mathrm{const} I_{DC}^2 \Delta f}{f^\beta} , \tag{9.92}$$

where const is a proportionality constant, Δf and f are the bandwidth and frequency respectively, and β is a constant close to 1. Note that this noise is a function of the direct-current component of the semiconductor photodiode I_{DC} only. In modern designs, this noise is negligibly small.

Johnson Noise. For the semiconductor photodiode, the Johnson noise mean square current is expressed by

$$\overline{i_j^2} = \frac{4kT\Delta f}{R_{eq}} , \tag{9.93}$$
Fig. 9.10 Typical dependence of NEP on the reverse bias for a 1 mm^2 Si photodiode at room temperature (*curve* 1). The Johnson noise component is shown by *curve* 3 and the shot noise by *curve* 2

in which the equivalent resistor is determined as $1/R_{eq} = 1/R_{sh} + 1/R_s$, where R_{sh} and R_s are the shunt and series resistances of the photodiode, respectively. The series resistance is usually much smaller that the shunt resistance and can be neglected.

Shot Noise. The mean square shot noise current of the photodiode consists of two main components: the photon-generated component and the "dark" current component of the semiconductor diode shot noise current:

$$\overline{i_{sh}^2} = \sqrt{2q \left(I_p + I_{dark} \right) \Delta f} , \qquad (9.94)$$

where $I_p = I_s + I_B$ describes the photocurrent produced by the signal and background radiation (I_s and I_B are the signal and background currents, respectively), and I_{dark} accounts for the contribution from all sources of dark current.

Signal–to–Noise Ratio and Noise Equivalent Power (NEP)

The signal-to-noise ratio of a semiconductor photodiode can be found using (9.93) and (9.94)

$$\frac{S}{N} = \frac{\mathfrak{R}_I \Phi_p}{i_n} = \frac{\mathfrak{R}_I h\nu \Phi}{\sqrt{\overline{i_j^2} + \overline{i_{sh}^2}}}$$

$$\approx \frac{I_p}{\sqrt{2q(I_p + I_{dark})\Delta f + (4kT\Delta f)/(R_{sh})}} ,$$

$$(9.95)$$

where $\mathfrak{R}_I$ is the current responsivity given by (9.75), $\Phi_p = h\nu\Phi$ is the incident radiant power, and the

approximate equality sign arises from the substitution $R_{eq} \approx R_{sh}$. By placing the signal-to-noise value equal to 1, one can calculate the photodiode NEP as $NEP = \Phi_p|_{S/N=1} = i_n/\mathfrak{R}_I$. In the case of photon-limited performance, the optical signal is rather strong compared to all sources of noise and $(I_{dark} + 2kT/qR_{sh})/q\Delta f \gg 1$. In this case, the photodiode NEP is determined by the quantum noise associated with the signal photon flux Φ^S (or the background photon flux Φ^B) itself

$$NEP = h\nu \sqrt{\frac{2\Phi^{S,B}\Delta f}{\eta_{ex}}} . \qquad (9.96)$$

In the case of a very low optical photon flux, when $I_p \ll (I_{dark} + 2kT/qR_{sh})$, the thermal noise from the shunt resistance and/or the photodiode leakage current noise becomes dominant and the corresponding value of NEP is given by

$$NEP = \frac{h\nu}{\eta_{ex}} \sqrt{\frac{2\Delta f}{q} \left(I_{dark} + \frac{2kT}{R_{sh}q} \right)} . \qquad (9.97)$$

A typical plot of NEP versus reverse bias is shown in Fig. 9.10 for a silicon photodiode 1 mm in diameter. At low bias values, the Johnson noise component usually dominates over other noise sources, whereas the shot noise component becomes increasingly large at large reverse bias values, when the dark leakage current increases.

Detectivity

The photodiode detectivity is derived using the general expression for detectivity $D = 1/NEP$. The specific detectivity for a photon-limited photodiode is determined by the expression

$$D^*(\lambda, f) = D\sqrt{A_{det}\Delta f} = \frac{1}{h\nu} \sqrt{\frac{\eta_{ex} A_{det}}{2\Phi^{S,B}}} , \qquad (9.98)$$

in which A_{det} is the photodiode active area and the superscripts (S, B) correspond to either signal or background photon flux, whichever is greater. For a Johnson noise limited photodiode with a load resistance R_L, the specific detectivity is

$$D^*(\lambda, f) = \frac{q\eta_{ex}}{h\nu} \sqrt{\frac{A_{det}}{2kT} \left(\frac{R_L R_{sh}}{R_L + R_{sh}} \right)} . \qquad (9.99)$$

Time Response and Frequency Bandwidth

During the process of light detection by photodiodes, the final step is usually nonequilibrium carrier collection into the external circuitry, which occurs through either

drift or diffusion mechanisms, with the time constants τ_{drift} and τ_{diff}, respectively. Since the diffusion and drift processes are independent of each other, the resulting response time is calculated via

$$\tau_{\mathrm{r}} = \sqrt{\tau_{\mathrm{drift}}^2 + \tau_{\mathrm{diff}}^2 + \tau_{\mathrm{RC}}^2} \, , \qquad (9.100)$$

in which τ_{RC} is the time constant determined by the terminal capacitance C and the load resistance R_{L}. The cutoff frequency f_{c} of the photodetector also defines the 3 dB breakpoint, and is given by

$$f_{\mathrm{c}} = \frac{1}{2\pi\tau_{\mathrm{r}}} \, . \qquad (9.101)$$

The upper limit for the carrier diffusion time can be estimated from the following straightforward considerations. The carrier diffusion length is related to the diffusion time and the diffusion constants $D_{\mathrm{n,p}}$ for electron and holes via

$$L_{\mathrm{n,p}} = \sqrt{D_{\mathrm{n,p}} \tau_{\mathrm{diff}}^{\mathrm{n,p}}} \, . \qquad (9.102)$$

Assuming that the carrier lifetime is long enough to allow nonequilibrium carriers to move without recombination along the carrier concentration gradient, $\tau_{\mathrm{diff}}^{\mathrm{n,p}}$

Table 9.1 Lowest energy gaps E_{g} and carrier mobilities for a number of intrinsic semiconductors at room temperature [9.6, 14]

Fig. 9.11 Absorption versus wavelength for several elemental and binary semiconductors

for electrons and holes can be calculated from (9.102) as the time necessary to diffuse through the undepleted region of the semiconductor bulk

$$\tau_{\mathrm{diff}}^{\mathrm{n,p}} = \frac{L_{\mathrm{n,p}}^2}{D_{\mathrm{n,p}}} \equiv \frac{(d-w)^2}{D_{\mathrm{n,p}}} \, , \qquad (9.103)$$

where d and w are the semiconductor substrate thickness and the depletion region width, respectively. The diffusion constants can be calculated from the known Einstein relation

$$D_{\mathrm{n,p}} = \frac{kT\mu_{\mathrm{n,p}}}{q} \, , \qquad (9.104)$$

where $\mu_{\mathrm{n,p}}$ are the carrier mobilities, specific to each semiconductor.

The upper limit for the carrier drift time τ_{drift} across the space-charge region can be estimated using

$$\tau_{\mathrm{drift}}^{\mathrm{n,p}} = \frac{w}{v_{\mathrm{drift}}^{\mathrm{n,p}}} = \frac{w}{\mu_{\mathrm{n,p}} E} \, , \qquad (9.105)$$

where the right-hand side states the known phenomenological relationship that the carrier mobility is the ratio

of the average drift velocity to the applied electric filed E

$$v_{\text{drift}}^{n,p} = \mu_{n,p} E .\qquad(9.106)$$

This expression is valid for a relatively low electric field strength, when the effects like electron–phonon scattering can be neglected. At high values of E, the carrier drift velocity saturates and becomes independent of E [9.15].

Ways of reducing the photodiode time response and making the cutoff frequency larger will be discussed below.

9.3.3 Semiconductor Photodiodes – Materials

The choice of semiconductor photodiode material depends primarily on the spectral range of interest. Figure 9.11 shows plots of absorption coefficient versus wavelength for the most common semiconductors. For the region of the spectrum below ≈ 1100 nm, Si is usually used. However, since both Si and the other popular semiconductor material – Ge – are indirect bandgap semiconductors, much of their sensitivity to large regions of the spectrum is due the occurrence of absorption processes involving phonons. Phonon-assisted photon absorption obviously have a much smaller probability of occurrence than the direct valence band to conduction band transitions that occur in direct bandgap semiconductors. This explains their significantly smaller
Fig. 9.13 Structure of a p–i–n photodiode (cross-sectional view); p$^+$ diffusion in the middle of the die forms the active area junction; the p$^+$ diffusions close to the edges are the guard rings. The spacing from the main (anode) junction used depends on the breakdown and leakage performance required. The n$^+$ diffusions at the edges are the channel stoppers

absorption coefficients and, correspondingly, the larger absorption lengths observed for Si and Ge than for many compound semiconductors. The band gap energies E_g for a number of important semiconductors are summarized in Table 9.1.

The other important photodiode parameter which is directly related to the absorption length is the time response. The time response is normally significantly shorter for direct bandgap semiconductors due to the much thinner absorption volume, which automatically translates into a shorter carrier collection time. However, some specific structural features can greatly improve the response time and we will describe these in the following sections.

The photodiode rise time and time response is a complex function of several parameters, the carrier mobility being among the most important. Table 9.1 shows the carrier mobility values for various semiconductors.

Single–Material Semiconductors

Because Si and Ge are associated with indirect photon absorption, they do not have sharp absorption edges. Si is the semiconductor material most often used for the visible and near-infrared (IR) spectral range. Si photodiodes usually have quantum efficiencies close to 100% at selected intervals within the spectral range from ≈ 400 nm to 1000 nm (Fig. 9.12). A typical spectral responsivity curve for a Si photodiode is also shown in Fig. 9.12. Special front surface treatment allows the high efficiency region of Si photodiodes to be extended to below 400 nm. Among the other advantages of Si photodiodes are their low noise currents (Fig. 9.10). The usual approach used to reduce the dark current in Si-based

Fig. 9.12 An example of the spectral response of a Si photodiode (*curve* 1). The quantum efficiency of the same photodiode is shown by *curves* 2 (external QE) and *curves* 3 (internal QE). *Curve* 4 shows the dependence of the theoretical responsivity of an imaginary photodiode on $\eta_{\text{ex}} = 100\%$

and other substrate photodiodes is to provide special structures like guard rings and surface leakage stoppers (channel stoppers) – see Fig. 9.13. The guard rings are usually designed to decrease the electric field strength in the depletion region, thus reducing the high-field ion-ization efficiencies of the host and dopant atoms. The surface leakage stoppers are designed to prevent minor-ity carriers outside the active area from reaching the space-charge region

The absorption edge of Ge extends beyond 1.6 μm, which is advantageous for the purposes of wide spectral range applications but at the same time limits the sen-sitivity of this material to low photon fluxes because of the high levels of thermally generated dark current. An example of the p–i–n photodiode structure typical of Si and Ge is given in Fig. 9.13.

Binary III–V Semiconductor Photodiodes

III–V binary semiconductors permit the design of pho-todiodes operating over a wide spectral range from the UV to mid-IR. Direct bandgap III–V group semicon-ductors have rather small absorption lengths, assuming a relatively high probability of nonequilibrium carrier recombination on surface defects. The latter effect is the main reason for the lower quantum efficiencies of pho-todiodes based on III–V compounds in comparison with those observed for Si and Ge.

Photodiodes based on III–V compounds usually show increased dark current values, which limit their field of application.

Binary II−VI Semiconductor Photodiodes

II–VI binary semiconductors have also been used in photodiode design, although these materials are not as widely used as III–V compounds. Among those that have been explored are CdTe, which has a bandgap of ≈ 1.48 eV [9.14] (some sources give a larger value of ≈ 1.6 eV [9.1]), and HgTe, which is actually a semimetallic compound with a "negative band gap"

Table 9.2 Values of the κ parameter for various semicon-ductors [9.1]

Material	κ(eV)
$Al_xGa_{1-x}As$	0.27

of ≤ 0.25 eV. Ternary and quaternary compounds based on II–VI group semiconductors have found much wider application.

Ternary and Quaternary Semiconductor Photodiodes

Ternary $A_{1-x}B_xC$ and quaternary $A_{1-x}B_xC_{1-y}D_y$ compounds are used to build photodiodes with optimized spectral sensitivity ranges. Various formulae have been suggested that may be used to calculate the band gap as a function of the stoichiometric parameters x and y. For example, one of the ideas is based upon the second-order perturbation of the Schrödinger potential, which yields the following expression for the change in the bandgap with x [9.16]

$$E_g(A_{1-x}B_xC) =$$
$$E_g(AC) + \left[E_g(BC) - E_g(AC) - \kappa\right]x + \kappa x^2 ,$$

$$(9.107)$$

where κ is a positive constant, specific to each compound. Note that in some ternary and quaternary compounds either the direct or indirect bandgap can be the lowest, depending on the values of x and y. Correspondingly, there are two versions of (9.107) for materials that change from direct to indirect gap: AlGaAs is an example. To calculate the direct bandgap value for $Al_{1-x}Ga_xAs$ ($0 < x < 0.44$), one should always use the direct band gap values of the corresponding binary compounds and vice versa. Table 9.2 shows some calculated κ values for several ternary compounds.

One of the main requirements for building ternary and quaternary structures is the lattice-matching requirement. Figure 9.14 shows the variation in the lattice constant as a function of the band gap for some III–V ternary alloys. Note that the successful growth of heterostructures requires that both the band gap and the lattice constant are considered. For example, $Al_{1-x}Ga_xAs$ can be grown on GaAs substrate for any

Fig. 9.17 (a) An example of an $In_{1-x}Ga_xAs_{1-y}P_y$ mesa structure photodiode, and **(b)** external quantum efficiencies for several different quaternary compositions

value of x without lattice mismatch-inducing defects. In contrast, for the $Ga_{1-x}As_xP/GaAs$ structure there is a substantial mismatch in lattice constant values between GaAs and GaP, which bars simple high-quality structures from being built over the whole range of x. However, in many cases this problem can be overcome by providing a grading layer between the substrate and the desired compound.

Instead of using grading layers, quaternary compounds can also be built. Not all quaternary compounds can be ideally matched to a substrate. However, the case of $In_{1-x}Ga_xAs_{1-y}p_y$ provides an exciting exception. The diagram in Fig. 9.15 demonstrates the correlation between the band gap and the lattice constant for this quaternary compound. The solid lines represent iso-bandgap lines. Every bandgap from 0.36 eV (InAs) to 2.2 eV ($In_{0.73}Ga_{0.27}P$) can be created in a direct-gap semiconductor. The dashed lines in Fig. 9.15 represent iso-lattice constant lines. The important feature of this diagram is shown by the bold dotted line, which illus-

trates a continuous set of quaternary structures with bandgap values from $\approx 1.33\,\mathrm{eV}$ to $\approx 0.5\,\mathrm{eV}$ that are perfectly lattice-matched to InP.

Figure 9.16 shows a typical example of a p–i–n photodiode that employs ternary III–V compounds. The intrinsic layer of $In_{1-x}Ga_xAs$ is grown on top of an n-type InP substrate. The ternary structure is sensitive up to $\approx 1.65\,\mu m$ for $x = 0.47$. A top layer of p-InP creates the junction and completes the structure. Since InP is transparent to wavelengths above $0.92\,\mu m$, the device can be used as an efficient p–i–n, back-illuminated photodiode for the wavelength range from 0.92 through to $1.65\,\mu m$, in which all absorption occurs within the intrinsic layer.

Another example of a quaternary structure p–i–n photodiode is shown in Fig. 9.17, along with typical quantum efficiency curves for a number of stoichiometries.

In terms of II–VI ternary compounds, structures based around the $Hg_{1-x}Cd_xTe$ (mercury–cadmium–telluride, MCT) system had a virtual monopoly over long-wavelength light detection ($3-5\,\mu m$ and $8-14\,\mu m$) until recently. Depending on x, this system provides tremendous flexibility when tuning the spectral sensitivity range from visible to far infrared. The bandgap of the alloy $Hg_{1-x}Cd_xTe$ is zero at $x \approx 0.15$ and is only slightly nolinear over the whole range of x up to $E_g = 1.48\,\mathrm{eV}$ at $x = 1$ [9.2]

$$E_g = -0.302 + 1.93x + 5.35 \times 10^{-4}T(1-2x) \\ -0.81x^2 + 0.832x^3 , \tag{9.108}$$

where T is the absolute temperature. Among the drawbacks of MCT photodiodes is a high leakage current, which requires that the device be cooled for noise-free operation.

Fast–Response Photodiodes

Short carrier transit time is one of the determining parameters when designing photodiodes with short response times τ_r. To minimize the carrier transit time, the carrier drift time should be reduced assuming that the photodiode bulk is fully depleted (9.100). However, for indirect bandgap semiconductors with low absorption coefficients, a thick absorption layer is required to achieve high quantum efficiency, and this condition is in conflict with the need to reduce the carrier transit time. There are several ways to overcome this conflict, one of which is to build resonantly enhanced structures; the other is to decouple the photodiode absorption length from the direction of nonequilibrium carrier drift.

The principle of a resonant cavity enhanced photodetector is based on the use of constructive interference in a Fabry–Perot cavity to enhance the optical field inside the photodetector bulk at specific wavelengths [9.17]. Such resonant cavities can be formed using a buried backside reflector and the air/semiconductor top interface. There are various types of backside reflector; the scattering reflector [9.18] and distributed Bragg reflector [9.19] are common examples.

For indirect bandgap semiconductors, it is difficult to achieve both high bandwidth and high efficiency with a vertical design since the length of the absorption region is proportional to the carrier transit time. Decoupling of the absorption length from the motion of nonequilibrium carriers is another efficient method used to improve the speeds and quantum efficiencies of Si- and Ge-based photodiodes. Such decoupling is achieved in lateral surface p–i–n photodiodes on silicon-on-insulator (SOI) substrates, which exploits the idea of using a grating coupler on top of the photodiode [9.20, 21]. The coupler promotes the propagation of the optical beam through a thin, waveguide-type surface layer of Si (Fig. 9.18).

Another way to decouple the absorption length from the carrier motion is to incorporate alternating p+ and n+ fingers in Si substrate [9.22]. In the example shown in Fig. 9.19, the deep carriers are blocked by the junction between the n-well and p-substrate, and the transit time is determined by the fast lateral motion of carriers between the fingers.

In top-illuminated, direct-bandgap semiconductor photodiodes, further reductions in the carrier transit time are limited by surface recombination processes, which decrease the responsivity. Side-illuminated photodiodes, in which the absorption length is decoupled from the carrier transit time, overcome the efficiency–bandwidth tradeoff associated with top-illuminated photodiodes [9.23, 24]. However, they cannot operate at high optical power levels, since carrier generation occurs in a very small volume at the diode input facet.

One of the solutions to this problem is to use evanescently coupled photodiodes that are monolithically integrated with a waveguide [9.25–27]. The evanescent coupling optimizes the distribution of nonequilibrium carriers along the absorption layer. Due to more uniform light absorption, devices that utilize evanescent coupling can achieve saturation currents that are several times higher than achieved in a traditional side-illuminated device. An example of an evanescently coupled photodiode is shown schematically in Fig. 9.20. The structure is usually based on a classical p–i–n photodiode with
Fig. 9.21 (a) Cross-section of the two-terminal position-sensitive detector. **(b)** Unequal resistance paths on the silicon four-terminal sensor

a very thin ($< 0.5\,\mu m$) undoped InGaAs absorbing layer 20–$30\,\mu m$ in depth and a p$^+$-doped InP layer on the top. The n$^+$-doped layer contains InGaAsP structures that may consist of two optical matching layers. The light is delivered from the side and propagates along the undoped diluted waveguide layer, which is a stack of several InP/InGaAsP sandwiches. The bandgaps and the thickness of the optical matching layers are chosen in such a way that they provide a gradual increase in the refractive index from the diluted waveguide towards the thin absorbing layer. Due to the evanescent wave coupling, when the optical wave propagates along the waveguide it is gradually transferred through the optical matching layers to the absorbing layer. A quantum efficiency of higher than 95% can be achieved with
Fig. 9.22 Cross-section of a silicon diode strip detector

a bandwidth of over 50 GHz, which should be beneficial for many applications. However, the fabrication of such structures is rather complex.

Position–Sensitive Photodiodes

Resistive Charge Division Sensor. A silicon resistive charge division sensor, also known as a silicon position sensor, consists of a segment of photodetective silicon (a moderately doped p^+-layer on top of an n-type substrate) with either two or four terminals for signal output and a terminal used for the application of back-bias voltage (Fig. 9.21, panel (a)). Position information is derived from this device by comparing the signal outputs from each terminal. For example, for the two-terminal device shown in Fig. 9.21a, the position can be calculated from

$$x = \frac{I_2}{I_1 + I_2} d \ . \tag{9.109}$$

The focused image causes a photocurrent to flow through the silicon to each terminal. Because the silicon has a given resistance per unit length, more current will flow to the closest terminals and less current to the terminals that are farthest from the focused image (Fig. 9.21, panel (b)).

Position sensors of this type have several advantages over other similar devices. Because there is no gap in the active area, the size of the image is not subject to minimum diameter constraints. A second advantage is that position information is available as long as the image falls somewhere on the active area of the detector. One disadvantage is that the frequency responses of such detectors tend to be lower than those of conventional silicon detectors of the same size because of the series resistance that the photocurrent encounters at the surface of the detector.

Strip Detector. Another way to measure position is to dividing a large-area photodiode into many small, strip-like regions and to read them out separately – see Fig. 9.22. Such strip detectors are produced in the same

way as planar photodiodes except that more stringent requirements are placed on mask precision and alignment. The measurement precision depends mainly upon the strip spacing and the readout method.

Quadrant Photodiode. A quadrant photodiode is variation on a strip detector, where the segments are four quadrants, each of which have separate connectors for signal output. Each quadrant functions and behaves like a regular p–i–n or avalanche photodiode. Quadrant photodiodes are widely used in tracking systems. Position information is derived by comparing the signals output from each segment (Fig. 9.23). When the focused image is centered on the quadrant detector, each segment will receive the same amount of optical radiation, and all four signal outputs will be equal (Fig. 9.23, left). As the image moves across the detector surface (corresponding to an angular change in the object being tracked), more radiation falls on one of the segments and less on the opposite segment.

If more optical energy falls above the horizontal line (Fig. 9.23, middle), more photocurrent will flow through the upper segments (A and B) than through the lower segments (C and D). The up–down position of the spot

Fig. 9.23 Output from the image at different positions on the quadrant detector
Fig. 9.24 (a) Typical structure of a color-sensitive element with three color filters overlaid over different photodiodes. **(b)** An example of the structure of a vertically arranged color detector. n-Type regions are *hatched*

is characterized by the relative amplitudes of $(A + B) - (C + D)$. Similarly, the term $(A + D) - (B + C)$ provides information on the left–right position.

In most tracking and alignment applications, the parameter of most concern is the ability of the detector to supply a very precise description of the location of the focused image on the face of the detector. In other words, the change in the output signal in relation to the change in the position of the spot is very important. "Sensitivity" is used in this case to describe the ratio

$$\text{Sensitivity} = \frac{\text{Change in output signal}}{\text{Change in position}} . \qquad (9.110)$$

An inherent problem with quadrant photodiodes is the finite width of the separation between segments. If the image is focused to a small spot size, erroneous information will result when the spot falls on the border between segments. This problem is usually avoided by defocusing the image or by using a long-focal-length objective that results in a larger image size and displacement. Additionally, some position information is lost when the entire image falls within one segment. This problem also can be avoided by defocusing or by using long-focal-length optics.

Color–Sensitive Detectors

The conventional way to detect a color image relies on the idea that any color, as perceived by the human eye, is based on the three primary colors: red, green, and blue. Mixing light of these wavelengths in varying proportions can generate other colors. The main principle of operation of any color sensor is therefore based on separating the incident beam into three primary colors and detecting them separately. The methods used to do this exploit two main principles: one uses color overlay filters on top of the active area of the photodetector, while the other performs color selection based on the inherent property of the semiconductor to absorb light of different wavelengths at different depths. A hue diagram is then used to infer the color of the incident light [9.28].

In the first type of color sensor, color detection is performed by using three filters, one for each of the primary colors, and three photodetectors fabricated on the same substrate. A typical structure of this type is shown in Fig. 9.24a. P–n or p–i–n photodiodes are built on an n-type Si wafer with a n^+ guard ring. The filters allow the transmission of one of the primary wavelengths, and the corresponding photodiode measures the intensity of the incident light at that wavelength. The responses of the photodetectors are then used to determine the relative contributions of each of the primary wavelengths to the incident light, and hence to infer its color. Drawbacks to such methods are that it can be complicated to use three sensors with their corresponding filters, and that such a design can take up excessive space when creating a color-sensing array.

Another type of multiple-wavelength sensor employs more than one sensor in a vertically oriented arrangement. Different designs include photodiodes formed in single-crystalline silicon and those formed in amorphous silicon. The operation of these devices is based on the intrinsic filtering property of a semiconductor, which results from the variation in the absorption coefficient with the wavelength of the incident light. An example of such a structure is shown in Fig. 9.24b [9.29]. The layers of the detector have different spectral sensitivities based on their different depths in the semiconductor substrate, doping levels, and biasing conditions. The three n-type regions are isolated vertically by p-regions. The blue, green, and red photodiode sensors are formed by the corresponding p/n junctions and are arranged one below the other underneath the sensor surface. The layers of the detector are individually connected to pixel sensor readout circuits.

9.4 QWIP Photodetectors

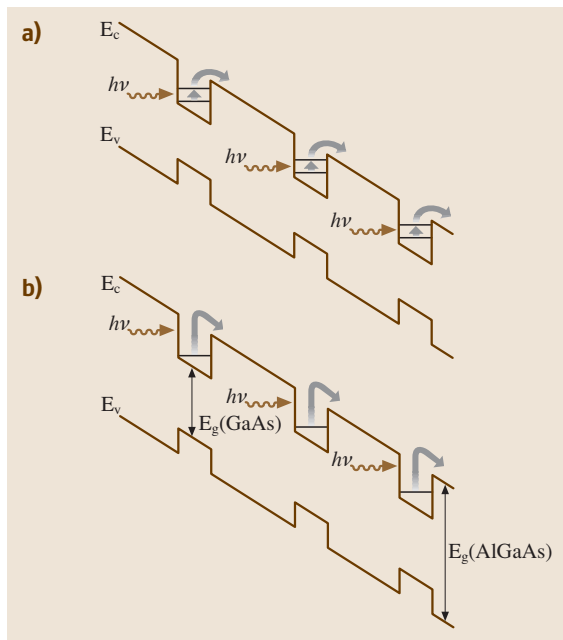
Quantum well infrared photodetectors (QWIPs) are efficient detectors for the detection of infrared radiation. A QWIP is a photoconductor and a unipolar device. QWIPs are fabricated by alternately growing thin layers of two different wide-bandgap semiconductors. The bandgap discontinuity between two materials creates quantized subbands in the potential wells associated with conduction bands or valence bands. Light absorption initiates electron transitions between the ground and first excited state subbands of multiquantum wells. The structure parameters are designed in such a way that the photoexcited carriers can escape from the potential wells and be collected as photocurrent, which is facilitated by bending the bands using an external electric field. Depending the structure of the QWIP, there can be three different types of electronic transitions: bound-


Fig. 9.25a,b Energy band diagram of QWIP under reverse bias showing (**a**) a bound-to-bound transition and (**b**) a bound-to-continuum transition

to-bound, bound-to-continuum, and bound-to-miniband transitions (Fig. 9.25).

9.4.1 Structure and Fabrication of QWIPs

The lattice-matched GaAs/Al$_x$Ga$_{1-x}$As material system is commonly used to create a QWIP structure such
Fig. 9.26 Examples of the responsivity spectra for different GaAs/AlGaAs QWIP structures

as that shown in Fig. 9.25. The quantum well layers of GaAs have a typical thickness of 50–70 Å and are usually n-type doped to $\approx 10^{18}$ cm^{-3}. The barrier layers AlGaAs are undoped and have a thickness in the range of 300–500 Å. Typical numbers of periods are 20 to 50. By controlling the quantum well width and the barrier height (which depends on the Al molar ratio of Al$_x$Ga$_{1-x}$As alloy), the intersubband transition energy can be varied over a wide enough range to enable the detection of light at any wavelength in the range 6–20 μm. Fabricated and experimentally investigated QWIPs can already detect wavelengths of up to 35 μm. Other contemporary structures used in QWIPs are InGaAs/InAlAs and InGaAs/InP, which have peak detection wavelengths of 4 μm and 8 μm, respectively.

9.4.2 QWIPs – Properties and Figures of Merit

Spectral Response
The spectral responsivity peak wavelength (λ_p) of a QWIP is determined by the difference in energy between the ground and excited states of the quantum well. Unlike the responsivity spectra of intrinsic infrared detectors, QWIP spectra are much narrower and sharper due to their resonance intersubband absorption. Typically, responsivity spectra of bound and quasi-bound excited state QWIPs are much narrower ($\Delta\lambda/\lambda \approx 10\%$) than those of continuum QWIPs ($\Delta\lambda/\lambda = 24\%$). This is due to the fact that, when the excited state is positioned in the continuum band above the barrier, the range of energies associated with the state becomes wider. The spectral bandwidths of these QWIPs can be further increased by replacing single quantum wells with small superlattice structures (several quantum wells separated by thin barriers) in a multiquantum well structure. Such a scheme creates an excited state miniband due to the overlap of excited state wavefunctions of quantum wells. Energy band calculations based on a two-band model show excited state energy levels spread over greater than 30 meV. Figure 9.26 shows experimentally measured responsivity spectra with FWHM bandwidth $\Delta\lambda > 5$ μm. The broadest responsivity bandwidth demonstrated so far is $\Delta\lambda \approx 6$ μm.

Quantum Efficiency
The QWIP photocurrent is given by the general expression used for photoconductors

$$I_p = q\Phi\eta_{ex}G \, , \tag{9.111}$$

where q is the elementary charge, Φ is the photon flux in reciprocal seconds, η_{ex} is the external quantum efficiency and G is the gain. The quantum efficiency is different from that of a regular photoconductor, since light absorption and carrier generation occurs only in the quantum wells in QWIPs, not homogeneously throughout the structure [9.14]:

$$\eta_{ex} = (1 - R_F)\left[1 - \exp\left(-N_p \alpha N_w L_w\right)\right] E_p P \, , \tag{9.112}$$

where R_F is the front surface reflection, N_p is the number of optical passes, N_w is the number of quantum wells, L_w is the well length, E_p is a term that depends on the bias inside the quantum well, and P is the polarization correction factor.

The photoconductive gain G is similar to that of the standard photoconductor:

$$G = \frac{\tau}{t} = \frac{(\tau \mu V)}{L^2} \, , \tag{9.113}$$

where V is the bias, τ is the minority carrier lifetime and t the transit time across the whole active length L of the QWIP, while μ is the minority carrier mobility. The right-hand side of (9.113) is written assuming that the field strength E is far from saturation, and the carrier drift velocity is given by $v_d = \mu E = \mu(V/L)$.

The photoconductive gain of the QWIP depends on the design of the device. It typically varies from 0.1 to 1. A photoconductive gain G of higher than 1 is possible with QWIPs that have fewer quantum wells.

Noise and Detectivity

The dominant noise observed in QWIP devices is due to the shot noise resulting from the total current in the device. There is no significant thermal noise in QWIPs because the thermally assisted tunneling of carriers is not significant at the operating bias used. To additionally decrease the thermal noise and limit the dark current, the QWIP must be operated at a low temperature. In addition, QWIPs show remarkable noise stability (i. e., very low $1/f$ noise), enabling long integration times.

The QWIP is a type of photodetector that can provide background-limited performance (BLIP), where the detector performance is limited by the noise generated by photons. The signal-to-noise ratio, the detectivity, etc., are independent of the photoconductive gain when the QWIP operates under background-limited conditions.

9.4.3 Applications of QWIPs

There are many ground-based and spaceborne applications that require long-wavelength, large, uniform, reproducible, low cost, low $1/f$ noise, low power dissipation, and radiation-hard infrared focal plane arrays, which often employ QWIPs [9.30]. For example, the absorption lines of many gas molecules, such as ozone, water, carbon monoxide, carbon dioxide, and nitrous oxide occur in the wavelength region from 3 to 18 μm. Thus, infrared imaging systems that operate in the long-wavelength IR (LWIR) region are required in many space applications such as global weather profile monitoring, earth resource mapping, deforestation mapping, and to map the distributions of minor constituents in the atmosphere. In addition, there is great astronomical interest in these very long wavelengths due to the fact that this spectral region is rich in information vital to our understanding of the compositions, structures and energy balances of molecular clouds and star-forming regions of galaxies.

9.5 QDIP Photodetectors

The quantum-dot infrared photodetector (QDIP) is similar to the QWIP except that the potential well is created by a quantum dot instead of a quantum well. In QDIP, the physical dimensions of the active structure are reduced to the de Broglie wavelength, which greatly enhances the degree of carrier confinement. As a result, the spectral response can be controlled even more precisely than for QWIP structures. In addition, the noise characteristics and detectivity of QDIPs can potentially be dramatically improved in comparison with those of QWIP structures.

9.5.1 Structures and Fabrication of QDIPs

There are two basic QDIP structures, one where the photogenerated carriers travel perpendicular to the quantum dot planes, the other where they travel parallel to the planes (Fig. 9.27). The technique used to form quantum dots has improved dramatically following the introduction of an epitaxial synthesis process called the Stranski–Krastanow growth mode [9.31, 32]. Typical structures employ InAs dots on GaAs, InGaAs dots on GaAs, and SiGe dots on Si. As an exam-
Fig. 9.27a,b Schematic of the cross-sectional structure of a QDIP. The photocurrent flows either **(a)** perpendicular or **(b)** parallel to the quantum dot planes

ple, the QDIP structure can comprise InAs islands on GaAs substrate. At an optimum layer thickness of roughly two monolayers ($\approx 6\,\text{Å}$), the InAs film nucleates into an array of islands (dots) to release the stress. The typical dimensions of the dots are $\geq 150\,\text{Å}$ across the base and $\geq 30\,\text{Å}$ in height. The density of the array is 10^{10}–$10^{11}\,\text{cm}^{-2}$. The ultrathin residual "wetting layer" is usually left underneath the quantum dots.

The doping level in quantum dots is tuned to provide up to five electrons per dot. Alternatively, the dots can be intrinsic but electrons can be introduced by modulation doping the incorporated delta-doped layer, from which electrons are injected and are trapped within the potential well of the quantum dot. The delta-doped layers are fully depleted and do not contribute to the dark current.

To improve light absorption, the quantum dot layers are repeated periodically. The thickness of the intrinsic barrier layer typically ranges from 100 to 500 Å.

The photocurrent from a QDIP is qualitatively described by (9.111), substituting the QDIP photocurrent for the QWIP photocurrent.

9.6 Metal–Semiconductor (Schottky Barrier) and Metal–Semiconductor–Metal Photodiodes

When a metal contacts a semiconductor, a Schottky barrier results. A Schottky-barrier photodiode can operate in two different detection modes. In one of them, electron–hole generation occurs due to the band-to-band excitation of the semiconductor; in the second mode, the carriers are transferred from the metal into the semiconductor across the Schottky barrier. In the front-illuminated version, which is advantageous for the first mode of operation mentioned above, the metal layer that forms the Schottky barrier is very thin (less than $\approx 150\,\text{Å}$), thus allowing more photons to reach the semiconductor bulk. For detectors that use the second mode of operation, backside (through the substrate) illumination is more efficient, since the barrier height $q\varphi_{\text{bn}}$ is always smaller than the energy gap E_{g} and infrared quanta with $q\varphi_{\text{bn}} < h\nu < E_{\text{g}}$ are not absorbed in the semiconductor.

9.6.1 Schottky Barrier Photodiode Properties

Figure 9.28 schematically shows the energy band for a Schottky diode. The metal work function φ_{m} is usually different from the semiconductor work function φ_{s}. The conditions needed to produce a useful barrier to the electrons in an n-type semiconductor–metal contact is $\varphi_{\text{m}} > \varphi_{\text{s}}$. The barrier height is given by

$$q\varphi_{\text{bn}} = q(\varphi_{\text{m}} - \chi)\,, \qquad (9.114)$$

where $q\chi$ is the semiconductor electron affinity.

Dark Current and Photocurrent
Metal–semiconductor junctions have properties similar to those of the p–n junction. In particular, the $I - V$ characteristic for dark conditions shows an exponential
Fig. 9.28a,b Energy band diagram for the Schottky-barrier photodiode operated under reverse bias V_r with (a) band-to-band excitation and (b) intrinsic photoelectron emission

dependence of I on V for the forward bias, and saturates at a constant value of the reverse bias

$$J_{dark} = J_s \left[\exp(qV/kT) - 1 \right] , \quad (9.115)$$

where the saturation current is

$$J_s = A_R T^2 \exp(-q\varphi_{bn}/kT) \quad (9.116)$$

and A_R is the Richardson constant, which is specific to each semiconductor. The main source of the dark current in Schottky-barrier photodiodes is known to be thermionic emission of majority carriers.

In either mode of operation, the photocurrent from a Schottky-barrier photodiode is given by

$$I_p = (1 - R_\Sigma) q \varphi \eta_{in} , \quad (9.117)$$

where R_Σ accounts for both the front side reflection of light and absorption by the metal film, η_{in} is the internal quantum efficiency, and Φ is the incident photon flux (in quanta per second).

Quantum Efficiency

For the case of band-to-band excitation, the internal quantum efficiency of an n-type Schottky-barrier photodiode is similar to that of a p–i–n photodiode, and it can be written as

$$\eta_{in} = 1 - \frac{\exp(-\alpha w)}{1 + \alpha L_p} , \quad (9.118)$$

where α is the absorption coefficient, w is the depletion width, and L_p is the hole diffusion length.

For intrinsic photoemission, the process of photocurrent generation is dependent on the incident quantum energy $h\nu$, and the internal quantum efficiency is given
Fig. 9.29 (a) Cross-section of the MSM mesa structure photodiode. (b) The energy band diagram of the MSM photodiode under a bias beyond flat-band. The increase in the barrier due to the barrier-enhancement layer is shown

by [9.14]

$$\eta_{\text{in}} = C_{\text{f}} \frac{(h\nu - q\varphi_{\text{bn}})^2}{h\nu} , \qquad (9.119)$$

in which C_{F} is the so-called Fowler emission coefficient.

Schottky barrier photodiodes do not perform as well as p–n or p–i–n photodiodes; however, they can be advantageous for wavelengths where the semiconductor absorption coefficient is very high ($>10^4 \, \text{cm}^{-1}$), and most absorption of light occurs within a thin surface layer of the photodiode [9.33]. In a regular p/n structure, the nonequilibrium carrier collection efficiency is very low close to the surface because of pronounced surface charge recombination. If the p semiconductor is replaced with a metal, the surface recombination–generation becomes much less pronounced or even disappears completely, increasing the carrier collection efficiency in the metal–semiconductor depletion layer.

Schottky-barrier photodiodes working in the second mode of operation have also proven to be very useful for infrared light detection, leading to the construction of efficient Schottky-barrier focal plane arrays [9.34–36]. The other advantage of Schottky-barrier photodiodes is their high operational speed.

9.6.2 Metal–Semiconductor–Metal (MSM) Photodiode

MSM photodetectors can be thought of as two Schottky barriers connected back-to-back (Fig. 9.29a). For compound semiconductors, a thin light absorption layer (n-InGaAs in Fig. 9.22a) is deposited on a semi-insulating substrate. A barrier-enhancement layer AlInAs with a thickness of several tens of nanometers may be deposited between the metal and absorption layer to decrease the dark current of the narrow-bandgap semiconductor that constitutes the absorption layer. A barrier enhancement layer fabricated from the wide energy gap semiconductor significantly increases the barrier height (Fig. 9.29b).

Applying bias of any polarity to an MSM photodetector creates one Schottky barrier in the forward direction and the other in the reverse direction. The dark current from the MSM photodetector has both electron and hole current components, and the saturation current is given by the following expression [9.37]

$$\begin{aligned} J_{\text{s}} = &A_{\text{Rn}} T^2 \exp\left(-q\varphi_{\text{bn}}/kT\right) \\ &+ A_{\text{Rp}} T^2 \exp\left(\frac{-q\varphi_{\text{bp}}}{kT}\right) , \end{aligned} \qquad (9.120)$$

where A_{Rn}, A_{Rp} are the Richardson constants and φ_{bn}, φ_{bp} are the barrier heights at the cathode side and the anode side, respectively (Fig. 9.29b).

The photocurrent first rises with bias and then becomes saturated, indicating that punch-through (complete depletion of the structure) is reached. The saturation voltage corresponds to flat-band conditions, in which the electric field at the anode becomes zero.

MSM photodetectors are advantageous in applications where a very low capacitance is required. The other important advantage of MSM structures is their compatibility with field effect transistor (FET) technology.

9.7 Detectors with Intrinsic Amplification: Avalanche Photodiodes (APDs)

9.7.1 APD: Principles, Basic Properties, and Typical Structures

An APD can be considered to be a family of p–n junction photodiodes working in photoconductive mode and capable of supporting high reverse bias. Upon the generation of an electron–hole (e–h) pair through photon absorption, the electron and/or hole are accelerated in the electric field and gain sufficient kinetic energy to collide with the atoms of the crystal ionizing them. The primary carriers and the products of this impact ionization are also accelerated, creating more nonequilibrium electron–hole pairs. Under favorable conditions, multi-ple collisions can create an avalanche-type increase in output current. Hence, the avalanche photodiode can be thought of as a type of photoconductor. It can work in either linear or nonlinear modes.

In the avalanche regime, each absorbed photon creates a finite number M of e–h pairs on average. The typical internal gain is tens to hundreds in the linear mode, where the photocurrent is proportional to the incident optical flux.

At high reverse bias, the rate of nonequilibrium carrier extraction on the electrodes falls back the impact ionization rate, which produces a highly nonlinear mode of APD operation – avalanche breakdown. The
Fig. 9.30 (a) Cross-sections of typical reach-through APD structures with separated absorption and multiplication regions. The intrinsic (or π) layer that separates the n^+ implant and the p^+ implant in the structure shown in panel **(b)** greatly improves the photoresponse uniformity and the noise characteristics of the APD

Fig. 9.31 Ionization coefficients for electrons and holes in a number of semiconductors

population of nonequilibrium carriers in the high-field region and the associated photocurrent grow exponentially over time. This growth continues until the drop in voltage across the series resistance reduces the voltage drop across the photodiode high-field region, slowing the avalanche and ultimately stopping it. Since the avalanche breakdown is not a destructive effect and is stable against thermal runaway, this nonlinear mode of operation has found many practical applications and has been afforded a specific name – the Geiger mode. High-performance Geiger mode APDs can be used for single photon counting [9.38].

The noise current from an APD has an additional term that goes beyond the simple scaling up of the photocurrent that would flow in a regular photodiode by a factor of M. The origin of this additional noise is the statistic (and stochastic) nature of the multiplication process. Fluctuations in gain produce excess noise, which gets progressively worse as the average gain M of the diode is increased by raising the reverse bias. When the multiplication noise exceeds the noise introduced by downstream circuitry, further increases in gain deteriorate the system's signal-to-noise ratio.

Figure 9.30 shows the APD structures typically employed in practice. Starting material with either n-type or p-type conductivity is chosen based on the maximum value of the minority carrier impact ionization rate. For Si, the electron ionization rate is much higher than that for holes; hence, p-type material is used to build Si APDs.

The diode is fabricated by ion implantation of n-type and p-type dopants. The structure that results, rather than being a simple p–n diode, is either p–π–p–n (Fig. 9.30a) or p–π–p–π–n (Fig. 9.30b). Here π denotes a very lightly – close to intrinsic – p-doped region. A thin layer of lightly π-doped material between the
top n electrode and a highly doped p region in Fig. 9.30b improves the APD noise, response speed and uniformity, as well as the quantum efficiency in comparison with the structure shown in Fig. 9.30a. Both structures in Fig. 9.30 have their absorption regions separated from their multiplication layers. These structures are also called reach-through structures, because the electric field extends all the way from the n/p(π) junction and reaches the p layer. The lower π layer is where the photons are absorbed for either front- or back-illuminated structures. Reverse biasing at the appropriate operating voltage establishes a modest electric field in this photon absorption layer that causes the photoelectron to drift up into the upper p layer. The field in that layer (sometimes called the "p-well") is much stronger, sufficient to cause impact ionization, which initiates an avalanche. The photoelectron and the secondary electrons are collected at the top n layer, and the photohole and secondary holes are collected at the substrate.

Note that the p-well exists only in the central portion of the APD. Because of the absence of a p implant, the diode's peripheral portion is a simple p–i–n structure, in which the field is intermediate in strength between the photon-absorption region and the avalanche region. This peripheral diode serves as a "guard ring" that performs two functions. First, it tailors the electric field profile so that avalanche breakdown occurs in the central portion of the diode, not at the periphery. Second, it ensures that electrons generated outside the region directly under the p implant do not drift to the avalanche region, but are

Part B | 9.7

collected in the peripheral portion of the n layer without being able to start an avalanche. This collection minimizes the volume from which dark current is multiplied, and therefore minimizes the dark count rate.

9.7.2 APD: Main Characteristics and Figures of Merit

Ionization Rates

The electron and hole ionization rates, α_n and α_p, respectively, are defined as the number of ionizing collisions per unit distance. The ionization rates depend strongly (exponentially) on the threshold electric fields required to overcome different carrier scattering effects. Examples of the experimental ionization rates at 300 K for Si, Ge, GaAs, and GaP versus electric filed are given in Fig. 9.31. The ionization rates can be equal for electrons and holes, as for GaP, or they can significantly differ from each other, as in the cases of Si, Ge, and most compound semiconductors.

Avalanche Gain (Multiplication Factor)

The multiplication factor M is defined as the ratio of the number of carriers leaving the avalanche region to those entering it. Since the ionization rates are strongly dependent on the electric field, which is usually position-dependent, it appears to be almost impossible to explicitly calculate the avalanche gain for any real structure. However, reasonable estimations may be obtained for some practically important cases [9.1, 6, 12].

The low-frequency gain for the electrons/holes is given by

$$M_{n,p} = \left\{ 1 - \int_0^L \alpha_{n,p} \right. $$

$$\left. \times \exp\left[-\int_x^L (\alpha_{n,p} - \alpha_{p,n})\,dx' \right] dx \right\}^{-1}, $$

(9.121)

where L is the high-field layer width. This expression is simplified for position-independent ionization coefficients, which, for the case of the electron current gain, yields

$$M_n = \frac{(1 - \alpha_p/\alpha_n)\exp[\alpha_n L(1 - \alpha_p/\alpha_n)]}{1 - (\alpha_p/\alpha_n)\exp[\alpha_n L(1 - \alpha_p/\alpha_n)]}. $$

(9.122)

For equal, position-dependent ionization rates $[\alpha_n = \alpha_p = \alpha(x)]$

$$M_p = M_n = \left[1 - \int_0^L \alpha(x)\,dx \right]^{-1}, $$

(9.123)

from which we can conclude that the avalanche breakdown ($M_{n,p} \to \infty$) corresponds to the case $\alpha_{n,p}L \to 1$.

The maximum achievable multiplication is limited by the series resistance and the space-charge effect. Combining these two factors into a single equivalent series resistance R, the dependence of the multiplication of photogenerated carriers M_{ph} on the reverse bias V and the breakdown voltage V_B can be empirically described as [9.6]

$$M_{ph} = \frac{I - I_{MD}}{I_p - I_d} = \left[1 - \left(\frac{V - IR}{V_B} \right)^\gamma \right]^{-1}, $$

(9.124)

where I_p and I are the total primary and multiplied currents, and I_d and I_{MD} are the primary and multiplied dark currents, respectively. The exponent γ depends on the semiconductor material, the doping profile, and wavelength, and it is usually in the range 3–6 [9.14]. For a relatively high light intensity $I_p \gg I_d$ and low parasitic losses $IR \gg V_B$, the maximum value of M_{ph} is given by

$$M_{ph}^{max} \approx \frac{V_B}{\gamma I_p R}. $$

(9.125)

For small photocurrents, $I_p \ll I_d$, the maximum avalanche multiplication is:

$$M_{ph}^{max} \approx \frac{V_B}{\gamma I_d R}, $$

(9.126)

which means that a high dark current limits the maximum multiplication.

Excess Noise Factor

Due to the statistical nature of the avalanche gain, the mean-square value $\overline{M^2}$ of the gain M is greater than the square M^2 of the mean value. The shot noise of any photodiode is determined by the statistics of the nonequilibrium carriers, electrons and holes. For the p–i–n photodiode, each nonequilibrium carrier generation event creates one electron and one hole only, whereas for each incident photocarrier in the multiplying region of APD three non-equilibrium particles are present: one primary carrier and two newly created secondary carriers. If the spectral density of the noise in the total primary current I_p is $2qI_p$, the spectral density of the
Gain

Fig. 9.32 Gain–voltage characteristics of an APD at different stages of processing, as described in the text

noise in the total multiplied current $I = I_p M$ can be written as

$$i_{sh}^2 = 2qI_p \overline{M^2} = 2qI_p M^2 F(M) \ , \tag{9.127}$$

where we put the frequency bandwidth $\Delta f = 1$ and introduce the *excess noise factor* $F(M) = (\overline{M^2}/M^2)$,
Gain

Fig. 9.33 "Universal" gain–voltage characteristics for a reach-through APD. The applied reverse bias V and the breakdown voltage at $20\,°\mathrm{C}$ $V_B(20\,°\mathrm{C})$ are in volts, while the depletion width w is in microns

which is the ratio of the actual noise to that which would exist if the multiplication process were noiseless.

Since the excess noise depends strongly on the total number of the secondary carriers, its value is large when the electron and hole ionization rates, α_n and α_p, are close to each other. When either $\alpha_n \gg \alpha_p$ or $\alpha_n \ll \alpha_p$ the excess noise decreases. For the ratio (α_n/α_p), which is constant throughout the avalanche region, the excess noise can be approximated by [9.39]

$$F(M) = k_i M + \left(2 - \frac{1}{M}\right)(1 - k_i) \ , \tag{9.128}$$

in which $k_i = (\alpha_p/\alpha_n)$ for the case of electron injection alone, and $k_i = (\alpha_n/\alpha_p)$ for hole injection.

Signal–to–Noise Ratio

The thermal noise in an APD is the same as that for a p–i–n photodiode and it is given by (9.93). The shot noise spectral density of an APD is given by (9.127) above. The signal-to-noise ratio for an avalanche photodiode is then

$$\frac{S}{N} = \frac{I_s}{i_n} \equiv \frac{I - I_{MD}}{i_n}$$

$$= \frac{\frac{1}{\sqrt{2}}\left(\frac{q\eta_{ex}\Phi_p}{h\nu}\right)M}{\left\{2q\left[I'_D + I_p F(M)M^2 \Delta f\right] + \frac{4kT\Delta f}{R}\right\}^{1/2}} \ , \tag{9.129}$$

where I_s and i_n are the average output photocurrent and rms noise current, respectively, I is the total multiplied current, I_{MD} is the multiplied dark current, I_p is the total primary current that is multiplied, I'_D is the component of the dark current (usually the surface leakage current) that is not multiplied, Δf is the noise bandwidth, Φ_p is the incident optical power, and η_{ex} is the external quantum efficiency.

Noise Equivalent Power

Equation (9.129) can be solved for the optical power required to produce a signal-to-noise ratio equal to 1:

$$\mathrm{NEP} = \frac{\sqrt{2}h\nu}{\eta_{ex}}\left(\frac{I_p F(M)\Delta f}{q} + \frac{2I_0 \Delta f}{q}\right)^{1/2} \ , \tag{9.130}$$

where

$$I_0 = I_d F(M) + \frac{2kT}{qRM^2} \tag{9.131}$$

is an equivalent current, similar to that introduced by (9.17) of Sect. 9.1.3.

For the case when the thermal noise dominates, the APD sensitivity is determined by

$$S_0 = \text{NEP} = \frac{2h\nu}{q\eta_{ex}M}\sqrt{\frac{kT\Delta f}{R}}, \qquad (9.132)$$

which indicates that the APD sensitivity threshold is substantially reduced (by a factor of M) due to the avalanche effect.

For the case of photon-limited performance, the NEP value is given by

$$\text{NEP}^{B,S} = \sqrt{2}h\nu\sqrt{\frac{\Phi^{B,S}\Delta f}{\eta_{ex}}F(M)M^2}, \qquad (9.133)$$

indicating that for high signals the noise grows along with the signal, thus limiting the APD performance. The superscripts B,S in expression (9.133) correspond to either the signal-limited or background-limited characteristics.

Gain–Voltage Characteristics

The three general gain–voltage characteristics that can occur are shown in Fig. 9.32. For example, for the APD structure of Fig. 9.30a, if the top diffusion (n-type implant in Fig. 9.30a) has not been adequately completed so that the implant concentration in the multiplication region (p-well) and the width of that region facilitate avalanche breakdown before reach-through is achieved, the case shown by curve 1 in Fig. 9.32 is realized. This case describes nonoptimal operating conditions, because avalanche breakdown is attained before the photodiode intrinsic layer is completely depleted. In this case, the gain becomes very high even at relatively low bias, and the excess noise factor increases progressively with voltage. Curve 2 in Fig. 9.32 describes the conditions where reach-through occurs at intermediate gain levels of 10 to 20. Further increases in the bias value gradually increase the gain without deteriorating the noise and detectivity performance. Curve 3 describes the other extreme case, where the top implant (e.g., the n-type implant in Fig. 9.30a) diffuses too far, so that useful gain is achieved at an excessively high voltage. Similar situations can occur for the APD structure shown in Fig. 9.30b; however, for this type of structure the p^+ implant parameters will control the behavior of the APD.

Figure 9.33 presents example "universal" gain–voltage curves for a reach-through APD. At constant bias, decreasing the temperature increases the ionization rates for electrons and holes, so the gain also increases. The curves in Fig. 9.33 can be applied to the given reach-through structure independent of the
Fig. 9.34 A cross-section of a typical APD structure based on III–V compounds

thickness of the absorption and avalanche layers and the room-temperature breakdown voltage V_B.

9.7.3 Materials Used to Fabricate APDs

The following materials have proved to be appropriate for the fabrication of high-performance APDs:

- Silicon (for wavelengths of 400 to 1100 nm). Both front-illuminated and backlit structures are employed. The electron ionization rate in much higher than the hole ionization rate ($\alpha_n \gg \alpha_p$);
- Germanium (for the wavelengths of up to 1.65 μm). Since the bandgap in Ge is lower than in Si, and the ionization rates for electrons and holes are approximately equal ($\alpha_n \approx \alpha_p$), the noise is considerably higher and this limits the applications of Ge-based APDs;
- GaAs based devices. Most compound materials have $\alpha_n \approx \alpha_p$, so designers usually use heterostructures like GaAs/Al$_{0.45}$Ga$_{0.55}$As, for which $\alpha_n(\text{GaAs}) \gg \alpha_n(\text{AlGaAs})$. The large increase in gain occurs due to the avalanche effect that occurs in GaAs layers. GaAs/Al$_{0.45}$Ga$_{0.55}$As structures are used below 0.9 μm. Applying InGaAs layers allows the sensitivity to extend to ≈ 1.4 μm;
- InP-based devices (for the wavelengths of 1.2−1.6 μm). One example is a double heterostructure with lattice-matched layers – n^+-InP/n-GaInAsP/p-GaInAsP/p^+-InP – in which either of the carriers may be preferentially injected into the high field region, which is essential for low-noise operation. The other example is an APD with separate absorption and multiplication regions – p^+-InP/n-

InP/n-InGaAsP/n$^+$-InP – which is similar to the Si reach through devices shown in Fig. 9.30 above. The absorption occurs in the relatively wide InGaAsP layers and avalanche multiplication of the minority carriers proceeds in the n-InP layer – see Fig. 9.34 for an example.

9.8 Detectors with Intrinsic Amplification: Phototransistors

Like diodes, all transistors are light-sensitive. Phototransistors are specifically designed to take advantage of this fact. A phototransistor can be thought of as a device with intrinsic amplification that operates as a photoconductor.

Early phototransistors were made of Si and Ge. Most recent devices include III–V compounds, especially heterostructures like AlGaAs/GaAs, InP/InGaAs, CdS/Si, Cu$_2$Se/Si, and PbS/Si.

9.8.1 Photosensitive Bipolar Transistor

The most common variant is an NPN bipolar transistor with an exposed base region. Here, light striking the base replaces what would ordinarily be voltage applied to the base – in other words, a phototransistor amplifies variations in nonequilibrium carrier density created by incident light. To optimize the light collection, the base–collector junction (the light-collecting element) of the bipolar transistor is made as large as possible. While not required for the operation of the device as a photodetector, a base connection is often provided in order to use base current to bias the transistor. The typical gain of a phototransistor can range from 100 to over 100 000. In its mode of operation, a photoelectric transistor corresponds to that of a photodiode with a built-in amplifier. The cross-section of a homojunction bipolar phototransistor and its simplified equivalent circuit is shown in Fig. 9.35. The emitter and base leads are affixed laterally to make the base diode as accessible to light as possible. The large collector zone ensures that the largest possible number of radiation quanta are absorbed and will contribute to the photocurrent.

Characteristics and Figures of Merit

In the dark, a small collector–emitter current flows due to the leakage current of the collector base junction I_{C0}. At illumination, the photogenerated carriers contribute to the photocurrent value I_p. In addition, the majority carriers generated in the base and those swept into the base region from the collector lower the base–emitter potential, allowing electrons to be injected across the base to the collector. Thus, the output (photo)current I of the phototransistor will be

$$I = I_{CEO} = (1 + h_{FE})(I_{C0} + I_p) \,, \tag{9.134}$$

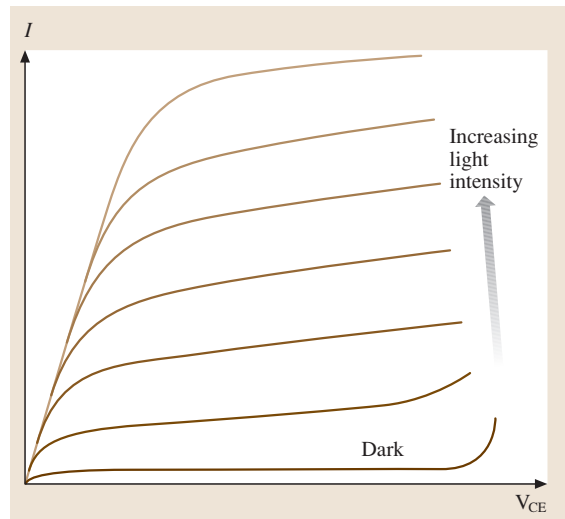
where h_{FE} is the DC common-emitter current amplification (gain) that yields a photocurrent gain (and also a quantum efficiency gain) of $\beta = (1 + h_{FE})$. The output photocurrent I depends in a nonlinear fashion on the incident radiation intensity, since the current gain β depends on the current. Figure 9.36 shows typical current–voltage characteristics of a phototransistor.
Fig. 9.35a,b A cross-section (**a**) and a simplified equivalent circuit (**b**) of a homojunction bipolar phototransistor


Fig. 9.36 I–V characteristics of a phototransistor under different illumination intensity levels

These curves are similar to those of a conventional bipolar transistor with the base current replaced by photocurrent. Note that the photodiode dark current is also amplified by the same amount as the photocurrent.

Since the reverse current, I_{C0}, of the base diode is amplified in the same way as the photocurrent, I_p, the signal-to-noise ratio and the noise equivalent power of the phototransistor are similar to those of a photodiode. For example, the NEP can be written as

$$\text{NEP} = \frac{\sqrt{2}h\nu}{\eta_{\text{ex}}}\sqrt{\frac{I_{\text{eq}}}{q}} \tag{9.135}$$

with an equivalent current I_{eq}

$$I_{\text{eq}} = I_{\text{CEO}}\left(1 + \frac{2h_{\text{fe}}^2}{h_{\text{FE}}}\right), \tag{9.136}$$

where h_{fe} is the common-emitter AC current gain [9.6].

The operating point of the phototransistor may be preset by biasing the base lead; this controls both the speed and gain of the device. The speed of the phototransistor is limited by the base-to-emitter (C_{BE}) capacitance and is specified in terms of the rise time of the device. Since C_{BE} interacts mainly with the load resistor (R_{L}), the rise time is linearly dependent on R_{L}. Phototransistors are not as fast as photodiodes. A photodiode is in fact the input section of a phototransistor (collector-to-base section) without an emitter and so it does not suffer from the C_{BE} effect.

9.8.2 Darlington Phototransistor (Photo–Darlington)

A Photo-Darlington is simply a cascaded pair of bipolar transistors (Fig. 9.37). One transistor in the pair serves as a primary photodetector while the other acts as an additional amplifier. The advantage of this design is higher amplification, but the time response is pretty long (several tens of μs).

9.8.3 Field–Effect–Based Phototransistors

Examples of the other type of phototransistors include photosensitive field effect transistors like JFET, MESFET, and MOSFET. These employ various modes of operation, the simplest of which is based on photoconductivity, where photogenerated excess carriers increase
Fig. 9.37 A simplified schematic diagram of a Darlington phototransistor

the conductivity of the channel. In the mode specific to JFET or MESFET, the gate is not insulated and the gate-to-channel junction can be considered to be a photodiode that has the gate current as the primary photocurrent. For the MOSFET, the gate is insulated and different modes of operation are possible. For example, photogenerated carriers can be trapped at the surface of the semiconductor, which changes the surface potential and induces a change in the channel current.

One interesting design uses the depleted field effect transistor structure (DEPFET) [9.10, 40]. This is based on a combination of the sideward depletion principle and the principle of the field effect transistor. In this structure, a p-channel MOSFET is built on one side of an n-type wafer whereas a p–n diode structure is created on the opposite side. Applying a reverse bias to the diode creates a depletion layer that propagates towards the MOSFET on the wafer's front side. If the MOS gate is biased and an inversion layer is created on the oxide–semiconductor interface, then the minimum potential for the majority carriers (electrons) will occur in the bulk of the wafer, right underneath the MOSFET gate. Upon the photogeneration of electron–hole pairs in the depleted bulk, the minority carriers (holes) will drift in the depleted region towards the diode p/n junction on the back surface of the structure, while the majority carriers will be trapped in the potential well underneath the transistor p-channel. This trapped charge will induce a charge of opposite polarity in the channel, thereby increasing its conductance and the transistor current.

The DEPFET structure is characterized by a smaller overall capacitance, thereby potentially yielding a better noise performance than a photodiode coupled to a transimpedance amplifier. The DEPFET structure allows the amount of charge stored in the MOSFET gate region to be controlled, thus allowing either multiple readouts of stored information or the clearing of that information.

9.9 Charge Transfer Detectors

The detectors described in the previous sections operate primarily as single-element detectors. When designing multi-element arrays, the simplest solution – adding a number of individual detectors together – did not prove to be very fruitful. This became even more evident in applications where high-resolution images with a large number of pixels and a small element size were required. In the early 1970s, a new concept for creating images was introduced, based on the use of charge transfer devices [9.41–44]. This idea appeared to be very promising and triggered extensive research in this area.

The structures of all charge transfer devices – charge-coupled devices (CCD), charge transfer image sensors (CTIS) or charge-coupled image sensors (CCIS), and (more recently) complementary metal–oxide–semiconductor detectors (CMOS) – are based on a metal–insulator–semiconductor (MIS) capacitor. The most important MIS is the metal–oxide–semiconductor (MOS) capacitor made from silicon, which uses silicon dioxide as the insulator. The simplest version of a CCD is an array of closely spaced MOS capacitors. Under the application of a proper sequence of clock voltage pulses, the charges accumulated in the capacitors of the array can be moved in a controlled manner across a semiconductor substrate. This basic mechanism has been applied to build a variety of electronic and op-toelectronic devices that perform image sensing, data storage, and signal processing.

9.9.1 MOS Capacitor

An MOS capacitor is a building block for a charge storage device. A cross-section of such a capacitor is shown in Fig. 9.38a. First consider a MOS capacitor at thermal equilibrium conditions with no fixed or mobile charge in the oxide layer and zero probability that the charge carriers will cross that layer. In this case, the thermal equilibrium can be considered separately in two regions (oxide and semiconductor regions).

Modes of Operation
Flat-Band Conditions. A simplified band diagram of the ideal p-type MOS capacitor at thermal equilibrium and for so-called flat-band conditions is given in Fig. 9.33b. Under these conditions, semiconductor band-bending is absent (the electric field strength throughout the semiconductor is zero) and the electrode voltage applied to the gate V_{FB} corresponds to the difference
Fig. 9.38 (a) Cross-section of a MOS capacitor. (b) Simplified energy band diagram of an ideal MOS capacitor biased at $V_G = V_{FB}$
Fig. 9.39a–c Different modes of MOS capacitor operation: (a) accumulation, (b) depletion, and (c) inversion

between the metal and semiconductor work functions

$$V_{\mathrm{FB}} = \varphi_{\mathrm{m}} - \varphi_{\mathrm{s}} \,. \tag{9.137}$$

Note that for Si, the barrier height at the Si-SiO$_2$ interface is 3.2 eV for electrons and 4.3 eV for holes. The Fermi level E_{F} is shifted down from the intrinsic level $E_{\mathrm{i}}^{\mathrm{p}}$ by

$$q\psi_{\mathrm{Bp}} = E_{\mathrm{i}}^{\mathrm{p}} - E_{\mathrm{F}} = kT \ln \frac{N_{\mathrm{A}}}{n_{\mathrm{i}}} \,, \tag{9.138}$$

where N_{A} is the acceptor concentration and n_{i} is the intrinsic carrier concentration.

Applying a bias to the gate electrode $V_{\mathrm{G}} \neq V_{\mathrm{FB}}$ allows the potential ψ_{s} of the oxide–semiconductor interface to be shifted, which drives the MOS capacitor into different regimes. There can be three distinctly different modes of operation depending on the gate voltage polarity and amplitude: (a) accumulation, (b) depletion, and (c) inversion. These three modes are shown schematically in the band diagrams of Fig. 9.39a–c. The Fermi level remains flat for any operational regime because of zero current flow.

Accumulation Mode. Upon applying a more negative voltage than V_{FB} to the gate of a p-type MOS capacitor, holes will be attracted to the semiconductor–oxide interface, and a thin layer of positive charge (majority carriers) will form in the semiconductor at the boundary. The bands bend upwards near the semiconductor-oxide interface, and the edge of the valence band approaches the Fermi level, thereby filling the potential well at the boundary with free holes. The surface potential energy $q\psi_{\mathrm{s}}$ is negative in this case. Since these free holes are concentrated in a very thin interfacial layer, the surface charge density can be written as

$$Q_{\mathrm{acc}} = -\varepsilon_{\mathrm{ox}}\varepsilon_0 \frac{V_{\mathrm{G}} - V_{\mathrm{FB}}}{d_{\mathrm{ox}}} = -C_{\mathrm{ox}}\,(V_{\mathrm{G}} - V_{\mathrm{FB}}) \,, \tag{9.139}$$

where $\varepsilon_{\mathrm{ox}}$ and ε_0 are the oxide dielectric constant and vacuum permittivity, respectively, d_{ox} is the oxide layer thickness, and C_{ox} is the capacitance per unit area of the oxide layer.

Depletion Mode. When a small positive excess voltage $V_{\mathrm{G}} > V_{\mathrm{FB}}$ is applied, the majority carriers are repelled from the semiconductor–oxide interface, the bands bend downwards at the interface, and a relatively small positive surface potential $\psi_{\mathrm{s}}(0 < q\psi_{\mathrm{s}} < q\psi_{\mathrm{Bp}}$, Fig. 9.39b) is formed.

To find the distribution of potential inside the semiconductor, the depletion approximation is usually used, which assumes that the edge of the depletion region is abrupt and that no mobile majority carriers exist in this depletion region. The potential ψ in the depletion region for the thermal equilibrium case (no photoexcitation, no imperfections in the oxide and interface layers) is described by the Poisson equation

$$\nabla^2 \psi = \frac{\partial^2 \psi}{\partial x^2} = -\frac{\rho}{\varepsilon_{\mathrm{s}}\varepsilon_0} = \frac{qN_{\mathrm{A}}}{\varepsilon_{\mathrm{s}}\varepsilon_0} \,, \tag{9.140}$$

where ρ is the charge density, N_{A} is the acceptor concentration in a uniformly doped p-type semiconductor, and ε_{s} is the dielectric constant of the semiconductor. The electric field $E = -\nabla \psi$ can be found by integrating (9.140) with a constant electric field E_{ox} in the insulator layer assumed as a boundary condition. One more integration provides the potential distribution as a function of depth x inside the semiconductor

$$\psi = \int_0^x E(x)\,\mathrm{d}x = \int_0^x \frac{qN_{\mathrm{A}}\,x}{\varepsilon_{\mathrm{s}}\varepsilon_0}\,\mathrm{d}x = \frac{qN_{\mathrm{A}}\,x^2}{2\varepsilon_{\mathrm{s}}\varepsilon_0} \,, \tag{9.141}$$

where the potential is assumed to be zero throughout the semiconductor outside the depletion region. The potential varies linearly with distance across the insulator and quadratically in the depletion region. The minimum potential at the interface takes the value

$$\psi_{\mathrm{s}} = \frac{qN_{\mathrm{A}}}{2\varepsilon_{\mathrm{s}}\varepsilon_0} w^2 \,, \tag{9.142}$$

where w is the semiconductor depletion layer width.

The gate voltage V_{G} is distributed between the voltage drop V_{ox} that charges the oxide capacitance, the work function difference (9.137), and the semiconductor surface potential ψ_{s}

$$V_{\mathrm{G}} = V_{\mathrm{FB}} + V_{\mathrm{ox}} + \psi_{\mathrm{s}} \,. \tag{9.143}$$

The potential drop across the oxide is given by

$$\begin{aligned}
V_{\mathrm{ox}} &= E_{\mathrm{ox}}d_{\mathrm{ox}} = \frac{qN_{\mathrm{A}}\,w}{\varepsilon_{\mathrm{s}}\varepsilon_0}d_{\mathrm{ox}} \equiv \frac{qN_{\mathrm{A}}\,w}{C_{\mathrm{ox}}} \\
&= \frac{\sqrt{2qN_{\mathrm{A}}\varepsilon_{\mathrm{s}}\varepsilon_0\psi_{\mathrm{s}}}}{C_{\mathrm{ox}}} \,,
\end{aligned} \tag{9.144}$$

where on the right-hand side we substituted w for the (9.142). Solving (9.143) and (9.144) for the surface

potential at thermal equilibrium yields

$$\psi_s = V_G - V_{FB} + \frac{qN_A\varepsilon_s\varepsilon_0}{C_{ox}^2} - \frac{1}{C_{ox}}$$
$$\times \sqrt{2qN_A\varepsilon_s\varepsilon_0 (V_G - V_{FB}) + \left(\frac{qN_A\varepsilon_s\varepsilon_0}{C_{ox}}\right)^2} .$$
(9.145)

The surface layer depletion width w is given by [9.10]

$$w = \sqrt{\frac{\varepsilon_s\varepsilon_0}{qN_A} (V_G - V_{FB}) + \left(\frac{\varepsilon_s}{\varepsilon_{ox}}d_{ox}\right)^2} - \frac{\varepsilon_s}{\varepsilon_{ox}}d_{ox} .$$
(9.146)

The capacitance of the MOS structure in the depletion mode can be described as a series capacitance involving the insulator and semiconductor layer capacitance

$$C = \left(\frac{d_{ox0}}{\varepsilon_{ox}\varepsilon_0} + \frac{w}{\varepsilon_s\varepsilon_0}\right)^{-1} .$$
(9.147)

Inversion Mode. When a larger positive voltage is applied, the bands bend even more so that the intrinsic level E_i at the semiconductor–oxide interface crosses the Fermi level E_F (Fig. 9.39c). For this mode, the surface potential becomes large ($q\psi_s > q\psi_{Bp}$) and the minority carriers (electrons) at the surface may outnumber the majority carriers (holes). A thin conducting layer of minority carriers forms close to the semiconductor–insulator interface and the surface becomes inverted.
Fig. 9.40 Typical C–V characteristics of a MOS capacitor for a low frequency (*curve* 1) and a high frequency (*curve* 2). *Curve* 3 shows a drop-off in the capacitance in accord with the depletion approximation

If the gate voltage increases further, the minority carrier concentration at the surface surpasses the majority carrier bulk concentration. This situation is called "strong inversion" and it begins at a surface potential of [9.6]

$$\psi_s(\text{inv}) \approx 2\psi_{Bp} = \frac{2kT}{q}\ln\left(\frac{N_A}{n_i}\right) .$$
(9.148)

The depletion width reaches its maximum value at

$$w_{max} = \sqrt{\frac{4\varepsilon_s\varepsilon_0\psi_{Bp}}{qN_A}} = \sqrt{\frac{4\varepsilon_s\varepsilon_0 kT\ln(N_A/n_i)}{q^2 N_A}} ,$$
(9.149)

and the gate threshold (turn on) voltage, at which strong inversion occurs is given by

$$V_T = V_{FB} + 2\psi_{Bp} + \frac{d_{ox}}{\varepsilon_{ox}\varepsilon_0}\sqrt{4qN_A\varepsilon_s\varepsilon_0\psi_{Bp}} .$$
(9.150)

Further increases above the threshold voltage will only increase the strength of the inversion layer, while the depletion depth remains constant at w_{max}.

MOS Capacitor Characteristics

C–V Characteristics. The dependence of the capacitance on the gate voltage in the MOS structure is shown schematically in Fig. 9.40. Capacitance stays high in the accumulation mode and starts decreasing in the depletion mode due to the increase in the depletion layer width with voltage. When inversion is reached, the capacitance continues to drop until the minimum value

$$C_{min} = \left(\frac{d_{ox}}{\varepsilon_{ox}\varepsilon_0} + \frac{w_{max}}{\varepsilon_s\varepsilon_0}\right)^{-1}$$
(9.151)

is reached at the maximum depletion width w_{max}. For strong inversion, the behavior of the capacitance differs between low and high frequencies.

At low frequencies, minority carriers can follow the AC signal to modulate the inversion layer, and the capacitance rises to C_{ox} at $V_G > V_T$ (curve 1 in Fig. 9.40). At high AC frequencies, minority carriers are not generated quickly enough to follow the AC signal. The depletion width either saturates at w_{max} (with a slow ramp of the gate voltage V_G) or it becomes even wider (at fast V_G ramp), so that the overall capacitance of the MOS structure either saturates at C_{min} level (curve 2 in Fig. 9.40) or continues to drop in accord with the depletion layer approximation, which is similar to the abrupt p/n junction approximation (curve 3 in Fig. 9.40).

For the light-induced generation of minority carriers, the equilibrium high-frequency curve, as shown by curves 2 or 3, can be obtained with either a slow or a fast V_G ramp.

MOS Capacitor Under Nonequilibrium Conditions – Concepts of Charge Storage

Under illumination, and for either the depletion or the inversion mode, the photogenerated minority carriers (electrons for the p-type semiconductor) will tend to collect in the potential well ψ_s close to the semiconductor–oxide interface. As the electrons accumulate at the semiconductor interface, the field across the insulator starts to increase, and the surface potential and the depletion width begin to shrink [9.14]

$$\psi_s = V_G - V_{FB} + \frac{qN_A\varepsilon_s\varepsilon_0}{C_{ox}^2} - \frac{Q_{sig}}{C_{ox}} - \frac{1}{C_{ox}}$$

$$\times \sqrt{2qN_A\varepsilon_s\varepsilon_0\left(V_G - V_{FB} - \frac{Q_{sig}}{C_{ox}}\right) + \left(\frac{qN_A\varepsilon_s\varepsilon_0}{C_{ox}}\right)^2},$$
$$(9.152)$$

where Q_{sig} is the signal charge density. The maximum charge density that can be collected in the ideal case is estimated from the condition $\psi_s = 0$

$$Q_{sig}^{max} = C_{ox}V_G, \qquad (9.153)$$

which is to be avoided. In practice, the maximum achievable charge density is $\approx 10^{11}$ cm^{-3}, which limits the dynamic range of any MOS detector to $\approx 10^4$.

Effects of Dark Currents, Interface Traps and Oxide Charges

Various imperfections deteriorate MOS capacitor performance. For example, mobile oxide charges, oxide trapped charges, and fixed oxide charges near the oxide–semiconductor interface cause a parallel shift in the $C–V$ curve shown in Fig. 9.40 in the V_G direction, although main performance parameters do not suffer significantly from these imperfections. Special attention is usually paid to interface charge traps, which are among the major limitations of MOS capacitor performance. If the charge traps are empty prior to the illumination of the MOS capacitor, they are able to capture the nonequilibrium carriers created by the light and then to release them so slowly that the readout electronics will not detect them correctly.

The effect of interface traps can be substantially reduced by passing a constant background charge to the MOS capacitor. Then, to first order, the interface traps remain permanently filled and interact with the signal charges to a minimal extent. However, the drawback of this method is a reduction in the dynamic range by approximately 10 to 20%.

In addition to light generation, various sources that generate dark current also supply charge to the interface and act as background noise. The dark current density can be expressed as the sum of the currents generated in the depletion region, in the neutral bulk, and at the surface [9.14]

$$J_{dark} = \frac{qn_iw}{2\tau} + \frac{qD_nn_i^2}{L_nN_A} + \frac{qS_rn_i}{2}, \qquad (9.154)$$

where τ is the minority carrier lifetime, D_n the diffusion constant, L_n the diffusion length, and S_r is the surface recombination rate. The dark current limits the accumu-
Fig. 9.42 A simplified cross-sectional diagram of an n-channel charge-coupled device

lation time of the MOS detector to a maximum value of

$$t_s = \frac{Q_{sig}^{max}}{J_{dark}} . \tag{9.155}$$

If the gate voltage remains fixed, thermally generated minority carriers will gradually fill the surface potential well and the MOS capacitance will increase toward its low-frequency asymptotic inversion condition C_{ox}.

Buried Channel MOS Capacitor

Previous sections described the surface-channel MOS capacitor. One of the major limitations of this type of MOS structure is the effect of interface traps. To circumvent this problem, the potential well can be buried deeper in the semiconductor bulk, producing a "buried-channel MOS structure" [9.45]. In this structure, the accumulation of nonequilibrium minor carriers is confined to a valley beneath the surface.

Figure 9.41a schematically shows the structure of a buried-channel MOS capacitor built on a p-type semiconductor. The structure has a thin layer ($< 0.5\,\mu m$) of opposite type (n-type) dopant at the semiconductor surface. This layer is fully depleted when the gate pulse is applied. The potential well in this case is formed close the p/n junction and photogenerated carriers are kept away from the interface. The energy band diagram

Fig. 9.43 (a) Clock waveforms and the output signal from the CCD structure shown in Fig. 9.42; **(b)** Energy levels and charge distribution of the same device with the clock from panel **(a)**

for this capacitor under a high gate pulse is shown in Fig. 9.41b.

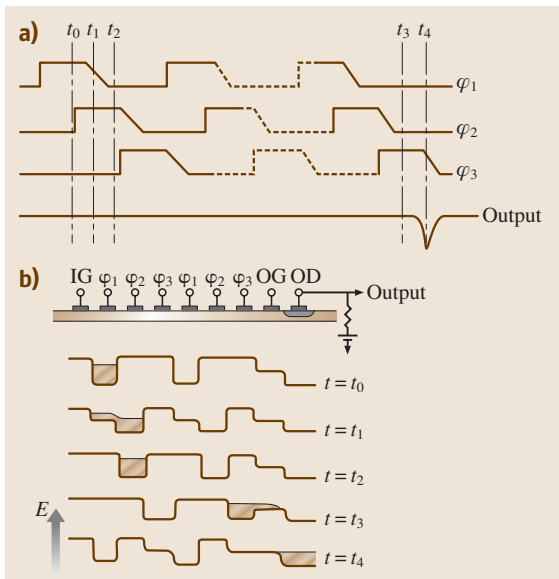
9.9.2 CCDs Employed as Charge–Coupled Image Sensors (CCISs)

A charge-coupled device is an array of MOS capacitors placed close together. The gates are made semitransparent for front-illuminated devices or they can be opaque if the device is back-illuminated. Illumination with light creates nonequilibrium charge carriers via the photoelectric effect under each gate electrode. Applying a proper sequence of gate voltages allows minority carriers to be transferred across the array, thereby delivering an electrical signal proportional to the amount of photons absorbed by each pixel to the output register.

Basic CCD Structure

The CCD photodetection process can be broken down into four steps : charge generation, charge collection, charge transfer, and charge measurement. In a CCD array sensor, the charge from each pixel is transferred through a limited number of output nodes (often just one), converted into a voltage, buffered, and sent off-chip as an analog signal. A cross-section of a simple, typical back-illuminated CCD sensor is shown in Fig. 9.42. The device in Fig. 9.42 is a three-phase CCD that consists of a number of n-channel MOS capacitors connected to φ_1, φ_2, and φ_3 clock lines. Those capacitors participate in the charge generation, charge collection, and charge transfer steps. The output gate OG and the output diode OD are the structures needed to detect output charge packets. The input gate IG forms part of a structure that stops charge from flowing outside of the main CCD array. The surface channel stoppers p^+ at the edges of the structure ensure the unidirectional transfer of charge. In order to increase the efficiency of charge generation and collection, CCDs are usually made by using a high resistivity material to deplete up to $10\,\mu m$ of the semiconductor bulk underneath the gate of each MOS capacitor.

Assuming that the charge is generated and collected in the MOS capacitor on the left-hand side only, the charge transfer mechanism can be described using the following scheme. Fig. 9.43a shows the clock waveforms and Fig. 9.43b illustrates the corresponding potential wells and charge distribution for the structure in Fig. 9.42 where the charge is collected by the capacitor on the left-hand side only.

At $t = t_0$, the clock line φ_1 is at high voltage and φ_2 and φ_3 are at low gate voltages. The output diode (OD)


is biased with a high positive voltage to prevent the inversion of the surface under the output gate. Thus the surface under the OG is stongly depleted and the OD cannot supply electrons to the main CCD array. If the first MOS capacitor is illuminated, the charge is collected in the well under the first capacitor gate, as shown in Fig. 9.43b for $t = t_0$. At $t = t_1$, the voltage applied to φ_1 returns to the low value while a high voltage is applied to the φ_2 electrodes. The second MOS capacitor becomes depleted and electrons stored under the first gate are then transferred to the well under the second gate. The voltage at φ_1 has a trailing edge because the charge carriers require a finite time to move across the width of the gate. At $t = t_2$, the charge transfer process is completed and the original charge packet is stored under the second gate. This process is repeated until the charge packet reaches the output terminal. At $t = t_4$ the voltages of the φ_3 electrodes return to low values, pushing the electrons towards the output diode OD.

Charge Transfer Mechanisms. Charge is transferred from one gate to another by three mechanisms: (1) self-induced drift (repulsion of like charge); (2) thermal diffusion; and (3) fringe field drift. These mechanisms operate within a free charge transfer model, and the charge transfer process is governed by the continuity equation

$$\frac{\partial n}{\partial t} = \frac{1}{q} \frac{\partial J}{\partial x} , \tag{9.156}$$

where n is the charge carrier concentration, J is the current density, and x is the distance in the direction of transfer. As a rule, self-induced drift accounts for $\approx 95\%$ of the charge transfer and two other mechanisms account for the rest. The expression for the decay of the initial charge packet Q_0 due to the self-induced drift can be expressed via the decay process given by [9.46, 47]

$$Q(t) = Q_0 \left(1 + \frac{\tau_{si}}{t} \right) \tag{9.157}$$

where

$$\tau_{si} = \frac{\pi L^3 HC}{2\mu_n Q_0} \tag{9.158}$$

is the decay time constant, L is the gate length, H is the gate electrode width, C are the total capacitances of the insulator and semiconductor layers, and μ_n is the minority carrier mobility.

However, for a small amount of signal charge, thermal diffusion is the dominant transfer mechanism. The total stored charge decreases exponentially with time,

and the time constant is [9.6]

$$\tau_{th} = \frac{4L^2}{\pi^2 D_n} , \tag{9.159}$$

where D_n is the minority carrier diffusion constant.

Fringe field drift originates due to the two-dimensional coupling of the electrostatic field from the biased adjacent electrodes. Because the fringe field is present even at very low charge concentrations, the last bit of the signal charge will be transferred by the fringe field.

CCD: Figures of Merit

Spectral Response. The spectral response of a CCIS (CCD) is determined by the same relationships as those that determine the spectral response of a semiconductor photodiode. Since a relatively high-resistivity material is used to manufacture the CCIS, efficient nonequilibrium charge collection occurs from the charge-space (depletion) region, which may be up to $10\,\mu m$ thick. This is why CCISs have high sensitivity and quantum efficiency over a broad spectral range. For example, Si-based CCISs are typically sensitive to wavelengths from $300\,nm$ to $1000\,nm$.

Besides the figures of merit of traditional detectors, charge transfer detectors can be characterized by a number of specific parameters discussed below.

Transfer Efficiency. The transfer efficiency η_{tr} is the ratio of the charge Q transferred to the initial charge Q_0 stored

$$\eta_{tr} = \frac{Q}{Q_0} . \tag{9.160}$$

The related figure of merit is the transfer inefficiency ε_{tr}, defined as

$$\varepsilon_{tr} \equiv 1 - \eta_{tr} . \tag{9.161}$$

The charge transfer efficiency for n charge transfer steps can be approximated by [9.3]

$$(\eta_{tr})^n = \frac{V_m - \Delta V}{V_m} , \tag{9.162}$$

where V_m is the maximum signal packet voltage and ΔV is the voltage loss for a lead pulse in a packet. Using (9.162), and by rearranging terms and taking the first two terms of a binomial expansion, one obtains for a large number n of transfer steps

$$\eta_{tr} \cong 1 - \frac{\Delta V}{n V_m} . \tag{9.163}$$

For the case of incomplete free charge transfer in a clock period, the charge transfer efficiency can be written as [9.6]

$$\eta_{tr} \cong \frac{Q_0 - Q(t)}{Q_0} = 1 - \frac{8}{\pi^2} \exp\left(\frac{-t}{\tau_{th}}\right) . \quad (9.164)$$

Time Response. Charge collection inside the depletion region is a relatively fast process that does not usually limit the operational frequency of the CCIS. Consider other factors that influence the time response and the frequency range of a charge coupled device.

The pixel charge density is given by the summation of various sources of dark current and photocurrent,

$$\frac{dQ}{dt} = J_{dark} + J_{ph} = \frac{qn_iw}{2\tau} + \frac{qD_nn_i^2}{L_nN_A}$$
$$+ \frac{qS_rn_i}{2} + \eta_{ex}q\Phi , \quad (9.165)$$

where the first three terms on the left-hand side are described by (9.154), Φ is the incident optical photon flux for the pixel, and η_{ex} is the external quantum efficiency. Note that the overall detection efficiency of a CCIS can be thought of as a convolution of the quantum efficiency term with the terms that determine the charge transfer efficiency.

The charge transfer efficiency is influenced by different terms in (9.165) for different frequency ranges. Transfer efficiency at high frequencies can be described by the free charge transfer model of (9.156) and it is limited by the clock rates for a given device.

At medium frequencies, the trapping of the signal charge at the interface traps determines the transfer efficiency. Methods used to overcome the problems due to interface traps have been discussed above.

At low clock frequencies, the time response is determined by the dark current (9.165). The low-frequency degradation of the frequency response is due to the buildup of dark current in the charge packets, which distorts the shape and size of the signal charge. To improve the low-frequency response, one must reduce all of the dark current components in (9.165) by minimizing the gate length and choosing a material with a high minority carrier mobility, a long carrier lifetime, a large diffusion length, and a low surface recombination velocity. As mentioned previously, the lower limit frequency response is limited to the inverse of the maximum integration time given by (9.155).

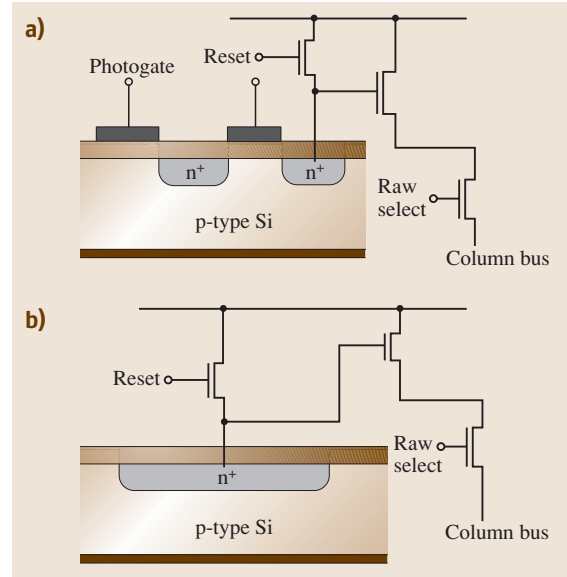
Noise. The most important noise sources in a CCIS are [9.47, 48]:


Fig. 9.44a,b Two CMOS sensor pixel designs: **(a)** photogate architecture and **(b)** photodiode architecture

1. The photon shot noise, which provides the basic limit on the sensitivity of the device

$$N_{sh} = \sqrt{2\eta_{ex}\Phi\Delta f} , \quad (9.166)$$

where N_{sh} is given in rms electrons;

2. The dark current shot noise N_{sh_DC}, which can be expressed in rms electrons by

$$N_{sh\_DC} = \sqrt{\frac{2J_{dark}\Delta f}{q}} , \quad (9.167)$$

where J_{dark} is given by (9.154);

3. The charge transfer noise, which is usually negligible due to the use of buried channels;

4. The readout diffusion reset noise, which is usually added after the charge/voltage conversion step.

CCD thermal noise originates in the same way as for photodiodes, and it can be greatly reduced by cooling the detector. Contemporary cooled CCIS can yield photon-limited performance and operate in single photon counting mode.

9.9.3 Complementary Metal Oxide Semiconductor (CMOS) Detectors

Many of the newer imaging devices use a different chip, known as a CMOS chip. CMOS technology is standard computer chip technology that has been around

for years. Originally, CCD technology gave better images than CMOS detectors. Recently however, CMOS image detectors have evolved to the stage where they provide images comparable to or better than those obtained with CCD chips. In addition, CMOS chips are simpler and require fewer external devices that support their operation.

In a CMOS sensor, each pixel has its own charge-to-voltage conversion. Such sensors include MOS transistors that provide buffering and addressing capability, and may also include a digitizing circuit. The price paid for these additional functions is a reduction in the area available for front-side light collection.

Basic CMOS Structure and Properties

Similar to a CCD, a CMOS detector also performs four steps: charge generation, charge collection, charge transfer, and charge measurement. However, unlike the CCD, the first three steps are performed within each individual pixel in a CMOS sensor.

In order to convert two-dimensional spatial information into a serial stream of electrical signals, electronic scan circuits read out each pixel in the of CMOS photodetector sequentially. First, the vertical scan circuit selects a row of pixels by setting a high DC voltage on all of the gates of the MOS switches in that row. Next, the horizontal scan circuit selects the pixels in one particular column using the same technique. As a result, only one pixel in the two-dimensional matrix has a high DC voltage at its row and its column switches, which electronically selects it for readout. After the pixel dumps its information into the output stage, it is reset to begin a new integration, and the readout process progresses to the next pixel in the row. This organization, in contrast with CCD architecture, provides random access to each pixel and avoids multiple charge transfers over long distances through semiconductor material.

The most common pixel architectures used for CMOS sensor pixels are photogate conversion and photodiode conversion (Fig. 9.44). The photosensitive element in the photogate design is a MOS capacitor that performs the functions of charge generation and collection. Once the scan circuitry has selected a pixel,

a pulse on the transfer gate triggers charge transport from the photosensitive area toward the potential well of a sensing node, created by an n^+ diffusion area at the semiconductor interface (Fig. 9.44a). This node is part of the floating-diffusion amplifier, which performs the charge-to-voltage conversion. The charge-to-voltage conversion in this case is independent of the active area size, which allows a high conversion gain to be achieved.

The photodiode pixel looks very similar to the photogate pixel. However, the additional "transfer gate" is not required since the photodiode capacitance stores the charge and n^+ diffusion is used for the output diffusion of the floating-diffusion amplifier (Fig. 9.44b). For the photodiode pixel, the conversion gain depends on the active area of the photodiode, and it is usually several times smaller than that for the photogate pixel. To allow the detection of low flux levels, most CMOS sensors operate in charge integration mode for both photogate and photodiode designs.

Quantum Efficiency and Spectral Sensitivity

The quantum efficiencies of CMOS detectors are not as high as those of CCD sensors because the CMOS fabrication process requires low-resistivity wafers and relatively low power supply levels, which limits the depletion width of the semiconductor bulk to $1-3\,\mu m$. The spectral range across which CMOS sensors are sensitive is usually narrower than the range for CCIS detectors since the absorption length increases towards the red region of the spectrum.

Noise

Noise from a CMOS sensor consists of photon shot noise, dark current shot noise, reset noise, and thermal noise. The noise properties are the same as described above for CCD photodetectors. However, there is an important difference between the noise properties of CCD and CMOS detector arrays. In a CCD, the noise is captured at the highest bandwidth at the output. However, in a CMOS array, due to its column-parallel organization, the noise bandwidth is set to the row readout bandwidth by the column sampling circuitry, which filters the in-pixel noise [9.47].

9.10 Photoemissive Detectors

The operational principle that underpins photoemissive detectors is the external photoelectric effect, which is

the emission of electrons from a surface upon exposure to electromagnetic radiation. Detectors with multiple
Fig. 9.45 Cross-section of a photomultiplier tube

electrodes have been developed to amplify the resulting signal.

9.10.1 Photoemissive Cell

In their simplest form, photoemissive detectors consist of a metal anode–cathode pair in a vacuum tube. The cathode is made of a material with a very low work function, usually a combination of alkali and other metals. Some common photocathode materials are Ag–CsO–Cs (S-1), Ag–Rb (S-3), and Sb_3Cs (S-4), which are sensitive between 300–1200 nm, 300–1000 nm and 350–600 nm, respectively. Electrons emitted from the cathode following the absorption of a photon are accelerated towards the anode. The photosignal is directly proportional to the intensity of the incident radiation. One method of improving the sensitivity of a photoemissive cell is to add an inert gas, resulting in subsequent ionization.

Figures of Merit
Signal Current. Assuming that the quantum efficiency of a photocathode is η and that the incoming photon flux is Φ, the current signal I_s is equal to

$$I_s = q\eta\Phi \, , \tag{9.168}$$

where q is the elementary charge.

Current Responsivity. The current responsivity of a photoemissive cell is given by the general expression

$$\mathfrak{R}_I = \frac{q\eta\lambda}{hc} \, , \tag{9.169}$$

in which λ is the wavelength, c is the speed of light, and h is Planck's constant.

9.10.2 Photomultiplier

One common way to increase the sensitivity of a photoemissive detector is to use multiple anodes. This kind

of a device is called a photomultiplier tube (PMT). Similar to a photoemissive cell, light causes the emission of electrons from a photosensitive cathode. Instead of just one anode, a sequence of electron absorbers that cause enhanced secondary emission, called dynodes, is used in a PMT.

Figure 9.45 shows a schematic of a PMT. The dynodes are connected along a series of resistors that divide up the high voltage applied between the photocathode and the anode. For a typical gain of 200 eV in kinetic energy between adjacent dynodes, each electron is able to set free between four and eight secondary electrons. There are typically ten dynodes in a PMT device, giving a total multiplication factor of about $10^6 – 10^8$.

The dynamic range of a PMT is limited for low signals by the dark current. The biggest contribution to the dark current is the thermal emission of electrons, which can be effectively suppressed by cooling the tube to $-40\,^\circ$C. Other contributions are leakage currents inside the tube and noise generated by incoming ionizing radiation. At the high end, space-charge effects cause the photocurrent to level off with increasing photon flux on the cathode. A cloud of electrons begins to build up behind the last dynode, thus effectively shielding the anode from additional charge carriers.

Photomultipliers are extremely sensitive and can be used for single photon counting purposes [9.49–51]. In this mode the PMT must be operated such that a single photon generates an electron cloud, resulting in the transfer of an anode pulse of several millivolts into a 50 Ω load. Due to the statistical nature of the amplification process, the signal pulse varies in height. A fast discriminator is used to set a threshold that only accepts an analog signal above the noise level and transforms such signals into logic pulses. These pulses are subsequently counted. Setting an appropriate threshold can reduce the thermal noise of a cooled PMT still further, since noise pulses from dynode thermionic emission
Fig. 9.46 Single-channel electron multipliers (microchannel)
Fig. 9.47 Two microchannel plates in a chevron configuration

have a reduced mean height distribution compared to pulses triggered by an incoming photon.

Figures of Merit

Gain. The PMT gain is

$$G = P_d V^{k \cdot n} \, , \tag{9.170}$$

where n is the number of dynodes, V is the voltage, P_d is the dynode collection efficiency and k is a constant that depends on the geometry and the dynode material.

Dark Current. Thermionic emission characterizes the PMT dark current I_D

$$I_d = C_1 T^2 e^{-\frac{C_2 \varphi}{k_B T}} \, , \tag{9.171}$$

where φ is the photocathode work function, k_B is the Boltzmann constant and T is the absolute temperature. C_1 and C_2 are constant factors.

Noise Equivalent Power (NEP). Under dark-current-limited conditions, the noise-equivalent power of a photomultiplier is

$$\text{NEP} = \frac{hc}{\eta \lambda} \sqrt{\frac{2 I_d}{q}} \, , \tag{9.172}$$

Signal-to-Noise Ratio. The signal-to-noise for a photomultiplier is

$$\frac{S}{N} \approx \frac{I_c}{\sqrt{2q \Delta f \frac{\delta}{\delta - 1}(I_c + 2 I_d) + I_A^2}} \, , \tag{9.173}$$

where I_c is the cathode current, Δf is the bandwidth, I_d is the dark current, I_A is the amplifier noise current, and δ is the secondary emission ratio at each stage.

9.10.3 Single-Channel Electron Multipliers and Microchannel Plates

If the discrete dynode structure described in the previous section on photomultipliers is replaced by a single continuous dynode, the resulting light detector can be much smaller than a PMT but can have similar detection characteristics. These devices are usually referred to as *single-channel electron multipliers*, by their trade name *Channeltrons* [9.52], or, if combined with arrays, as *microchannel plates* (MCPs) [9.53].

A single channel is typically made of a glass tube that has been coated on the inside with first a conductive and then an emissive layer (Fig. 9.46). A high voltage (1000–3000 V) is applied across the length of the tube, which accelerates electrons emitted due to the absorption of photons at the negative end. If the tube is straight, the maximum gain of the device is generally limited to about 10^5. The reason for this is that the high electron density near the anode desorbs ions from the tube walls or ionizes residual gas ions. These positive ions are accelerated back to the cathode, where unwanted secondary electron pulses are created (ion feedback). Therefore, curvature is often introduced into the tube design. Even with this modification some positive ions will still be created in the tube, but due to the short distance they travel and their large masses compared to those of electrons they do not gain enough kinetic energy to set secondary electrons free when they impact the inner tube wall. Depending on the voltage and the resistivity of the conductive material ($\approx 10^{15} \, \Omega$cm), the gain can be tuned to as high as 10^8 for such a device.

Microchannels like those described above can be manufactured to be as small as 10 to 100 µm in diameter. A combination of many of these minute detectors in an array is called a microchannel plate (Fig. 9.47). These plates are very thin, typically around 0.5 mm. Curved channels like those used for the single device are difficult to manufacture. Therefore, a different design is used to suppress the ion feedback. The detector is made of two similar plates that have straight channels at a slight bias angle. The plates are combined in such a way that the charge carriers need to change direction when leaving the first plate before entering the second. This so-called chevron configuration stops positive ions from traveling from the output of the rear plate all the way to the input of the front plate [9.54].

9.11 Thermal Detectors

A wide region of the electromagnetic spectrum, stretching from the UV to the far infrared, can be covered by thermal detectors. In most cases they are a combination of two components. The first one is an absorber in contact with a heat sink, and the second is a temperature-sensitive element (Fig. 9.48). The optical absorbance of the material that converts incoming photons into heat determines their spectral response. By choosing an appropriate material, photons from within a broad wavelength region are absorbed, causing some other physical parameter to change as well. This change is the signal registered by the temperature-sensitive element.

Detector Response

Besides the material of the absorber and the type of temperature sensor used, the sensitivity and the response time of a thermal detector are limited by some general constraints. The temperature change in a thermal detector resulting from a change in the incident light can be calculated as follows. The heat balance equation for a detector with a heat capacity C_{th} that is linked to a heat reservoir by a thermal resistor R_{th} is

$$C_{th}\frac{d}{dt}(\Delta T) + \frac{1}{R_{th}}\Delta T = \eta_s \Phi_p \ . \tag{9.174}$$

The parameter η_s is the surface emissivity of the detector, which is mainly given by the surface finish of the absorber. In general, the change in temperature ΔT and the incident radiant power Φ_p are functions of time. For simplicity the latter is assumed to be a sinusoidal excitation

$$\Phi_p = \Phi_{p0}\, e^{i\omega t} \ . \tag{9.175}$$
Fig. 9.48 Schematic of a thermal detector

Solving and introducing the thermal time constant τ_{th}

$$\tau_{th} = R_{th} C_{th} \tag{9.176}$$

gives a temperature change of

$$\Delta T = \left| \frac{\eta_s \Phi_{p0} R_{th}}{1 + i\omega\tau_{th}}\, e^{i\omega t} \right| = \frac{\eta_s \Phi_{p0} R_{th}}{\sqrt{1 + \omega^2 \tau_{th}^2}} \ . \tag{9.177}$$

To achieve high sensitivity, the optically induced temperature change can be increased by choosing good thermal insulation. The price to be paid for this improvement is a lower response speed due to a larger τ_{th}. Another option is to decrease the heat capacitance. However, this usually means a smaller detector size, which also reduces the amplitude of the signal.

The temperature-sensitive element that records the change in temperature caused by the irradiation of the absorber can be based on a variety of physical processes, as discussed below. These also contribute to the overall time response of the system.

9.11.1 Mechanical Displacement

Noting the thermal expansion in a solid or liquid is a common way to detect radiation-induced temperature changes. *Bimetal springs* or alcohol-filled *glass thermometers* are examples of devices commonly used to monitor and control the temperature.

The *Golay cell* is an example of a radiation detector that makes use of the expansion of a gas [9.55]. Golay cells are broadband and extremely sensitive, which makes them suitable for detecting wavelengths very far into the infrared part of the spectrum ($> 300\,\mu m$). Another of their advantages is that their operation is mostly independent of the ambient temperature, thus eliminating the need for cooling.

Golay cells consist of a gas reservoir that is heated by the incoming radiation. The heat causes minute pressure changes, which deflect a membrane, which in turn is registered by an optical system. The sensitivity of such a system can reach $10^{-10} - 10^{-11}\,W/\sqrt{Hz}$. One variation on this pneumatic detector is the gas-filled *capacitor microphone*.

Advances in microfabrication technology make it possible to create smaller and more sensitive thermal detectors. A good example of this is the *microcantilever*, which is based on a bimetal strip combined with piezoelectric resistance readout, a laser and a position-sensitive photodetector or capacitance meter.

9.11.2 Voltage

If two wires or thin films made of different metals are brought into contact with each other, the difference between the Fermi levels of the materials leads to an electromotive force. This so-called Seebeck effect causes a drop in voltage across the metal/metal junction, the extent of which depends on the temperature. Thermal detectors based on this principle are termed *thermocouples* or *thermoelectric elements*. The measured voltage ΔV is directly proportional to the temperature difference ΔT

$$\Delta V = \alpha_s \Delta T \,, \tag{9.178}$$

where α_s is the Seebeck coefficient (Table 9.3). Using (9.177) and the last equation, it is easy to determine the voltage responsivity of a thermocouple:

$$\mathfrak{R}_v = \frac{\Delta V}{\Phi_{p0}} = \frac{\alpha_s \eta_s R_{th}}{\sqrt{1 + \omega^2 \tau_{th}^2}} \,. \tag{9.179}$$

For low frequencies ($\omega \gg 1/\tau_{th}$), the voltage response becomes a constant

$$\mathfrak{R}_v = \alpha_s \eta_s R_{th} \,. \tag{9.180}$$

In many applications two metal junctions are combined in series. The first one is thermally linked to the absorber that is exposed to the radiation, whereas the second is kept at a constant reference temperature. To increase the voltage signal an additional junction can be added (a *thermopile*). The voltage response of a thermopile is simply the right-hand side of (9.180) multiplied by the number of junctions.

Using (9.25) and (9.179), the noise equivalent power of a thermocouple can be derived as

$$\text{NEP} = \frac{\sqrt{4kT \Delta f}}{R_v \sqrt{R_{el}}} = \frac{\sqrt{4kT \Delta f}}{\alpha_s \eta_s} \frac{\sqrt{1 + \omega^2 \tau_{th}^2}}{R_{th} \sqrt{R_{el}}} \,, \tag{9.181}$$

where R_{el} is the ohmic resistance of the detector.

9.11.3 Capacitance

Some dielectric materials, like lithium tantalite or triglycerine sulfate, exhibit spontaneous electrical polarization without the need for an external electrical field. The magnitude of the polarization and therefore the dielectric constant are a function of the temperature. The effect vanishes above a certain threshold (the Curie temperature) completely.

Thermal detectors based on this effect are called *pyroelectric detectors*. They consist of a crystal between two metal electrodes. If the temperature of the device is held constant, leakage currents eventually redistribute charges between the two surfaces facing the electrodes. Thus any internal electric field is canceled out, and under steady state conditions no current or voltage signal is observed between the electrodes. Therefore a pyroelectric detector is AC-coupled. It must be operated at a frequency high enough to prevent leakage current from playing a role. A change in temperature, however, cause charge to move to accommodate for the change in the internal field. An operational amplifier working in either voltage or current mode can pick up this signal.

Responsivity

The magnitude of the electrical readout depends upon the frequency of the input signal. In a crude analysis, one can identify two major contributions that determine this frequency dependence: the thermal response and the electrical response of the system. A more rigorous

Table 9.3 Seebeck coefficients α_s for different materials at $0\,^\circ\text{C}$ (in $\mu\text{V}/^\circ\text{C}$)

Tungsten	7.5

treatment of the problem is given, for example, in [9.2, 56].

A temperature change ΔT can generate a pyroelectric charge Q that is proportional to the surface area of the electrodes A

$$Q = \gamma_p A \Delta T \,, \tag{9.182}$$

where γ_p is the pyroelectric constant. The temperature change can be calculated by applying the solution to the heat balance (9.177).

Taking the time derivative and calculating the absolute value yields the change in temperature with time

$$\frac{\mathrm{d}}{\mathrm{d}t}(\Delta T) = \left| \frac{\mathrm{d}}{\mathrm{d}t} \left(\frac{\eta_s \Phi_{p0} R_{th}}{1 + \mathrm{i}\omega R_{th} C_{th}} \, \mathrm{e}^{\mathrm{i}\omega t} \right) \right|$$
$$= \frac{\eta_s \Phi_{p0} R_{th} \omega}{\sqrt{1 + \omega^2 \tau_{th}^2}} \,. \tag{9.183}$$

Combining this result with the derivative of (9.182) gives the electric current induced by a sinusoidal temperature change:

$$I_{el} = \frac{\mathrm{d}Q}{\mathrm{d}t} = \gamma_p A \frac{\mathrm{d}}{\mathrm{d}t}(\Delta T) = \frac{\gamma_p \eta_s A \Phi_{p0} R_{th} \omega}{\sqrt{1 + \omega^2 \tau_{th}^2}} \,. \tag{9.184}$$

Using this expression, the current responsivity $\mathfrak{R}_i$ can be written as

$$\mathfrak{R}_I = \left| \frac{I_{el}}{\Phi_p} \right| = \frac{\gamma_p \eta_s A R_{th} \omega}{\sqrt{1 + \omega^2 \tau_{th}^2}} \,. \tag{9.185}$$

In order to get the voltage responsivity $\mathfrak{R}_V$, the electrical capacitance C_{el} and the ohmic resistance R_{el} of the detector must be taken into account (Fig. 9.49). The voltage V_{el} across the output terminals is then

$$V_{el} = \left| \frac{R_{el} I_{el}}{1 + \mathrm{i}\omega \tau_{el}} \right| \tag{9.186}$$

where $\tau_{el} = R_{el} C_{el}$ is the electrical time constant. The resulting voltage responsivity is then

$$\mathfrak{R}_V = \left| \frac{V_{el}}{\Phi_p} \right|$$
$$= \gamma_p \eta_s A R_{th} R_{el} \frac{\omega}{\sqrt{1 + \omega^2 \tau_{th}^2} \sqrt{1 + \omega^2 \tau_{el}^2}} \,. \tag{9.187}$$

The frequency response of the system is determined by the values for the thermal and electrical time constants. The thermal response is usually much slower than the
Fig. 9.49 Electrical equivalent circuit for a pyroelectric detector
Fig. 9.50 Frequency response of a pyroelectric detector

electrical response. At low frequencies the current signal generated by the periodic temperature change increases until it levels off at a threshold of about $1/\tau_{th}$. This behavior is also seen for the voltage response. At higher frequencies $(1/\tau_{el})$, however, the electrical capacitance and ohmic resistance of the detector begin to dominate and the voltage starts to drop (Fig. 9.50).

Specific Detectivity
In the typical case, where the noise performance of a pyroelectric detector is limited by the Johnson noise, the specific detectivity D^* can be obtained using the result for the voltage responsivity (9.187) as well as (9.25) and (9.28):

$$D^* = \frac{\gamma_p \eta_s}{\sqrt{4kT}} A R_{th} \sqrt{A R_{el}} \frac{\omega}{\sqrt{1 + \omega^2 \tau_{th}^2} \sqrt{1 + \omega^2 \tau_{el}^2}} \,. \tag{9.188}$$

It is notable that the performance of the system improves linearly with the product of the detector area and the thermal resistance, as well as with the square root of the product of the area and shunt resistance.

9.11.4 Electrical Resistance

If the heat generated by the optical flux changes the electric resistance of the detector, the device is often called a *bolometer*. To a first-order approximation, the temperature dependence of the resistance R_b of a conductor

can be written as

$$R_b = R_0[1 + \alpha_{th}(T - T_0)] \,, \tag{9.189}$$

where R_0 is the resistance of the conductor at the reference temperature T_0.

In this equation, α_{th} denotes the temperature coefficient of the resistance. This is a material constant and can be either positive (e.g., for metals) or negative (e.g., for semiconductors). In order to detect the change in resistance, an electrical current must be made to flow through the bolometer. Figure 9.51 shows a simple circuit diagram for a bolometer that uses only one load resistor (panel a) and a Wheatstone bridge (panel b).

Since the operating current leads to energy dissipation in the detector and the connecting wires, a detailed calculation of the responsivity must take into account the contribution from Joule heating. Furthermore, depending on the temperature range encountered during operation, heating due to background radiation may also play a role. In the case of semiconductor bolometers, the electrical resistance is not a linear function of the temperature and (9.189) is not valid. The following estimation for the responsivity of a bolometer neglects all of these corrections. For this reason it is only a very crude and general description.

The voltage change across the bolometer is assumed to be proportional to the change in resistance under illumination

$$dV_b = I \, dR_b \,, \tag{9.190}$$

where R_b is the electrical resistance of the bolometer. From (9.189) and (9.190), one obtains

$$dV_b = I\alpha_{th} R_b \, dT \,. \tag{9.191}$$

The current through the bolometer and the load resistor R_L is $I = V_b/(R_L + R_b)$, which together with (9.185)

Table 9.4 Resistivities and temperature coefficients of resistivity for different materials at room temperature

Material	Resistivity $(10^{-8}\,\Omega m)$	Temperature coefficient $(10^{-3}\,C^{-1})$
Silver	1.6	4.1
Copper	1.7	4.3
Aluminum	2.7	4.3
Tungsten	5.4	4.8
Iron	10.1	6.5

Lead	20.6	4.2
Mercury	95.6	1.0
Fig. 9.51a,b Circuit diagram used to bias a bolometer. (**a**) Single load resistor, (**b**) Wheatstone bridge

yields the following equation for the voltage responsivity of a bolometer:

$$\mathfrak{R}_V = \frac{R_b V_b}{R_L + R_b} \frac{\alpha_{th} \eta_s R_{th}}{\sqrt{1 + \omega^2 \tau_{th}^2}} \,. \tag{9.192}$$

Metal Strip Bolometer

The bolometer was invented in 1880 by Langley, who measured the change in resistance of platinum strips upon changes in illumination. Other metals were later tested too. A typical value for the temperature coefficient α_{th} is $+0.5\%/°C$ (Table 9.4).

Thermistor

For many industrial applications where ruggedness and high performance under challenging environmental conditions are mandatory, thermistors are the detectors of choice. In thermistors, metal oxides serve as radiation-sensitive elements; these oxides are pressed into small beads, disks, wafers, or other shapes, which are sintered at high temperatures. The assembly is coated with epoxy or glass and mounted on an electrically insulating thermally conductive material like sapphire.
Fig. 9.52 Transition region of a superconductor

The temperature coefficient of this system is typically around 5%/°C.

Johnson noise is the primary contributor to the noise budget of thermistors. Collecting more light on the detector surface can therefore improve the signal-to-noise ratio. Many thermistors incorporate a lens onto the detector surface in order to enhance light collection. These devices have a NEP of 10^{-10} W$/\sqrt{\text{Hz}}$ in the spectral range of $1-40\,\mu\text{m}$ for uncooled operation [9.2, 57, 58].

Semiconductor Bolometer

A variety of low temperature semiconductor bolometers have been developed for applications that demand high-performance detectors [9.59, 60]. At cryogenic temperatures, the phonon modes of the bulk material freeze out and the specific heat becomes very small while the temperature coefficient for the resistance increases. Therefore detectors with very small heat capacitances and high sensitivities are feasible. A good example of such a detector is a germanium bolometer operated at liquid helium temperatures [9.59]. This can be operated near the theoretical limit between 5 and $100\,\mu\text{m}$. Due to their low heat capacities, Germanium bolometers are very fast thermal detectors with a typical response time of $400\,\mu\text{s}$. The voltage responsivity of such a device is around 5×10^{-3} V/W.

An even better time response than that obtained with the simple semiconductor bolometer can be realized if germanium is used solely for the temperature sensor and a large-area absorber (typically bismuth) is placed on a sapphire or diamond substrate that is in thermal contact with the semiconductor. The heat capacity of the electrically nonconducting substrate is much (orders of magnitude) smaller than it would be if the whole assembly was made of germanium [9.55].

Superconductive Bolometer

The electrical resistance of a superconductor changes dramatically with temperature, which means that superconducting devices are very sensitive to small changes in temperature . However, for a metallic superconductor the transition from the superconducting to normal conducting state occurs within a narrow transition region at very low temperatures (≈ 4 K). Therefore, liquid helium cooling and millikelvin-resolution temperature control are required for proper operation. Thermometers made of high-temperature superconducting material (e.g., niobium nitride or yttrium barium copper oxide) are much easier to handle. Since they show a more gradual transition at about 77 K, only liquid nitrogen cooling is required. Figure 9.52 shows a typical R–T characteristic for a superconductive bolometer.

As well as the bolometric mode, superconducting detectors can also be operated beyond the transition temperature (nonequilibrium mode) and in the so-called "photon-assisted tunneling mode." In the latter case, changes in the I–V characteristic of the junction are detected.

9.12 Imaging Systems

Imaging arrays usually combine the photoconductors or photodiodes described above with electronic readouts. Imaging systems are very often referred to as "focal plane arrays" (FPAs) – an assembly of individual detector picture elements (pixels) located at the focal plane of the imaging system. In general, the FPA architectures can be classified as either monolithic or hybrid.

In the monolithic approach, some of the multiplexing is done in the detector material itself rather than in an external readout circuit. The basic element of a monolithic array is a MIS (MOS) capacitor. There are a few obvious advantages to the monolithic structure, principally its simplicity and the lower costs associated with a directly integrated structure. Monolithic structures like CCD and CMOS arrays can be built in silicon to form arrays with millions of high-performance pixels for visible and infrared detection (see, e.g., the review by *Rogalsky* and *Bielecki* [9.61]).

Ultraviolet and infrared imagers are most commonly built with a hybrid structure. Visible hybrids have also been built for specific applications (e.g., p–i–n photodiode arrays). Hybrid FPA detectors and multiplexers are fabricated on different substrates and mated with each other by flip-chip bonding or loophole interconnection. In this case, the detector material and the multiplexer can be optimized independently. Indium bump, solder bump, or gold stud bump bonding of readout electronics permit the multiplexing of signals from thousands of pixels onto a few output lines, greatly simplifying the interface between the sensor and the system's electronics. For infrared detection, large-dimension, multiple-element hybrid arrays with several millions of pixels are commonly used. Each element of the IR array performs

Table 9.5 CCD versus CMOS: comparison of features and performance

Feature and performance	CCD	CMOS
Signal out of pixel	Electron packet	Voltage
Signal out of chip	Voltage (analog)	Bits (digital)
Signal out of camera	Bits (digital)	Bits (digital)
Fill factor	High	Moderate

Uniformity	High	Low to moderate
Speed	Moderate to high	Higher
Antiblooming	High to none	High
Biasing and clocking	Multiple, higher voltage	Single, low-voltage

at close to the fundamental photon noise limit within the spectral range between 1 and 40 μm. Materials used to build IR FPAs include PtSi (Schottky-barrier array), InSb, QWIP-based arrays (GaAs/Al$_x$Ga$_{1-x}$As, In$_{0.53}$Ga$_{0.47}$As / In$_{0.52}$Al$_{0.48}$As, In$_{0.53}$Ga$_{.47}$As / InP, InGaAsP-based quaternary QWIPs, etc. [9.30]), and HgCdTe.

9.12.1 CCD Arrays and CMOS Arrays

In Sect. 9.9 above, we described the principles of operation and the main properties of charge transfer sensors. A comparison of CCD and CMOS arrays is now presented.

   CCD technology has been able to provide top-level detection performance, but at the cost of several draw-
Fig. 9.53 Cross-section of a p–i–n photodiode array manufactured on a thin Si wafer ([9.62])

backs for the user. The first technology choice requires cheap (relatively) arrays, which CCD technology can provide using thin, back-illuminated devices. On the
Fig. 9.54 Cross-section of a vidicon

other hand, CMOS detectors have intrinsic advantages (low power consumption, readout rate, noise, radiation hardness, integration capability) that make them well suited to several applications. Thanks to recent efforts to develop optimized detectors compatible with the CMOS core process, CMOS can provide enhanced quantum efficiency (although it remains weaker than CCD in this aspect) [9.47]. Table 9.5 compares some of the important features and properties of CCD and CMOS imaging systems.

9.12.2 p–i–n Photodiode Arrays

Multiple-element 2-D p–i–n and avalanche photodiode arrays have a virtual monopoly in some fields of medical imaging, light detection and ranging (LIDAR), 3-D laser radar (LADAR) systems, laser vibrometers, etc. What makes p–i–n and avalanche photodiode arrays unique is their ability to provide rapid access to any single pixel in the array, a wide dynamic range, high-frequency bandwidth (up to 1 GHz or more), and a high-speed parallel readout regime.

State of the art p–i–n photodiode arrays with very high quantum efficiency over virtually the whole visible and near infrared spectral range were designed on thin (30–100 µm) Si wafers with back-illumination capability [9.62–64]. The features of the structure shown in Fig. 9.53 – narrow neutral region width, iso-

lation of n^+ diffusion between adjacent pixels, and the ability to control the gap width – provide unique properties that make arrays promising for many applications. In particular, rise and fall times of ≈ 1 ns with a small reverse bias of few volts are characteristic of the pixels in such photodiode arrays. The other important feature of the design shown in Fig. 9.53 is very low DC and AC crosstalk between adjacent elements.

9.12.3 Vidicon

A vidicon is a photoconductive detector that was used in the first TV cameras. It consists of a light sensor and an electron beam that provides readout inside a vacuum tube (Fig. 9.54). The photoconductive material, typically antimony sulfide (Sb_2S_3), is suspended in the form of little beads inside a dielectric matrix (mica). The image is focused through an entry window and a transparent and conductive layer (the signal plate) held at positive potential onto the photoconductive material (cathode), which is held at close to ground potential. Electron–hole pairs are generated at the cathode, and the negative charge carriers are pulled by the field towards the anode. An electron beam scans the backside of the cathode, thus depositing electrons onto the illuminated positive areas. This generates a capacitively coupled signal in the signal plate.

9.13 Photography

Photography is undoubtedly one of the oldest methods used to detect light and to create images. The main fields of photography include black-and-white photography, color photography, and holography. This section describes black-and-white and color photographic detectors; optical holography methods are described in detail in a separate chapter.

Photography is a process based on the chemical changes triggered by a photoexcited electron in some types of semiconductors and dye molecules. These changes accumulate during the exposure of the photographic film to light, forming a latent image. Subsequent chemical processing amplifies the image, making it visible.

The compositions used for photographic films and developing chemicals depend on whether a negative or positive image on a transparent film or a positive image on a solid substrate is required. We now con-

sider some basic processes and physics associated with photographic image formation.

9.13.1 Black and White Photography

Basics and Image Creation

The materials most commonly used for black and white photography are silver halide grains (micro crystals of AgBr, AgCl, and AgI), which are included in the active part of the photographic detector. Photographic films consist of multiple layers, each perform a specific function [9.65]. The silver halide grains are suspended in a gelatin binder (creating an emulsion), which is then coated onto a glass or plastic film for mechanical stability. An interface layer is used to improve the bonding of the gelatin to glass, and a protective gelatin layer is usually placed on the top to protect the grains. The backside of the glass or plastic film is covered with an

Table 9.6 Experimental E_g values (in eV) for AgF, AgCl, AgBr, and AgI crystals

Halide	Indirect transition $\Gamma \leftarrow L$	Direct transition at Γ
AgF	2.8±0.3 [9.66]	4.63 [9.66]
AgCl	3.25 [9.67]	5.15 [9.68]
AgBr	2.69 [9.67]	4.29 [9.68]
AgI	2.0±0.3	3.0±0.2

absorptive layer to stop light reflection from the rear surface.

The photographic process is centered on the silver halide grains. Photon absorption in the silver halide results in the creation of a electron–hole pair, with the electron in the conduction band and the hole in the valence band. The process may be described by the following equation (assuming that Br is the halide atom involved):

$$h\nu + Br^- \rightarrow Br + e^- . \tag{9.193}$$

Here we have taken into account the fact that silver halides are ionic crystals and that the negative charge is associated with Br, and the right-hand side infers that the photoexcited electron can move freely in the conduction band across the AgBr crystal structure. The photoinduced hole at the bromine atom can migrate to the grain surface and react with the gelatin, or it can couple with another hole, forming a bromine molecule. In either case, the bromine atom is excluded from further reactions.

At the same time, photoelectrons can be trapped by the silver atoms,

$$e^- + Ag^+ \Leftrightarrow Ag , \tag{9.194}$$

which can act as a trap for a second electron,

$$Ag + e^- \rightarrow Ag^- . \tag{9.195}$$

The resulting negative ion combines with a positive silver ion from the crystal structure, producing a stable two-atom silver molecule

$$Ag^- + Ag^+ \rightarrow Ag_2 . \tag{9.196}$$

This cluster is still not developable. In further reactions, a silver molecule (9.196) can trap additional positive silver ions from the crystal and photoexcited electrons, thereby forming a cluster with either three or four Ag atoms. A center with a critical size of three or four silver atoms can catalyze the further reduction of silver ions

to silver during subsequent chemical processing, thus providing an area of nucleation for the latent image.

Visualization (amplification) of the latent image is accomplished by immersing the exposed film into a chemical reducing agent – known as the "developer." The aggregates of silver atoms act as electrodes and conduct electrons from the reducing agent to the grain, promoting the growth of the silver atom aggregate. The final number of silver atoms in the aggregate exceeds 10^7, which makes the aggregate visible, and remaining silver ions are washed away.

Spectral Response
The primary event associated with photography is the absorption of light by semiconductor microcrystals of silver halides. Silver halides form face-centered cubic crystals with the smallest indirect bandgaps [9.69]. Table 9.6 summarizes the energies of the smallest indirect and direct bandgap transitions for a few silver halide crystals.

Indirect absorption yields a reasonably high photoexcitation rate in the short-wavelength spectral range below 500 nm. The overall efficiency of photographic films is reduced in the UV spectral range due to strong gelatin absorption at $\lambda < 250$ nm. Film response can be extended further into the ultraviolet by using an extremely thin gelatin coating on top of the film.

The extension of the film response into the red is achieved by dye sensitization [9.65]. In sensitized films, photons photoexcite the dye molecule, which is closely attached to the silver halide grain. There are two ways for the photoexcited dye molecule to create conduction electrons in the halide crystal grain. One is through a direct electron transfer process from the dye molecule to the grain [9.70, 71]; the other is through resonant and nonresonant energy transfer processes between the photoexcited dye molecule and the silver halide microcrystal [9.72–74]. In the spectral region to which the dye is sensitized, only the grain surface, as opposed to the entire grain volume, takes part in the initial photon detection.

9.13.2 Color Photography

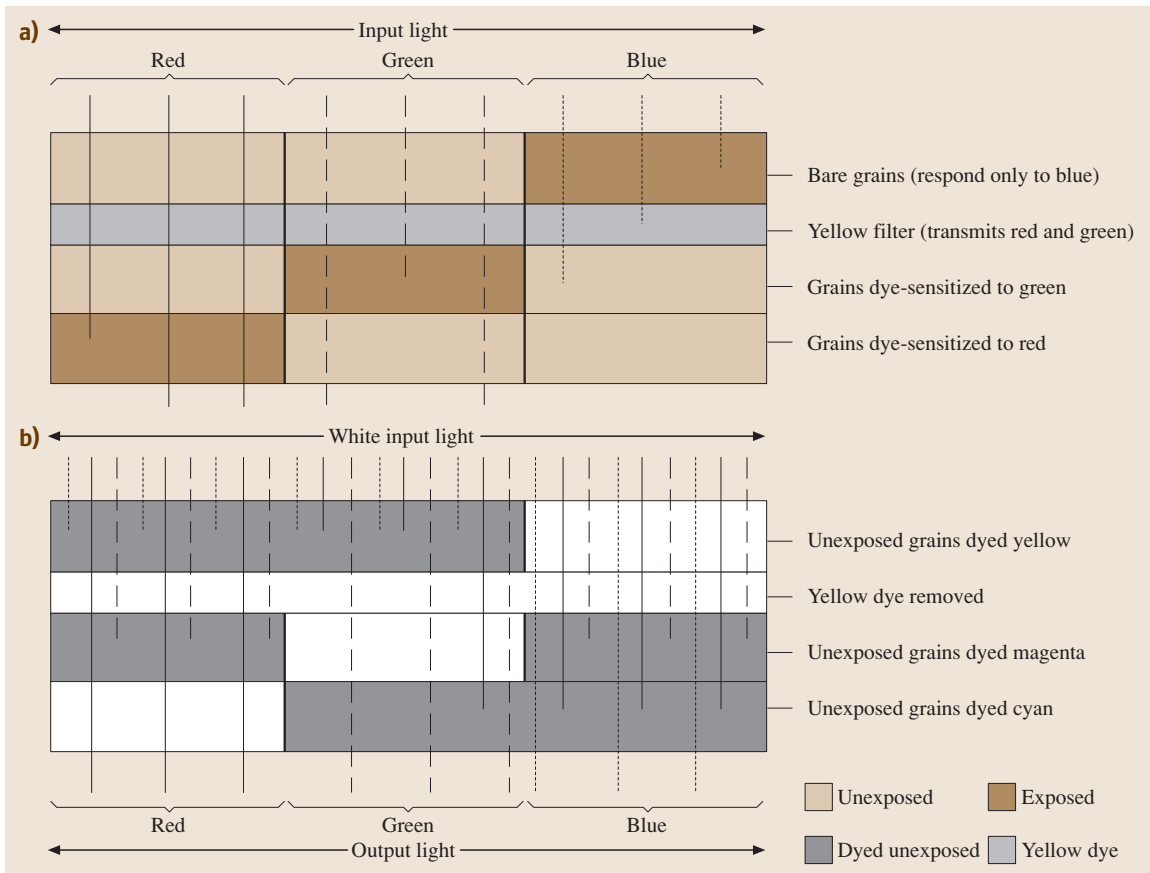
Additive and Subtractive Processes
Additive and subtractive processes relate the properties of light to color. The additive process is based on the production of color through the combination of two or more primary colors. Thus, combining red, green, and blue in various ways produces all of the colors in the visible spectrum.


Fig. 9.55a,b Forming a color image using a positive film: (**a**) exposure of the film to the three primary colors; (**b**) development of the positive film

However, the additive process cannot be used in dye-superimposed systems because one layer of an additive primary-color dye removes the whole complementary portion of the light spectrum, and the superposition of two different primary-color dyes will always produce a black color.

The subtractive process is based on the production of color by either the subtraction or the absorption of primary colors. The three primary subtractive colors are yellow, magenta, and cyan, and they are complementary to the additive colors. They each absorb only one primary color. Yellow absorbs blue light, cyan absorbs red light, and magenta absorbs green light. The superposition of two layers with different complementary dyes will always produce a single primary color. Like the majority of photographic film processes, the concept of subtractive color is utilized in the dye-coupled process.

Basics and Image Creation

A variety of methods have been used to produce color photography, but most modern approaches are based on stacking a number of emulsion layers with color couplers on top of each other [9.65, 75]. Figure 9.55 exemplifies the process of color image creation using a positive film. Assume that all layers forming the film are uniform and that the left-hand side of the film is exposed to red light, the center is illuminated with green light, and the right-hand side is illuminated with blue light. The top layer of the structure is an emulsion with bare silver halide grains, which only respond to blue light. A yellow filter removes the blue light, protecting the underlying emulsion layers against their exposure to blue light. This means that those two underlying layers can only be exposed to light containing green and red photons only. One of the underlying layers is sensitized with a dye that responds only to green, whereas the other emulsion

layer is sensitized with the red-sensitive dye. Thus, the three primary colors are recorded separately in the three layers of emulsion (Fig. 9.55a).

When the film is developed, the yellow filter is removed and latent image sites are reduced by color-developing agents. The reaction of oxidized color-developing agents with the color couplers in the emulsion produces a color dye via the method described by Fig. 9.55b. First, the development of the exposed silver halide grains amplifies the latent image. After that, development with color couplers forms the complementary dye in the unexposed grains in each layer. The yellow dye is produced in the unexposed grains of the top, blue-sensitive emulsion layer. Magenta dye is produced in the unexposed grains of the middle, green-sensitive layer, and cyan dye is produced in the unexposed areas of the bottom, red-sensitive layer. At the end of the process, all of the silver has been washed out and only the image color dyes remain. As a result, the areas of the film containing stacked yellow and magenta dye layers will transmit or reflect red light (see the left-hand side of Fig. 9.55b) – the same color that originally illuminated this portion of the film; compare with Fig. 9.55a, left. In a similar way, the middle portion of the film in Fig. 9.55b will transmit or reflect green light, whereas the right-hand side of the film will be transparent to or reflect blue light. Thus, the colors with which the film was illuminated will be directly reproduced.

9.13.3 Photography: Properties and Figures of Merit

The properties of photographic films and images are usually described using quantities that have historically proved to be adequate for characterizing photographic images. Below we summarize some of the most important properties and figures of merit.

Detective Quantum Efficiency (DQE)
The latent image formation and the development process usually introduce some degradation into the input signal, resulting in either a loss of information or the addition of noise. The detective quantum efficiency describes this degradation in terms of a ratio of the number of imaginary signal photons N_{out} that would produce, in a perfect detection system, the same information content in the output signal as that received from the real system to the actual number N_{in} of input signal photons [9.50]:

$$DQE = \frac{N_{out}}{N_{in}} = \frac{(S/N)_{out}^2}{(S/N)_{in}^2} , \qquad (9.197)$$
Fig. 9.56 Typical characteristic curve of photographic film. Different portions of the curve describe different exposure levels: (1) gross fog level; (2) underexposure level; (3) normal exposure level; (4) saturation level

where the right-hand side assumes Poisson photon statistics. It is obvious from (9.197) that the DQE is just the external absorptive quantum efficiency η_{ex}, as defined in Sect. 9.1.4 (9.22) as the probability that a photoelectron is produced when the photon is incident on the detector, if there is no subsequent degradation of the signal-to-noise ratio.

In reality, the DQE of a photographic material is much lower than the absorptive quantum efficiency η. On average, up to 20 photons must be absorbed by a grain over a short period of time to provide a grain-developing probability of 50%. This alone reduces the quantum efficiency by a factor of at least 20. Two other effects that reduce the DQE are the nonuniform distribution of grains in the emulsion film and variations in grain properties. These two effects may be expressed quantitatively as the granularity of the film, which refers to the variations in response measured through a tiny fixed aperture for a film that is uniformly exposed to light. When all of these effects are combined, the real DQE for the photographic plate is usually well below 5%.

Some of the methods used to improve the quantum efficiency of photoinduced silver cluster formation in silver halide microcrystals are based on doping the silver halide crystals with dopants that inhibit hole activity, suppressing electron–hole recombination [9.76].

Optical Density and Spectral Sensitivity
The optical density D of the image in the photographic film characterizes the ability of the layers of emulsion

to transmit light:

$$D = -\log T ,\tag{9.198}$$

where T is the transmittance, defined as the amount of light that passes through the developed film divided by the incident amount of light. The density can be measured as either the diffuse density (measured over a hemisphere from an incident collimated beam) or the specular density, which refers to the density measured over a particular solid angle only. The diffuse density is usually used to compare different photographic films.

In photography, the sensitivity can be given as an absolute value or as a relative value (the ratio of the energy required to expose a material compared to some reference). Sensitivity can be measured as the reciprocal of the exposure, expressed in radiant energy flux per unit area Φ_p during an exposure time t, that is required to produce a certain density D_0. The definition of the spectral sensitivity of a photographic emulsion is [9.65]:

$$S(\lambda) = \frac{1}{H(\lambda)} ,\tag{9.199}$$

in which $H = \Phi_p t$.

Characteristic Curve

The response of a photographic film is usually nonlinear with the intensity of light, as described by the characteristic curve shown in Fig. 9.56. The central portion, 3, of the curve describes the condition at which the net response of the film depends only on the total number of photons received (the reciprocity law). In the two nonlinear regions, the reciprocity law fails.

At low exposure (underexposure, see portion 2 of the characteristic curve), which occurs for either very low exposure times or for very low photon arrival rates, electrons can escape from the trapping centers before a stable development center forms. Note that the characteristic curve usually exhibits a nonzero density even at zero exposure, which is due to both the background radiation from different sources and to chemical development without receiving any light. This level of exposure is called the gross fog level – see portion 1 of the characteristic curve in Fig. 9.56.

High photon rates and long exposure times produce saturation and nonlinearity – see region 4 (overexposure) in Fig. 9.56.

Speed

The speed of a photographic film can be characterized by assuming that the grain must absorb a certain number of photons to become developable [9.50]. This number of photons depends on the grain size. Thus, there is a correlation between the speed and the grain size. For the bare silver halide emulsion (which is sensitive below 500 nm), the whole volume of the grain absorbs and the speed of the film goes as the grain volume times the absorption coefficient. In the case of dye-sensitized grains, only the surface is effective at absorbing photons, so the speed is proportional to the grain surface. For very small grains with diameters close to the wavelength of the light absorbed, diffraction effects reduce the absorption efficiency and hence the emulsion speed.

To improve the speed of the film at low light levels, special efforts must be made to improve the sensitization of the emulsion and the illumination optics.

Contrast and Noise

The slope $\gamma = \tan\theta$ of the linear portion of the characteristic curve in Fig. 9.56 characterizes the contrast of the film. The higher the contrast of the film, the larger the separation between the signal and noise. Emulsions with smaller grains generally achieve higher contrasts, partially because small-grained emulsions are more homogeneous in terms of grain size.

Random variations in the number of grains per resolution element, variations in the properties of the grains themselves, and the stochastic nature of the processes of light absorption, electron transfer, and silver aggregate growth lead to density nonuniformities and detection process noise.

Assuming that the density is defined for each given exposure, the output signal-to-noise ratio can be written as the ratio of the exposure H to the uncertainty in exposure (the noise) σ_H, $(S/N)_{out} = H/\sigma_H$ [9.50]. Not-
Fig. 9.57 MTF of a typical photographic film

ing that for any small exposure and density variations, the relationship between the uncertainty in exposure σ_H and uncertainty in density σ_D can be expressed as $\sigma_H/\sigma_D \approx dH/dD$, and also noting (from Fig. 9.56) that the contrast $\gamma = dD/d(\log H)$, then the signal-to-noise ratio is

$$
\begin{aligned}
\left(\frac{S}{N}\right)_{out} &= \frac{H}{\sigma_H} = \frac{H}{\sigma_D}\frac{dD}{dH} \\
&= \frac{H}{\sigma_D}\frac{dD}{d(\log H)} = \frac{H}{\sigma_D}\gamma \, ,
\end{aligned}
\tag{9.200}
$$

where we have taken into account the fact that $d(\log H) = dH/H$.

For Poisson photon statistics, the signal-to-noise ratio for the incident information content is

$$
\left(\frac{S}{N}\right)_{in} = \frac{\Phi_p t}{\sqrt{\Phi_p t}} = \sqrt{\Phi_p t} \equiv \sqrt{H} \, ,
\tag{9.201}
$$

where Φ_p is the radiant energy flux per unit area during the exposure time t. Hence, the detective quantum efficiency can be written as

$$
DQE = \frac{H\gamma^2}{\sigma_D^2} \, .
\tag{9.202}
$$

Resolution and Modulation Transfer Function

Exposing the photographic film to a pattern of alternating black and white lines and then determining the minimum distinguishable line spacing provides a measure of the resolution of the film. This method has its shortcomings, since the film is usually just one part of an imaging system that includes image-forming optics, and it is difficult to separate the effects arising from the different components of the whole system.

A more general concept is to use the modulation transfer function (MTF) to characterize the quality of each component of the imaging system. More specifically, the MTF is the magnitude of the response of the optical system to a variety of spatial frequencies x [9.77]. Performance wise, MTF characterizes the modulation depth of the image $M_{out}(x)$ relative to that of the incident information packet $M_{in}(x)$

$$
MTF(x) = \frac{M_{out}(x)}{M_{in}(x)} \, .
\tag{9.203}
$$

A typical example of the MTF for a photographic emulsion is presented in Fig. 9.57. It is possible to enhance the sensitivity of the detector to some particular spatial frequencies, resulting in an MTF with a more complex shape than that shown in Fig. 9.57.

The MTF can be calculated from a Fourier transform function (e.g., FFT) of the source object. For example, for a single, ideal, rectangular photodetector pixel, where the one-dimensional spatial response is described by a π-function, the theoretical limit for the MFT is a sinc function, $[\text{sinc}(x) = \sin(x)/x]$. In practice, the closer the FFT of the photodetector spatial response is to the sinc function, the better the imaging properties (resolution, etc.) of the photodetector. Zeros in the FFT function correspond to the harmonics of the fundamental frequency, which is the physical size of the active area in the case of the photodetector.

The MTF is useful because the MTF of an entire linear optical system can be determined by simply multiplying the MTFs of its components. The overall resolution capability of a complex optical system is easily determined in this way.

10. Incoherent Light Sources

Since the invention and industrialization of incandescent lamps at the end of the 19th century electrical lighting has become a commodity in our daily life. Today, incoherent light sources are used for numerous application areas. Major improvements have been achieved over the past decades with respect to lamp efficiency Fig. 10.1, lifetime and color properties.

In the following chapters an overview of various lamp types and their properties is given. They are subdivided by light generation mechanism: thermal emission of radiation close to thermal equilibrium (incandescent lamps), atomic and molecular emission in gas discharge lamps, and emission from solid-state light sources (LEDs).

10.1 Incandescent Lamps

The incandescent lamp is the oldest electrical light source still in widespread use. It can be found in almost any application, especially where comparatively small lumen packages are required and where simplicity and compactness are favored.

10.1.1 Normal Incandescent Lamps

Incandescent lamps produce light by the electrical heating of a metal wire to such a high temperature that radiation in the visible part of the spectrum is emitted [10.1]. The metal wire is mounted in a glass bulb filled with an inert gas (Fig. 10.2).

According to Planck's law the filament must be heated up to at least 2400 K for a white emission color. In view of the efficiency for converting electrical energy into visible light, even higher filament temperatures would be favorable. Unfortunately, increasing the temperature reduces lamp life due to enhanced evaporation rates of the metal. Since tungsten has a high melting point and a low vapor pressure it permits high operating temperature and consequently higher efficiencies can be attained than by any other metal. A possible measure to

improve lifetime is the reduction of the tungsten evaporation rate by the addition of rare gases (Kr, Xe). Alternatively, halogens are used in a so-called regenerative cycle
Fig. 10.1 Temporal development of the luminous efficacy of electrical light sources (LP = low pressure, HP = high pressure)
Fig. 10.2 Schematic drawing of an incandescent lamp

effectively to transport tungsten back to the filament. An increase in luminous efficiency is achieved by coiling the tungsten wire. A coiled filament allows higher operation temperatures for a specified lifetime (typically 1000 h). Most common operation parameters yield luminous efficiencies between 8 lm/W and 17 lm/W at filament temperatures of 2400 K and 3100 K, respectively. These values correspond to an energy efficiency of a few percent. Incandescent lamp wattages range up to 2000 W.

Fig. 10.3 Principle of the chemical transport cycle in tungsten halogen lamps

10.1.2 Tungsten Halogen Lamps

In a normal incandescent lamp, tungsten evaporates off the filament and condenses on the bulb wall, resulting in so-called blackening. Halogen lamps comprise a halogen, i. e. iodine, bromine, chlorine, added to the normal gas filling. These form volatile tungsten compounds at the glass wall, which are transported back to the hot filament. Here, the tungsten halides are decomposed enabling a so-called chemical transport cycle (Fig. 10.3).

By reduction of the net tungsten evaporation rate, the filament of halogen lamps can be operated at higher temperature compared to standard incandescent lamps. Thus, luminous efficiencies can be increased for reduced lamp size. This allows their application in compact reflectors. Halogen incandescent lamps are available up to 2000 W with luminous efficacies up to 25 lm/W. This value has recently been improved to 35 lm/W by coating the glass bulb with infrared reflective multilayers, and lifetimes up to 2000 h were obtained.
10.2 Gas Discharge Lamps

10.2.1 General Aspects

A gaseous discharge is obtained by driving an electric current through a gas, typically present between two electrodes. Alternatively, electrodeless microwave-excited discharges and pulsed dielectric-barrier discharges (e.g. used for plasma displays) are known as incoherent light sources.

The actual carriers of the electric current in the gas are electrically charged particles, positive ions and negative electrons. In a neutral nonconductive gas the number of charge carrying particles is extremely small. These particles can be released from the fill gas or the cathode surface by energetic collisions. Many physical factors influence the properties of a gas discharge, the most important ones being the type and pressure of the gas, the electrode material, the operating temperature of the electrodes, the shape and surface structure of the electrodes, the distance between the electrodes, the geometry of the discharge vessel, and the cur-

rent density. For the purpose of light generation, two main types are distinguished: low-pressure and high-pressure discharge lamps. For lighting applications, both are operated in the arc discharge mode, which is characterized by high current densities ($> 1 \, \text{A/cm}^2$). To limit the discharge currents, electronic ballasts are used [10.2].

In a low-pressure discharge lamp (gas pressure typically less than 100 Pa) the electrons have a mean free path length larger or of the order of the vessel diameter (e.g. a few cm). Due to low collision rates with the neutral gas atoms they gain high energies ($> 1 \, \text{eV}$) from the applied electrical field and effectively excite the cold atoms by inelastic collisions. The electrons and atoms are not in thermal equilibrium (Fig. 10.4).

In high-pressure discharge lamps the operating pressure is typically in the range between 10 kPa and 10 MPa. Here, collisions between electrons and atoms or ions are much more frequent, resulting in a thermal equilibrium that is characterized by equal particle temperatures.

In low-pressure discharges atomic line radiation is emitted preferably from resonance transitions of the element with the lowest excitation potential (e.g. Hg: 185 nm and 254 nm, Na: 589 nm). In high-pressure lamps various contributions to the spectrum are obtained: broadened atomic lines (resonance-, van der Waals- and Stark-broadening), molecular radiation bands and quasi-continuous emission due to free–free (Bremsstrahlung) and free–bound (recombination of electrons with ions and atoms) transitions. As a result of these quasi-continuous spectra, the color
Fig. 10.4 Relationship between electron temperature, gas temperature and gas pressure

rendering properties of high-pressure discharge lamps are fair to excellent, depending on the type of filling [10.3].

10.2.2 Overview of Discharge Lamps

In Fig. 10.5 the most relevant types of discharge lamps are displayed. The light sources are distinguished with respect to their emission spectra and application fields. In the case of low-pressure mercury and xenon excimer lamps luminescent materials are applied for conversion of ultraviolet (UV) radiation into visible light. The temporal improvement in efficiencies is depicted in Fig. 10.1.

Fig. 10.5 Overview of gas discharge lamps

10.2.3 Low–Pressure Discharge Lamps

The most widely applied radiators in low-pressure discharge lamps are Hg and Na. These elements are the best choice with respect to efficiency for the conversion of electrical input power into radiation.

Low–Pressure Mercury Lamps

The working principle of a low-pressure Hg (also known as a fluorescent lamp) is given in Fig. 10.6. Fluorescent lamps are generally designed in the form of a linear or bent tubular bulb with an electrode sealed in at each end (electrodeless versions are available where the electrical energy is coupled inductively into the discharge vessel via metal coils). The discharge vessel is filled with an inert gas (typically Ar) and a few mg Hg. Since the major part of the emission of Hg atoms (97%) at low pressures (e.g. 5 Pa) is in the ultraviolet, the inner surface of the bulb is coated with a fluorescent powder or phosphor, which converts the UV radiation into visible light. The composition of the phosphor determines the spectral power distribution and the color of the emitted light.

The generation of UV photons is due to transitions of Hg atoms between the excited state levels $^1P_1$, $^3P_1$ and the ground state level $^1S_0$. About 64% of the electrical input power is converted into photons at a wavelength of 185 nm and 254 nm. According to the transitions indicated in Fig. 10.7 only 3% are emitted in the visible part of the spectrum. As a result of the Stokes shift, the overall efficiency is only 28%. This value corresponds to a luminous efficiency of 100 lm/W.

Typical lamp parameters for fluorescent lamps are: electrical input power up to 140 W, luminous efficiency up to 100 lm/W, color temperature between 2700 K and 8000 K. Lamps are available in a large variety
Fig. 10.7 Simplified energy-level scheme and radiative transitions of the Hg atom

of geometries, e.g. cylindrical or circular or U-shaped tubes. The latter are also known as energy-saving or compact fluorescent lamps. Depending on the construction of fluorescent lamps, the lifetime ranges from 5000 to 25 000 h.

Fluorescent Coatings

The most important component of a fluorescent lamp is the fluorescent powder. It is coated onto the inner side of the glass tube. The powder consists of one or several luminescent materials (phosphors), which are in general inorganic compounds doped by transition metals (e.g.
Fig. 10.6 Sketch of a low-pressure mercury discharge (fluorescent) lamp

Mn^{2+}, Mn^{4+}) or rare-earth ions (e.g. Tb^{3+}, Eu^{3+}). The composition of the fluorescent powder is optimized to convert the absorbing atomic resonance lines of mercury low-pressure discharges (185 nm and 254 nm) into the desired lamp spectrum. In some cases the fluorescent composition also includes so-called sensitizers (e.g. Ce^{3+}) if the first dopant, i.e. the activator, does not sufficiently absorb the mercury lines. Figure 10.8 displays the principle of photon down-conversion in a luminescent material.

The first step of light conversion is the absorption of incident photons either by the activator or the sensitizer. In the case of absorption by the sensitizer the energy is subsequently transferred to the activator. The excited activator ion, for instance Eu^{3+}, decays to the ground state by emitting a photon with a wavelength according to the energy gap between the excited and ground state. The energy difference between the emitted and the absorbed photon (Stokes shift), which is about 50%, is dissipated as heat in the fluorescent powder.

Nowadays, fluorescent compositions with quantum efficiency close to unity are commercially available for many lamp application areas. Table 10.1 gives an overview of most commonly applied luminescent materials. For illumination purposes, halophosphate phosphors, invented in the 1940ies, are still widespread since they yield a white emission spectrum with a reasonable efficiency and color rendering. However,
Fig. 10.8 Simplified mechanism of light generation in a fluorescent powder. The abbreviations "S" and "A" indicate sensitizer and activator, respectively

a trichromatic phosphor blend results in higher lamp efficacy and improved color rendition. A typically applied phosphor blend comprises $BaMgAl_{10}O_{17} : Eu$, $LaPO_4 : CeTb$, and $Y_2O_3 : Eu$. These so-called color 80 lamps (indicated with an [a] in Table 10.1) exhibit a spectral power distribution as depicted in Fig. 10.9.

Lamps with an even higher color rendition are obtained by a tetra- or pentachromatic phosphor blend. Color 90 lamps additionally contain phosphors with an emission-band position where the trichromatic phosphor blend does not radiate, viz. in the yellow ($Y_3Al_5O_{12} : Ce$) and deep red ($GdMgB_5O_{10} : Ce, Tb, Mn$) spectral range.

Table 10.1 Overview of the most commonly used luminescent materials in fluorescent lamps

Composition of luminescent materials	Emitted peak wavelength (nm)	Color point x, y [a] (after CIE 1931)	Application area
$LaB_3O_6 : Bi, Gd$	311	–	Medical lamps
$LaPO_4 : Ce$	320	–	Tanning lamps
$BaSi_2O_5 : Pb$	350	–	Tanning lamps
$SrB_4O_7 : Eu$	368	–	Black light lamps
$Sr_2P_2O_7 : Eu$	420	0.167, 0.014	Reprography lamps
$BaMgAl_{10}O_{17} : Eu$	453	0.150, 0.070	Color 80 lamps [b]
$Zn_2SiO_4 : Mn$	530	0.256, 0.700	Decoration lamps
$LaPO_4 : Ce, Tb$	543	0.343, 0.585	Color 80 lamps [a]
$CeMgAl_{11}O_{19} : Tb$	543	0.350, 0.582	Color 80 lamps [a]
$GdMgB_5O_{10} : Ce, Tb$	543	0.346, 0.531	Color 80 lamps [a]
$Y_3Al_5O_{12} : Ce$	560	0.453, 0.523	Color 90 lamps [a]

Fig. 10.9 Spectrum of a color 80 fluorescent lamp with a blend of $BaMgAl_{1017}:Eu$, $LaPO_4:Ce$, Tb, and $Y_2O_3:Eu$ and the eye sensitivity curve V_λ

Due to the tunability of the spectra, fluorescent lamps have entered many other application areas beyond illumination, such as medical and cosmetic skin treatment, decoration, reprography, horticultural lighting. The latter, for instance, comprises a dichromatic phosphor blend consisting of $BaMgAl_{10}O_{17}:Eu$ and $Y_2O_3:Eu$. The spectrum of this mixture is adjusted according to the action spectrum for photosynthesis of green plants.

Other Low–Pressure Discharge Lamps

In low-pressure sodium lamps the discharge has the same origin as in mercury lamps. Sodium emits almost monochromatic yellow light, viz. a doublet consisting of 589.0 nm and 589.6 nm lines (Na D-lines). However, the melting point of Na is higher than Hg. Thus the optimal operating temperature is at about 530 K. At these temperatures the highly reactive Na metal requires a chemically stable wall material such as quartz (SiO_2) or alumina (Al_2O_3). To reduce thermal losses the discharge vessel is mounted inside an outer evacuated bulb Fig. 10.10.

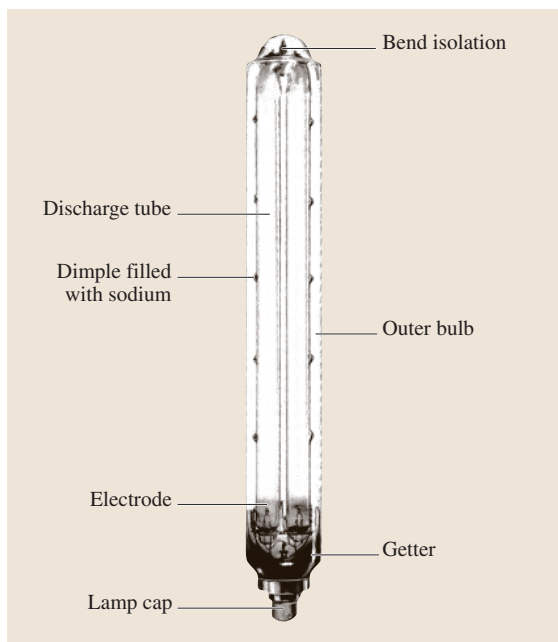
Low-pressure sodium lamps exhibit the highest ever achieved luminous efficiency due to the favorable position of the Na lines with respect to the spectral sensitivity of the human eye, which peaks at a wavelength of 555 nm. At a discharge power of 200 W luminous efficiencies of 200 lm/W (172 lm/W system efficiency) are obtained. A disadvantage is the low rendition of colors due to missing emission at other wavelengths, e.g. in the blue, green and red parts of the spectrum. For this reason their applica-


Fig. 10.10 Sketch of a low-pressure sodium lamp

tion is limited to street and outdoor lighting where high efficiencies are of importance. In addition, an advantage is their long lifetime, which are of the order of 20 000 h.

When increasing the Na vapor pressure, as realized in high-pressure Na lamps, the broadened spectral lines improve color rendition significantly (see below).

Besides low-pressure Hg and Na lamps other types of radiators are used for special applications: low-pressure neon discharges and xenon excimer discharges. The former are applied in automotive brake lights and advertisement lighting. Excimer radiation from xenon is used in plasma displays and flat backlights, photocopier lamps and UV purification. The major advantage of these discharges is their fast switching behavior: in contrast to Hg and Na, Xe does not need to be evaporated. Fast switching is achieved with pulsed barrier discharge resulting in the formation of Xe excimers. Atomic and molecular radiation at 147 nm and 172 nm is observed, respectively.

10.2.4 High–Pressure Discharge Lamps

As the pressure is raised in a low-pressure discharge, the rate of elastic collisions increases. Although each collision transfers little energy to heavy particles the plasma is heated effectively due to the high particle

densities. To sustain central plasma temperatures in the range 4000–10 000 K a temperature gradient is established. The heat flux along this gradient to the discharge wall is a loss, which limits the radiation efficiency of such arcs to around 60%. Fortunately, selective emission of the plasma allows for efficient radiation in the visible part of the spectrum. High-pressure discharge lamps containing metals like Hg or Na are known.

Besides, other efficient radiators are added to the lamp filling in so-called metal halide lamps. Each combination of metals used generates radiation with a specific color and radiant efficiency. In theory at least, no fewer than 50 different metals can be used to dose metal halide lamps. As a result, lamp manufacturers have introduced various combinations on the market with a wide range of applications.

A technical breakthrough in high-pressure sodium and metal halide lamps has been achieved by the introduction of polycrystalline alumina (sintered Al_2O_3 ceramics) as a wall material. Compared to quartz, a major advantage is its chemical resistance against the hot sodium vapor that is present in high-pressure sodium lamps. In addition ceramic materials offer the possibility to achieve the high wall temperatures needed for effective evaporation of the salt fillings. In quartz envelopes, the maximum temperature is limited by recrystallization of the wall at about 1370 K. This value can be greatly exceeded by using Al_2O_3 instead of SiO_2. On the other hand, vacuum tight sealing of electrodes and the design of the lamps' end construction is more complicated with ceramic materials. This fact is due to their inconvenient thermal expansion behavior and brittleness. In the lighting industry, this is still a current field of research and development of modern light sources.

High-Pressure Mercury Lamps

The construction of a high-pressure mercury lamp is shown in Fig. 10.11. The discharge vessel is filled with mercury, and argon is used as a starting gas [10.1]. Thermal isolation of the discharge vessel is achieved by use of an evacuated outer bulb. The lamp is switched on using a high-voltage ignition pulse, typically of the order of several kV. After ignition, the voltage across the discharge drops down to about 20 V, which is mainly the sum of the cathode and anode fall voltage. At this stage, the lamp is operating as a low-pressure discharge emitting UV radiation mainly at 254 nm. Thermal losses in the arc result in an increase of the wall temperature and thus increasing evaporation of the liquid mercury with time. With a further increase in mercury vapor pressure the radiated energy is concentrated progressively

towards the spectral lines of longer wavelengths. When fully run up the lamp establishes a typical mercury pressure 200–1000 kPa and a bluish-white light is produced
Fig. 10.11 Sketch of a high-pressure mercury lamp. The inner surface of the outer bulb may be coated with phosphor, which additionally converts UV light into visible light
Fig. 10.12 Spectrum of a high-pressure mercury lamp
Fig. 10.13 UHP lamp system (lamp, reflector and electronic driver) for application in projection systems and beamers

(Fig. 10.12). At these pressures a part of the emission is still in the UV. By coating the inner surface of the outer bulb with a fluorescent powder, e.g. $YVO_4 : Eu$, that converts this UV radiation into visible light, the luminous efficiency can be further increased. In addition, the spectral composition of this light considerably improves the color-rendering properties.

Besides its radiative properties Hg also serves as a buffer gas in today's high-pressure discharge lamps; the electrons are elastically scattered by mercury atoms, which results in a low arc electrical conductivity According to Ohm's law, electrical field strengths of the order of several $10\,V/mm$ are present in the discharge column, which enables an input electrical power at moderate discharge currents. The lamp current must not be too large with respect to electrode stability: electrode temperatures are in the range $2400-3500\,K$ when the electrons are generated thermionically. It should be emphasized that both properties – the volatile character enabling high atom densities and the large cross section for elastic electron scattering – are unique to mercury.

High-pressure mercury lamps are used in various indoor and outdoor applications.

The power range is $50-1000\,W$ with luminous efficiencies around $50-60\,lm/W$. Color rendition is only moderate to poor. Color temperatures are $3400-6000\,K$.

A recent development of a high-pressure mercury discharge is the so-called UHP lamp (ultra high performance lamp), which was invented by Philips in the 1990s (Fig. 10.13 [10.4]). This lamp has a very high operating mercury pressure (about $2 \times 10^7\,Pa$) and a very short arc length of about 1 mm. This point-like light source with its broadened white spectrum is used in projection systems and beamers. In contrast to conventional high-pressure mercury lamps at these high pressures

a significant part of the visible radiation is generated not only by pressure-broadened atomic mercury lines but also by Hg_2 molecules. UHP lamps are available on the market in the power range $100-250\,W$. A key issue for UHP lamps is the maintenance of stable properties of the discharge and electrodes for more than 5000 h. This is achieved with a chemical cycle in which evaporated tungsten is transported back onto the electrodes via compounds including oxygen and bromine. In addition, UHP lamps have to be operated with special electronic gear to control electrode erosion and arc jumping.

Metal Halide Discharge Lamps

Metal halide lamps are similar in construction to high-pressure mercury lamp. The major difference between the two types is that the discharge tube of the former contains metal halides in addition to the mercury, and argon as the starting gas. The metal halides determine the spectral properties of the lamps. As mentioned above mercury serves as a buffer gas that determines the electrical properties, e.g. lamp voltage. The metals are dosed in the form of halides because of their volatile character. High particle densities are needed for efficient radiation. Furthermore, the metal halides are less aggressive with respect to wall corrosion compared to pure metals.

There are three main groups of metal halide lamps: multi-line radiators, molecular radiators and three-band color radiators. In the first type rare-earths and associated elements such as Dy, Ho, Tm or Sc are added to the lamp filling. These species have a large number of transitions at low mean excitation energy. Consequently, such plasmas efficiently emit multi-line radiation in the visible spectrum. Furthermore, NaI and TlI are often added to such lamp fillings to improve luminous efficiency and color properties. The second type is based on molecular radiators such as SnI_2 or $SnCl_2$, which produce a quasi-continuous spectrum. Finally, the third class is based on NaI, TlI and InI_3. Such spectra consist of three color bands in the yellow, green and blue, respectively.

Typical spectra of these three metal halide lamp types are shown in Figs. 10.14a–c. Metal halide lamps are used for a variety of indoor and outdoor lighting applications. The electrical input power ranges from 35 W to more than 1000 W. In general, metal halide lamps have high luminous efficiencies of up to $100\,lm/W$ at good to excellent color rendering. Lifetime is up to 20 000 h, depending on the type of filling used.

A speciality of metal halide lamps is its halide cycle (Fig. 10.15), which is quite similar to the aforementioned tungsten–halogen cycle. When a metal halide lamp first starts, the spectrum is initially that of mercury vapor,

contribution of atomic radiation takes place. The metals then move nearer the cooler discharge wall where they recombine with the halogen atoms to form once again the halide compound. The whole cycle then repeats itself.

since the halides remain unevaporated at the relatively cool wall of the discharge tube (typical wall temperature of 1000 K). As the wall temperature increases, the halides melt and partly vaporize. The vapor is carried into the hot region of the arc by diffusion and convection, where the halide compounds are dissociated into the halogen and metal atoms. As indicated in Fig. 10.14, different halides dissociate at different temperatures. The metal atoms are excited at the hot plasma center, which typically has a temperature of 5000 K. Here the main

Fig. 10.15 Schematic diagram of the halide cycle of a three-band color metal halide lamp (NaI, TlI, InI_3)

As mentioned above a recent improvement of metal halide lamps was achieved by the introduction of a ceramic wall material (polycrystalline alumina) instead of quartz. Such lamps show improved color stability and long lamp life. However, these lamps are not suitable for optical applications, e.g. in projection systems. The reason is the translucent behavior of polycrystalline Al_2O_3 (PCA) due to multiple scattering of light at grains and pores. Nevertheless, the total transmission for visible light is nearly 95%. The application of PCA to high-power metal halide lamps is also limited due to cracking of the material induced by thermal shock and thermal expansion. In the lighting industry, the applicability of ceramic wall materials is still a current field of research and development of modern light sources. Furthermore, upcoming legislation has initiated several activities on the replacement of mercury in this type of discharge by nontoxic materials [10.3].

Other High-Pressure Discharge Lamps

Besides high-pressure mercury and metal halide lamps, other high-pressure light sources are also known. The so-called blended-light lamp is derived from the conventional high-pressure mercury lamp. The principal difference between the two is that, whereas the latter is dependent on an external ballast to stabilize the lamp current, the blended-light lamp has a built-in ballast in the form of a tungsten filament connected in series with the discharge tube. Consequently, the light from the discharge and the filament combine (or blend). The improved spectral quality is traded off against reduced total efficiency of the system.

In high-pressure sodium lamps, the broadening of the D-lines is used to improve color properties compared to a low-pressure Na discharge. Luminous efficiencies of up to 130 lm/W are obtained. A technical breakthrough has been achieved with the introduction of a ceramic wall material (polycrystalline Al_2O_3). This withstands the hot and highly aggressive Na vapor, resulting in a much longer lamp life compared to quartz (SiO_2).

Another class of high-pressure discharge lamps is represented by the sulphur lamp, invented by Turner et al. at Fusion Systems in 1994. The advantage of such a lamp is their long life due to electrodeless operation. It is operated with a microwave at a wavelength of 2.45 GHz, the electrical input power being of the order of 3 kW. A spherical bulb having a diameter of about 30 mm is filled with sulphur powder. Under continuous operation, sun-like white light is emitted by S_2 molecules, having a partial pressure of about 600 kPa. The high burner efficiency of about 170 lm/W is possible since at these high pressures UV radiation from the sulphur molecules is reabsorbed by the plasma. Thus, emission mainly occurs in the visible part of the spectrum. A technical drawback of microwave lamps is the low energy efficiency of the generator, typically about 65%. Therefore, the overall efficiency of the system is reduced to about 100 lm/W, being of the order of conventional discharge lamps.

Nevertheless, electrodeless discharge lamps are still a hot topic in research and development. A general advantage of these systems is their potentially long life and large luminous flux. The latter, for instance, might be distributed by light pipes for use in industrial and general lighting applications.

10.3 Solid-State Light Sources

10.3.1 Principle of Electroluminescence

In solid-state lamps the electric current is converted into light by recombination of excited states of atoms into the ground state via emission of a photon, i.e. radiative recombination. The nature of the excited state may differ for different types of electroluminescence (EL) principles. Typically the applied voltage has to be at least as large as the emission of the material to fulfill the energy-conservation law.

Besides radiative recombination, many other decay mechanisms are possible in electroluminescence that reduce the overall efficiency, which is typically measured in $w_{opt,out}/w_{el., in}$, given as a percentage. Weighted by the eye response curve, the use of lumens per Watt (lm/W) gives the optically relevant light output in relation to the invested electrical power. The most important loss factors are non-radiative recombination through phonons or second-order processes converting the electrical power primarily into heat. An important additional loss factor is the outcoupling of the light. Since most EL materials have a higher refractive index than air, part of the light is trapped inside the device by total internal reflection. Due to absorption losses, this light is partly lost, which reduces the overall efficiency. In addition, more specific loss channels will be discussed for the different mechanisms.

General illumination was not feasible using EL devices for a long time, since the total emitted power or lumen package was fairly low and/or the efficiencies were low. This has changed in recent years with the advent of InGaN technology, which turned out to be very stable against high power densities and the resulting heat development. Thus electroluminescence has started to become the third class of illumination devices, creating a new market for lamps, gears and luminaries.

10.3.2 Direct Versus Indirect Electroluminescence

Electroluminescence (EL) in general appears in two distinctly different mechanisms: direct EL and indirect EL. Direct EL describes the direct recombination of electrons and holes in a suitable semiconductor structure. This material can be inorganic, like in most conventional light-emitting diodes (LEDs), which were initially built from GaP and GaAs or more recently and very successful from InGaN, or organic such as, e.g., Alq_3 ($q =$ 8-hydroxychinolinate). In this version, charge carriers are injected from contacts via direct transport with ultimately very little kinetic energy. The carriers meet in the recombination zone, wherein excitons are formed, which successively decay radiatively or non-radiatively; the first process releasing a photon, the latter creating heat. Ideally, the injection barrier from the contacts to the conduction levels of the materials is low and thus the energy necessary to generate recombination and thus light is simply the energy of the emitted light, resulting from the effective band-gap of the material. Thus the theoretically achievable efficiency of direct EL generation is unity.

In contrast, the indirect EL process results from creating excited states through impact ionization. This type of EL is found in classical thin-film (TF) or powder EL devices, also called TFEL or alternating-current thin-film EL (ACTFEL) devices. Here carriers are accelerated by means of an external electrical field. These accelerated electrons collide with ions in the matrix. By impact ionization, these ions or luminescent centers are excited and the radiative recombination of the generated electron–hole pairs releases a photon. Therefore the theoretical efficiency of this process is limited to about 40%. These devices are typically operated using high-voltage high-frequency AC bias and the brightness as well as the spectrum is a function of voltage and frequency. Typically, a few hundred cd/m^2 maximum brightness are achieved in state-of-the-art indirect EL devices. Because efficiency and brightness are limited, we will not consider indirect EL in much detail, since the respective devices have achieved little importance as light sources. They are mainly used in displays, indication or signaling and decorative lighting. It is not expected that dramatic improvements will occur in the near future. The interested reader is referred to detailed descriptions in [10.5].

10.3.3 Inorganic Light-Emitting Diodes (LEDs)

The first practical inorganic semiconductor LEDs were conceived at Texas Instruments in 1961 by Biard and Pitman. These devices emitted in the near infrared because the material used was InGaP with a band-gap of 1.37 eV. One year later the first LED in the visible was built by Holonyak and co-workers at General Electric. They used a different composition to fabricate a device that emitted red light. From that time on, the use of more refined processing and other materials (such as

Fig. 10.16 Schematic of a classical indicator and high-power illumination LED
Fig. 10.17 AlInGaP LED shaped as a truncated inverted pyramid (TIP) for efficient light extraction

e.g. AlGaAs) has led to the development of the common LED, mainly used for indicator lights as, for example, shown in Fig. 10.16.

For several decades, LEDs were not attractive for illumination purposes, mainly for the two following reasons. First, the optical output power (i. e. the lumen package, defining the amount of light emitted from a single LED) was fairly limited, since the packaging and the materials in use did not allow high current densities in the small chips. Since the efficiency was far less than 100%, a lot of heat would have been generated, destroying the semiconductor chip. Secondly, and more important, no real blue LED material was available. For several years II–VI compound semiconductors such as ZnSSe/ZnTe were researched as possible candidates for blue with limited success. However, in 1993 Nakamura et al. achieved the breakthrough for solid-state lighting by proving the successful use of InGaN as a material in LEDs [10.6]. Since the material is chemically very stable, it is on one hand difficult to achieve high-quality epilayers for high-efficiency LED operation, on the other hand, the high stability allows very high current densities without disintegration of the LED material. Therefore the lumen package can be increased to values relevant for lighting applications. More important, however, is the insensitivity of InGaN to defects. Although the defect density in common InGaN LEDs is much higher than what would be acceptable in other material combinations, such as e.g. AlGaAs (10^9/cm^3 vs. 10^6/cm^3), the low surface recombination velocity of InGaN and other properties allows efficient LEDs to

be built from defect-rich layers. Additionally, with the advent of bright and stable blue LEDs it became possible to generate white light from solid-state devices, either by color conversion of blue LEDs using phosphors or by externally mixing the light from blue, green and red LEDs.

The principal of LEDs is explained in great detail in the semiconductor device literature [10.6–8]. We will limit ourselves here to the use of LEDs for light generation and the respective relevant aspects. Due to the importance of color conversion in generating white light from LEDs, we will discuss in more detail the nature of the phosphors being used.

Pure-Color LEDs

White light is, generally speaking, always a mixture of several pure colors. At least a combination of blue and orange light is needed, which yields a white appearance, however a very low color rendering (CRI, color rendering index), i. e. many colors are poorly reproduced under illumination of such a light source. Increasing the number of colors by combining red, green and blue (RGB) LEDs already enables much higher CRI values and thus a high-quality white light. In the limit of many different visible LEDs, the black-body radiation spectrum of 5500 K (essentially the spectrum of sunlight) is generated, which has, by definition, a CRI of 100. However, due to the finite size of the LED dies and their package, it is rather difficult to achieve homogeneous mixing of the discrete LEDs, at least in a small package. The following paragraph will briefly describe the technology of pure-color LEDs, which are already widely used in all applications, where colored light is necessary, like e.g. signaling. The advantage here is clearly the much higher efficiency, since they replace filtered white light, which has very low efficiency and lifetime.

Two major materials are used in colored LEDs: AlInGaP for red, orange and yellow and InGaN for green and blue (see Fig. 10.18).

The quaternary mixture of AlInGaP is the prime candidate for red to yellow emission colors. It is typically grown on GaAs wafers, since the lattice matching of substrate and epilayer guarantees a low number of defects, which is essential for high efficiency and long lifetime. After deposition of the various layers, the wafer is bonded to a GaP substrate and the original GaAs substrate, which absorbs in the spectral region of the LED emission is removed. This increases the efficiency, since half of the light is emitted towards the substrate and would be lost if the substrate was absorbing. A lot of

light is still trapped inside the die due to total internal reflection. Since the refractive index of the material is larger than one, all light emitted under an angle larger than the Brewster angle is reflected back into the crystal. Due to some residual absorption, e.g. at the metal contacts, multiple internal reflections further diminish the efficiency. By shaping the semiconductor chip in the form of a truncated inverted pyramid, the highest efficiency of a red light source has been obtained by an LED from Lumileds [10.9] (see Fig. 10.17).

This LED is estimated to have close to 100% internal efficiency and an outcoupling efficiency of about 55%, resulting in 102 lm/W wall plug efficiency. This value demonstrates the potential of LED technology as a future lighting source, since this is the most efficient red-light source available. The lumen package of AlInGaP LEDs is, however, limited due to thermal quenching of the emission. For power densities beyond 0.1 W/cm^2, the efficiency and also the lifetime of AlInGaP LEDs drops significantly, since the chip temperature increases.

For the higher energy emission from green to blue and beyond, InGaN has become the material of choice. After several years of intense research, it became possible to create working LEDs in the InGaN material system. The major difficulty to overcome was the problem of p-doping of GaN. This is achieved by doping Mg into the InGaN lattice, which happens at temperatures above 1100 °C in the deposition process. By varying the amount of In in the composition of the LED, the emission can be tuned from UV to green. However, due to segregation effects and subsequent development of lattice defects, the efficiency drops with increasing wavelength, i.e. for high In contents. Comparing the different materials classes, it turns out, that the defect density of InGaN LEDs is much higher than what would be tolerable in more conventional III–V compound semiconductors. This is mainly due to the lack of a lattice-matched substrate material. So far mostly Al_2O_3 (sapphire) with a lattice mismatch of approx. 15% is used. Nevertheless, the devices, with unsurpassed stability and high efficiency, prove that the InGaN system is obviously much less sensitive to defects than other material combinations. The reason for that is not yet entirely clear. However, it has been measured that InGaN has the lowest surface recombination velocity of all III–V composite semiconductors, thus giving excited carriers more chances of radiative recombination. Current efficiencies range from 20% (20 lm/W) for blue to 12% (60 lm/W) at green wavelengths, with continuously increasing ten-
Fig. 10.18 Spectra of blue and green InGaN and red AlInGaP LEDs and the eye sensitivity curve V_λ

dency in new values literally being published week by week.

As a summary, the efficiencies as a function of wavelength are plotted in Fig. 10.19 together with the eye's sensitivity curve for the two material systems.

White LEDs

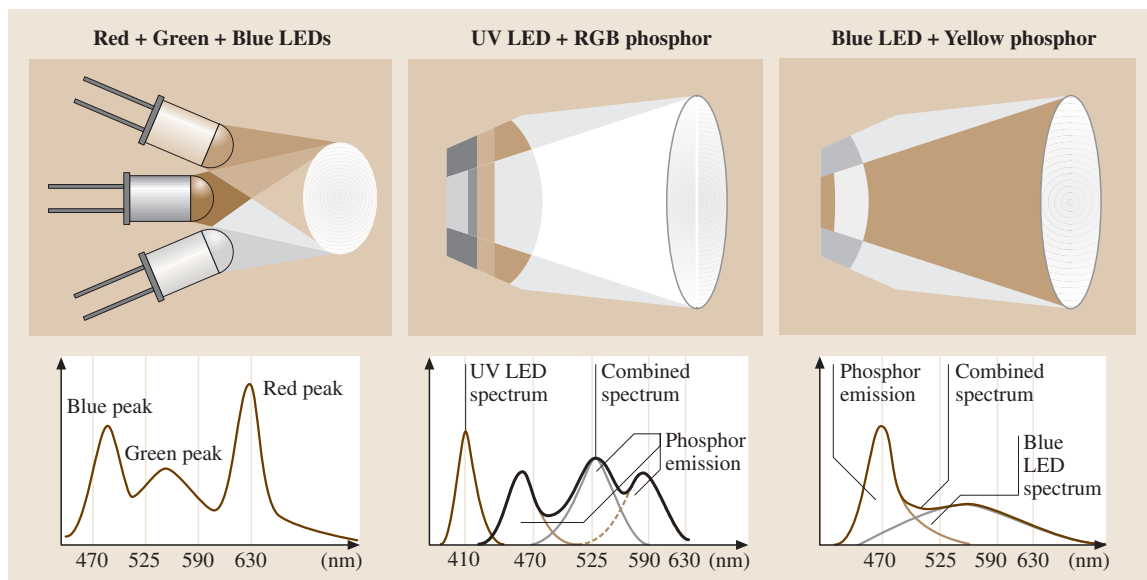
As mentioned above, combining the light of several colored LEDs can create white light. Several different concepts have been used, which will be briefly reviewed here (see Fig. 10.20). All of them have in common that a volume of light mixing has to be provided, since the different colors have to be directionally randomized before emission to avoid inhomogeneous illumination colors.
Fig. 10.19 Efficiency of InGaN and AlInGaP LEDs as a function of emission wavelength


Fig. 10.20 Summary of different methods of generating white light with LEDs

This is typically achieved through multiple reflections of the different LEDs in an appropriate housing. A common method is the use of a poly(methyl methacrylate) (PMMA) plate, where the light from different LEDs is coupled. Through total internal reflection, the colors are randomized and thus homogeneously mixed to the desired white. A second way to achieve a white color from polychromatic LED modules is to use a diffuser plate in front of the LEDs, again to randomize the spatial distribution of the different colors emitted by the LEDs. Finally tube-like hollow reflectors are being used for the same purpose, however in these systems the de-mixing and thus non-white appearance is often obvious at large angles.

To date, the most common method of achieving white emission from LEDs is by partially converting blue light from the semiconductor to lower-energy emission by means of phosphors, which are deposited onto the LED chip. This implies that the phosphor must show strong absorption of the blue light and a high photochemical stability due to the high excitation density of up to several $100 \, \text{W/cm}^2$. The widely used combination of blue InGaN LEDs (430–480 nm) with $(Y, Gd)_3(Al, Ga)_5O_{12} : Ce$ (YAG : Ce) thereby dominates the white-LED market today [10.7]. However, more advanced concepts are being realized, including blue LEDs in combination with yellow and red phosphors or red and green phosphors. The former concept aims at the enhancement of red radiation

in the entire spectrum to realize illumination-grade warm-white LEDs. The red luminescent materials used in combination with yellow YAG : Ce in so-called red-enhanced LEDs are $(Ca, Sr)S : Eu$ [10.10, 11] and $(Ca, Sr)_2Si_5N_8 : Eu$ [10.12]. Red-enhanced LEDs show high CRIs above 90 for low color temperatures between 2500 K and 4000 K.

White LEDs with high color rendering at arbitrary color temperatures between 2500 K and 10 000 K are obtained by applying blue LEDs with a combination of green and red phosphors. *Mueller–Mach* and *Mueller* e.g. found that $SrGa_2S_4 : Eu$ (535 nm) and SrS : Eu (615 nm) are an appropriate combination for trichromatic LEDs [10.13].

Compared to dichromatic YAG : Ce LEDs, LEDs with a trichromatic spectrum yield higher color rendering while the luminous efficacy is still almost as high.

10.3.4 Organic LEDs

Organic LEDs became an important area of research and development after the publication of direct EL observed from a device incorporating only organic charge-transfer materials and emitters by *Tang* and *van Slyke* from Kodak in 1987 [10.14]. The authors were working with organic photoconductors, which have been used for several decades in copiers and printers. Applying a forward bias to an appropriate device built with these mater-

ials, light was generated from directly injected carriers. A second important date was the publication of direct organic EL observed in a single-layer polymer-based device by *Friend* et al. in 1990, making a new class of materials available: semiconducting polymers [10.15]. These marked the beginning of intense R&D in organic EL.

The general build-up of an organic LED (OLED) is represented in Fig. 10.21. The stack typically consists of a substrate (mostly glass, however plastic is considered) with a thin layer (typically 100 nm) of indium–tin oxide (ITO). This is the most prominent representative of transparent conducting materials, which is needed to be able to couple the light out. On top of the ITO layer the organic material is deposited, either as a multilayer stack in small-molecule OLEDs or as a polymer coat in polymeric OLEDs. The top contact, usually the cathode, is built by evaporating reactive materials such as e.g. Ca, Mg or Ba to facilitate injection of electrons into the molecular materials. This is often followed by a less reactive metal, such as Al, to prevent fast oxidation of the top contact. Since many of the organic materials and especially the reactive cathode metal are water- and oxygen-sensitive, a nearly hermetic sealing is required to achieve a practical lifetime of the devices. This is achieved by encapsulating the glass with a second glass or metal can, which often also contains additional getter materials to absorb residual water and oxygen.

In general two types of organic direct EL are distinguished: polymeric and small-molecule organic LEDs. Both systems rely in principle on the same basic mechanisms and, although there are distinctive differences, especially in the case of conjugated polymers, the device set-up is identical for the two versions. Whereas small-molecule OLEDs are deposited using high-vacuum sublimation or gas-phase transport, polymeric OLEDs are typically spin-coated or in the case of displays, ink-jetted.

The conduction mechanism in organic materials is different to inorganic semiconductors. In the molecular solid, after charge injection, the molecule becomes oxidized and reduced, respectively, depending on the nature of the charge injected. If an electron is injected from the molecule to the electrode, a hole is injected into the molecule, which oxidizes the molecule. The charge then moves under the influence of the applied electric field across the molecule and by hopping from the originally excited molecule to the neighboring one. Thus the conductivity of organic layers is rather low, on the order of 10^{-3} cm^2/Vs in good materials, down
Fig. 10.21 Schematic build-up of an organic LED

to 10^{-8} cm^2/Vs for nearly insulating ones. The hole mobility is typically larger (10^{-3} cm^2/Vs) than the electron mobility (10^{-5} cm^2/Vs). The mobility can be higher in certain materials classes (up to 10^{-1} cm^2/Vs), but those are not typically used in EL devices.

The materials fabricated in OLEDs depend on which type of system is being used.

In small-molecule devices the organic layers are usually brought onto the substrate in a layer of multiple materials having defined functions for each material. A typical device layout is shown in Fig. 10.21. On top of the ITO a hole conductor is deposited. This is in most cases a material with high electron affinity to facilitate injection of holes from the anode and high hole mobility to achieve good hole transport. The next layer is than a matrix material with a large band-gap and high triplet energy, doped with an emitter material. These two functions can also be combined into the same material. On top of this layer a hole-blocker is deposited, to prevent the fast-moving holes from flowing directly to the anode. The hole-blocker has to have a very large band-gap and a large electron affinity to efficiently prevent holes from flowing through the structure. Finally an electron conductor/injector is deposited on top to facilitate electron injection into the device.

In polymeric OLEDs all these functions are combined in the material, a conjugated or non-conjugated polymer. Thus the layer sequence is typically reduced to two layers. First, a hole-injection layer, which also serves as a smoothing layer for the roughness of the substrate. This layer is made insoluble and is finally coated with the light-emitting polymer. The total thickness is typically 100–200 nm. Charge transport of electrons and holes as well as emission is provided from the different functional groups of the polymer. A schematic com-
Fig. 10.22 Schematic band diagram of polymeric (single-layer) and small-molecule (double-layer) OLEDs, respectively

parison of the different electronic structures of small molecules and polymer OLEDs is shown in Fig. 10.22.

In the recombination zone, electrons and holes meet and create excitons on the excited molecules. These excitons can have either a total spin of 1 or 1/2, thus creating a singlet or a triplet state. The singlet state is optically allowed and therefore able to generate a photon, whereas the triplet state is a forbidden transition, thus no emission of light is possible from these excitons. By statistics, the probability of creating a singlet is only 1/4 for all injected pairs, limiting the principle efficiency of organic EL devices to 25%. However, using other emitters, which have strong spin–orbit coupling it is possible to overcome the selection rules and the probability of forming a radiatively decaying exciton theoretically increases to unity, thus opening the road to very efficient organic LEDs.

Since the delocalization of the electron density across the molecule depends on the steric configuration of the molecule, and the electrical properties depend on the relative position between the molecules in the layer, the film formation is highly important in organic LEDs.

Additionally, the coupling of two neighboring molecules can lead to the formation of cooperative electronic states, which exhibit a new excited state, only present in the coupled molecules. This phenomenon is called excimer in the case of identical molecules and exciplex, if two different molecules are involved. The energy of this excited state without ground state is typically lower than the excited states of the single molecules. Therefore, this effect can be used to generate other wavelengths than those available from the constituent molecules only. However, the efficiency of singlet excimers and exciplexes is typically very low.

A crucial problem in organic LEDs (as well as in inorganic ones) is the outcoupling efficiency of the generated light. Due to the fact that many of the materials used have a high refractive index, light generated within the film and emitted at an angle larger than the critical angle of the material suffers from total internal reflection and the light is guided through the structure. Multiple reflections at partially absorbing interfaces reduce the amount of light coupled out. An estimate of the outcoupling ratio, using classical ray optics, gives a value of $1/n^2$, where n is the refractive index of the material. For most materials, this value amounts to 20%, i. e. 4/5 of the light generated does not leave the structure, rendering OLEDs often much less efficient than what could be achieved with improved outcoupling. Intense work is being conducted to identify the most promising methods to improve light outcoupling from thin-film organic LEDs. Recent measurements, using an optically coupled hemispherical lens on top of an OLED substrate indicate that the outcoupling can at least be doubled by appropriate means, improving the efficiency by the same factor of two. This topic is certainly one of the most important areas of OLED research.

Many of the materials used in today's OLEDs are sensitive to moisture and oxygen. Irreversible oxidation occurs at the surface, rendering the material insulating and thus creating a nonemissive (black) spot. These black spots are progressive, i. e. once formed they have a tendency to grow until the OLED is rendered useless. These black spots often start at pinholes in the electrode materials, which in the case of many cathode materials are themselves often the most critical materials with respect to oxidation within the whole OLED stack. To save the OLED from these failure mechanisms, near-perfect encapsulation is necessary, which often includes a getter material put in a sealed package, in close proximity to the OLED cathode to capture any remaining oxygen and water molecules before damage to the OLED occurs. In the near future, it is hoped that thin-film packaging, i. e.

the deposition of a nearly impermeable material on top of the OLED will solve this problem.

Although this is one of the most often encountered failure mechanisms of OLEDs, it is not the only one by far. Also, many OLED materials are intrinsically unstable, limiting the useful life of OLEDs and creating the need for more research and development in the field of organic LED materials.

For application as light sources OLEDs have some way to go to achieve high efficiency at high brightness and a long lifetime. However, since all of these properties have been shown in single devices, it is thought possible that OLEDs will be able to deliver. Due to the way in which they generate light, OLEDs will provide a very different light source to existing sources. A diffuse, large area, flat lamp that can eventually become flexible, color-tuneable and transparent is envisioned with OLEDs, creating new potential applications for light sources in the future. To generate white light from OLEDs several possibilities can be used. External mixing of colors (e.g. from pixelated sources), intrinsic broadband (white) emitters, mixed emitters, stacked emitters or phosphor-converted blue or UV-emitting OLEDs (using e.g. the phosphors described above) can be fabricated; the different options having different advantages and disadvantages depending on the applications for the light source. Most estimates establish a time frame of five to ten years before OLEDs will become an important incoherent light source.

10.4 General Light-Source Survey

Table 10.2 gives a summary of the main types of light sources and selected electrical and light technical properties as discussed in this chapter.

Table 10.2 Electrical and technical data of the basic types of light sources (state of affairs 2003)

Light source	Electrical input power (W)	Luminous flux (lm)	Luminous efficacy (lm/W)	Color rendering quality
Incandescent	10–1000	80–15000	8–15	Excellent
Halogen	20–2000	300–60000	15–30	Excellent
Low-pressure Hg discharge	7–150	350–15000	50–100	Good
High-pressure Hg discharge	50–1000	2000–60000	40–60	Good
Metal halide discharge	20–2000	1600–24000	80–120	Good to excellent
Low-pressure Na discharge	20–200	2000–40000	100–200	Poor
High-pressure Na discharge	40–1000	1600–14000	40–140	Moderate to good
Sulphur microwave discharge	up to 5000	up to 450000	80–90 (system)	Good
White dichromatic inorganic LED	1–5	20–150	20–30	Good
White trichromatic inorganic LED	1	20–25	20–25	Excellent
Organic LED (at 1000 cd/m^2)	15 mW (per cm^2)	0.3 lm (per cm^2)	30	Excellent

11. Lasers and Coherent Light Sources

This chapter describes lasers and other sources of coherent light that operate in a wide wavelength range. First, the general principles for the generation of coherent continuous-wave and pulsed radiation are treated including the interaction of radiation with matter, the properties of optical resonators and their modes as well as such processes as Q-switching and mode-locking. The general introduction is followed by sections on numerous types of lasers, the emphasis being on today's most important sources of coherent light, in particular on solid-state lasers and several types of gas lasers. An important part of the chapter is devoted to the generation of coherent radiation by nonlinear processes with optical parametric oscillators, difference- and sum-frequency generation, and high-order harmonics. Radiation in the extended ultraviolet (EUV) and X-ray ranges can be generated by free electron lasers (FEL) and advanced X-ray sources. Ultrahigh light intensities up to 10^{21} W/cm^2 open the door to studies of relativistic laser–matter interaction and laser particle acceleration. The chapter closes with a section on laser stabilization.

11.1 Principles of Lasers

11.1.1 General Principles

A laser (an acronym for *light amplification by stimulated emission of radiation*) is a device that produces and amplifies an intense beam of highly coherent, highly directional light. The original proposal of extending the maser (*microwave amplification by stimulated emission of radiation*) idea to the infrared or visible region of the electromagnetic (EM) spectrum, thus giving a laser, was however first made in 1960 by *Maiman* [11.1] using a flash-pumped rod of ruby with polished ends (ruby laser) after a proposal in 1958 by *Townes* and *Schawlow* [11.2]. Nowadays laser devices range in size from semiconductor lasers as small as a grain of salt to solid-state lasers as large as a storage building. Lasers are widely used in industry for, e.g., cutting and welding metals and other materials, in medicine for surgery, in optical communications, in optical metrology, and in scientific research. They are an integral part of such familiar devices as bar-code scanners used in supermarkets, laser printers, compact disc and digital versatile disc (DVD) players. The output wavelength of a laser is determined by the properties of its active medium. Altogether, several thousand lasing lines have been reported ranging from the soft-X-ray down to the far-infrared spectral region and new lines appear frequently in optics and laser journals. Depending upon the type of laser and its operational regime, the corresponding output power may vary from a fraction of a milliwatt to several hundred kilowatts in continuous-wave operation, and from tens of kilowatts to petawatt peak power in pulsed-mode operation.

A laser consists of at least three components (Fig. 11.1):

1. a gain medium that can amplify light by means of the basic process of *stimulated emission*;
2. a pump source, which creates a *population inversion* in the gain medium;
3. two mirrors that form a *resonator* or optical cavity in which light is trapped, traveling back and forth between the mirrors.

The laser beam is usually the fractional part of light trapped in the cavity that escapes from one of the two
Fig. 11.1 Schematic of a laser oscillator

Fig. 11.2a–c Fundamental interaction processes of a quantized atom with an EM wave. (a) Spontaneous emission. (b) Stimulated emission. (c) Absorption

mirrors (the *output coupler*), which has a nonvanishing transmission at the laser oscillation wavelength. The gain medium can be solid (including semiconductors), liquid, or gas, and the pump source can be an electrical discharge, a lamp, or another laser. Other specific components of a laser vary depending on the gain medium and whether the laser is operated continuously or pulsed. Lasers may be in fact divided into two broad groups:

1. continuous wave (CW) or quasi-CW,
2. pulsed.

A CW laser exhibits a steady flow of coherent energy and its output power undergoes little or no change with time. Many gas lasers, such as HeNe and Ar-ion lasers, operate CW; several solid-state lasers, such as Nd^{3+} and $Ti^{3+}:Al_2O_3$ lasers, are also often operated in CW mode. In pulsed lasers, the output beam power changes with time so as to produce a short optical pulse, usually in a repetitive way and with pulse duration usually ranging from nanoseconds (1 ns = 10^{-9} s) to femtoseconds (1 fs = 10^{-15} s). Typical examples of pulsed lasers are many solid-state and liquid lasers, such as Nd:YAG, $Ti:Al_2O_3$, and dye lasers.

Spontaneous and Stimulated Emission, Absorption

A laser exploits three fundamental phenomena that occur when an electromagnetic wave interacts with a material, namely the processes of spontaneous and stimulated emission, and the process of absorption (Fig. 11.2).

Spontaneous emission and nonradiative decay. Let us consider the energy levels of some given material and indicate by E_1 and E_2 the energies of the ground level, 1, and of an excited level, 2, of the medium. If the atom is initially raised in the excited state 2, it spontaneously tends to decay into the stable ground state 1. If the available energy for the transition, $E_2 - E_1$ is released in
the form of an EM wave, the process is referred to as spontaneous, or radiative, emission (Fig. 11.2a). Owing to energy conservation, the frequency ν_0 of the emitted radiation is given by:

$$\nu_0 = \frac{(E_2 - E_1)}{h} , \tag{11.1}$$

where h is the Planck's constant. Since the previous relation can also be written as $E_2 - E_1 = h\nu_0$, we can say that a single photon of energy $h\nu_0$ is emitted during each spontaneous emission process. Note also that this process occurs even if the atom is isolated and no external perturbation is applied. The probability of spontaneous emission can be characterized in the following way. Let us consider an ensemble of atoms and assume that, at time t, there are N_2 atoms per unit volume (*population*) in level 2.

Quantum mechanical calculations show that the rate of decay of these atoms due to spontaneous emission, i.e., $(dN_2/dt)_{sp}$, is proportional to N_2 according to:

$$\left(\frac{dN_2}{dt}\right)_{sp} = -\frac{N_2}{\tau_s} , \tag{11.2}$$

where τ_s is referred to as the spontaneous emission lifetime and depends on the particular transition involved. The direction, the polarization, and the phase of the emission event are random, so that the overall emitted light by the different atoms of the given population is said to be incoherent.

If the atom is not isolated but interacts, e.g., by collisions with other atoms, the decay from the excited state 2 to the ground state 1 may occur by a release of the internal energy ($E_2 - E_1$) into some form other than EM radiation (e.g., into kinetic or internal energy of surrounding atoms in a gas or lattice vibrations in a crystal). The phenomenon is referred to as *nonradiative decay*. The corresponding rate of decay from the excited state 2 can usually be expressed in a similar manner as (11.2), namely $(dN_2/dt)_{nr} = -N_2/\tau_{nr}$,

where τ_{nr} is the nonradiative lifetime. When both radiative and nonradiative decay are taken into account, the rate of decay of population N_2 can be written as:

$$\left(\frac{dN_2}{dt}\right)_{decay} = -\frac{N_2}{\tau_s} - \frac{N_2}{\tau_{nr}} \equiv -\frac{N_2}{\tau} , \qquad (11.3)$$

where the time constant τ, defined by $1/\tau = 1/\tau_s + 1/\tau_{nr}$, is referred to as the *lifetime* of the excited state 2.

Stimulated emission. If an EM wave of frequency ν close to ν_0 is incident onto the atom while in its excited state 2, the interaction of the wave with the atom may stimulate the atom to decay to level 1 with the simultaneous emission of EM radiation. The process is referred to as *stimulated emission*. In this case, one photon, with the same frequency ν of the incoming radiation and with the same propagation direction, polarization state and phase is emitted (Fig. 11.2b). This is a major distinction to spontaneous emission. It is the fundamental reason why a laser emits coherent light as compared to the incoherent light emitted by other light sources [such as lamps or light-emitting diodes (LEDs)], which exploit spontaneous emission. Quantum mechanical calculations show that the process of stimulated emission can be described by the equation

$$\left(\frac{dN_2}{dt}\right)_{st} = -W_{21}N_2 , \qquad (11.4)$$

where W_{21} is the rate of stimulated emission. This rate is proportional to the photon flux $F = I/(h\nu)$ of the incoming wave, where I is the wave intensity. We can in fact write $W_{21} = \sigma_{21}F$, where σ_{21} is a quantity having the dimension of an area (the stimulated emission *cross section*), which depends on the characteristics of the given transition and on the frequency difference $\Delta\nu = \nu - \nu_0$, i.e., $\sigma_{21} = \sigma_{21}(\Delta\nu)$. Owing to energy conservation in the process of stimulated emission, the function $\sigma_{21}(\Delta\nu)$ is very narrow at around $\Delta\nu = 0$.

Absorption. Lastly, let us consider the case of an atom initially lying in its ground state 1. In the absence of perturbations, such as collisions with other atoms or with photons, the atom stably remains in this state. However, if an EM radiation of frequency $\nu \simeq \nu_0$ is incident onto the atom, there is a finite probability that the atom will be raised to level 2. The energy difference $E_2 - E_1$ required by the atom to undergo the transition is obtained from the energy of the EM wave, namely one photon of the incoming wave is destroyed. This process is referred to as *absorption* (Fig. 11.2c). As for stimulated emission, the absorption process can be described by

$$\left(\frac{dN_2}{dt}\right)_a = -W_{12}N_2 , \qquad (11.5)$$

where W_{12} is the rate of absorption. Again one can show that $W_{12} = \sigma_{12}F$, where σ_{12} is the absorption cross section. Einstein showed at the beginning of the 20th century that, for nondegenerate levels, $W_{12} = W_{21}$, and thus $\sigma_{12} = \sigma_{21}$. If levels 1 and 2 are g_1-fold and g_2-fold degenerate, respectively, one then has $g_2\sigma_{21} = g_1\sigma_{12}$.

Coherent Amplification of Light

Consider a monochromatic EM plane wave at frequency ν which propagates along the z-direction inside a medium made of a collection of atoms. Let E_1 and E_2 be the energies of two nondegenerate levels 1 and 2 of the atom (this time 1 is not necessarily the ground state). We assume that the resonance frequency of the transition, $\nu_0 = (E_2 - E_1)/h$, is coincident (or very close) to ν. If $F(z)$ is the photon flux of the EM wave at plane z and N_1, N_2 are the populations in levels 1 and 2 (which are assumed to be z-independent), the change dF of the photon flux due to the processes of absorption and stimulated emission along the elemental length dz of the material is given by (Fig. 11.3a)

$$dF = \sigma(N_2 - N_1)F(z)dz , \qquad (11.6)$$

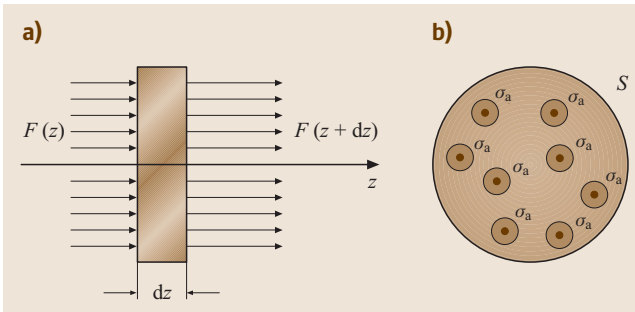
where $\sigma \equiv \sigma_{21} = \sigma_{12}$ is the transition cross section. Note that in writing (11.6) we did not consider radiative and nonradiative decays since nonradiative decay does not add new photons whereas spontaneous emission creates photons which are emitted in any direction and thus gives negligible contribution to the incoming photon flux. Most importantly, note that for $N_2 > N_1$, one has $dF/dz > 0$ and the EM wave is amplified during propagation, i.e., the medium acts as a coherent *optical amplifier*. Conversely, for $N_2 < N_1$, one has $dF/dz < 0$


Fig. 11.3a,b Coherent amplification of an EM wave. (**a**) Photon flux-balance diagram in an infinitesimal section dz of the amplifier. (**b**) Physical meaning of the transition cross section

and the medium behaves as an *absorber*. If we let l be the length of the medium, the photon flux $F(l)$ at the output plane is related to the one $F(0)$ at the input plane by the relation $F(l) = F(0)\exp(g)$, where $g = (N_2 - N_1)\sigma l$ is the gain coefficient. The condition for light amplification ($g > 0$) is therefore $N_2 > N_1$, which is often referred to as *population inversion*. We note that in the previous calculation N_1 and N_2 have been assumed independent of the intensity I of propagating wave. This is fine however provided that I is weak enough so as that changes of N_1 and N_2 due to absorption and stimulated emissions can be neglected; however, for strong intensities one needs to account for the phenomenon of *saturation*.

As a final comment, we note that an examination of (11.6) leads to a simple physical interpretation of the transition cross section σ. First, let us suppose that all the atoms of the medium are in the ground state and let us associate with each atom an effective absorption cross section σ_a in the sense that, if a photon enters this cross section, it is absorbed by the atom (Fig. 11.3b). If S is the cross-sectional area of the EM wave, the number of atoms in the element dz of the material is $N_t S dz$ (N_t is the total atomic population, i.e., $N_1 = N_t$ and $N_2 = 0$), thus giving a total absorption cross section of $\sigma_a N_t S dz$. The fractional decrease of photon flux in the element dz of the material is therefore $(dF/F) = -(\sigma_a N_t S dz/S) = -\sigma_a N_t dz$. If we compare this expression with (11.6), we conclude that $\sigma_a = \sigma$, so that the meaning we can attribute to σ is that of an effective absorption cross section as just defined.

Population Inversion: The Pumping Process

At thermal equilibrium any material behaves as an absorber. In fact, the distribution of populations N_2^e and N_1^e of levels 1 and 2 at thermal equilibrium is described by the Boltzmann statistics

$$\frac{N_2^e}{N_1^e} = \exp\left(-\frac{E_2 - E_1}{k_B T}\right), \tag{11.7}$$

where k_B is the Boltzmann constant and T is the absolute temperature. Note that $N_2^e < N_1^e$; in particular N_2^e is negligible as compared to N_1^e if $k_B T \ll E_2 - E_1$; at room temperature ($T = 300\,\mathrm{K}$) one has $k_B T \simeq 208\,\mathrm{cm}^{-1}$. [A reciprocal centimeter is a simple convenient unit for measuring energies in spectroscopy and refers to the inverse of the wavelength of a photon possessing the given energy E. The actual energy E in the SI unit (Joule) can be obtained by multiplying cm^{-1} by hc, with $c = 3 \times 10^{10}$ cm/s and $h = 6.63 \times 10^{-34}$ Js]. Therefore the condition $N_2^e \ll N_1^e$ is well satisfied for transitions in the near-infrared and visible. To obtain op-

tical amplification instead of optical absorption, we need to create population inversion in the medium by means of a *pumping process* [11.3, 4], which drives the population distribution far from thermal equilibrium. At first sight one might think to achieve population inversion between levels 2 and 1 through the interaction of the material with some strong EM radiation at frequency ν_0, such as that emitted by a flash or arc lamp. Since at thermal equilibrium $N_1^e > N_2^e$, absorption will dominate over stimulated emission, and this will produce an increase of N_2 and a decrease of N_1 from their thermal equilibrium values. However, when N_1 tends to reach the same value of N_2, absorption and stimulated emission processes compensate each other, i.e., the medium tends to become transparent. Such a situation is referred to as *saturation* of the two-level transition. Therefore, owing to saturation, it is impossible to produce population inversion in a two-level system (at least in the steady state). This goal can be achieved, however, when more than two energy levels are considered. Typically three or four energy levels are involved (Fig. 11.4), and correspondingly one speaks of *three-level* or *four-level* lasers. In a three-level laser (Fig. 11.4a), atoms are raised from the ground level 1 to the level 3 through a pumping mechanism. If the material is such that, once an atom excited into level 3 rapidly decays into a lower level 2 (by, e.g., a fast nonradiative decay), then population inversion can be obtained between level 2 and 1. Note that, in a three-level laser scheme, to achieve population inversion it is necessary to raise at least half of the atoms from the ground state 1 to state 3. In a four-level laser (Fig. 11.4b), atoms are again raised from the ground level 0 to an excited state 3, with a rapid decay to the upper laser level 2; however this time laser action takes place from level 2 to an excited lower-lying level 1. Once laser oscillation starts, level 1 is populated by stimulated emission; therefore to maintain popula-
Fig. 11.4a,b Schematic of the energy-level diagram for **(a)** a three-level laser, and **(b)** a four-level laser

tion inversion in stationary conditions (continuous-wave operation), the lower laser level 1 should rapidly depopulate through, e.g., a very fast nonradiative decay into the ground state 0. Compared to a three-level laser, the four-level laser offers the great advantage that population inversion is ideally achieved when just one atom is raised to the pumping level 3. Four-level lasers are thus more used, whenever possible, than three-level lasers. More recently, the so-called *quasi-three-level lasers* have also become a rather important laser category. In these lasers the energy level scheme is similar to that of a four-level laser, however levels 0 and 1 are now nondegenerate sublevels of the ground energy level. The population of the ground state is distributed in all the sublevels according to Boltzmann statistics, and therefore, at room temperature, some population is left in level 1.

The mechanism that allows atom excitation from the ground energy level into the excited pump level 3 is referred to as the *pumping process*. The rate of population of the upper state, 2, due to the pumping, $(dN_2/dt)_p$, can be written as:

$$\left(\frac{dN_2}{dt}\right)_p = W_p N_g \,, \tag{11.8}$$

where W_p is the pumping rate and N_g is the population of the ground state. For a four-level laser, one can assume N_g to be constant (and much larger than N_2). In this case one can write from (11.8) $(dN_2/dt)_p = R_p$, where $R_p = W_p N_g$ is the pump rate per unit volume. The energy required for pumping is generally supplied either optically or electrically. The minimum pump power P_m needed to produce a given pump rate R_p is given by $P_m = (dN_2/dt)_p V h \nu_{mp}$, where $(dN_2/dt)_p$ is the number of atoms per unit volume and time raised to the upper laser level by the pumping process, V is the volume of the active medium, and ν_{mp} is the minimum pump frequency, given by the difference between the ground level and the upper laser level. For either electrical or optical pumping, the actual pump power P_p turns out to be larger than the minimum value P_m, so that one can define a pump efficiency $\eta_p = P_m/P_p$. Therefore, the relation between the pump rate R_p and the actual pump power P_p is given by:

$$R_p = \eta_p \left(\frac{P_p}{V h \nu_{mp}}\right) \,. \tag{11.9}$$

Optical pumping. In optical pumping by an incoherent source, light from a powerful lamp (usually medium- to high-pressure Xe and Kr flashlamps for pulsed lasers, or high-pressure Kr lamps for CW lasers) is absorbed by the active medium. Solid-state gain media, such as Nd:YAG, and liquid lasers are particularly well suited to optical pumping: absorption lines are in fact very broad and this makes the absorption of the (broadband) light of the lamps efficient. The flashlamps generate significant heat into the material that must be dissipated by water cooling. The pumping source may, however, itself be a laser; in this case one speaks of *laser pumping*. Among the most used laser pump sources, we just mention semiconductor lasers (*diode laser pumping*), argon-ion laser and second-harmonic or third-harmonic generation of Nd lasers. With the advent of powerful and reliable semiconductor lasers, diode-laser pumping is nowadays commonplace for many solid-state and fiber lasers.

Electrical pumping. In gas lasers and semiconductor lasers, the excitation mechanism usually consists of an electrical current flow through the active medium. Gas lasers generally need to be electrically pumped because, due to the small width of their absorption lines, optical pumping would be very inefficient. In gas lasers, electrical pumping is achieved by passing an electric current either CW, at radio frequency or pulsed, directly through the gas itself. During the discharge, ions and free electrons are produced which acquire kinetic energy from the applied field and are able to excite neutral atoms via collisions: $A + e \rightarrow A^* + e$, where A^* denotes the atomic species in an excited state. Since electron impact excitation is a nonresonant process, it is a rather efficient pumping method for a gas. In some cases, the gas may contain two species, one of which is first excited by the discharge and then undergoes resonant energy transfer with the other via collision (an example is the HeNe laser). Electrical pumping in semiconductor lasers is achieved by flowing a large current density in a p–n or p–i–n diode. Though optical pumping can be used for semiconductor lasers, electrical pumping proves to be much more convenient.

Pumping processes different from optical or electrical pumping may also be employed in some special lasers; we just mention chemical pumping in chemical lasers, where population inversion is produced directly from an exothermic reaction.

Laser Oscillation

To obtain laser oscillation, the amplifying medium is placed between two mirrors, forming a laser cavity (Fig. 11.1). Light propagating along the cavity axis and passing through the pumped laser medium is reflected back through it, stimulating further emission in the same

direction. This means that laser photons undergo multiple reflections within the cavity, being amplified at each pass through the laser medium. One mirror (total reflector) reflects almost all the incident light back through the laser medium while the other (partial reflector or output coupler) transmits a fraction $T_2 = 1 - R_2$, which constitutes the output laser beam. The combination of laser gain medium, pumping source and optical cavity forms a simple laser oscillator: if the amplification is large enough to overcame losses, i.e., when a *threshold condition* is reached, a single photon (which is always present due to quantum noise) can be amplified by several orders of magnitude to produce a huge number of coherently generated photons trapped inside the resonator. In addition, for an open resonator, only the photons which propagate in the paraxial direction of the resonator axis can reach the threshold for oscillation, so that an important property of the output laser beam is that it is *directional*. We can obtain the threshold condition for laser action by a simple argument based on gain/loss balance of light photons in one cavity round-trip. In fact, in one round-trip the photons pass twice through the gain medium and hence the round-trip gain of photons is $\exp(2\sigma Nl)$, where $N = N_2 - N_1$ is the population inversion, and l is the length of the active medium. On the other hand, the round-trip loss for photons can be written as $(1 - T_1)(1 - T_2)(1 - L_i)^2$, where $T_1 = 1 - R_1$ and $T_2 = 1 - R_2$ are the power transmission of the two mirrors whereas L_i accounts for the one-way internal loss in the cavity (due to, e.g., scattering or diffraction loss for open resonators). The population inversion N_c needed to reach threshold (also called *critical inversion*) is simply obtained by equating the round-trip gain and loss. After setting $\gamma_1 = -\ln(1 - T_1)$, $\gamma_2 = -\ln(1 - T_2)$ and $\gamma_i = -\ln(1 - L_i)$, the critical inversion turns out to be given by

$$N_c = \frac{\gamma}{\sigma l} , \qquad (11.10)$$

where

$$\gamma = \gamma_i + \frac{\gamma_1 + \gamma_2}{2} \qquad (11.11)$$

is referred to as the single-pass *logarithmic loss* of the cavity. Once the critical inversion is reached, oscillation builds up from spontaneous emission.

To calculate the pump rate R_{cp} needed to reach the threshold condition (the *critical pump rate*), let us consider the four-level laser (Fig. 11.4b). In steady-state conditions and in the absence of lasing, the population accumulated on the upper laser level can simply

be calculated from a balance between the number of atoms pumped per unit volume and time in the upper laser level and the number of atoms that decay via radiative and nonradiative ways. Assuming $N_1 \simeq 0$, one obtains $\Delta N \simeq N_2 = R_p \tau$. When $N_2 = N_c$, from the previous equation and with the help of (11.10) the critical pump rate is obtained as $R_{cp} = \gamma/(\sigma \tau l)$. Note that the critical pump rate increases as $\sigma \tau$ decreases. Therefore the product $\sigma \tau$, which depends on the properties of the given transition, can be regarded as a figure of merit for a given laser.

Properties of Laser Beams

Laser radiation shows an extremely high degree of monochromaticity, coherence, directionality and brightness as compared to other noncoherent light sources [11.3].

The *monochromaticity* of laser radiation results from the circumstance that light oscillation sets in at one resonance frequency of the optical cavity, and owing to the balance between gain and loss in CW operation the line width $\Delta \nu_L$ of the oscillating mode is ultimately limited by quantum noise. Conversely, light from incoherent sources which exploit spontaneous emission (including LEDs) has a much lower degree of monochromaticity (as much as 11 orders of magnitude) since the spectral distribution of spontaneously emitted photons is broadened at around the atomic resonance frequency ν_0 owing to various broadening mechanisms. For laser radiation in the visible or near-infrared, line widths $\Delta \nu_L$ as low as a few Hz may, in fact, be achieved in frequency-stabilized laser sources.

The *coherence* of laser radiation refers to either *temporal* or *spatial* coherence. To define *spatial coherence*, let us consider two points P_1 and P_2 that, at a time $t = 0$, belong to the same wavefront, i.e., the phase difference between their electric fields at time $t = 0$ is zero. If the difference $\varphi_2(t) - \varphi_1(t)$ of their phases also remains zero at times $t > 0$, we say that there is perfect spatial coherence between the two points P_1 and P_2. In practice, for any point P_1, in order to have some degree of phase correlation, point P_2 must lie within some finite area around P_1, which is called the *coherence area*. The high degree of spatial coherence of laser radiation stems again from the fact that the spatial field distribution of the beam generated by stimulated emission is a mode of the optical resonator.

To define *temporal coherence* at a given point P, let us consider the phase difference $\varphi(t + \tau) - \varphi(t)$ for the electric field at P at times $t + \tau$ and t. For a given delay τ, if the phase difference is independent of time t,

we say that there is temporal coherence over a time τ. If this occurs for any value of τ, the EM wave is said to have perfect temporal coherence. If, conversely, this occurs only for delays τ smaller than a given delay τ_0, the wave is said to have partial temporal coherence, and τ_0 is called the *coherence time* of the EM wave at point P. The concept of temporal coherence is closely related to that of monochromaticity; in fact, for a CW laser one can show that the coherence time τ_0 is related to the laser line width $\Delta\nu_L$ by the simple relation $\tau_0 \approx 1/\Delta\nu_L$. The high degree of temporal coherence of laser radiation is therefore due to its extreme degree of monochromaticity.

The *directionality* of the laser beam is due to the fact that the gain medium is placed inside an *open* optical resonator and, as a consequence, stimulated emission preferentially occurs in the direction orthogonal to the two cavity mirrors (Fig. 11.1), where feedback from the mirrors is most effective and diffraction losses are the smallest. The laser beam emitted from the output coupler shows a divergence angle which, in the ideal case, is limited by diffraction. From diffraction theory, the divergence angle for a monochromatic beam of wavelength λ turns out to be given by

$$\theta_d = \beta\left(\frac{\lambda}{2w}\right),\qquad(11.12)$$

where β is a numerical coefficient (of order 1) whose specific value depends on the particular transverse field distribution and $2w$ is the diameter of the beam. For example, considering laser radiation in the visible ($\lambda = 500$ nm), the divergence of a laser beam of transverse diameter $2w \approx 1$ cm is solely $\theta_d \approx \lambda/2w \simeq 5 \times 10^{-5}$ rad. This means that, after propagation for a length $L = 1$ km, the beam size is increased to solely $w + \theta_d L \approx 6$ cm!

The *brightness* of laser radiation is closely related to the directionality and stems from the capability of a laser oscillator to emit a high optical power in a small solid angle of space. For a given emitting source, of area ΔS, if P denotes the optical power delivered in a fractional solid angle $\Delta\Omega$ of space, the brightness of the emitter is defined as $B = P/(\Delta S \Delta\Omega)$. The brightness of a laser source, in which the solid angle of emission $\Delta\Omega$ is determined by its divergence angle θ_d, is given by

$$B = \left(\frac{2}{\beta\pi\lambda}\right)^2 P.\qquad(11.13)$$

A laser of moderate power (e.g., a few milliwatts) has a brightness several orders of magnitude greater than that of the brightest conventional sources.

11.1.2 Interaction of Radiation with Atoms

Absorption and Stimulated Emission Rates

Consider a monochromatic EM wave of frequency ν incident on a two-level atom with a transition frequency $\nu_0 = (E_2 - E_1)/h$ close to ν. The calculation of the absorption and stimulated emission rates W_{12} and W_{21} can be done following a semiclassical approach, in which the atom is treated quantum mechanically whereas the EM wave classically [11.3,5–9]. If the atom is initially in its ground state (level 1), the incident wave may induce a transition to level 2 owing to the coupling of the electromagnetic field with the electric and magnetic dipole (and multipole) moments of the atom. The strongest interaction is usually that arising between the electric field $E(t) = E_0 \cos(2\pi\nu t)$ of the EM and the electric dipole moment of the transition, which is defined by the matrix dipole element $\mu_{12} = \int u_2^*(r)er u_1(r)\,dr$, where r is the distance of the electron of the atom, with charge e, from its nucleus, and where $u_1(r)$ and $u_2(r)$ are the electronic eigenfunctions for the atomic energy levels 1 and 2 respectively. In this electric-dipole approximation, a perturbation theory, which assumes that the interaction between the EM wave and the atom is not disturbed by, e.g., collisions or other phenomena (including spontaneous emission), leads to the following expression for the absorption and stimulated emission rate

$$W_{12} = W_{21} = \frac{2\pi^2}{3n^2\epsilon_0 h^2}|\mu_{12}|^2\rho\delta(\nu - \nu_0),\qquad(11.14)$$

where $\rho = n^2\epsilon_0 E_0^2/2$ is the energy density of the EM wave, n is the refractive index of the medium, and δ is the impulse Dirac function. In particular, for a plane wave of intensity $I = c\rho/n$, from (11.14) the following expression for the cross section $\sigma_{12} = W_{12}/F = h\nu W_{12}/I$ can be derived:

$$\sigma_{12} = \frac{2\pi^2}{3n\epsilon_0 ch}|\mu_{12}|^2\nu\delta(\nu - \nu_0).\qquad(11.15)$$

Analogously, if initially the electron is on level 2, owing to the interaction with the EM wave there is a probability that the electron decays into state 1 emitting a photon by stimulated emission. The semiclassical perturbation calculation leads for the stimulated emission cross section $\sigma_{21} = h\nu W_{21}/I$ the same expression as that of σ_{12}, i.e., $\sigma_{21} = \sigma_{12}$, provided that the two levels are not degenerate.

The expression for $\sigma_{12} = \sigma_{21}$ as given by (11.15) is unphysical since it implies that the transition probability is zero for $\nu \neq \nu_0$ and ∞ for $\nu = \nu_0$. The inconsistency is removed by observing that the interaction of

the monochromatic EM wave with the atom is not perfectly coherent, but it is disturbed by, e.g., collisions with other atoms or with lattice phonons, spontaneous emission and nonradiative decay of the atom. The effect of such disturbing interactions is to broaden the transition line of each atom in the ensemble, in the sense that in (11.15) the Dirac δ function $\delta(\nu - \nu_0)$ should be replaced by a new function $g(\nu - \nu_0)$, symmetric about $\nu = \nu_0$ with $\int g(\nu - \nu_0)d\nu = 1$, which is generally given by the Lorentzian function (Fig. 11.5a):

$$g(\nu - \nu_0) = \frac{2}{\pi \Delta \nu_0} \frac{1}{1 + [2(\nu - \nu_0)/\Delta \nu_0]^2} , \quad (11.16)$$

where $\Delta \nu_0$ depends on the particular broadening mechanism involved. Note that the full width at half-maximum (FWHM) of the Lorentzian function is simply $\Delta \nu_0$. The resonant character of the stimulated emission and absorption processes is maintained since the line broadening $\Delta \nu_0$ is typically several orders of magnitude smaller than ν_0 (e.g., in a low-pressure gas, for a transition in the visible one has $\nu_0 \approx 5 \times 10^{14}$ Hz whereas $\Delta \nu_0 \approx 10^6 - 10^8$ Hz). Since the aforementioned broadening mechanism act in the same way on each atom of the ensemble, it is referred to as a *homogeneous broadening* mechanism.

A somewhat different case occurs when the resonance frequencies ν_0' of the atoms in the ensemble are distributed around a central frequency ν_0 (*inhomogeneous broadening*). This distribution is described by the function $g^*(\nu_0' - \nu_0)$ such that $\int g^*(\nu_0' - \nu_0)d\nu_0' = 1$ and $g^*(\nu_0' - \nu_0)d\nu_0'$ is the fractional part of the atoms in the ensemble whose resonance frequency lies in the interval $(\nu_0', \nu_0' + d\nu_0')$. For the most common mechanisms of inhomogeneous line broadening (such as Doppler broadening in a gas or local-field effects in ionic crystals or glasses) the distribution $g^*(\nu_0' - \nu_0)$ is given by a Gaussian function (Fig. 11.5b):

$$g^*(\nu_0' - \nu_0) = \frac{2}{\Delta \nu_0^*} \left(\frac{\ln 2}{\pi} \right)^{1/2}$$
$$\times \exp \left(-\frac{4 \ln 2 (\nu_0' - \nu_0)^2}{\Delta \nu_0^{*2}} \right) , \quad (11.17)$$

where $\Delta \nu_0^*$ is the transition line width (FWHM), which depends on the particular broadening mechanism.

Taking into account the simultaneous presence of both homogeneous and inhomogeneous broadening mechanisms, one can show that the cross section $\sigma = \sigma_{12} = \sigma_{21}$ for stimulated emission and absorption
Fig. 11.5 Lorentzian (*left side*) and Gaussian (*right side*) line shapes corresponding to homogeneous and inhomogeneous transition broadening, respectively

assumes the most general form:

$$\sigma = \frac{2\pi^2}{3n\epsilon_0 ch} |\mu_{12}|^2 \nu g_t(\nu - \nu_0) , \quad (11.18)$$

where the total line shape g_t is given by the convolution:

$$g_t(\nu - \nu_0) = \int g^*(\nu_0' - \nu_0)g(\nu - \nu_0')d\nu_0' . \quad (11.19)$$

If we consider an ensemble of atoms and indicate by N_1 and N_2 the populations of atoms in the energy levels 1 and 2, as discussed in the previous section a small-signal EM wave of frequency ν which propagates inside the medium experiences amplification for $N_2 > N_1$ or absorption for $N_2 < N_1$. In the former case, one can introduce the absorption coefficient per unit length $\alpha(\nu) = \sigma(\nu - \nu_0)(N_1 - N_2)$, whereas in the latter case one can introduce the gain coefficient per unit length $g(\nu) = \sigma(\nu - \nu_0)(N_2 - N_1)$. For a weak-signal wave, so that saturation can be neglected, the intensity of the propagating wave is thus exponentially attenuated or amplified along the propagation direction according to $I(z) = I(0)\exp(-\alpha z)$ or $I(z) = I(0)\exp(gz)$, respectively.

These considerations apply to atomic or molecular transitions which are *electric-dipole* allowed, i.e., for which the dipole matrix element μ_{12} of the transition does not vanish. Transitions between atomic or molecular energy levels with the same parity (e.g., between s states in an atom) are electric-dipole forbidden. This does not mean however that the atom or molecule cannot pass from level 1 to level 2 when interacting with an EM wave; in this case the transition can occur owing to the interaction of the EM wave with, e.g., the magnetic dipole moment (or the electric quadrupole moment) of the transition, though the strength of the cross section describing this process is much smaller than that of an allowed electric dipole transition. For an

electric dipole transition the absorption transition rate W_e is proportional to $\sim |\mu_e E_0|^2$, where μ_e is the electric dipole moment of the transition, E_0 the amplitude of the electric field of the EM wave and $-E_0\mu_e$ is the classical energy of an electric dipole in an external field E_0. Likewise, for a magnetic dipole interaction, the transition rate W_m is proportional to $\sim |\mu_m B_0|^2$, where μ_m is the magnetic dipole of the transition, B_0 is the amplitude of the magnetic field of the EM wave, and $-B_0\mu_m$ is the classical energy of a magnetic dipole in an external magnetic field B_0. By approximating $\mu_e \approx ea$ and $\mu_m \approx \beta$, where $a = 0.529 \times 10^{-10}$ m is the Bohr radius and $\beta = 9.27 \times 10^{-24}$ Am^2 is the Bohr magneton, one then obtains:

$$\left(\frac{W_e}{W_m}\right) = \left(\frac{eaE_0}{\beta B_0}\right)^2 = \left(\frac{eac}{\beta}\right)^2 \simeq 10^5 . \quad (11.20)$$

Spontaneous Emission

Spontaneous emission is the phenomenon by which an atom in an excited energy level tends to decay toward the ground state (even in absence of any external perturbation) by emitting an EM wave, i. e., one photon. A correct explanation of spontaneous emission requires a quantum electrodynamic approach in which both the atom and the EM field are quantized. In practice, due to quantization of the EM field, the mean values of both E^2 and H^2 fields are nonvanishing even in the absence of a (classical) EM wave (zero-point field fluctuations). Such intrinsic fluctuations always perturb the atom in an excited state and trigger its decay toward a lower energy level with the emission of one photon with frequency ν close to the atomic transition frequency ν_0. Atomic decay due to spontaneous emission follows an exponential law with a time constant τ_s, which is referred to as the spontaneous emission lifetime [see (11.2)]. The quantum electrodynamic calculation of τ_s in the electric dipole approximation and for an atom placed in an optical cavity was done by *Weisskopf* and *Wigner* [11.10]. A simple and rigorous calculation of τ_s may be derived using an elegant thermodynamic argument, which was proposed by Einstein well before any development of the quantum electrodynamics [11.11]. Assume that the material is placed inside a black-body cavity whose walls are kept at a constant temperature T. Once the thermodynamic equilibrium is reached, the spectral EM energy density distribution $\rho(\nu)$ inside the cavity is given by the Planck distribution

$$\rho(\nu) = \left(\frac{8\pi\nu^2}{c^3}\right)\frac{h\nu}{\exp(h\nu/kT)-1} \quad (11.21)$$

where $\rho(\nu)$ is such that $\rho(\nu)\,d\nu$ is the EM energy per unit volume of the cavity associated to modes with frequencies in the interval $(\nu, \nu + d\nu)$. We note that in (11.21) the factor $(8\pi\nu^2/c^3)$ represents the density of EM modes per unit volume of the cavity, whereas the term $h\nu/[\exp(h\nu/k_B T) - 1]$ is the energy per mode. The populations N_1^e and N_2^e in the atomic levels 1 and 2 at thermal equilibrium are described by a Boltzmann statistics (11.7); on the other hand, at steady state the number of excitation per unit time from level 1 to level 2 due to the absorption of black-body radiation should balance the number of decays per unit time from level 2 to level 1 due to both stimulated emission and spontaneous emission, i. e., $W_{12}N_1^e = W_{21}N_2^e + N_2^e/\tau_s$. One then obtains $1/\tau_s = W_{12}\exp(h\nu_0/kT) - W_{21}$. For a spectrally broad radiation (such as black-body radiation) one can write $W_{12} = W_{21} = \int d\nu c\sigma(\nu - \nu_0)\rho(\nu)/nh\nu = 2\pi^2|\mu_{12}|^2\rho(\nu_0)/(3n^2\epsilon_0 h^2)$, where we used (11.15). Using this expression for $W_{12} = W_{21}$ and (11.21) for $\rho(\nu_0)$, one finally obtains

$$\tau_s = \frac{3h\epsilon_0 c^3}{16\pi^3 \nu_0^3 n|\mu_{12}|^2} . \quad (11.22)$$

Using a similar thermodynamic argument, one can also show that the spectrum of the photon emitted by spontaneous emission is given by the line shape $g_t(\nu - \nu_0)$ of the transition (11.19), i. e., the probability that the photon emitted by spontaneous emission has a frequency in the range $(\nu, \nu + d\nu)$ is given by $g_t(\nu - \nu_0)\,d\nu$. This property is very interesting since it enables one to measure the transition line shape $g_t(\nu - \nu_0)$ simply in an emission experiment by passing the spontaneously emitted light through a spectrometer of sufficiently high resolution.

To estimate the radiative lifetime τ_s, let us consider for instance an electric-dipole-allowed transition at a frequency corresponding to the middle of the visible range ($\lambda_0 = c/\nu_0 = 500$ nm). Assuming $|\mu_{12}| \simeq ea$ (where $a \simeq 0.1$ nm is the atomic radius), from (11.22) one obtains $\tau_s \simeq 10$ ns. For a magnetic dipole transition $1/\tau_s$ turns out to be 10^5 times smaller, i. e., $\tau_s \simeq 1$ ms. Note that, according to (11.22), τ_s decreases as the cube of the transition frequency, so that the importance of spontaneous emission increases rapidly with frequency. This implies that, as spontaneous emission is often negligible in the middle- to far-infrared, where nonradiative decay dominates, in the X-ray region (e.g., $\lambda_0 < 5$ nm) spontaneous emission is the dominant decay process and τ_s becomes exceedingly short (10–100 fs). Such a short lifetime represents a major challenge for achieving a population inversion in X-ray lasers. It should finally be noted that the rate of spontaneous emission as

given by (11.22) can be either enhanced or reduced when the atom radiates in a dielectric cavity whose density of EM modes (i.e., the number of resonant cavity modes per unit frequency and per unit volume) is changed from the value $(8\pi v^2/c^3)$ due to, e.g., tight spatial confinement, such as in *microlasers*. For instance, spontaneous decay is fully inhibited for an atom placed inside a photonic crystal whenever the atomic transition frequency v_0 falls inside a bandgap of the photonic crystal.

Line Broadening Mechanisms

Homogeneous broadening. A line broadening mechanism is said to be homogeneous when it broadens the line of each atom in the same way. In this case the line shape of the single-atom cross section and that of the overall absorption cross section are identical. There are two main homogeneous broadening mechanisms: *collisional broadening* and *natural broadening*.

Collisional broadening occurs in a gas, where the atom may collide with other atoms, ions, free electrons, or with the walls of the container, as well as in a solid, where collisions are due to the interaction of the atom with the lattice phonons. During a process of absorption or stimulated emission of a two-level atom with a monochromatic EM wave, the collisions interrupt the coherent interaction of the EM with the atom; if we write the electronic wave function ψ of the atom during the transition as $\psi = c_1(t)u_1(\boldsymbol{r})\exp[-iE_1t/\hbar] + c_2(t)u_2(\boldsymbol{r})\exp[-iE_2t/\hbar]$, assuming that the collision does not induce a decay, it simply introduces a random and rather instantaneous relative phase jump of the coefficients c_1 and c_2, and thus of the oscillating part of the atomic dipole $\mu = \int -er|\psi(\boldsymbol{r},t)|^2\,\mathrm{d}\boldsymbol{r}$, which is proportional to $c_1c_2^*$. Since in the electric-dipole interaction the radiation–atom coupling is expressed by the energy term $-\mu_\mathrm{e}\boldsymbol{E}$, a different but equivalent picture is to assume that it is the phase of the electric field that shows random phase jumps rather than the atomic dipole moment (Fig. 11.6). Therefore we can consider the case of coherent (i.e., not disturbed) interaction of the two-level atom with an EM wave which is not monochromatic but whose spectral content is broadened at around v owing to the phase jumps. Let $I(v') = Ig(v'-v)$ be the spectral intensity distribution of the EM wave with random phase jumps (Fig. 11.6), where I is the total field intensity and g its spectral shape (with $\int g(v'-v)\,\mathrm{d}v' = 1$). For each fractional spectral component $Ig(v'-v)\,\mathrm{d}v'$ of the EM wave, we may introduce an elemental absorption transition rate $\mathrm{d}W_{12}$ given, according to (11.14), by $\mathrm{d}W_{12} = [2\pi^2|\mu_{12}|^2/(3n\epsilon_0ch^2)]\delta(v'-v_0)Ig(v'-v)\,\mathrm{d}v'$. The total transition rate, $W_{12} = \int \mathrm{d}W_{12}$, is then given
Fig. 11.6 Schematic of the sinusoidal electric field of frequency v showing random phase jumps at time intervals τ

by $W_{12} = \sigma_{12}(v-v_0)I/hv$, where the cross section σ_{12} is given by (11.15) after replacing the delta function $\delta(v-v_0)$ with $g(v-v_0)$. To calculate the line shape g, let us assume that the distribution of the time interval τ between two successive collisions be described by an exponential probability density, $p(\tau) = [\exp(-\tau/\tau_\mathrm{c})]/\tau_\mathrm{c}$, where τ_c is the mean value of τ. According to the Wiener–Kintchine theorem, the spectrum g can be calculated as the Fourier transform of the autocorrelation function of the sinusoidal field with phase jumps at time intervals τ (Fig. 11.6). This yields a Lorentzian line shape (11.16) with a FWHM of Δv_0, related to the mean value of collision time τ_c by the equation

$$\Delta v_0 = \frac{1}{\pi\tau_\mathrm{c}}\,. \tag{11.23}$$

For instance, for an atomic or molecular gas at pressure p and absolute temperature T, from kinetic theory and employing the hard-sphere model of a gas, one has $\tau_\mathrm{c} = (2Mk_\mathrm{B}T/3)^{1/2}[1/(8\pi pa^2)]$, where M is the atomic mass and a its radius. Note that τ_c is inversely proportional, and hence Δv_0 is directly proportional, to the gas pressure p. As a rough rule of thumb, we can say that, for any atom in a gas, collisions contribute to the line broadening by an amount $(\Delta v_\mathrm{coll}/p) \approx 1\,\mathrm{MHz/Torr}$.

For an atom or an ion in a crystal, collisions occur with lattice phonons. Since the number of phonons in a given lattice vibration is strongly dependent on the lattice temperature T, the corresponding line broadening Δv_0 increases with increasing values of T. For instance, in the Nd:YAG laser Nd^{3+} ions are hosted in the YAG crystal, and collision broadening increases from $\Delta v_0 \approx 126\,\mathrm{GHz}$ at room temperature ($T = 300\,\mathrm{K}$) to about $250\,\mathrm{GHz}$ at $T = 400\,\mathrm{K}$.

A second homogeneous line broadening mechanism originates from spontaneous emission and is referred to as natural (or intrinsic) line broadening. It can be shown that the natural broadening is again described by

a Lorentzian function with a FWHM of $\Delta \nu_0$ given by

$$\Delta \nu_0 = \frac{1}{2\pi \tau_s} , \tag{11.24}$$

where τ_s is the spontaneous lifetime. For, e.g., an electric dipole transition at the center of the visible ($\lambda \approx 500$ nm), one has $\Delta \nu_{nat} \simeq 16$ MHz. Since $\tau_s \approx 1/\nu^3$, the natural line width rapidly increases for transitions at shorter wavelengths (to the UV or X-ray spectral regions).

We finally note that, when the two aforementioned homogeneous line broadening mechanisms act simultaneously, the overall line shape is obtained from the convolution of the two corresponding Lorentzian functions. One then obtains a Lorentzian function with a FWHM given by $\Delta \nu_0 = \Delta \nu_{coll} + \Delta \nu_{nat}$.

Inhomogeneous broadening. A line broadening mechanism is said to be inhomogeneous when it distributes the atomic resonance frequencies over some spectral range. A first case of inhomogeneous broadening is that of ions in ionic crystals or glasses, where the local crystal field induces, via the Stark effect, a local variation of the energy-level separation of the ion. For random local field variations, the corresponding distribution of the transition frequencies $g^*(\nu - \nu_0)$ turns out to be given by a Gaussian function (11.17) with a line width $\Delta \nu_0^*$ that depends on the amount of field inhomogeneity within the crystal or glass.

A second inhomogeneous mechanism, typical of gases, arises from atomic motion and is referred to as *Doppler broadening*. In fact, due to the motion of the atom, the frequency ν' of the EM wave as seen in the rest frame of the atom is shifted as compared to the frequency ν of the wave in the laboratory reference frame according to the relation $\nu' = \nu[1 - (v_z/c)]$, where v_z is the component of the atomic velocity in the propagation z-direction of the EM wave. From the point of view of atom–radiation interaction, this shift is equivalent to a change of the resonance frequency of the atom rather than to a change of the EM frequency. Taking into account the Maxwellian distribution of molecular velocities in a gas, one can show that the distribution of the transition frequencies $g^*(\nu' - \nu_0)$ is given again by a Gaussian function (11.17) with a line width $\Delta \nu_0^*$ given by

$$\Delta \nu_0^* = 2\nu_0 \left(\frac{2k_B T \ln 2}{Mc^2} \right)^{1/2} , \tag{11.25}$$

where M is the atomic (or molecular) mass and T the gas temperature. As an example, for the $\lambda = 632.8$ nm line of

the HeNe laser, at $T = 300$ K and using the appropriate mass for Ne, one obtains $\Delta \nu_0^* \simeq 1.7$ GHz. As a general rule, Doppler broadening in a gas is usually larger than collisional broadening for a gas pressure lower than the atmospheric pressure; collisional broadening, in turn, is usually larger than the natural broadening.

Nonradiative Decay

Besides decaying via radiative emission, an atom in an excited state may decay toward a lower-lying level in a nonradiative way. A first mechanism of nonradiative decay arises from collisions and is called *collisional deactivation*. In this case, for a liquid or a gas, the transition energy is released as excitation and/or kinetic energy of the colliding species, or it is transferred to the container walls; for an ion in a crystal or in a glass the deactivation occurs through the interaction with lattice phonons or glass vibrational modes. When, e.g., the excitation energy of an atomic excited species B^* in a gas is released as a kinetic energy of the species A, the collisional deactivation process occurs via the superelastic collision $B^* + A \rightarrow B + A + \Delta E$, where ΔE, the excitation energy to be released, is left as kinetic energy of the colliding partners. When the electronic energy of species B^* is released in the form of the internal energy of species A, we have instead $B^* + A \rightarrow B + A^* + \Delta E$, where now ΔE is the difference between the internal energies of the two colliding species. In this latter case, deactivation process is efficient provided that ΔE is appreciably smaller than the thermal energy $k_B T$ of colliding species. A simple description of the nonradiative decay of a given species in an excited state is expressed by a nonradiative lifetime τ_{nr} such that N_2/τ_{nr} is the number of atoms, per unit volume and time, that decay owing to the deactivation process.

Nonradiative decay acts in combination with spontaneous emission and, according to (11.3), the overall lifetime τ of an excited state is given by: $\tau = (1/\tau_{nr} + 1/\tau_s)^{-1}$.

Concluding Remarks

From the preceding discussions, we can say that the most important material parameters of interest for a laser are the transition wavelength λ, the transition cross section at the peak σ_p, the lifetime of the upper laser level τ, and the line width $\Delta \nu_0$ of the transition line shape. These parameters, for the most common gas, liquid and solid-state lasers, are summarized in Table 11.1. We note that, as compared to gas and liquid lasers, the cross sections for solid-state lasers (Nd:YAG, Nd:glass, and $Ti^{3+}:Al_2O_3$) are relatively small and, correspondingly,

Table 11.1 Main parameters for transitions in most common gas, liquid and solid-state lasers

Transition	λ (nm)	σ_p (cm^2)	τ (μs)	$\Delta\nu_0$
HeNe	632.8	5.8×10^{-13}	30×10^{-3}	1.7 GHz
Ar$^+$	514.5	2.5×10^{-13}	6×10^{-3}	3.5 GHz
Nd:YAG	1064	2.8×10^{-19}	230	120 GHz
Nd:glass	1054	4×10^{-20}	300	5.4 THz
Rhodamine 6 G	570	3.2×10^{-16}	5.5×10^{-3}	46 THz
Ti^{3+}:Al$_2$O$_3$	790	4×10^{-19}	3.9	100 THz

the lifetimes relatively long because in these lasers the transitions are electric-dipole forbidden (or weakly allowed). We note also that the line widths of gas lasers are much smaller than those of solid-state or dye lasers.

11.1.3 Laser Resonators and Modes

As discussed in the introductory section, in a laser oscillator the inverted amplifying medium is placed inside a *laser resonator* or *laser cavity*, which can be viewed as a *trapping box* for light radiation capable of sustaining stationary (i. e., monochromatic) or weakly damped electromagnetic field configurations at some selected optical frequencies [11.3, 5]. Such EM field configurations and the corresponding optical frequencies are called *cavity modes* and *resonance frequencies*, respectively. The most widely used resonators for lasers are open cavities, composed of at least by two plane or spherical mirrors of circular shape (spherical resonators), placed in front each other at some distance L. Except for microlasers, in ordinary lasers the resonator length L is typically much larger than the oscillating wavelength λ, ranging from a few centimeters to a few tens of centimeters, whereas mirror dimensions range from a fraction of centimeter to a few centimeters. The optical cavity is open to reduce drastically the number of modes that can oscillate with low loss. In fact, if the cavity were closed, the number N of resonant modes that might oscillate, i. e., the number of modes whose resonance frequency falls within the gainline of the active medium, is approximately given by $N \approx (8\pi\nu^2/c^3)V\Delta\nu_0$, where $(8\pi\nu^2/c^3)$ is the density of modes, $\Delta\nu_0$ the line width of the gain medium, and V is the cavity volume. Note that V is usually several orders of magnitude larger than λ^3 at optical wavelengths. To estimate N, let us consider an active medium with a narrow line width, such as the $\lambda = 633$ nm transition of the HeNe laser ($\Delta\nu_0^* = 1.7$ GHz). Assume a resonator length $L = 50$ cm closed by a lateral cylinder with diameter $2a = 3$ mm. The cavity volume is then $V = \pi a^2 L$, and the number of cavity modes that fall

under the gainline of the HeNe laser is $N \approx 1.2 \times 10^9$. In the open optical resonant cavities only those modes traveling nearly parallel to the resonator axis experience low losses to allow for laser oscillation. Therefore, the oscillating modes are expected to show a field distribution mostly confined around the optical axis of the resonator and propagating paraxially along it, making the output laser beam highly directional. These cavity modes and corresponding resonance frequencies depend upon three integer numbers n, m and l, which are referred to as *mode indices*. The latter two indices m and l (transverse mode indices) determine the transverse field distribution (i. e., in a plane orthogonal to the paraxial resonator axis) of the mode, whereas the former index n (the longitudinal mode index) determines the longitudinal field distribution (i. e., along the resonator axis) of the mode and gives, in particular, the number of longitudinal nodes of the standing wave. For spherical mirrors with sufficiently wide apertures, transverse modes are expressed by Gauss–Hermite or Gauss–Laguerre functions, depending on rectangular or circular boundary conditions. In particular, the leading-order mode, corresponding to transverse mode indices $m = l = 0$, is a *Gaussian beam* and represents the most common transverse field distribution of any output laser beam. For this reason the study of laser modes is closely related to the propagation properties of Gaussian (or Gauss–Hermite) beams.

Gaussian Beams

The electric field of a monochromatic (and uniformly polarized) light wave propagating at a small angle (i. e., paraxially) along the z-direction of an xyz cartesian system of coordinates can be described as follows:

$$E(x, y, z, t) = E_0 u(x, y, z) e^{i(\omega t - kz)} + \text{c.c.} , \quad (11.26)$$

where $\omega = 2\pi\nu$, ν is the *optical frequency*, $k = 2\pi/\lambda$ is the wavenumber, λ is the optical wavelength, $u(x, y, z)$ is the complex field envelope obeying the so-called *paraxial wave equation*, which in case of free-space

propagation reads

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} - 2ik\frac{\partial u}{\partial z} = 0 \, . \tag{11.27}$$

Among the solutions of (11.27) that retain their functional form during propagation, the *fundamental Gaussian beam* solution turns out to be particularly suited to describe laser beams both inside and outside the resonator [11.12]. A Gaussian beam is a solution of the paraxial equation (11.27) of the form:

$$u(x, y, z) = \frac{w_0}{w(z)} \exp\left(-\frac{x^2 + y^2}{w^2(z)}\right)$$
$$\times \exp\left(-ik\frac{x^2 + y^2}{2R(z)}\right)$$
$$\times \exp[i\varphi(z)] . \tag{11.28}$$

In the preceeding equation, $w(z)$, $R(z)$ and $\varphi(z)$ are given by

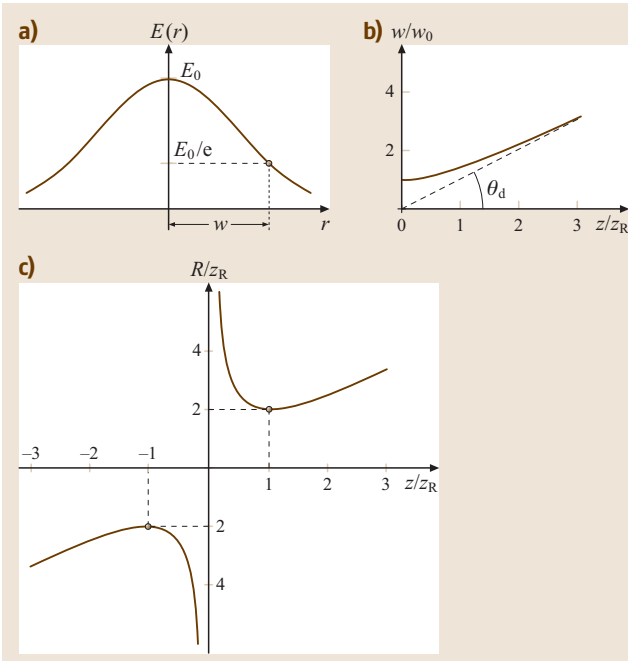
$$w(z) = w_0 \sqrt{1 + \left(\frac{z}{z_R}\right)^2} \, , \tag{11.29}$$


Fig. 11.7a–c The fundamental Gaussian beam in free-space propagation: **(a)** the Gaussian transverse amplitude profile, being $r = (x^2 + y^2)^{1/2}$; **(b)** the beam spot size $w(z)$; **(c)** the wavefront radius of curvature $R(z)$

$$R(z) = z\left[1 + \left(\frac{z_R}{z}\right)^2\right] \, , \tag{11.30}$$

$$\varphi(z) = \tan^{-1}\left(\frac{z}{z_R}\right) \, , \tag{11.31}$$

where $z_R = \pi w_0^2/\lambda$ is a parameter referred to as the *Rayleigh range*. Note that $u(x, y, z)$ is given by the product of three terms: an amplitude factor with a transverse Gaussian distribution, $(w_0/w)\exp[-(x^2 + y^2)/w^2]$ (see Fig. 11.7a); a transverse phase factor, $\exp[-ik(x^2 + y^2)/(2R)]$; and a longitudinal phase factor $\exp(i\varphi)$. The amplitude factor in (11.28) shows that, while propagating, the beam intensity distribution retains its shape, but its transverse size w, which is called the *beam spot size*, changes along the propagation direction z according to (11.29). Note that $w(z)$ is a symmetric function of z with a minimum spot size $w = w_0$ at the plane $z = 0$, which is hence referred to as the *beam waist* (Fig. 11.7b). For $z = z_R$, one has $w = \sqrt{2}w_0$ so that the Rayleigh range z_R represents the distance from the beam waist at which the beam spot size increases by a factor $\sqrt{2}$. At large distances (i. e., for $z \gg z_R$), w increases linearly with z, according to $w \approx (w_0/z_R)z$. Hence we can define a beam divergence due to diffraction as $\theta_d = \lim_{z\to\infty} w(z)/z$, obtaining

$$\theta_d = \frac{\lambda}{\pi w_0} \, . \tag{11.32}$$

The transverse phase factor in (11.28) has the same form as that for a spherical wave in the paraxial approximation, R playing the role of the radius of curvature of the spherical wavefront. Thus, we can say that a Gaussian beam has an approximately spherical wavefront with a radius of curvature varying along propagation according to (11.30). Note that $R(z)$ is an odd function of z (Fig. 11.7c), showing a minimum $R_{min} = 2z_R$ at $z = z_R$; for $z \gg z_R$, R increases linearly with z, whereas one has $R \to \infty$ as $z = 0$. Thus the wavefront is flat at $z = 0$ and, at large distances, its radius increases linearly with z just as for a spherical wave. The longitudinal phase factor φ provides, in addition to the usual phase shift $-kz$ of plane waves, a longitudinal phase shift (sometimes referred to as the *Gouy phase shift*), slowly varying with z from $-(\pi/2)$ to $(\pi/2)$ on going from $z \ll z_R$ to $z \gg z_R$.

An important parameter of a Gaussian beam at a given propagation plane z is the so-called *complex-q parameter*, defined by the relation:

$$\frac{1}{q} = \frac{1}{R} - i\frac{\lambda}{\pi w^2} \, . \tag{11.33}$$

It can be shown that, for a Gaussian beam propagating in free space, the q parameter changes along propagation

according to

$$q(z) = z + \mathrm{i}z_R \,. \tag{11.34}$$

Equations (11.29) and (11.30) can indeed be obtained upon inserting the parameter q from (11.33) into (11.34) and then separating the real and imaginary part of the resulting equation.

The fundamental Gaussian beam described above belongs to a more general set of eigensolutions of (11.27) which can be written as the product of an Hermite polynomial with a Gaussian function. These are known as *Hermite–Gaussian beams*, and assume the following form [11.3, 5]

$$u_{l,m}(x, y, z) = \frac{w_0}{w(z)} H_l\left(\frac{\sqrt{2}x}{w(z)}\right) H_m\left(\frac{\sqrt{2}y}{w(z)}\right)$$
$$\times \exp\left(-\frac{x^2 + y^2}{w^2(z)}\right)$$
$$\times \exp\left[-\mathrm{i}k\frac{x^2 + y^2}{2R(z)}\right]$$
$$\times \exp[\mathrm{i}(1 + l + m)\varphi(z)] \,, \tag{11.35}$$

where $w(z)$, $R(z)$ and $\varphi(z)$ are given by (11.29, 30, 31), respectively, and H_l, H_m are Hermite polynomials of order l and m. The lowest-order Hermite–Gaussian beam is obtained by setting $l = m = 0$ in (11.35). These solutions are often referred to as TEM_{lm} beams, where TEM stands for transverse electric magnetic: within the paraxial approximation, both electric and magnetic fields of the EM wave are, in fact, approximately transverse to the z-direction. Note that, for a TEM_{lm} beam, the number of zeros of the field along the x- and y-directions is given by the subscripts l and m, respectively, and therefore the intensity distribution of the TEM_{lm} beam consists of $l + 1$ lobes in the horizontal direction and $m + 1$ lobes in the vertical direction (Fig. 11.8).

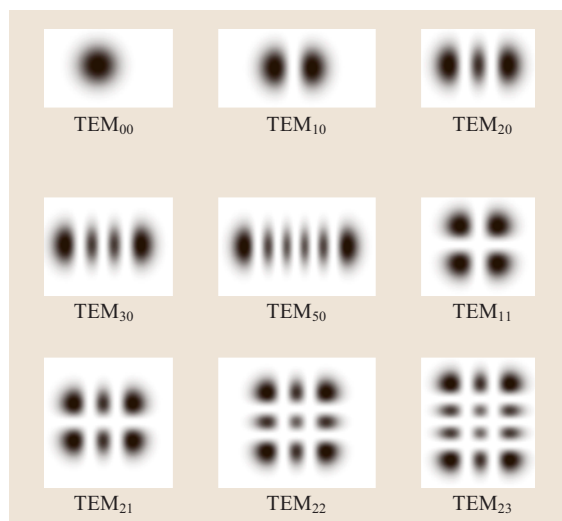
As a final remark, it should be noted that Gauss–Hermite beams maintain their functional shape as they propagate along *an arbitrary* paraxial optical system, described by a paraxial ray matrix $ABCD$. Beam propagation, in this case, is simply ruled by an algebraic relation for the complex q parameter of the Gaussian beam, which is known as the *ABCD law*. In fact, if $z = z_1$ and $z = z_2$ are the input and output planes of the $ABCD$ paraxial optical system, a Gauss–Hermite field distribution $u(x, y, z_1) = H_l(\sqrt{2}x/w_1) H_m(\sqrt{2}y/w_1) \exp[-\mathrm{i}k(x^2 + y^2)/(2q_1)]$ at the input plane $z = z_1$ is transformed, at the output plane


Fig. 11.8 Grey scale intensity patterns of a few low-order Hermite–Gaussian modes

$z = z_2$, into the distribution

$$u(x, y, z_2) = \left(\frac{1}{A + (B/q_1)}\right)^{1+l+m}$$
$$\times H_l\left(\frac{\sqrt{2}x}{w_2}\right) H_m\left(\frac{\sqrt{2}y}{w_2}\right)$$
$$\times \exp[-\mathrm{i}k(x^2 + y^2)/(2q_2)] \,, \tag{11.36}$$

where the values q_1 and q_2 of the complex-q parameter at the input ($z = z_1$) and output ($z = z_2$) planes are related by the so-called *ABCD law*

$$q_2 = \frac{Aq_1 + B}{Cq_1 + D} \,. \tag{11.37}$$

As a particular case, note that for free-space propagation from $z_1 = 0$ to $z_2 = z$ one has $A = 1$, $B = z$, $C = 0$, and $D = 1$, so that the $ABCD$ law (11.37) yields (11.34).

Optical Resonators: Introductory Concepts

The simplest optical resonator is the *plane-parallel* or *Fabry–Pérot* resonator, consisting of two plane metallic or dielectric mirrors set parallel to one another [11.13]. At first approximation, the modes of this resonator can be considered as the superposition of two plane EM waves propagating in opposite directions along the cavity axis (Fig. 11.9a). In this approximation, resonance frequencies can be readily obtained by imposing the condition that the cavity length L must be an integer multiple of half-wavelengths, i. e., $L = n(\lambda/2)$, where n is a positive integer. This is a necessary condition for the electric

Part C | 11.1

field of the EM standing wave to be zero on the two, e.g. metallic, mirrors. It follows that the resonant frequencies are given by

$$\nu_n = n \left(\frac{c}{2L} \right) . \tag{11.38}$$

Note that (11.38) can also be obtained by imposing the condition that the phase shift of a plane wave due to one round-trip through the cavity must equal an integral number times 2π, i. e., $2kL = 2n\pi$. This condition is readily obtained by a self-consistency argument: if the frequency of the plane wave is equal to that of a cavity mode, the phase shift after one round-trip must be zero (apart from an integer multiple of 2π). Only in this case, in fact, do the amplitudes at any arbitrary point, due to successive reflections, add up in phase to give an appreciable total field. According to (11.38) the frequency difference between two consecutive modes, i. e., differing by 1 in the longitudinal mode index n, is given by

$$\Delta \nu = \frac{c}{2L} . \tag{11.39}$$

This difference is referred to as the *frequency difference* between two consecutive longitudinal (or *axial*) modes. Note that, since the number n indicates the number of half-wavelengths of the mode along the resonator axis, the two consecutive modes have a different longitudinal pattern.

A more general class of laser resonators is the one made of *spherical resonators*, which are formed by two spherical mirrors of radius of curvatures R_1 and R_2, either concave ($R > 0$) or convex ($R < 0$), placed at some arbitrary distance L (Fig. 11.9b). These resonators can be divided into two categories: *stable* resonators and *unstable* resonators. A resonator is said to be unstable when, in bouncing back and forth between the two mirrors, an arbitrary paraxial ray diverges indefinitely away from the resonator axis, either radially or angularly. Conversely, a resonator whose paraxial rays remain bounded is said to be stable. An example of an unstable resonator is shown in Fig. 11.9c. Among stable spherical resonators, symmetric resonators (i. e., having $R_1 = R_2$) are of particular importance; the *confocal* resonator, in which the two spherical mirrors have the focus in common ($R_1 = R_2 = L$), is a noteworthy example of a spherical symmetric resonator. Another important scheme for laser cavities is that employing a *ring* resonator, where the path of the optical rays is arranged to form a closed loop (Fig. 11.9d). Also in this case the resonant frequencies can be obtained by imposing the condition that the total phase shift along the ring path must equal an integer number of 2π. The expression for the resonance frequencies of longitudinal (or axial) modes is thus given by
$$\nu_n = n \left(\frac{c}{L_p} \right) \tag{11.40}$$

where L_p is the length of the closed loop path. In general, a standing-wave pattern may be formed in ring resonators, because the beam can propagate either clockwise or counterclockwise along the loop. Anyway, unidirectional ring resonators can be realized by means of optical diodes inserted along the beam path.

Stability Condition

In general, a laser cavity can be viewed as made of two spherical mirrors comprising a set of intermediate optical elements like lenses, mirrors, prisms, and so on (Fig. 11.10a). If we define an arbitrary plane β orthogonal to the cavity optical axis, it is intuitive (and can be rigorously demonstrated) that the round-trip propa-

Fig. 11.9 (a) Plane-parallel resonator; **(b)** Spherical two-mirror resonator; **(c)** An unstable resonator; **(d)** A unidirectional ring resonator
Fig. 11.10 (a) A general laser cavity, and **(b)** its equivalent representation given by resonator unfolding with respect to an arbitrary β plane

gation along the cavity is equivalent to the propagation in a suitable optical system S having β as input and output planes, a transformation known as the *unfolding* of the resonator. Paraxial propagation in such a system can be described by means of the $ABCD$ cavity round-trip matrix (Fig. 11.10b). Accordingly, if we let r_0 and r_0' be, respectively, the transverse coordinate and angle that a ray make with the optical axis when intercepting plane β at time $t = 0$, and r_n and r_n' be the coordinate of the same ray after n cavity round-trip, we have

$$\begin{vmatrix} r_n \\ r_n' \end{vmatrix} = \begin{vmatrix} A & B \\ C & D \end{vmatrix}^n \begin{vmatrix} r_0 \\ r_0' \end{vmatrix} = M^n \begin{vmatrix} r_0 \\ r_0' \end{vmatrix} . \tag{11.41}$$

Therefore, the optical resonator is stable if and only if, for any initial set of coordinates (r_0, r_0'), the corresponding coordinates (r_n, r_n') do not diverge as n increases. This condition is met provided that the eigenvalues $\lambda_{1,2}$ of M are, in modulus, not larger than one. Since $\lambda_{1,2} = \exp(\pm i\theta)$, where $\cos(\theta) = (A + D)/2$, the stability condition requires that θ be real, i.e., that

$$\left| \frac{A+D}{2} \right| \leqslant 1 . \tag{11.42}$$

For the particular case of two-mirror resonators, we can go one step further by explicitly calculating the corresponding $ABCD$ matrix. We recall that a given overall matrix can be obtained by the product of matrices of individual optical elements traversed by the beam, with the matrices written in the reverse order compared to ray propagation through the corresponding elements. In our case, the $ABCD$ matrix is then given by the ordered product of the following matrices: reflection from mirror 1, free-space propagation from mirror 1 to 2, reflection from mirror 2, free-space propagation from mirror 2 to 1:

$$\begin{vmatrix} A & B \\ C & D \end{vmatrix} = \begin{vmatrix} 1 & 0 \\ -2/R_1 & 1 \end{vmatrix} \begin{vmatrix} 1 & L \\ 0 & 1 \end{vmatrix} \begin{vmatrix} 1 & 0 \\ -2/R_2 & 1 \end{vmatrix} \begin{vmatrix} 1 & L \\ 0 & 1 \end{vmatrix} .$$

After performing matrix multiplication we obtain

$$\frac{A+D}{2} = \left(1 - \frac{L}{R_1}\right)\left(1 - \frac{L}{R_2}\right) - 1 . \tag{11.43}$$

It is customary to define dimensionless quantities, referred to as the g_1 and g_2 parameters, defined as $g_1 = 1 - L/R_1$ and $g_2 = 1 - L/R_2$. In terms of these parameters, the stability condition transforms into the very simple relation:

$$0 < g_1 g_2 < 1 . \tag{11.44}$$
Fig. 11.11 Stability diagram for a general two-mirror spherical resonator. Stable resonators correspond to (g_1, g_2) points lying in the *gray region* of the plane

The stability condition given by (11.44) can be conveniently displayed in the (g_1, g_2)-plane as reported in Fig. 11.11. Stable resonators correspond to those points in the gray region of the plane, excluding those which lie on the boundaries, (i.e., satisfying the conditions $g_1 g_2 = 0$ or $g_1 g_2 = 1$), which are referred to as marginally stable resonators. Note that symmetric resonators (i.e., having mirrors of the same radius of curvature $R_1 = R_2 = R$) lie on the bisector line b. As particular examples of these symmetric resonators, one can see that those corresponding to point A, B and C of the figure are the concentric ($L = 2R$), confocal ($L = R$) and plane ($R = \infty$) resonators, respectively. Since points A, B and C lie on the boundary of the stability region, the corresponding resonators are only marginally stable.

Laser Modes

The modes of an optical resonator are defined as the stationary (i.e., monochromatic) or weakly damped field distributions that can be sustained inside the cavity and that satisfy the boundary conditions imposed by the cavity mirrors. We note that, in open resonators, diffraction losses due to the finite aperture of the mirrors make the modes always leaky. The electric field for a mode in a leaky resonator can then be generally represented as

$$E(x, y, z, t) = a(x, y, z) \cos(\omega t)$$
$$\times \exp\left[\frac{-t}{2\tau_c}\right] \quad (t > 0) , \tag{11.45}$$

where $a(x, y, z)$ is the mode field distribution, ω is the resonance frequency, and τ_c describes field decay due to cavity losses and is referred to as the *cavity pho-*

ton lifetime. In order to determine the resonator modes, the corresponding resonance frequencies and diffraction losses let us consider the rather general class of resonators with an optical axis z, as shown in Fig. 11.10a. Propagation of an EM wave back and forth between the two end mirrors of the cavity is equivalent to the unidirectional propagation of an EM wave in a periodic sequence of optical elements (e.g., a lens guide) which is obtained by unfolding the resonator, as shown in Fig. 11.10b. Note that, in the unfolding scheme, the end spherical mirrors should be replaced by thin spherical lenses with focal length equal to the mirror radius of curvature.

Let us first consider the propagation of a monochromatic EM field in a periodic lens guide. By writing the electric field along the lens guide as $E(x, y, z, t) = \tilde{E}(x, y, z) e^{i\omega t} + \text{c.c.}$, due to the linearity of the Huygens–Fresnel integral the complex field amplitude $\tilde{E}$ after one period of the lens guide can generally be written by an integral transformation, namely (Fig. 11.12)

$$
\tilde{E}(x, y, 2L)
$$
$$
= \exp(-\mathrm{i}2kL)
$$
$$
\times \iint_1 K(x, y; x_1, y_1)\tilde{E}(x_1, y_1, 0)\,\mathrm{d}x_1\,\mathrm{d}y_1 , \quad \textbf{(11.46)}
$$

where $K(x, y; x_1, y_1)$ is a function of the transverse coordinates of both input and output planes, known as the *propagation kernel*. Note the phase term $(-2kL)$, which represents the phase shift if the wave were a plane wave. The kernel K accounts for all the elements encountered during propagation from input plane 1 $(z = 0)$ to output plane 2 $(z = 2L)$ and represents, from a physical viewpoint, the field distribution observed at the (x, y)-plane (i.e., at $z = 2L$)

Fig. 11.12 Field calculation at plane 2 $(z = 2L)$ when the field $\tilde{E}(x_1, y_1, 0)$ at plane 1 $(z = 0)$ is known

when a point-like source at the (x'_1, y'_1) point is placed at the $z = 0$ input plane. Indeed, if $\tilde{E}(x_1, y_1, 0)$ were a bidimensional Dirac δ-function centered at $x_1 = x'_1$ and $y_1 = y'_1$, i.e., if $\tilde{E}(x_1, y_1, 0) = \delta(x_1 - x'_1, y_1 - y'_1)$, then from (11.46) one would readily get $\tilde{E}(x, y, 2L) = K(x, y; x'_1, y'_1) \exp(-2ikL)$. For a general optical system, the calculation of the kernel K is usually rather complicated. However, within the assumption of infinite aperture of all optical elements, the kernel K is simply expressed in terms of the round-trip resonator-matrix elements $ABCD$ by the relation (Huygens–Fresnel–Kirchhoff kernel)

$$
K(x, y; x_1, y_1)
$$
$$
= \frac{\mathrm{i}}{\lambda B} \exp \left\{ -\frac{\mathrm{i}k}{2B} \right.
$$
$$
\left. \times \left[A(x_1^2 + y_1^2) + D(x^2 + y^2) - (2xx_1 + 2yy_1) \right] \right\}
$$
$$
\textbf{(11.47)}
$$

and the integral in (11.46) can be extended from $-\infty$ to ∞.

Let us now define a mode of a periodic lens guide as a field distribution which reproduces itself after one guide period except for an overall amplitude reduction, due to lens-guide losses, and a phase shift $\Delta\varphi$ accounting for field propagation. Hence $\tilde{E}(x, y, 2L) = |\tilde{\sigma}| \exp(\mathrm{i}\Delta\varphi)\tilde{E}(x, y, 0)$, where $|\tilde{\sigma}| < 1$. It is now convenient to write the phase shift as $\Delta\varphi = -2kL + \varphi$, where $-2kL$ is the shift of a plane wave and φ is an additional phase term due to the fact that the lens-guide mode is not a plane wave. Hence, for a lens-guide mode we require the condition

$$
\tilde{E}(x, y, 2L) = \tilde{\sigma} \exp(-2ikL)\tilde{E}(x, y, 0) , \quad \textbf{(11.48)}
$$

where $\tilde{\sigma} = |\tilde{\sigma}| \exp(\mathrm{i}\varphi)$. Substitution of (11.48) into (11.46) yields

$$
\iint_1 K(x, y; x_1, y_1)\tilde{E}(x_1, y_1, 0)\,\mathrm{d}x_1\,\mathrm{d}y_1
$$
$$
= \tilde{\sigma}\tilde{E}(x, y, 0) . \quad \textbf{(11.49)}
$$

Note that the mode distribution $\tilde{E}(x, y, 0)$ is an eigenfunction of a Fredholm homogeneous integral equation of the second kind corresponding to the eigenvalue $\tilde{\sigma}$. As a rather general property, it turns out that the Fredholm integral equation admits a doubly infinite discrete set of confined eigensolutions, which can be distinguished by a pair of integer positive numbers l and m. Accordingly, the corresponding eigenvalues will generally be indicated as $\tilde{\sigma}_{lm} = |\tilde{\sigma}_{lm}| \exp(\mathrm{i}\varphi_{lm})$, with $|\tilde{\sigma}_{lm}| < 1$ owing to
the overall losses (namely, diffraction losses, scattering losses from optical elements, and so on) encountered in one period of propagation along the lens guide.

Now, let us return to the problem of cavity mode calculation. In this case, the mode $\tilde{E}$ of the lens guide corresponds to a mode of the resonator of Fig. 11.10a provided that, after one cavity round-trip, the overall phase shift $\Delta\varphi$ accumulated in one cavity round-trip is zero apart from an integer number of 2π, i.e., $\Delta\varphi = -2kL + \varphi_{lm} = -2\pi n$. From this condition and using the relation $k = 2\pi\nu/c$ between the wavenumber k and frequency ν of the mode, one readily obtains the cavity resonance frequencies as

$$\nu_{nlm} = \frac{c}{2L}\left(n + \frac{\varphi_{lm}}{2\pi}\right) . \tag{11.50}$$

Note that we have indicated explicitly that these frequencies depend on the three integer numbers l, m, and n. The integers l and m define the transverse field profiles of the mode (Fig. 11.8), i.e., they represent the number of zeros of the field along the x- and y-coordinates, respectively. The integer n defines the longitudinal field configuration, i.e., the number of zeros of the EM standing wave (nodes) as previously discussed for the plane-parallel resonator (11.38).

For stable resonators with infinite apertures the eigenmodes of the Fredholm equation are given by the Gauss–Hermite functions, and their resonance frequencies can be calculated from (11.50) using the propagation law (11.36). For instance, for the important case of two-mirror spherical resonators, it turns out that $\varphi_{lm} = 2(1+l+m)\cos^{-1}(\pm\sqrt{g_1 g_2})$, where the plus or minus sign depends on whether g_2 (and hence g_1) is positive or negative. The resonance frequencies of the two-mirror spherical resonator are thus given by:

$$\nu_{nlm} = \frac{c}{2L}\left[n + \frac{1+l+m}{\pi}\cos^{-1}(\pm\sqrt{g_1 g_2})\right] . \tag{11.51}$$

For, e.g., a confocal resonator, one has $g_1 = g_2 = 0$, and hence $\nu_{nlm} = [c/(4L)](2n + 1 + l + m)$. Note that modes with the same value of $(2n + l + m)$ have the same resonance frequency, and they are said to be frequency degenerate. Note also that, for a confocal resonator, the mode spacing is $c/(4L)$.

Photon Lifetime and Cavity Q

The modes of an optical resonator are always leaky and therefore show a finite photon cavity lifetime τ_c. In fact, besides diffraction losses due to finite aperture effects of mirrors or intracavity optical elements, some other

loss mechanisms are always present in a laser resonator. For instance, the mirror reflectivity of the output coupler is always smaller than 100%, which means that a fractional part of the photons ϕ stored in the cavity escapes from the resonator at each round-trip. Scattering or absorption losses of intracavity optical elements are also another common cause of photon leakage. To calculate the rate of energy decay in a given cavity mode, let I_0 be the initial intensity corresponding to the field amplitude at a fixed point within the cavity, and let R_1 and R_2 be the (power) reflectivities of the two mirrors and L_i the fractional internal loss per pass, which accounts for scattering, absorption and diffraction losses. The intensity at the same point, after a round-trip time $\tau_R = 2L_e/c$, is $I(\tau_R) = R_1 R_2(1 - L_i)^2 I_0 = I_0 \exp(-2\gamma)$, where L_e is the *cavity optical length* and γ is the logarithmic loss per pass, defined by the relation

$$\gamma = \frac{\gamma_1 + \gamma_2}{2} + \gamma_i \tag{11.52}$$

with $\gamma_1 = -\ln(R_1)$, $\gamma_2 = -\ln(R_2)$, and $\gamma_i = -\ln(1 - L_i)$. In view of the exponential decay law introduced in (11.45), after a round-trip time we must have $I(\tau_R) = I_0 \exp(-\tau_R/\tau_c)$, and thus we conclude that the photon lifetime is given by

$$\tau_c = \frac{\tau_R}{2\gamma} = \frac{L_e}{c\gamma} . \tag{11.53}$$

Having calculated the photon lifetime, the time behavior of the electric field at any point inside the resonator can be written as $E(t) = E_0 \exp(-t/2\tau_c + i\omega t) +$ c.c., where ω is the angular frequency of the mode. The same time behavior then applies for the field of the wave leaving the resonator through the output mirror. Taking the Fourier transform of this field (for $t > 0$) we find that the power spectrum of the emitted light has a Lorentzian line shape with line width (FWHM) given by

$$\Delta\nu_c = \frac{1}{2\pi\tau_c} . \tag{11.54}$$

We can now introduce an important quality factor which is strictly related to the photon lifetime. This is the *cavity Q-factor* which is defined, for any resonant system, as 2π times the ratio between the energy stored in the resonator and the energy lost in one oscillation cycle. Thus a high cavity Q-factor implies low losses in the resonant system. Since in our case the energy stored is $\phi h\nu$ and the energy lost per cycle is $(-d\phi/dt)h$ we obtain

$$Q = -\frac{2\pi\nu\phi}{d\phi/dt} = \frac{\nu}{\Delta\nu_c} , \tag{11.55}$$

where the exponential decay law $\phi(t) = \phi_0 \exp(-t/\tau_c)$ for the stored cavity photons ϕ has been used and where the expression for $\Delta\nu_c$ given by (11.54) has also been utilized.

As an example, consider a two-mirror spherical resonator with $R_1 = R_2 = R = 0.98$ and assume $L_i \simeq 0$. From (11.53) we obtain $\tau_c = \tau_T/[-\ln(R)] = 49.5\,\tau_T$, where $\tau_T = L/c$ is the transit time of the photon for a single pass in the cavity. Note that the photon lifetime is much longer than the transit time, a typical result of low-loss cavities. If we now assume $L = 90$ cm, we get $\tau_T = 3$ ns and $\tau_c \simeq 150$ ns. From (11.54) we can then calculate $\Delta\nu_c \simeq 1.1$ MHz. Finally, assuming a laser wavelength $\lambda \simeq 630$ nm corresponding to an optical frequency $\nu = 5 \times 10^{14}$ Hz, from (11.55) we have $Q = 4.7 \times 10^8$. Thus laser resonators have a remarkably high Q-value, which means that a very small fraction of the energy is lost during one oscillation cycle.

11.1.4 Laser Rate Equations and Continuous–Wave Operation

A simple and powerful approach for understanding the basic dynamical behavior of a laser is based on a *rate-equation* model, in which simple balance equations for the total number of atoms undergoing a transition and the total number of photons created or annihilated are written [11.3]. For a more-refined treatment of laser dynamics based on either a semiclassical or a full-quantum electrodynamic approach, which may account for certain phenomena such as dynamical laser instabilities, laser coherence and photon statistics, we refer the reader to more-specialized literature [11.6, 8].

Laser Rate Equations
Let us consider a four-level laser scheme (Fig. 11.4b) and make the following assumptions:

1. the laser transition is homogeneously broadened,
2. the lifetime τ_1 of the lower laser level 1 is short enough that we may neglect the population in level 1,
3. a single longitudinal and transverse mode is oscillating in the cavity,
4. we neglect the precise transverse and longitudinal spatial variation of the cavity mode,
5. we assume uniform pumping of the active medium.

Under these assumptions, we can write the following rate equations for the population inversion $N = N_2 - N_1 \simeq N_2$ in the active medium and the number of photons ϕ of the oscillating mode stored in the cavity:

$$\frac{dN}{dt} = R_p - B\phi N - \frac{N}{\tau} \tag{11.56}$$

$$\frac{d\phi}{dt} = -\frac{\phi}{\tau_c} + V_a\, B\phi N \,, \tag{11.57}$$

where R_p is the pump rate per unit volume, τ is the lifetime of the upper laser level 2, and τ_c is the photon lifetime for the oscillating mode. In (11.56), the terms R_p, N/τ and $B\phi N = W_{21}N$ account for the pumping process, radiative and nonradiative decay, and stimulated emission, respectively. The constant B, which represents the stimulated transition rate per photon, per mode is related to the transition cross section σ by the simple equation $B = \sigma c/V$, where V is the mode volume in the laser cavity [11.3]. The first term on the right-hand side in (11.57), ϕ/τ_c, represents the number of cavity photons that are lost per unit time due to internal loss, diffraction loss and output coupling through the mirrors. Finally, the second term in (11.57) represents the number of photons (per unit time) that are created in the oscillating mode owing to stimulated emission: since $B\phi N$ represents the number of atoms per unit volume and per unit time that decay creating a photon in the oscillating cavity mode, the total number of photons created per unit time can be expressed as the product of $B\phi N$ with the volume V_a occupied by the cavity mode inside the gain medium. Spontaneous emission in not included in the balance equation (11.57) since only a negligible fraction of spontaneously emitted photons belongs to the oscillating mode. However, spontaneous emission photons are important to allow laser action starting.

The laser output power P_{out} is related to the photon number ϕ by the simple relation

$$P_{out} = \frac{\gamma_2}{2\gamma}(h\nu)\frac{\phi}{\tau_c} = \frac{\gamma_2 c}{2L_e}h\nu\phi \,. \tag{11.58}$$

In fact, $(h\nu)(\phi/\tau_c)$ is the total EM energy lost in the cavity per unit time, and solely a fraction $\gamma_2/(2\gamma)$ of this power is available due to transmission through the output mirror. For a typical CW laser operated in the continuous-wave regime, the number of photons ϕ stored in the cavity may vary from about 10^{10} photons for low-power lasers (such as a HeNe laser delivering $P_{out} = 10$ mW power at $\lambda = 632.8$ nm) to 10^{17} photons for high-power lasers (such as a CO_2 laser delivering an output power $P_{out} = 10$ kW at $\lambda = 10.6\,\mu$m).

Threshold Condition
The population inversion needed to reach the threshold for laser oscillation is simply obtained from (11.57) by

imposing $\mathrm{d}\phi/\mathrm{d}t = 0$. An initially small number of photons turns out to be exponentially damped for $N < N_c$ or exponentially amplified for $N > N_c$, where:

$$N_c \equiv \frac{1}{\tau_c B V_a} = \frac{\gamma}{\sigma l} \tag{11.59}$$

is referred to as the *critical inversion* (or threshold inversion). In this equation, l is the length of the active medium and the threshold condition $\sigma N_c l = \gamma$ is reached when the gain in the inverted medium, $g = \sigma N l$, equals the logarithmic loss γ of the cavity. The pump rate corresponding to the threshold condition is $R_{cp} = N_c/\tau = \gamma/(\sigma l \tau)$; the corresponding pump power at threshold P_{th} is then obtained using (11.9). The perturbation that starts the laser action when the pump rate R_p reaches the critical value R_{cp} is provided by spontaneous emission.

Output Power and Slope Efficiency

For a pump rate $R_p > R_{cp}$, the rate equations (11.56, 57) admit the solution $N_0 = N_c$ and $\phi_0 = [1/(B\tau)](x - 1)$, corresponding to laser being above threshold (Fig. 11.13). Here $x = R_p/R_{cp} = P_p/P_{th} > 1$ is the above-threshold pump behavior parameter, where P_p is the pump power and P_{th} is its threshold value. The corresponding output laser power can be then calculated from (11.58) and can be cast in the form

$$P_{out} = \eta_s(P_p - P_{th}), \tag{11.60}$$

where

$$\eta_s = \eta_p \eta_c \eta_q \eta_t. \tag{11.61}$$

Equation (11.60) shows that, within the approximation made, a linear relation is obtained between the output power and the pump power. One can then define the slope efficiency of the laser as $\eta_s = \mathrm{d}P_{out}/\mathrm{d}P_p$. According to (11.61), η_s is given by the product of four contributions:

1. the *pump efficiency* η_p
2. the *output coupling efficiency* $\eta_c = \gamma_2/(2\gamma)$
3. the laser *quantum efficiency* $\eta_q = (h\nu)/(h\nu_{mp})$
4. the *transverse efficiency* $\eta_t = A_b/A$

where $A_b = V_a/l$ is the transverse mode area in the active medium and A the transverse pumping area. The slope efficiency of a laser may typically vary from less than 1% in low-efficiency lasers (such as in the HeNe laser) to 20–50% or even higher in high-efficiency lasers.

Relaxation Oscillations

One can show that the solution, given above, for lasers above threshold is stable, i.e., that any initial pertur-
Fig. 11.13 Behavior of population inversion N and photon number ϕ in the oscillating mode versus the pump rate R_p for a four-level laser. R_{cp} is the critical pump rate above which laser action takes place

bation of the system (e.g., of cavity losses) is damped. When the ratio τ/τ_c between the upper laser level lifetime and cavity photon lifetime is larger than 1 (or much larger, such as in laser transitions which are electric-dipole forbidden), relaxation to the steady state occurs through damped oscillations in both photon number and population inversion. This results in damped oscillations of the output power referred to as *relaxation oscillations*. In solid-state lasers, the frequency of relaxation oscillations typically fall in the 10 kHz–10 MHz region, whereas, in semiconductor lasers, it falls in the GHz region. Relaxation oscillations in slow-gain media (such as in solid-state lasers) triggered by technical noise or by pump power fluctuations are one of the major cause of amplitude noise in the output laser power. Whenever a high degree of intensity stability is required, laser amplitude stabilization may be provided by a suitable active feedback loop.

Laser Tuning

The gain line width of some lasers (e.g., dye lasers or vibronic solid-state lasers) is very wide and, for several applications, one needs to tune the laser output wavelength away from the line center and across the entire available line width. In other cases, different lasing transitions may compete or may potentially be used, and one needs to select one of them. In both circumstances, one can employ a wavelength-selective element inside the laser cavity, which is often referred to as *laser tuner*. For lasers in the middle infrared (such as CO_2 lasers), one generally uses a diffraction grating in the so-called Littrow configuration (Fig. 11.14a) as one of the cavity mirror. Wavelength tuning is simply
Fig. 11.14 (a) Laser tuner based on a diffraction grating in the Littrow configuration. **(b)** Laser tuner based on the use of a dispersive prism

achieved by grating rotation. In the visible or near-infrared spectral regions (such as for the Ar^{3+} laser), a dispersive prism is more commonly used and wavelength tuning is simply achieved by prism, or mirror, rotation (Fig. 11.14b). To reduce insertion losses, the two prisms facets are approximately inclined at Brewster angle. A third wavelength-selective element, which is becoming increasingly popular in the visible or near-infrared, uses a birefringent filter inside the cavity. This device exploits a birefringent plate, inclined at the Brewster angle, which generally changes the polarization state of the intracavity laser beam. In the presence of an intracavity polarizer, or just exploiting the polarizing properties of the Brewster-angle filter, the birefringence filter thus generally produces additional cavity losses. However, at certain wavelengths, λ, the
Fig. 11.15 Schematic of a birefringent laser tuner made of an intracavity birefringent plate and polarizer

birefringent plate does not change the polarization state of the beam and thus allows for laser oscillation with low loss. Upon rotation of the plate around the axis orthogonal to its faces (Fig. 11.15) the direction of the birefringence axes of the plates is changed and this correspondingly changes the wavelength at which low loss occurs.

Single Mode Selection and Limit to Laser Monochromaticity

Most often, lasers tend spontaneously to oscillate on several transverse and longitudinal modes, especially when the gainline is relatively broad. The reasons for multimode oscillations are rather involved and their study goes beyond the scope of the present contribution. For many applications, single-mode operation may be required, and therefore one needs to force the laser to oscillate on a single transverse (usually the fundamental TEM_{00} Gaussian mode) and longitudinal mode. For stable resonators, single transverse mode oscillation is easily achieved by placing an aperture inside the cavity of appropriate size in order to increase diffraction loss of higher-order modes with respect to the TEM_{00} mode. In some cases, such as in longitudinally pumped solid-state lasers, limitation on the pump spot size lends itself to TEM_{00} mode selection.

Even when a laser is oscillating on a single transverse mode, it can still oscillate on several longitudinal modes. This usually occurs since the longitudinal-mode separation $\Delta \nu = c/(2L)$ is smaller (or much smaller) than the gain line width $\Delta \nu_0$. For some gas lasers, where the gain line width is relatively small (up to a few GHz), single-longitudinal-mode selection is simply obtained by making the cavity length short enough that the longitudinal-mode separation $\Delta \nu$ becomes larger than $\Delta \nu_0/2$. For, e.g., a HeNe laser ($\Delta \nu_0^* \simeq 1.7 \, \text{GHz}$), this condition implies $L \leq 17.5 \, \text{cm}$. For solid-state lasers with a bandwidth up to a few hundred GHz, this condition requires cavity lengths in the sub-millimeter region (*microchip lasers*). For lasers with much larger bandwidths (e.g., dye lasers or tunable solid-state lasers), the required length is too small to make the technique of practical relevance and to make the gain in the medium large enough to reach threshold. In these cases, different techniques are employed. For solid-state or dye lasers, the simplest method is to use one (or more) Fabry–Pérot etalons within the cavity, which acts as a narrow frequency spectral-selective element (Fig. 11.16). The etalon thickness and finesse should be designed to ensure single mode selection. This implies that:

1. the half width $\Delta\nu_{FP}/2$ of the transmission peaks of the Fabry–Pérot must be smaller than the longitudinal-mode separation $\Delta\nu = c/(2L)$;
2. the etalon free spectral range $\Delta\nu_{FSR}$ must be larger than the half width of the gain line $\Delta\nu_0/2$ (Fig. 11.16).

For semiconductor lasers, single mode selection is achieved by using a distributed feedback (DFB) structure, in which a longitudinal corrugation of the refractive index in the semiconductor induces frequency mode selection according to Bragg scattering theory.

A special case of single mode selection that deserves mention is that of a laser with a homogeneously broadened line (e.g., Nd:YAG and dye lasers). In this case, multimode oscillation is mainly due to the standing-wave character of the laser mode arising from the interference of counter-propagating waves established between the two cavity mirrors. The use of a ring resonator instead of a linear cavity, in which unidirectional operation is forced by, e.g., an intracavity optical diode, may be enough in this case to achieve single longitudinal-mode operation.

We finally discuss the limit of monochromaticity (and hence of temporal coherence) of a laser. The line width $\Delta\nu_L$ of a laser that oscillates on a single longitudinal mode is ultimately established by spontaneous emission noise. The quantum theory of a laser shows that the spectral shape of emitted light is Lorentzian with a FWHM given by the well-known Schawlow–Townes formula:

$$\Delta\nu_L = \frac{N_2}{N_2 - N_1} \frac{2\pi h \nu_L (\Delta\nu_C)^2}{P} , \qquad (11.62)$$

where P is the output power, $\Delta\nu_C = 1/(2\pi\tau_c)$ is the line width of the cold cavity mode, N_2 and N_1 are the steady-state populations in the upper and lower laser levels, respectively, and ν_L is the emission frequency. Typically the line width predicted by the Schawlow–Townes formula is negligibly small compared to that produced by other cavity disturbances (e.g., fluctuations of cavity length or *technical noise*), except for the very important class of semiconductor lasers. For, e.g., a typical HeNe laser oscillating on its red transition ($\lambda = 632.8$ nm), τ_c is of the order of tens of μs, so that $\Delta\nu_L$ is of the order of $\simeq 1$ mHz, which turns out to be much smaller than the line broadening due to technical noise. For instance, a small cavity length change ΔL, due to technical noise, contributes to the frequency broadening $\Delta\nu_L$ by an amount given by $|\Delta\nu_L| = (\Delta L/L)\nu_L$; for $L = 1$ m and $\nu_L = 4.7 \times 10^{14}$ Hz (visible transition), a change of
Fig. 11.16 Schematic of single longitudinal mode selection by use of an intracavity Fabry–Pérot etalon

ΔL by just $\approx 10^{-8}$ times the atomic dimension leads to a contribution to $\Delta\nu_L$ comparable to the quantum limit. Conversely, in semiconductor lasers the quantum limit of $\Delta\nu_L$ is considerably larger and typically falls in the MHz range, owing to the much short photon lifetime (τ_c is of the order of few ps). Therefore, the laser line width of a typical semiconductor laser arises from quantum noise.

11.1.5 Pulsed Laser Behavior

In lasers operating in the CW or quasi-CW regimes, the maximum achievable optical output power is limited by the maximum available pump power. For high-power CW lasers (such as CO_2 lasers), power levels up to ≈ 100 kW can be reached; however larger power levels, which can be of interest for many applications, are prevented in the CW regime. Transient laser behavior allows one to obtain higher peak powers by concentrating the available energy in a single, short optical pulse or in a periodic sequence of optical pulses [11.3, 5]. Additionally, transient laser behavior is a powerful tool for the generation of ultrashort optical pulses, with durations down to ≈ 10 fs in lasers with a broad gainline (notably the Ti^{3+}:Al_2O_3 laser). From a dynamical viewpoint, pulsed laser behavior can be divided into two rather distinct categories:

1. Laser transients occurring on a time scale of the order of the cavity photon lifetime τ_c, i.e., appreciably larger than the cavity round-trip time. This includes the so-called Q-switching and gain-switching regimes, which enable the generation of optical pulses as short as a few nanoseconds with optical peak powers typically in the megawatt range. These are basically single-longitudinal-mode regimes and can be described by means of a rate equation model (11.56, 57).

2. Laser transients occurring on a time scale appreciably shorter (and often much shorter) that the cavity round-trip time. These are basically multi-longitudinal-mode regimes, i.e., they involve the simultaneous oscillation of many longitudinal laser modes, and include the so-called mode-locking regime, which enables the generation of trains of ultrashort laser pulses with durations down to a few femtoseconds.

Laser Q–switching: Dynamical Aspects

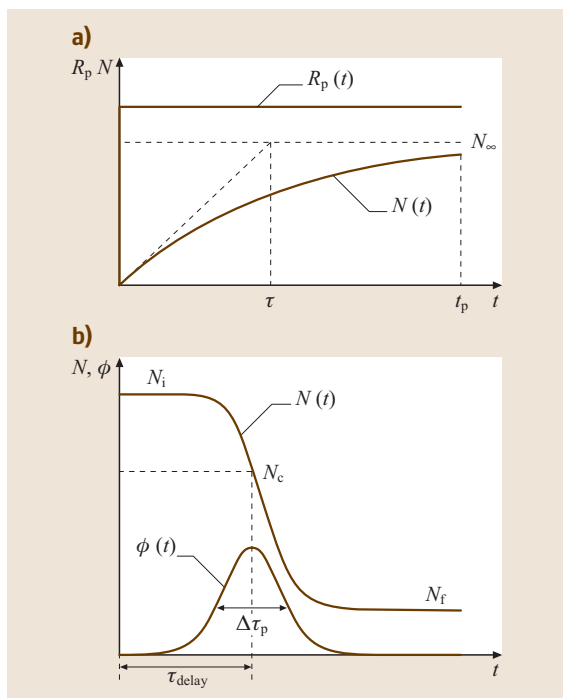
Q-switching is a technique that enables the generation of a short optical pulse (of the order of the cavity photon lifetime τ_c) by a sudden switching of the cavity Q factor, i.e., of the cavity loss γ. The change of Q is produced, in principle, upon placing inside the laser cavity an opaque shutter which can be opened or closed. When the shutter is closed (i.e., the cavity Q is low), laser action is prevented and the population inversion N can reach a relatively large value (well above the critical value N_c) due

a)

b)

Fig. 11.17a,b Dynamics of fast switching in a four-level laser. **(a)** Temporal behavior of pump rate and population inversion when the cavity Q is low. **(b)** Temporal behavior of population inversion and cavity photons when the cavity Q is suddenly switched to a high value, showing the formation of the Q-switching pulse

to pumping. When the shutter is opened, the Q factor is suddenly switched to a high value and the laser exhibits a gain $g = \sigma l N$ that greatly exceeds the loss γ. Light emission then occurs via the generation of a short and intense laser pulse. The duration of a Q-switching pulse typically ranges from a few nanoseconds to a few tens of nanoseconds, whereas its peak power is in the megawatt range. To achieve sufficient population inversion when laser action is prevented, a long lifetime τ of the upper laser level is required. Thus Q-switching can be effectively used for electric-dipole-forbidden laser transitions, where τ generally falls in the millisecond range. This is the case of most solid-state lasers (e.g., Nd, Yb, Er in different host materials; Cr-doped materials, such as alexandrite, Cr:LiSAF, and ruby) and some gas lasers (e.g., CO_2 or iodine).

To understand the basic dynamics of Q-switching, let us consider a four-level laser and assume that a step pump pulse is applied at time $t = 0$, i.e., $R_p(t) = 0$ for $t < 0$ and $R_p = $ constant for $0 < t < t_p$, where t_p is the duration of the pump pulse; meanwhile the shutter is closed (Fig. 11.17a) and laser action is prevented. From (11.56) with $\phi = 0$, one then obtains that the transient population inversion increases accordingly to the relation $N(t) = N_\infty[1 - \exp(-t/\tau)]$, where the asymptotic value N_∞ is given by $N_\infty = R_p\tau$ (Fig. 11.17a). After a pump time of about 2τ, the population inversion already reaches a value close to its asymptotic limit N_∞, and therefore the pump pulse can be switched off and the shutter opened. In fact, for t_p larger than $\approx 2\tau$ the energy supplied to the medium is not useful for increasing the population inversion any further but is lost as radiative and nonradiative decay. Suppose now that the shutter is opened very rapidly at time t_p (*fast switching*), and take the origin of time at the instant when switching occurs (Fig. 11.17b). From this time on, the evolution of both population inversion and number of photons in the cavity can be numerically computed by solving the rate equations (11.56) and (11.57) with the initial conditions $\phi(0) \simeq 1$ and $N(0) = R_p\tau[1 - \exp(-t_p/\tau)] \equiv N_i$, where the initial condition $\phi(0) \simeq 1$ accounts for the fact that the laser action is started by spontaneous emission (the so-called *extra photon*). The qualitative transient behavior of both N and ϕ is shown in Fig. 11.17b and can be simply understood by observing that, just after the switching time $t = 0$, the gain $g = \sigma N l$ in the gain medium greatly exceeds the single-pass cavity loss γ; therefore the number of photons, which increases nearly exponentially with time starting from the extra photon due to spontaneous emission, typically takes from several hundreds to a few thousand cavity round-trips to


reach a sufficient value to saturate the laser transition, thus producing a reduction of the available inversion (Fig. 11.17b). This means that the time delay for the peak of the laser pulse, τ_{delay} typically ranges from several tens to a few hundred of nanoseconds. Note that, on such a time scale, the radiative and nonradiative decays of the population N (which typically occur on the millisecond time scale) are negligible, and therefore population decay just occurs by stimulated emission. The decrease of N as ϕ increases leads, in turn, to a decrease of the gain $g = \sigma Nl$. The peak of the pulse occurs at the delay time, τ_{delay}, such that the population inversion N decreases to its critical value, N_{c}. In this case, in fact, laser gain g equals cavity loss γ and one has from (11.57) $d\phi/dt = 0$. For $t > \tau_{\text{delay}}$, one has $N < N_{\text{c}}$ and $d\phi/dt < 0$. This means that the number of photons now decreases towards zero. Meanwhile, due to stimulated emission, the population inversion also keeps decreasing until the photon pulse has decreased to zero. At this time some population inversion, say N_{f}, is generally left in the medium after Q-switching (Fig. 11.17b). Note that the quantity $\eta_{\text{E}} = (N_{\text{i}} - N_{\text{f}})/N_{\text{i}}$ represents the fraction of the energy initially stored in the material that goes into stimulated emitted photons, usually referred to as the inversion, or energy, utilization factor. The duration $\Delta\tau_{\text{p}}$ of the Q-switched pulse, the output energy $E = (1/\tau_{\text{c}})[\int \phi(t)\,dt](h\nu)(\gamma_2/(2\gamma))$, the energy utilization factor η_{E}, as well as the time τ_{delay} needed for pulse formation can be derived in a closed form by an analysis of the rate equations (11.56) and (11.57) in which pumping and radiative and nonradiative decay are neglected. One obtains:

$$\Delta\tau_{\text{p}} = \tau_{\text{c}} \frac{(N_{\text{i}}/N_{\text{c}})\eta_{\text{E}}}{(N_{\text{i}}/N_{\text{c}}) - \ln(N_{\text{i}}/N_{\text{c}}) - 1} , \tag{11.63}$$

$$E = \left(\frac{\gamma_2}{2\gamma}\right)(N_{\text{i}}\eta_{\text{E}}V_{\text{a}})(h\nu) , \tag{11.64}$$

$$\tau_{\text{delay}} \approx \frac{\tau_{\text{c}}}{(N_{\text{i}}/N_{\text{c}}) - 1}\ln(\phi_{\text{p}}/10) , \tag{11.65}$$

where $N_{\text{i}}/N_{\text{c}}$ is the ratio between the initially stored population inversion and critical inversion; ϕ_{p} is the peak photon number of the Q-switching pulse, given by $\phi_{\text{p}} = V_{\text{a}}(N_{\text{i}} - N_{\text{c}}) - N_{\text{c}}V_{\text{a}}\ln(N_{\text{i}}/N_{\text{c}})$; and η_{E} is the energy utilization factor. The value of η_{E} can be calculated from the implicit equation $(N_{\text{i}}/N_{\text{c}})\eta_{\text{E}} = -\ln(1 - \eta_{\text{E}})$ from which a plot of $(N_{\text{i}}/N_{\text{c}})$ vs. η_{E} can readily be obtained (Fig. 11.18). Note that (11.64) can readily be obtained by a simple energy-balance argument: the stored energy in the medium released as EM wave is in fact equal to $h\nu(N_{\text{i}} - N_{\text{f}})V_{\text{a}} = h\nu(\eta_{\text{E}}N_{\text{i}})V_{\text{a}}$, and, out
Fig. 11.18 Behavior of the energy utilization factor η_{E} versus the normalized initial inversion $N_{\text{i}}/N_{\text{c}}$

of this energy, only the fraction $[\gamma_2/(2\gamma)]$ goes into the output beam.

Q-switched lasers may generally be operated in two distinct regimes. In so-called pulsed Q-switching, the pump rate $R_{\text{p}}(t)$ generally consists, as explained above, of a pulse with duration comparable to the upper-state lifetime τ. Of course, the pulsed operation can be periodically repeated upon repeating the pulsed pump (generally up to a rate of a few tens of Hz). In so-called CW repetitive Q-switching, the pump rate R_{p} is held constant and cavity losses are periodically switched from a high to a low value (generally with a rate from a few to a few tens of kHz).

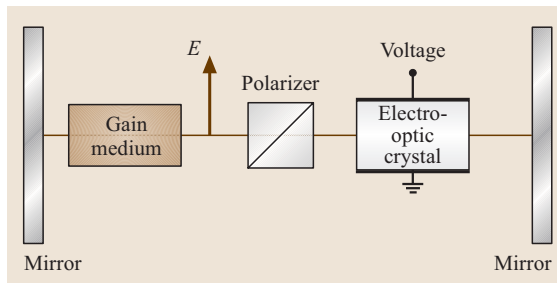
So far we have considered the dynamic behavior corresponding to fast switching, where the switching of the cavity loss is treated as instantaneous (in practice, much shorter than the time τ_{delay}). In the case of *slow switching*, the dynamic behavior is somewhat more complicated and multiple pulses may result, as shown
Fig. 11.19 Gain and photon dynamics in a slow-switching laser, showing the formation of multiple pulses

in Fig. 11.19. In the figure, the behavior of the cavity loss γ and laser gain $g = \sigma Nl$ is depicted. The multiple intersections of the slowly decaying curve for the loss $\gamma(t)$ with the gain curve $g(t)$ explain the formation of multiple Q-switching pulses.

Methods of Q–Switching

Several methods have been developed to achieve switching of the cavity Q; the most common are [11.3, 4]:

1. Electrooptic Q-switching;
2. Rotating prism;
3. Acoustooptical Q-switching;
4. Saturable absorber Q-switching.

Electrooptic Q–switching. In this case the shutter placed inside the laser cavity is made of a Pockels cell and a polarizer in the configuration shown in Fig. 11.20 (electrooptic shutter). The Pockels cell consists of a suitable nonlinear electrooptic crystal (such as KD*P or lithium niobate for the visible-to-near-infrared region or cadmium telluride for middle-infrared), in which an applied dc voltage induces a change in the crystal refractive indices. The induced birefringence turns out to be proportional to the applied voltage. The transmission axis of the polarizer is set at 45° with respect to the birefringence axes of the crystal. When no dc field is applied to the crystal, no polarization losses are introduced in the cavity by the electrooptic shutter, i. e., cavity losses are low. However, when a dc field is applied such that the phase difference $\Delta\varphi$ between the ordinary and extraordinary waves in the birefringent-induced crystal is equal to $\pi/2$, the Pockels cell operates as a $\lambda/4$ birefringent plate. Therefore, the linearly polarized light, coming from the polarizer, is rotated by 90° after a double pass through the cell and it is then fully reflected out of the cavity by the polarizer. The electrooptic shutter is now closed and cavity Q is zero. The dc voltage to the


crystal required to produce the phase shift $\Delta\varphi = \pi/2$ is referred to as the quarter-wave voltage and typically ranges from 1 to 5 kV. To avoid multiple pulses, this voltage must be switched off in a time typically smaller than 20 ns.

Rotating prism. In this simple Q-switching technique, one of the cavity mirror is generally made of a rooftop prism and rotation is made through the axis parallel to the other mirror and orthogonal to the prism edge (Fig. 11.21). The high-Q condition is achieved when the prism edge passes through a position parallel to the other cavity mirror. Although rotating prisms are simple and inexpensive devices which can be used at any wavelength, they suffer the limitation arising from the limited rotation speed (≈ 400 Hz). The Q-switching time is then rather long (typically ≈ 400 ns) which often results in the production of multiple pulses (slow switching).

Acoustooptic Q–switching. In this case the shutter consists of an acoustooptic modulator, driven by a radio-frequency (RF) oscillator, which is placed inside the laser cavity. The modulator consists of a transparent block of material (usually fused quartz in the visible to near-infrared or cadmium selenide in the mid- to far-infrared) bonded on one side to a piezoelectric transducer and to an acoustic absorber on the other (Fig. 11.22). When the transducer is on, traveling sound waves are then produced in the material in the direction orthogonal to the plane of the transducer. Due to the photoelastic effect, the resulting strain in the material results in local changes of the material refractive index, i. e., in the generation of an index grating which is traveling along the material itself. Bragg scattering of the laser

Fig. 11.20 Schematic of a Q-switched laser using a Pockels cell
Fig. 11.21 Schematic of a Q-switched laser using a rotating prism
Fig. 11.22 Schematic of an acoustooptic modulator used for laser Q-switching (θ_B is the Bragg angle)

beam propagating across such a grating (Fig. 11.22) thus produces a diffracted beam and hence additional losses in the cavity (low-Q condition). Maximum diffraction efficiency is achieved when the incident light angle θ_B satisfies the Bragg condition $\theta_B = \lambda/(2\lambda_a)$, where λ and λ_a are the optical and acoustical wavelengths, respectively. The high-Q condition is simply obtained by switching off the transducer voltage. Acoustooptic modulators have the advantages of introducing low values of optical insertion losses and can be driven at high repetition rates (several kHz). Therefore they are used mainly for repetitive Q-switching of low-gain CW-pumped lasers (e.g., Nd:YAG or Ar-ion lasers).

Saturable absorber Q-switching. The Q-switching techniques discussed so far use active Q-switches, in the sense that they need an external control source. A notable passive Q-switching technique, in which no external driving control is required, consists of placing a suitable *saturable absorber* inside the laser cavity. This absorber is basically an unpumped two-level medium which absorbs at the laser wavelength with a comparatively low saturation intensity. Thus, due to the phenomenon of saturation, the absorption coefficient of the absorber decreases as the intensity of the intracavity laser beam increases. To model this phenomenon we write the rate equation for the absorber as $(\mathrm{d}N_2/\mathrm{d}t) = \sigma_a(N_1 - N_2)I/(h\nu) - N_2/\tau$, where N_2 and τ are the population and lifetime of the excited level 2, N_1 is the population in the lower (ground) level 1, and $I = I(t)$ is the intracavity laser intensity. In CW operation or if τ is short enough as compared to the changes of $I(t)$, we may assume that $(\mathrm{d}N_2/\mathrm{d}t) \approx 0$ and therefore

obtain $N_1 - N_2 \simeq N_t/(1 + I/I_s)$, where $N_t = N_1 + N_2$ is the total absorber population and $I_s \equiv h\nu/(2\sigma\tau)$ is the *saturation intensity* of the absorber. Since now the absorption coefficient is $\alpha = \sigma_a(N_1 - N_2)$, from the last two equations we obtain

$$\alpha = \frac{\alpha_0}{1 + I/I_s} , \qquad (11.66)$$

where $\alpha_0 = N_t\sigma_a$ is the unsaturated absorption coefficient of the absorber. Equation (11.66) then shows that, as the intracavity laser intensity I increases, the losses introduced by the saturable absorber decrease and the cavity Q correspondingly increases, i.e., Q-switching is achieved. The detailed dynamics underlying the formation of a Q-switching pulse with the saturable-absorber Q-switch, is however more involved than the one previously discussed. Here we just say that the saturable absorber should have a low value of the saturation intensity so that, when laser action starts, the absorber is bleached earlier (i.e., at lower intensity) than the time when population inversion in the gain medium starts to decrease appreciably owing to stimulated emission.

Typical absorbers used for passive Q-switching consist of dyes in an appropriate solvent; the main drawback of these absorbers is their photochemical degradation, i.e., poor chemical stability, and inadequate thermal properties. Recently, the advent of solid-state absorbers (notably absorbers based on chromium doped into various crystalline hosts) are replacing dye absorbers, thus avoiding the problem of degradation.

Laser Mode–Locking: Dynamical Aspects

Mode-locking is a laser operation regime in which many longitudinal modes of the cavity are simultaneously forced to oscillate with a precise phase relation so that the output laser beam shows a repetitive train of ultra-short optical pulses [11.3, 5]. To achieve mode-locking operation, a suitable device, which is usually referred to as the *mode locker*, must be placed inside the cavity. For a given laser medium, the lower limit to the achievable pulse duration $\Delta\tau_p$ is set by the gain line width ($\Delta\tau_p \gtrsim 1/\Delta\nu_0$), whereas the pulse repetition rate $1/\tau_p$ is usually equal to the difference frequency between two consecutive longitudinal modes $\Delta\nu$ (or an integer multiple of $\Delta\nu$, as for harmonic mode-locking). Therefore, pulse duration, depending upon the gain line width, usually ranges from about 1 ns, in gas lasers, down to 10 fs in broad-bandwidth solid-state lasers. Pulse repetition rate depends, of course, upon the cavity length and usually ranges from about 100 MHz to a few GHz.

Frequency–domain description. The basic principle of laser mode-locking can be explained as follows. Let us consider, for simplicity, a traveling-wave ring laser of optical length L_e, and assume that the separation of the longitudinal cavity modes $\Delta v = c/L_e$ be smaller (usually much smaller) than the gain line width Δv_0. In this case, even in the absence of the mode locker, the laser tends spontaneously to oscillate on several longitudinal modes (*free-running* regime). Let $v_l = v_0 + l\Delta v$ be the frequency and $E_l = A_l \exp(i\varphi_l)$ the complex amplitude of the l-th oscillating longitudinal cavity mode, where l is an integer number and $l = 0$ corresponds to the longitudinal mode closest to the center of the gainline (Fig. 11.23). The electric field $E(z, t)$ inside the laser cavity is then given by the superposition of the oscillating longitudinal modes and can be written in the form $E(z, t) = A(t - z/c) \exp[2\pi i v_0 (t - z/c)]$, where z is the longitudinal coordinate measured along the perimetric axis of the ring and the envelope $A(t')$ is given by

$$A(t') = \sum_l A_l \exp(2\pi i l \Delta v t' + i\varphi_l), \qquad (11.67)$$

where $t' = t - z/c$ is a retarded time. Note that, owing to the dependence of the field on $t - z/c$, the field distribution in the cavity is a traveling wave which propagates with the speed of light; therefore we may limit the discussion to the field behavior at a given reference plane $z = 0$, e.g., at the output coupler of the laser. The output laser power, averaged over the rapidly varying optical cycle, will be then proportional to $|A(t)|^2$. Note that, if the mode amplitudes A_l and phases φ_l are constant or slowly varying in time compared to the cavity round-trip time $\tau_R = L_e/c = 1/\Delta v$, the signal $A(t)$ is basically periodic in time with a period equal to τ_R. However, the specific form of the signal in one period depends on the precise distribution of the mode amplitudes A_l and, most importantly, on their phases φ_l.
Fig. 11.23 Schematic of a laser oscillating on several longitudinal modes in the frequency domain

In a *free-running laser*, the phases φ_l do not have a precise relation to each other; they may also fluctuate in time. The superposition of N modes with, e.g., the same amplitude $A_l = A_0$ but with randomly distributed phases typically leads to a spiking signal $|A(t)|^2$ made of a periodic sequence of irregular pulses (Fig. 11.24a), each with duration approximately equal to $\Delta \tau_p \approx 1/\Delta v_L$, where $\Delta v_L = N\Delta v$ is the oscillating bandwidth. Note that, since the response time of a conventional photodetector is usually much longer than a few picoseconds, the complex temporal behavior shown in Fig. 11.24a is usually not resolved for free-running multimode lasers, instead its average value – proportional to NA_0^2 – is monitored.

In a *mode-locked laser*, the role of the mode locker is to lock the phases of oscillating modes in a precise manner. The most common and interesting case is that of a mode locker that imposes a *linear phase locking* condition, i.e., $\varphi_l = l\varphi$, where φ is a constant. In this case, one has:

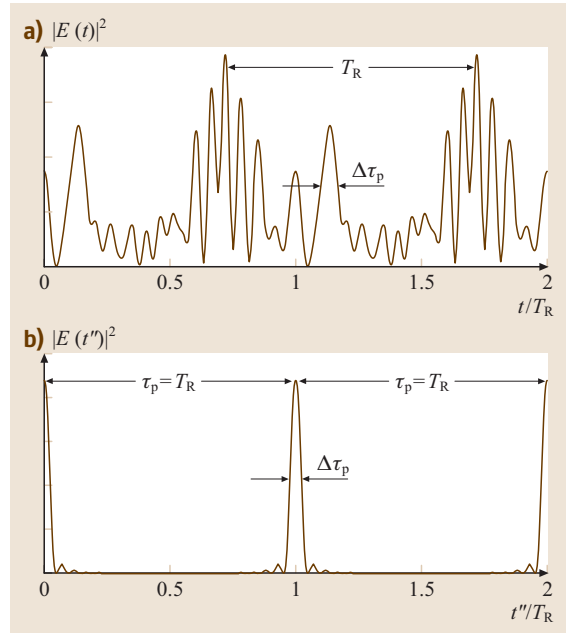
$$A(t'') = \sum_{l=-\infty}^{\infty} A_l \exp(2\pi i l \Delta v t''), \qquad (11.68)$$


Fig. 11.24a,b Behavior of output power in a laser oscillating on many longitudinal modes with equal amplitude (**a**) Free-running regime, corresponding to random phases ϕ_l. (**b**) Mode-locking regime, corresponding to linear phase locking $\phi_l = l\phi$

where t'' is a translated time given by $t'' = t' + \varphi/(2\pi\Delta\nu)$. Usually, in a mode-locked laser the envelope of the mode amplitudes A_l follows the shape of the gainline, i.e., A_l is maximum at the center of the gainline ($l = 0$) and decreases toward zero as $|l|$ increases; for instance, for active mode-locking in a homogeneously broadened medium, one can show that A_l follows a Gaussian distribution. However, to calculate the series in (11.68) simply, we assume that $A_l = A_0 = $ const. for $|l| \leq N$ and $A_l = 0$ for $|l| > N$, i.e., we assume an odd number $2N + 1$ of oscillating modes with the same amplitude. In this case one obtains in (11.68) a geometric progression which can be calculated in a closed form, yielding

$$A(t'') = A_0 \frac{\sin\left[(2N+1)\pi\Delta\nu t''\right]}{\sin(\pi\Delta\nu t'')} . \tag{11.69}$$

A plot of the squared amplitude of the electric field $|A(t'')|^2$ is reported in Fig. 11.24b. Note that a pulse train, at a repetition rate $\tau_p = 1/\Delta\nu$ equal to the cavity round-trip time τ_R, is obtained. The squared amplitude of the electric field at the peak pulse is given by $(2N + 1)^2 A_0^2$, whereas the FWHM pulse duration $\Delta\tau_p$ is approximately given by

$$\Delta\tau_p \simeq \frac{1}{(2N+1)\Delta\nu} = \frac{1}{\Delta\nu_L} , \tag{11.70}$$

where $\Delta\nu_L = (2N + 1)\Delta\nu$ is again the oscillating bandwidth. Therefore, for broad oscillating bandwidths, phase locking among longitudinal modes leads to the generation of short laser pulses with high peak power. The physical limit to the maximum number of phase-locked modes that can be forced to oscillate is ultimately determined by the gain bandwidth of the active material, i.e., $\Delta\tau_p$ is longer than or equal to $1/\Delta\nu_0$.

In general, when the actual shape (e.g., Gaussian) of the mode amplitudes A_l is taken into account, the overall field amplitude $A(t'')$ can be obtained approximately from (11.68) upon transforming the sum over all modes into an integral, namely $A(t'') \simeq \int_{-\infty}^{+\infty} A(l)\exp(2\pi i l\Delta\nu t'')\,\mathrm{d}l$. From this last equation one then sees that the pulse amplitude $A(t'')$ is the Fourier transform of the spectral mode envelope $A(l)$. Therefore, in this case, i.e., under linear phase-locking conditions, the pulse amplitude is said to be transform limited. Note, however, that under phase-locking conditions different from the linear case (e.g., $\varphi_l = \varphi_1 l + \varphi_2 l^2$, as in so-called frequency mode-locking) the mode-locked pulses are no longer transform-limited, i.e., their temporal duration is larger than that predicted by the Fourier limit.

Time–domain description. The previous analysis of mode-locking is often referred to as the *frequency-domain* description since the onset of the periodic pulse train is viewed as due to the coherent superposition of longitudinal modes of the laser cavity. A different description of the mode-locking regime, complementary to the frequency-domain approach, is also possible in the *time domain*. In fact, according to the results shown in Fig. 11.24b and since τ_R is the time for a round-trip, a single pulse of duration $\Delta\tau_p$ is circulating within the laser cavity (Fig. 11.25a). Note that the spatial extension of the pulse $\Delta z = c\Delta\tau_p$, according to (11.70) is given by $\Delta z = L_e/(2N + 1)$ where L_e is the length of the ring perimeter. For a sufficiently large number $(2N + 1)$ of oscillating modes, Δz is then much smaller than the cavity length L_e. The temporal periodicity of the output laser beam then simply results from the successive transits of the intracavity circulating pulse at the output mirror, which occur at intervals $\tau_p = L_e/c$ equal to the cavity transit time. According to this picture, we readily under-
Fig. 11.25a–c Schematic of the mode-locking regime in the time domain. (**a**) Mode-locking in a ring cavity. (**b**) Mode-locking in a linear cavity. (**c**) Harmonic mode-locking in a linear cavity (harmonic order $n = 3$)

stand that the mode-locking regime can be achieved by placing a suitable fast shutter inside the cavity. In fact, if an initially non-mode-locked beam is present within the cavity, its spatial amplitude distribution can be represented as in Fig. 11.24a, with the time t replaced by z/c. By periodically opening the shutter for a short time interval (of the order $\Delta\tau_p$) with period $\tau_p = L_e/c$, possibly at the time when the most intense noisy pulse in Fig. 11.24a reaches the shutter, then only this pulse will survive in the laser cavity, producing the mode-locking condition of Fig. 11.24b. After a transient leading from the temporal pattern of Fig. 11.24a to that of Fig. 11.24b, the mode-locked pulse will consistently reproduce itself after each transit in the cavity.

It should be noted that all considerations made above for a ring laser resonator apply *mutatis mutandis* to a linear (i. e., Fabry–Pérot) laser cavity. In this case, however, self-consistent propagation of the mode-locked pulse in one cavity round-trip requires that the shutter must be placed close to one end mirror of the cavity (Fig. 11.25b). Note that, if the shutter is placed at a distance $L/2$, $L/3$, $\cdots$, L/n from one end mirror and is opened at intervals $\tau_R/2$, $\tau_R/3$, $\cdots$, τ_R/n, where L is the cavity length, multiple pulses (precisely $2, 3, \cdots, n$ pulses) may be simultaneously generated and the repetition rate of the pulse train is correspondingly increased by a factor of $2, 3, \cdots, n$ (see, e.g., Fig. 11.25c for the case $n = 3$). Such a mode-locking regime is referred to as *harmonic mode-locking*. Harmonic mode-locking is typically employed in active mode-locked fiber lasers to increase the pulse repetition rate (≈ 1–$40\,\text{GHz}$); owing to the relatively long cavity length (≈ 1–$10\,\text{m}$), to reach high repetition rates harmonic orders n up to ≈ 1000 are usually needed.

Mode–Locking Methods

The methods to achieve mode-locking can generally be divided into two categories:

1. Active mode locking, in which the mode-locker is driven by an external source.
2. Passive mode locking, in which the mode-locker is not externally driven but exploits some nonlinear optical effect, such as the saturation of a saturable absorber or the nonlinear change of the refractive index in a Kerr medium.

Active mode locking. Active mode locking is usually achieved by placing, inside the laser cavity, either an amplitude modulator, which produces a periodic modulation in time of the cavity loss [amplitude-

modulation (AM) *mode locking*], or a phase modulator, which periodically varies the optical length of the resonator [frequency-modulation (FM) *mode locking*]. In lasers with upper-state lifetimes shorter than the cavity round-trip time (e.g., dye lasers), active mode locking can also be achieved by periodic modulation of the laser gain at a repetition rate equal to the longitudinal mode separation $\Delta\nu$ (*synchronous pumping*). We limit here to describe the basic principle of AM mode locking, since it is the most common among the three mentioned techniques. In AM mode locking, the mode locker is usually a Pockels-cell electrooptic modulator for pulsed and high-gain lasers, or an acoustooptic modulator for low-gain lasers. The electrooptic or acoustooptic modulator sinusoidally varies the cavity loss $\gamma(t)$ at a given modulation frequency ν_m (Fig. 11.26). It is thus expected that the mode-locked pulse circulating inside the cavity (Fig. 11.25b) will pass through the modulator at the time t_1 of the cycle where the cavity loss $\gamma(t)$ is minimum. Since the pulse propagating inside the cavity passes again through the modulator at times $t_2 = t_1 + \tau_R$, $t_3 = t_2 + \tau_R$, etc., where $\tau_R = 1/\Delta\nu$ is the cavity round-trip time, a steady mode-locking regime can be reached provided that the synchronization condition $\Delta\nu = \nu_m$ is satisfied. It should be noted that the steady-state pulse duration, $\Delta\tau_p$, is given by the inverse of the oscillation bandwidth, $(2N+1)\Delta\nu$, and, thus, it is ultimately established by the gain bandwidth $\Delta\nu_0$. However, the finite bandwidth of the gain medium influences the steady-state pulse duration in a quite different way for homogeneous or inhomogeneous lines. For an inhomogeneously broadened line, and for a laser well above threshold, the oscillating bandwidth tends to cover the whole gain bandwidth $\Delta\nu_0^*$ even in the absence of AM modulation, and the main role of the mode-locker is just to lock the phases of these oscillating modes. The resulting temporal duration of the mode-locked pulse is therefore given approxi-
Fig. 11.26 Schematic of AM active mode locking

mately by

$$\Delta \tau_p \simeq \frac{0.44}{\Delta \nu_0^*} \, . \tag{11.71}$$

Conversely, for a homogeneously broadened gain medium the number of longitudinal modes oscillating in the free-running regime is usually rather modest and the role of the mode-locker is both to enlarge the oscillating bandwidth of the laser (by power transfer from the central to lateral longitudinal modes) and to lock the phases of the oscillating modes. Under steady-state conditions, band enlargement due to the modulator is counteracted by band reduction due to the gain medium and the pulse duration is given by [11.14]

$$\Delta \tau_p \simeq \frac{0.45}{\sqrt{\nu_m \Delta \nu_0}} \, . \tag{11.72}$$

As an example, we will consider a mode-locked Nd:YAG laser oscillating on its homogeneously broadened line at $\lambda = 1064$ nm. Assuming $\Delta \nu_0 \simeq 126$ GHz ($T = 300$ K), a linear cavity of length $L_e = 1.5$ m and an AM mode-locker placed close to one cavity mirror, the modulator loss must be driven at a frequency $\nu_m = \Delta \nu = c/(2L_e) \simeq 100$ MHz, and the expected mode-locked pulse duration, according to (11.72), is $\Delta \tau_p \simeq 125$ ps.

It should be noted that in AM mode-locked lasers (as well as in the other active mode locking techniques) even small detunings of the modulation frequency ν_m from the cavity axial mode separation $\Delta \nu$ may result in the destruction of the mode-locking operation. In practice a detuning $|\nu_m - \Delta \nu|/\nu_m$ of the order of $\approx 10^{-4}$ is enough to destroy mode-locking. To obtain stable AM mode-locking, active control of the cavity length is sometimes required, especially when relatively long cavities are employed (such as for AM mode-locked fiber lasers).

Passive mode-locking. There are two main types of passive mode-locking (ML):

1. Fast saturable-absorber ML, which uses the saturation properties of a suitable absorber (e.g., a dye or a semiconductor) with a very short upper-state lifetime;
2. Kerr-lens mode-locking (KLM), which exploits the self-focusing property of a suitable transparent Kerr medium.

Fast saturable–absorber ML [11.15]. Consider a saturable absorber with a low saturation intensity and a relaxation time shorter than the duration of the mode-locked pulses. According to (11.66), the absorption
Fig. 11.27 Mode-locking with a fast saturable absorber

loss experienced by a pulse crossing the absorber is dependent on the instantaneous pulse intensity $I(t)$, and decreases as the intensity increases. Thus, starting from the random sequence of light bursts occurring in the unlocked case (Fig. 11.24a), the gain–loss balance will favor the growth and stabilization of the noise pulse with the highest intensity. The steady-state situation, occurring in this case, can be described with the help of Fig. 11.27. Here, gain saturation drives the gain g below the cavity losses $\gamma(t)$ except at those instants where, due to the arrival of the pulse $I(t)$ at the saturable absorber, the losses are reduced due to absorber saturation. During the time intervals corresponding to the hatched regions in Fig. 11.27, the gain is then larger than the instantaneous loss $\gamma(t)$. A so-called window of net gain is thus produced, which tends to increase the peak of the pulse and decrease its wings, i.e., it tends to narrow the pulse. This narrowing is again counteracted by pulse broadening due to the finite amplifier bandwidth until a steady-state pulse duration, whose duration again depends on the inverse of the gain bandwidth, is eventually reached. Good candidates for saturable absorbers must have a short relaxation time τ ($\sim$ a few picoseconds or shorter) and a small saturation intensity, given by $I_s = h\nu/(2\sigma_a\tau)$. Thus, very large values for the absorption cross section σ_a ($\approx 10^{-16}$ cm^2 or larger) are needed. Ideal absorbers are therefore dye molecules (e.g., cyanine dyes) or, even better, semiconductors. A particularly interesting saturable-absorber geometry consists of integrating a multiple-quantum-well absorber between two mirrors whose spacing is such that the resulting Fabry–Pérot etalon operates in antiresonance. Such a device has been convincingly proven to generate both picosecond and femtosecond laser pulses from several broadband solid-state lasers.

Kerr–lens mode-locking. This technique is based on the use of a nonlinear loss element simply consisting of a nonlinear Kerr medium placed in front of

an aperture (Fig. 11.28). The nonlinear medium shows, via the optical Kerr effect, an intensity-dependent refractive index $n = n_0 + n_2 I$, where n_0 is the linear refractive index of the medium, I is the local light intensity and n_2 is a positive coefficient (for a self-focusing medium) which depends on the strength of the nonlinearity (e.g., $n_2 \simeq 4.5 \times 10^{-16}\,\mathrm{cm^2/W}$ for fused quartz and $n_2 \simeq 3.45 \times 10^{-16}\,\mathrm{cm^2/W}$ for sapphire). A light beam with, e.g., a transverse Gaussian intensity distribution $I(r) = I_p \exp[-2(r/w)^2]$ that crosses a thin slice of the Kerr medium of length l thus experiences a transversely varying phase shift $\delta\varphi = 2\pi l n_2 I(r)/\lambda = (2\pi l n_2/\lambda) I_p \exp[-2(r/w)^2]$. Close to the beam center $r = 0$, one can write $\delta\varphi \approx (2\pi l n_2 I_p/\lambda)[1 - 2(r/w)^2]$, i.e., the thin medium introduces a quadratic phase change of the field and thus acts, for $n_2 > 0$, as a positive lens (called a *Kerr lens*) of dioptric power $1/f = 4n_2 l I_p/(n_0 w^2)$, which increases as the beam intensity I_p increases. If an aperture is placed at some suitable distance from the Kerr medium, a beam with higher intensity will be focused tighter and a higher fraction of the beam will be trans-
Fig. 11.28 Schematic of a Kerr lens with an aperture used in KLM

mitted through the aperture. Therefore, the Kerr medium with the aperture, like a fast saturable absorber, introduces losses that decrease when the instantaneous pulse intensity is increased, thus leading to mode-locking. Note that, by appropriately controlling the cavity dispersion, the shortest mode-locked pulses ($\approx 6\,\mathrm{fs}$) have been achieved by this technique for $Ti^{3+}:Al_2O_3$ lasers.

11.2 Solid–State Lasers

11.2.1 Basics

Solid–State Lasers
Based on Dielectric Insulators

The demonstration of the ruby laser [11.16] ($Cr^{3+}:Al_2O_3$) in 1960 led to a decade with the realization of a number of crystalline and glass lasers. Especially Nd:YAG [11.17], Nd-doped yttrium aluminum garnet ($Nd:Y_3Al_5O_{12}$), rapidly emerged as one of the most important crystalline dielectric lasers. The first glass laser was a fiber laser [11.18], which decades later led to the development of highly efficient Er-doped fiber amplifiers (EFDA) with important applications in optical communications.

In the last two decades progress in the area of diode-pumped lasers has contributed very much to a renaissance in the field of solid-state lasers. With diode laser pumping it is possible to obtain higher efficiencies and to build rigid all-solid-state devices with simpler and more compact design. Besides Nd^{3+} various efficient diode-pumped rare-earth lasers have been operated with Er^{3+}, Tm^{3+}, Ho^{3+} [11.19–21], and Yb^{3+} [11.22, 23]. In addition, the successful operation of Cr^{3+}-doped [11.24–27] and Ti^{3+}-doped

crystals [11.28, 29] as tunable room-temperature lasers has stimulated further research in transition-metal ions. Interesting new results have been obtained with the Cr^{4+} ion [11.30–33] and recently also with the divalent Cr^{2+} ion [11.34].

Nowadays, average and CW output powers for Nd^{3+}- and Yb^{3+}-doped crystals in the kW range are commercially available. Fiber lasers reach output powers in the $100\,\mathrm{W}$ range with nearly diffraction-limited beam quality.

Compact solid-state lasers in the visible spectral region (see for instance [11.35]) are of potential interest, especially for display and high-density optical data storage applications. Optical efficiencies of more than 20% with respect to the pump power can be obtained in Nd lasers by internal frequency doubling with nonlinear crystals. An alternative approach enables the generation of visible laser radiation by upconversion schemes, which incorporate energy transfer processes or two-step pump processes as ground-state and excited-state absorption.

In a most general sense lasers based on solids include both dielectric insulators and semiconductors as gain media. However, the development in the past yielded

a subdivision into two laser classes based on solids: solid-state lasers (the topic of this chapter) and semiconductor lasers (Sect. 11.3).

Nearly all modern, important solid-state lasers are based on impurity-doped crystals or glasses. Typically, the impurity ions have unfilled electronic shells. So far, only laser ions from the iron, rare-earth and actinide group are known. The most important laser lines of these ions correspond to 4f–4f, 4f–5d, and 3d–3d transitions. In special cases the laser active ions can also be fully substituted into the lattice (stoichiometric laser materials). It should be noted that in the past lattice defects also have been used as laser-active centers (color center lasers); these lasers are however not included in this chapter.

Spectra of Rare–Earth and Transition–Metal Ions in Solids

4f–4f transitions in rare-earth ions. In the free rare-earth ion the electrostatic interaction between the 4f electrons creates a splitting of the energy levels of the $4f^n$ configuration into different LS terms. The resultant wave functions are characterized by the quantum numbers L, S, M_L, and M_S. The electrostatic energy splitting of the $^{\{2S+1\}}L$ terms is typically 10^4 cm^{-1}, and each level is $(2L+1)(2S+1)$-fold degenerate with respect to M_L and M_S.

In addition, the energy levels are further split by spin–orbit coupling. If the energetic separation between different LS terms is large compared with the spin–orbit coupling energy there is only a small mixing of the LS terms. If this mixing is very small, the Russel–Saunders approximation holds and the wave functions are characterized by the quantum numbers L, S, J, M_J with a degeneration of $(2J+1)$. The typical splitting of $^{\{2S+1\}}L_J$ terms is of the order of 1000 cm^{-1}. Although LS coupling is not strictly valid for rare-earth ions, it is usual to describe the 4f energy states with the Russel–Saunders approximation [11.36].

The interaction of the 4f electrons with the crystal field, i. e., the electrostatic field of the surrounding ligands, results in a Stark splitting of the free ion $^{\{2S+1\}}L_J$ terms. This interaction can be treated as a perturbation of the free ion levels. The crystal field splitting and the remaining degeneracy depend on the symmetry of the local crystal field. Lower symmetries increase the number of split levels. However, according to Kramers theorem an odd number of electrons always yields at least twofold degeneracy. The Stark splitting is typically in the energy range of several 100 cm^{-1}. The ground state of a special $4f^n$ configuration (the number of 4f electrons $n = 1-14$)

can be determined according to Hund's rule. Fig. 11.29 shows the $4f^n$ energy levels of rare-earth ions (Dieke diagram [11.37]).

Electric dipole transitions within the 4f-shell are parity forbidden in the free ion. When doped in a solid, acentric perturbations of the crystal field can however create admixtures of wave functions with opposite parity (for instance $4f^{n-1}5d^1$ states) yielding so-called forced electric dipole transitions. Due to the screening of the outer filled $5s^2$ and $5p^6$ orbitals, the crystal field perturbation is small and electron–phonon coupling is very weak. So, for rare-earth ions at acentric sites one observes electric-dipole zero-phonon transitions with very weak vibronic sidebands. When doping occurs at centric sites, parity remains a good quantum number and all 4f–4f transitions remain electric dipole forbidden. The magnetic-dipole emission cross sections are then very small and are not useful for laser applications.

Further selection rules for electric dipole transitions between $4f^n$ states are:

- $\Delta J \leq 6$; $\Delta S = 0$, $\Delta L \leq 6$ (Russel–Saunders approximation)
- $J = 0 \Leftrightarrow J' = 0$ is forbidden.

3d–3d transitions in transition-metal ions. The 3d electrons of transition-metal ions are not shielded and experience a strong perturbation from the crystal field of the surrounding ligand ions. Therefore, the energy-level scheme and also the spectroscopic characteristics of a transition metal ion depend strongly on the strength and the symmetry of the crystalline field originating from the surrounding ions. The energy-level schemes of the transition-metal ions in crystalline hosts are described by so-called Tanabe–Sugano diagrams [11.38]. These diagrams are distinguished by the number of electrons within the 3d electron shell. In these diagrams the energy levels of the transition-metal ion are presented as a function of the crystal field strength (for some examples, see Sect. 11.2.3). For detailed reading appropriate literature can be found in [11.36, 39–42].

Due to the strong interaction with the surrounding ions of the lattice, transition-metal ions mostly exhibit broadband emission because of the electron–phonon coupling between the electronic 3d levels and lattice vibrations. As in the case of 4f–4f transitions, only acentric perturbations can induce electric dipole transitions. Generally the spectra consist of a purely electronic zero-phonon line with vibronic sidebands. In contrast to the situation in rare-earth ions, transition-metal ions at centric sites may also have reasonable transition
Fig. 11.29 Energy level diagrams of trivalent rare earth ions of RE^{3+} in LaCl$_3$ ("*Dieke-diagram*") [11.37]

probabilities due to dynamical admixtures of wave functions with different parity by acentric phonons. On the other hand, strong electron–phonon coupling can yield higher temperature-dependent nonradiative decay rates compared to 4f–4f transitions. The main interest in transition-metal ions is based on their broad tunability.

Interconfigurational 4f–5d transitions in rare-earth ions. Typically 4f↔5d interconfigurational transitions of rare-earth ions are located in the ultraviolet spectral range. In some cases 4f↔5d transitions are also observed in the visible spectral region. In contrast to 3d↔3d and 4f↔4f transitions, 4f↔5d transitions are electric-dipole allowed, because they obey the parity selection rule. Thus high transition probabilities and hence large absorption and emission cross sections ($\approx 10^{-18}$–10^{-17} cm^2) are observed.

Similar to 3d↔3d transitions strong electron–phonon coupling yields broad absorption and emission spectra with spectral half-widths of more than 1000 cm^{-1}. Therefore 4f↔5d interconfigurational transitions are in principle suitable for the generation of tunable laser oscillation.

However, the difficulty in finding suitable pump sources and often also excited-state absorption processes are major drawbacks with respect to the realization of 5d–4f lasers.

Basic Spectroscopic Properties and Laser Parameters

Ground–state absorption. The ground-state absorption of an ion is characterized by the absorption coefficient α and the ground-state absorption cross section σ_{GSA}. These values are derived using the Lambert–Beer law:

$$I(\lambda) = I_0(\lambda) e^{-\alpha(\lambda)d} = I_0(\lambda) e^{-n_{\mathrm{ion}}\sigma_{\mathrm{GSA}}(\lambda)d} ,$$
(11.73)

where $I(\lambda)$ is the intensity transmitted through the crystal at wavelength λ, $I_0(\lambda)$ is the intensity in front of the crystal, n_{ion} is the ion concentration, $\alpha(\lambda)$ is the absorption coefficient, $\sigma_{\mathrm{GSA}}(\lambda)$ is the absorption cross section, and d is the crystal thickness.

The ground-state absorption spectrum contains information about the energy-level structure of the ion, the cross sections $\sigma_{\mathrm{GSA}}(\lambda)$ and the oscillator strengths of the observed transitions. Note, that the calculation of cross sections needs a second independent measurement of the ion concentration, which is usually done by X-ray microprobe analysis. The relation between the absorption coefficient and the transition-matrix elements can be derived using Fermi's golden rule [11.36]. The energy-level structure of transition-metal ions is theoretically described by the ligand field theory and the angular overlap model (AOM), see for instance [11.43].

Spontaneous emission and emission cross section. The spontaneous emission is characterized by the Einstein coefficient A. In an emission measurement, the photon flux (the number of photons per area per time) is usually measured. The normalization process with respect to the instrument response function can be performed either with respect to photon flux or to the spectral intensity distribution $I_\lambda(\lambda)$ (energy per area per time). The relation between the spectral intensity distribution $I_\lambda(\lambda)$, the Einstein coefficient A ($A = \tau_{\mathrm{rad}}^{-1}$) and the emission cross section $\sigma_{\mathrm{em}}(\lambda)$ is given by the Füchtbauer–Ladenburg equation [11.44]:

$$\sigma_{\mathrm{em}}(\lambda) = \frac{\lambda^5 I_\lambda(\lambda) A}{8\pi n^2 c \int I_\lambda(\lambda)\lambda\,\mathrm{d}\lambda} ,$$
(11.74)

where n is the refractive index and c is the speed of light.

The emission cross sections can also be calculated from the absorption cross sections by the reciprocity method

$$\sigma_{\mathrm{em}}(\lambda) = \sigma_{\mathrm{GSA}}(\lambda) \frac{Z_{\mathrm{l}}}{Z_{\mathrm{u}}} \exp\left(\frac{E_{\mathrm{zl}} - hc/\lambda}{kT}\right) ,$$
(11.75)

where Z_{l} and Z_{u} are the partition functions of the lower and upper energy levels, E_{zl} is the energy of the zero-phonon line of the corresponding transition, k is the Boltzmann constant, and T is the temperature.

For Gaussian band shapes, which are often observed for emission spectra of transition-metal ions, the *McCumber* formula can be used for the determination of the peak emission cross section [11.45, 46]

$$\sigma_{\mathrm{em}} = \sqrt{\frac{\ln 2}{\pi}} \frac{A}{4\pi c n^2} \frac{\lambda_0^4}{\Delta\lambda} ,$$
(11.76)

where λ_0 is the peak emission wavelength and $\Delta\lambda$ is the full width at half-maximum (FWHM).

Excitation spectra. The excitation spectra allow the determination of those absorption transitions, which yield a specific emission. These measurements are interesting in the case of different absorbing and emitting centers and also for finding energy transfer channels between different optical active centers.

Emission lifetime. The decay time of the metastable level of an ion in a crystal is usually measured after excitation with a short pulse. The measured decay rate

(measured as the number of transitions per unit time) is the sum of radiative and nonradiative decay rates. In general, the nonradiative decay of an ion can consist of intra-ionic multiphonon processes and intra-ionic nonradiative transfer processes (for details of energy transfer processes see [11.36]). The equation for the decay is

$$\frac{1}{\tau} = A + \frac{1}{\tau_{nr}} = \frac{1}{\tau_r} + \frac{1}{\tau_{nr}} \quad \text{or}$$
$$W = A + W_{nr} = W_r + W_{nr} \,, \tag{11.77}$$

where τ, τ_r, and τ_{nr} are the total, radiative, and nonradiative decay times, respectively, and W, W_r, and W_{nr} are the total, radiative, and nonradiative decay rates, respectively.

The determination of the Einstein coefficient A is not an easy task, because in a simple decay measurement the combined lifetime is always measured. An additional measurement of the emission quantum efficiency η_{QE} would allow the determination of the radiative and nonradiative decay rate

$$\eta_{QE} = \frac{\tau}{\tau_r} = \frac{W_r}{W} = \frac{W_r}{W_r + W_{nr}}$$
$$\Rightarrow \quad \tau_r = \frac{\tau}{\eta_{QE}} \quad \text{and} \quad \tau_{nr} = \frac{\tau_r \tau}{\tau_r - \tau} \,. \tag{11.78}$$

However, a direct measurement of the quantum efficiency is difficult and usually contains a high error.

Another approach is the indirect determination of the quantum efficiency by analysis of the temperature dependence of the emission lifetime. The two most commonly used models are the simple Mott model of the activation energy [11.47] and the more-sophisticated model of *Struck* and *Fonger* [11.48] using the so-called single-configurational-coordinate model, which describes in a simplified way the interaction between the electronic center and the vibrating crystalline environment.

Excited–state absorption (ESA). Measurements of the excited-state absorption (ESA) spectrum give further insight into the energy-level structure of an ion. In the ground state absorption measurements spin-allowed transitions are mainly observed and often spin-flip transitions are hidden under these absorption bands. Thus the determination of the energy of these spin-flip transitions is often not possible. If the metastable level of the ion has a different spin to the ground state (e.g., Cr^{3+} in strong crystal fields, Mn^{5+}, Fe^{6+}), the ESA spectrum reveals the energetic positions of these states with different spin. By using these data the crystal field parameters can be determined with higher accuracy. The

knowledge of ESA processes is also very useful for the determination of their influence on the efficiency of a laser material. ESA may also inhibit gain and hence laser action.

The laser aspect. In this section only the case of steady-state conditions for laser oscillation will be discussed. For more details and for the case of pulsed excitation, see e.g. [11.49–52].

The efficiency of a laser system can be described by the laser threshold P_{thr} and the slope efficiency $\eta = dP_{out}/dP_{abs}$, where P_{out} and P_{abs} are the laser output power and the absorbed pump power, respectively. Under the assumptions of only one metastable level (i. e., the upper laser level), ideal overlap between pump beam and resonator mode, homogeneous pump profile, low mirror transmission and low passive losses as well as the absence of excited-state absorption, the following equations hold for continuous-wave operation [11.49, 50]

$$P_{thr} = \frac{h\nu_p}{\eta_p \sigma_{se}(\lambda_l)\tau}$$
$$\times \left[T + L + 2d\sigma_{GSA}(\lambda_l)(n_{ion} - n_{thr}) \right] \frac{V}{2d}$$
$$\text{(3-level system)} \,, \tag{11.79}$$

$$P_{thr} = \frac{h\nu_p}{\eta_p \sigma_{se}(\lambda_l)\tau}(T + L)\frac{V}{2d}$$
$$\text{(4-level system)} \,, \tag{11.80}$$

$$\eta = \eta_p \frac{\lambda_p}{\lambda_l}\frac{T}{T + L} \,, \tag{11.81}$$

where $h\nu_p$ is the energy of pump photon, η_p is the pumping efficiency, i. e., the fraction of absorbed pump photons that are converted into excited ions in the upper laser level, σ_{se} is the stimulated emission cross section, τ is the lifetime of the upper laser level, T is the mirror transmission, L is the passive losses, d is the length of the laser crystal, σ_{gsa} is the ground-state absorption cross section, n is the concentration of laser ions, n_{thr} is the threshold inversion density, λ_p is the pump wavelength, λ_l is the laser wavelength, and V is the pump volume.

In the following, several factors affecting the pump power threshold and the slope efficiency will be discussed.

Influence of the emission quantum efficiency η_{QE}. A quantum efficiency less than unity leads to lifetime shortening and therefore to an increase in the laser threshold, as can be seen from (11.79) and (11.80) after

replacing τ by $\eta_{qe}\tau_r$

$$P_{thr} = \frac{h\nu_p}{\eta_p \sigma_{se}(\lambda_1)\eta_{qe}\tau_r} \tag{11.82}$$

$$\times \left[T + L + 2d\sigma_{gsa}(\lambda_1)(n_{ion} - n_{thr})\right]$$

$$\times \frac{V}{2d} \frac{1}{\eta_{qe}}, \quad \text{(3-level)} \tag{11.83}$$

$$P_{thr} = \frac{h\nu_p}{\eta_p \eta_{qe}\sigma_{se}\tau_r}(T + L)\frac{V}{2d} \propto \frac{1}{\eta_{qe}} \quad \text{(4-level)}. \tag{11.84}$$

The quantum efficiency does not influence the slope efficiency directly (11.81). However in practice a corresponding, significant contribution of nonradiative transitions increases the temperature in the pump volume and usually leads to a lower slope efficiency due to further lifetime reduction and other problems such as thermal lensing.

Influence of passive losses L. Passive losses in a laser system are due to imperfect optical components in the laser resonator. This can be due to, e.g., stray centers and residual absorptions. Passive losses influence both the threshold and the slope efficiency (11.79, 80, 81). In a four-level system, the passive losses can be determined by the Findlay–Clay method [11.53]. For such an analysis, the laser threshold is measured as a function of the output mirror transmission. The following equation holds:

$$P_{thr} = \frac{h\nu_p}{\eta_p \sigma_{se}\tau}\frac{V}{2d}T + \frac{h\nu_p}{\eta_p \sigma_{se}\tau}\frac{V}{2d}L = mT + b, \tag{11.85}$$

with slope $m = \frac{h\nu_p}{\eta_p \sigma_{se}\tau}\frac{V}{2d}$ and axis parameter $b = mL$. From a linear fit to $P_{thr} = P_{thr}(T)$ both m and b are determined and thus the value of the passive losses L. An alternative way to determine the passive losses is to rewrite (11.81) for a so-called *Caird plot* [11.54]:

$$\frac{1}{\eta} = \frac{\lambda}{\eta_p \lambda_p}\frac{L}{T} + \frac{\lambda}{\eta_p \lambda_p} = m'\frac{1}{T} + b', \tag{11.86}$$

with slope $m' = \frac{\lambda}{\eta_p \lambda_p}L = b'L$. From a linear fit to $\frac{1}{\eta} = \frac{1}{\eta}\left(\frac{1}{T}\right)$ both m' and b' can be determined and thus the value of the passive losses L.

Influence of excited-state absorption. ESA at the pump wavelength reduces the number of pump photons converted into excited ions in the metastable laser level according to

$$\eta_p = \eta_{p,0}\left(1 - \frac{n_1\sigma_{ESA}(\lambda_p)}{n_1\sigma_{ESA}(\lambda_p) + (n_{ion} - n_1)\sigma_{gsa}(\lambda_p)}\right), \tag{11.87}$$

where $\eta_{p,0}$ is the pumping efficiency without ESA, n_{ion} is the concentration of active ions, and n_1 is the population density in the upper laser level. Therefore the pump threshold is increased and the laser slope efficiency is reduced according to (11.79, 80, 81).

ESA on the laser wavelength also affects the laser threshold and the slope efficiency. The stimulated emission cross section $\sigma_{se}(\lambda_1)$ in (11.79) and (11.80) is replaced by $\sigma_{EFF}(\lambda_1) = \sigma_{se}(\lambda_1) - \sigma_{ESA}(\lambda_1)$ and (11.81) has to be extended [11.54]

$$\eta = \eta_p \frac{\lambda_p}{\lambda_1}\frac{\sigma_{se}(\lambda_1) - \sigma_{ESA}(\lambda_1)}{\sigma_{se}(\lambda_1)}\frac{T}{T + L} \propto \frac{\sigma_{EFF}}{\sigma_{se}}. \tag{11.88}$$

If $\sigma_{ESA}(\lambda_1) > \sigma_{se}(\lambda_1)$ laser oscillation is not possible.

11.2.2 UV and Visible Rare-Earth Ion Lasers

Lasers based on 5d ↔ 4f transitions of trivalent and divalent rare-earth ions

In this section an overview of lasers oscillating in the ultraviolet and visible spectral range based on transitions of rare-earth ions is given. The first part deals with laser and possible laser systems based on interconfigurational transitions, i.e., $4f^{n-1}5d \rightarrow 4f^n$. In the second part, visible and UV lasers based on intraconfigurational $(4f^n \rightarrow 4f^n)$ transitions will be discussed. Both parts deal with crystals as host materials. Finally, in the third part an overview of fiber lasers in the visible spectral range is given.

The 4f↔5d interconfigurational transitions of some divalent (RE^{2+}) and trivalent (RE^{3+}) rare-earth ions are located in the visible and ultraviolet spectral range. They are in principle suitable for the realization of (tunable) laser oscillation. The transitions are electric-dipole allowed and have high transition probabilities and large absorption and emission cross sections of the order of 10^{-17} to $10^{-18}\,cm^2$. Due to their strong electron–phonon coupling, the observed absorption and emission transitions are broad ($> 1000\,cm^{-1}$). Difficulties with respect to laser operation are the non-availability of efficient and simple excitation sources and the high probability of excited-state absorption and solarization (photoionization), e.g., $Ce^{3+}:LiCaAlF_6$ and $Ce^{3+}:LiSrAlF_6$ depicted in Fig. 11.30.
Fig. 11.30 Scheme of the energy levels in Ce^{3+}-doped $LiCaAlF_6$ and $LiSrAlF_6$, where s_{ABS}, s_{EM}, s_{ESA}, and s_{SOL}, are the absorption, emission, ESA, and solarization cross sections, respectively. From [11.55]

In the following the trivalent and divalent rare-earth ions exhibiting short-wavelength emission will be briefly discussed together with a summary of the obtained laser results.

Ce³⁺ *Lasers.* The Ce^{3+} $4f^1$ ground-state configuration splits into the $^2F_{5/2}$ ground state and the $^2F_{7/2}$ excited-state multiplet with an energy separation of $\approx 2000\,cm^{-1}$. The 5d excited configuration consists in an ideal octahedral or cubic symmetry of a threefold orbital

degenerated $^2T_2$ state and of a twofold orbital degenerated ^2E level, from which the $^2T_2(^2E)$ state is at lower energy in octahedral (cubic) symmetry. In Fig. 11.31 the room-temperature absorption and emission spectrum of Ce^{3+}:$LiYF_4$ is shown. In general, in the absorption spectrum two to five broad bands are expected, depending on the crystal field symmetry. In emission two bands corresponding to the 5d→ $^2F_{5/2}$ and 5d→ $^2F_{7/2}$ transitions with an energetic separation of approximately $2000\,cm^{-1}$ are observed. The high cross sections of the electric-dipole- and spin-allowed $4f^1 \leftrightarrow 5d^1$ transitions correspond to an emission lifetime in the ns range. Ce^{3+}-doped materials were therefore thoroughly investigated for application as tunable solid-state lasers and scintillators, see e.g., the overview articles by Coutts et al. [11.57] and *Dorenbos* [11.58]. Laser oscillation was thus far achieved in $YLiF_4$ [11.56], $LuLiF_4$ [11.59], $LiCaAlF_6$ [11.60], $LiSrAlF_6$ [11.55, 61], LaF_3 [11.62], and BaY_2F_8 [11.63] crystals. The laser data are summarized in Table 11.2. For Ce^{3+}-doped materials the main obstacle with respect to laser oscillation is excited-state absorption assigned to transitions to the conduction band, e.g., as is the case for Ce^{3+}:YAG [11.64, 65]. For Ce^{3+}-doped $LiCaAlF_6$ and $LiSrAlF_6$ the ESA transition leads to a *solarization*, i.e., impurity traps with long lifetimes are populated (Fig. 11.30). With the help of an *anti-solarent* pump, these traps are depleted and higher efficiencies are obtained [11.66, 67].

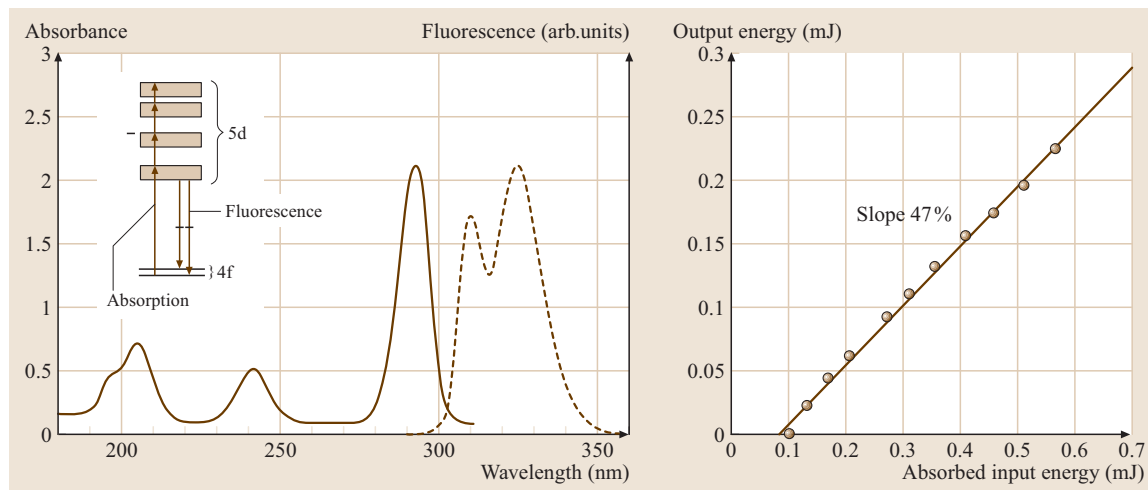
Pr³⁺ *(4f²).* The energy-level scheme of Pr^{3+} is shown schematically in Fig. 11.32. Pr^{3+} has a $4f^2$ ground-state


Fig. 11.31 *Left*: Absorption (*solid line*) and emission (*dotted line*) spectra of Ce^{3+}:$LiYF_4$. The inset shows the schematic energy level diagram. From [11.56]. *Right*: Input-output characteristic of a 2% Ce^{3+}, 2% Na:$LiSrAlF_6$

Table 11.2 Overview of lasers based on the 5d→4f transitions of trivalent and divalent rare-earth ions (CVL: copper vapor laser, RS: Raman-shifted)

Sm^{2+}:CaF$_2$	708.5 (20 K)			708.5–745 nm (20–210 K)	Xe flash lamp	[11.91, 92]

configuration. In this configuration 91 energy levels exist, distributed over 11 manifolds, from which the $^3H_4$ level is the ground state and $^1S_0$ is the highest level at approximately $46\,500\,cm^{-1}$. In the $4f^15d^1$ configuration, 140 energy levels exist. Depending on the crystal field strength and splitting, either the lowest $4f^15d^1$ level or the $^1S_0$ state is lower in energy. Thus after UV excitation, emission occurs either from the $4f^15d^1$ level as a $4f^15d^1 \rightarrow 4f^2$ transition or from the $^1S_0$ level as a $4f^2 \rightarrow 4f^2$ transition. In any case, the emission spectrum consists of several bands, because several $4f^2$ terminal levels exist. Spectroscopic investigations of the $4f \leftrightarrow 5d$ transitions have so far been carried out for a number of materials, e.g., $Y_3Al_5O_{12}$ [11.68, 69], $YAlO_3$ [11.68, 70, 71], CaF_2, $LiYF_4$ [11.71–73], and $K_5PrLi_2F_{10}$ [11.71]. Thus far laser oscillation based on the $4f^15d^1 \rightarrow 4f^2$ or on the $^1S_0 \rightarrow 4f^2$ emission of Pr^{3+} has not achieved. The main reason seems to be excited-state absorption into the conduction band, e.g., for $YLiF_4$ [11.73], and into higher-lying $4f^15d^1$ levels, e.g., for $Y_3Al_5O_{12}$ [11.74].

Other RE^{3+} ions. The lowest $4f^{n-1}5d^1$ energy levels for ions from Nd^{3+} to Yb^{3+} are at even higher energies and therefore in the vacuum ultraviolet (VUV) spectral region. Thus the corresponding transitions are not easy to access spectroscopically. A systematic study and detailed analysis of the VUV spectroscopy of trivalent rare-earth ions were performed by Wegh et al. [11.93]. The exploitation of these VUV transitions for laser oscillation still requires much experimental efforts. Laser oscillation on a 5d→4f transition besides for Ce^{3+} has thus far only been realized with Nd^{3+}:LaF$_3$ at 172 nm with a Kr_2 laser at 146 nm as the pump source [11.87].

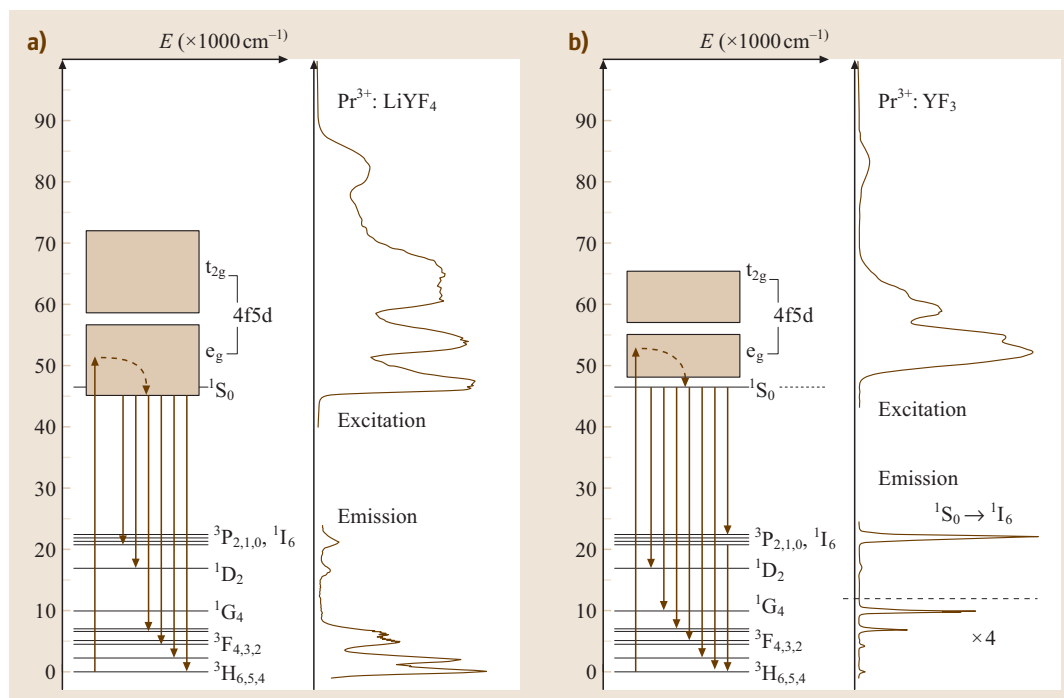
Divalent rare-earth ions. Rare-earth ions have a strong tendency to be incorporated into crystals in the trivalent state. In order to obtain the divalent state, the RE^{3+} ion needs to be reduced. Eu^{2+}, Yb^{2+}, Sm^{2+} and, with some limitations, Tm^{2+} can already be obtained in significant amounts during crystal growth by using suitable lattices containing divalent cation sites, appropriate codopants, and a reducing growth atmosphere. The other RE^{2+} ions


Fig. 11.32a,b Energy-level schemes of Pr^{3+} **(a)** Pr^{3+}:LiYF$_4$, E(4f^{1}5d^1) < E(^{1}S$_0$), **(b)** Pr^{3+}:YF$_3$, E(4f^{1}5d^1) > E(^{1}S$_0$). (After [11.94])

are rather difficult to obtain in crystals; usually special growth conditions as well as pre- and post-treatments are necessary, e.g., the use of sealed Ta ampoules during crystal growth, pre-synthesis of REF$_2$ and RECl$_2$, electron-beam irradiation etc.

5d→4f transitions are expected to occur for systems in which the 4f^{n-1}5d level is energetically located within a large energy gap between 4f^n multiplets. These ions are Sm^{2+}, Eu^{2+}, Tm^{2+}, and Yb^{2+}.

Sm^{2+} (4f^6). The 4f^6 energy-level scheme of Sm^{2+} is spectroscopically similar to that of Eu^{3+} (Fig. 11.29). For most crystals, Sm^{2+} emission occurs as a 4f^6 →4f^6 transition from the metastable ^{5}D$_0$ level, which is located at about 15 000 cm^{-1}. In CaF$_2$, the lowest 4f^{5}5d^1 level is located just below the ^{5}D$_0$ level and broadband emission occurs. Laser oscillation based on a 4f^{5}5d^1 →4f^6 transition was realized with Sm^{2+}:CaF$_2$ [11.91,92]. The laser wavelength is 708.5 nm at 20 K and increases with temperature to 745 nm at 210 K, which is the highest operation temperature of the Sm^{2+}:CaF$_2$ laser. This laser is affected by excited-state absorption assigned to transitions to the conduction band and to high-lying 4f^6 levels [11.95, 96].

Eu^{2+} (4f^7). The 4f^7 energy-level scheme of Eu^{2+} is spectroscopically similar to that of Gd^{3+} (Fig. 11.29). A large energy gap between the ^{8}S$_{7/2}$ ground state and the ^{6}P$_{7/2}$ first excited state exists. Depending on the crystal field strength, the lowest 4f^{6}5d^1 energy level is located above or below the ^{6}P$_{7/2}$ level. Therefore, either narrow line emission due to the ^{6}P$_{7/2}$ → ^{8}S$_{7/2}$ transition in the UV region or broadband emission due to the 4f^{6}5d^1 → ^{8}S$_{7/2}$ transition in the blue to yellow spectral range occurs. Laser oscillation based on a 4f^{6}5d^1 →4f^7 transition of Eu^{2+} has not been realized thus far due to excited-state absorption from the lowest 4f^{6}5d^1 level to the conduction band and to high-lying 4f^7 levels [11.96].

Tm^{2+} (4f^{13}). The 4f^{13} energy-level scheme of Tm^{2+} is spectroscopically similar to that of Yb^{3+} (Fig. 11.29). Laser oscillation of Tm^{2+} was realized in CaF$_2$ on the ^{2}F$_{5/2}$ → ^{2}F$_{7/2}$ transition at 1116 nm at temperatures below 27 K [11.97,98] (Table 11.9). Laser oscillation based on the 4f^{12}5d^1 → 4f^{13} transition has not been obtained thus far. However, Tm^{2+} is an interesting candidate for laser oscillation on a 4f^{12}5d^1 → 4f^{13} transition, because there are no high-lying 4f^{13} energy levels, which could interfere with the 4f^{12}5d^1 energy levels and thus act as

possible terminal levels for excited-state absorption transitions or quenching processes. The transition between the lowest $4f^{12}5d^1$ level and the ground state is parity allowed, but spin forbidden. Thus the emission cross sections are expected to be about one to two orders of magnitude smaller compared to, e.g., those of the $5d \rightarrow 4f$ transitions of Ce^{3+}. The $Tm^{2+} \rightarrow Tm^{3+}$ conversion observed under UV/VIS lamp excitation [11.98] indicates the strong tendency of the Tm ion towards the trivalent state and has to be considered as a possible major drawback for laser applications.

Yb^{2+} ($4f^{14}$). The ground-state configuration of the Yb^{2+} ion is $4f^{14}$. This completely filled shell leads to a $^1S_0$ ground state of the free ion and other $4f^{14}$ levels do not exist. In an octahedral crystal field, this state transforms like the $^1A_1$ irreducible representation. The excited $4f^{13}5d^1$ configuration consists in total of 140 energy levels. The $4f^{13}5d$ level splits in a highly symmetric crystal field into a threefold degenerated T_2 and a twofold degenerated E level. The $4f^{13}$ electrons can be considered as a Yb^{3+}-ion configuration with the two manifolds $^2F_{7/2}$ and $^2F_{5/2}$ separated by about $\Delta E_{4f} \approx 10\,000\,cm^{-1}$. The spin of the 5d electron can either be parallel or antiparallel to that of the $4f^{13}$ core, thus the whole energy-level scheme exists for singlet and for triplet states, from which, according to Hunds' rule, the triplet states are energetically lower. Note furthermore that for the Yb^{2+} free ion the 6s level is energetically lower than the 5d level. Therefore it might be the case that in some materials the $4f^{13}6s$ level is also the lowest excited state. This would lead to a parity- and spin-forbidden transition requiring $\Delta L = 3$ and $\Delta S = 1$. The emission spectra of Yb^{2+}-doped materials consists of a broad band ($\approx 6000\,cm^{-1}$) with the peak emission wavelength strongly dependent on the host material ($\lambda_{peak} \approx 390-575\,nm$) [11.99–103]. Laser oscillation has not been obtained thus far. The main reason is excited-state absorption. In Yb^{2+}:MgF_2 strong ESA transitions in the whole spectral range of absorption and emission are observed, preventing laser oscillation. The ESA cross section is about one order of magnitude larger than the absorption cross section and three orders of magnitude larger than the stimulated emission cross section [11.102, 103].

Lasers based on 4f ↔ 4f transitions of trivalent and divalent rare-earth ions

This section deals with UV and visible lasers based on the 4f↔4f transitions of trivalent and divalent rare-earth
Fig. 11.33 Energy-level scheme of the Pr^{3+} ion. The observed laser transitions in the visible spectral range are indicated by *arrows*

ions. Laser oscillation has been realized under flashlamp pumping, direct laser pumping into the upper laser level or higher-lying energy levels and under upconversion pumping.

Pr^{3+} *lasers.* The Pr^{3+} ion is a very interesting and promising ion for obtaining efficient visible laser oscillation. Its energy-level scheme is shown in Fig. 11.33.
Fig. 11.34 Emission spectra of Pr^{3+}:BaY_2F_8 at room temperature for different polarizations

Laser transitions in the visible spectral range occur from the $^3P_0$ and the thermally populated $^3P_1$ and $^3P_2$ levels. In Fig. 11.34 the emission spectrum of the Pr^{3+}:BaY_2F_8 as an example is shown. The peak cross sections are in the range of ≈ 1 to 5×10^{-19} cm^2 and thus comparable to the values of the Nd^{3+} $^4F_{3/2} \rightarrow {}^4I_{11/2}$ transition. The highest cross sections are in the orange and red spectral range, therefore the most efficient lasers are expected there. The first Pr^{3+} laser ($\lambda = 1047$ nm) was realized in CaWO$_4$ as early as 1962 by Yariv et al. [11.104]. Since then, laser oscillation has been obtained in more than 20 materials on several transitions and under different pumping conditions, see e.g., the review article by *Kaminskii* [11.105]. The major drawback of Pr^{3+} lasers is their excitation; see the discussion in section on Pr^{3+} laser.

Directly pumped Pr^{3+} lasers. In Fig. 11.35 the absorption spectrum of Pr^{3+}:BaY_2F_8 for the spectral range between 420 nm and 500 nm is shown. Direct pumping of the $^3P_0$ upper laser level is possible for several wavelengths in the blue spectral range corresponding to the $^3H_4 \rightarrow {}^3P_2$, $^3P_1$, $^3P_0$, and $^1I_6$ transitions. In principle the following pumping schemes for direct excitation are possible:

1. Ar$^+$-ion laser pumping. Ar$^+$-ion lasers offer the possibility of continuous-wave pumping with a high-quality pump beam. Therefore it allows the

characterization of a Pr^{3+}-doped laser material. For Pr^{3+}:LiYF$_4$, laser oscillation on several transitions has been obtained with slope efficiencies up to $\approx 26\%$ and output powers up to ≈ 270 mW [11.106] (Fig. 11.36). However, the wavelength match between the Ar$^+$ pump and Pr^{3+} absorption is bad (Fig. 11.35). Furthermore Ar$^+$-ion laser pumping itself is very inefficient, therefore the overall efficiency of a gas-laser-pumped Pr^{3+} laser is very low.

2. Pumping with a frequency-doubled Nd^{3+} laser operating on the $^4F_{3/2} \rightarrow {}^4I_{9/2}$ ground-state transition. These ground-state lasers operate, depending on the host material, between 910 nm and 960 nm, i.e., the frequency doubling yields wavelengths between 455 nm and 480 nm. A Pr^{3+} laser directly pumped by a frequency-doubled Nd^{3+}:YAG ground-state laser operating at 473 nm has been successfully demonstrated by *Heumann* et al. [11.107]. Pr^{3+} laser oscillation occurred at 639.5 nm on the $^3P_0 \rightarrow {}^3F_2$ transition with an output power of nearly 100 mW and a slope efficiency of 12%. Also for frequency-doubled Nd^{3+} ground-state lasers the match between the pump and absorption wavelength is crucial.

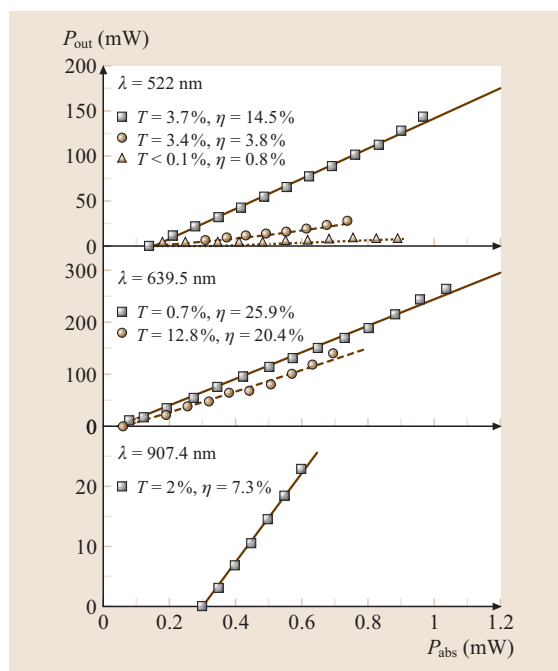
Fig. 11.35 Absorption cross section spectrum of Pr^{3+}, Yb^{3+}:BaY_2F_8 at room temperature. The relevant transitions are assigned. The possible pump laser wavelengths are also shown


Fig. 11.36 Input–output diagram of the CW Pr^{3+}:LiYF$_4$ laser at different laser wavelengths pumped by an Ar$^+$-ion laser at 457.9 nm. (After [11.106])

3. Frequency-doubled optically pumped semiconductor lasers (OPS). These lasers are commercially available with powers up to 200 mW [11.108]. In principle, the laser wavelength is adjustable (by choosing the material parameters of the semiconductor) and can be tuned to match the absorption line of the Pr^{3+} ion. Output powers of approximately 35 mW with slope efficiencies of approximately 30% have been obtained [11.109]. Furthermore, *Richter* et al. used an OPS operating at 480 nm as a direct pump source [11.110]. A slope efficiency of 40% and a maximum output power of 75 mW were obtained for Pr^{3+}:YLiF$_4$. For Pr^{3+}:BaY$_2$F$_8$, the corresponding data are 30% and 51 mW. It is worth noting that intracavity frequency doubling leads to continuous-wave UV radiation of about 19 mW for Pr^{3+}:YLiF$_4$ and Pr^{3+}:BaY$_2$F$_8$. Due to the multi-wavelength operation of Pr^{3+} lasers, UV generation at 360 nm, 303 nm and even 261 nm seems possible. These pump lasers are still expensive; however power scalability of OPS lasers can be expected making these pump sources very attractive for Pr^{3+}.

4. Blue and UV GaN laser diodes. These diodes operate thus far in the spectral region below 450 nm and with output powers in the mW range. Recently, *Richter* et al. obtained laser oscillation at room temperature with Pr^{3+}:YLiF$_4$ under pumping with a 442 nm GaN laser diode [11.35]. The Pr^{3+} laser emits 1.8 mW at 639.7 nm. The threshold pump power and slope efficiency were 5.5 mW and 24%, respectively. If the development of these diodes towards higher output powers proceeds, laser diodes will certainly be one of the best choices for the direct pumping of Pr^{3+} lasers.

5. Flashlamp pumping [11.111]. Under flashlamp excitation only a small fraction of the emitted radiation of the lamp can be used for the excitation of the Pr^{3+} $^3P_0$ level, because of the narrow line width of the Pr^{3+} absorption lines and of the small spectral range of these lines. Output energies up to 87 mJ and slope efficiencies of 0.3% have been obtained [11.111].

6. Dye-laser pumping. The pump laser wavelength is tunable and thus can be adjusted to match the absorption lines of the Pr^{3+} ion. Therefore, the obtained lasers exhibit a high efficiency. For Pr^{3+}:LiGdF$_4$ lasers, oscillation on several wavelengths and transitions with slope efficiencies up to 37% have been reported [11.112]. However, dye lasers are limited in their practical use.

Table 11.3 lists Pr^{3+} lasers operating in the visible spectral range under direct excitation. In Table 11.4 an overview of the room-temperature laser data for visible Pr^{3+} lasers is given.

Upconversion pumped Pr^{3+} lasers. Because of the difficulties of direct excitation, other pumping schemes using upconversion processes are under investigation for Pr^{3+} lasers. Upconversion describes a process in which the photon energy of the excitation light (pump light) is converted via interaction with the active ions inside the optical material into higher-energy photons [11.113–116]. For Pr^{3+} with its high-lying energy levels upconversion is a suitable way to obtain visible laser oscillation under infrared pumping. Especially the photon-avalanche pumping scheme, which is a combination of different upconversion and energy transfer processes, has been efficiently exploited for the Pr,Yb codoped system. For crystals the Ti:Al$_2$O$_3$ laser is mainly used as the excitation source, but investigations are being performed on the use of commercially available laser diodes. In fibers, efficient laser operation has already been achieved under laser-diode pumping (see page 633, Visible fiber lasers).

The principle scheme of the photon-avalanche process is shown in Fig. 11.37. A weak ground-state absorption yields the excitation of a few ions into the intermediate (*reservoir*) level. The strong ESA process efficiently brings these ions to the emitting level. An effective feedback mechanism for the reservoir level (in our system a cross-relaxation process) is necessary, which couples the emitting level, the reservoir level and the ground-state level. After these two steps there are two ions in the reservoir level. This cycle repeats and thus the population of the emitting (upper laser) level increases like an avalanche. If the threshold population is reached, the laser oscillation on any transition from the upper laser level may start. The general characteristics are described in detail in [11.113, 114, 117–119]; here only the main points are given for the example of Pr^{3+}, Yb^{3+}:BaY$_2$F$_8$ [11.120, 121]. The pump-power dependence of the emission intensity exhibits a threshold-like behavior. At this threshold, the slope increases significantly. A second characteristic of the avalanche mechanism is the temporal *S*-shaped evolution of the upconverted emission (Fig. 11.38).

The photon-avalanche process has already been observed in a variety of materials, see e.g. [11.113, 114]. However, laser oscillation has only been obtained in a few materials, see Table 11.5 for Pr^{3+} systems and Table 11.6 for other rare-earth-ion-doped systems. The

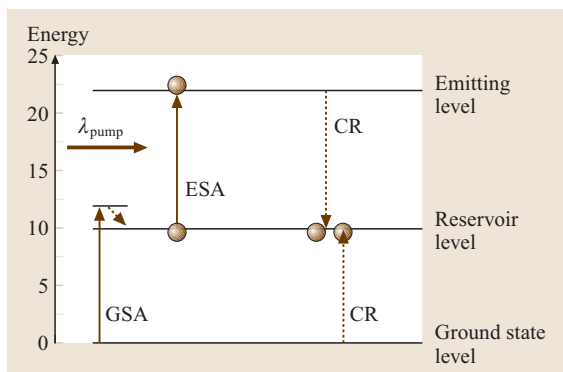

Fig. 11.37 Scheme of the photon-avalanche process (GSA: ground-state absorption, ESA: excited-state absorption, CR: cross-relaxation)

reason is that there exist special requirements for an efficient avalanche process; its efficiency depends strongly on the transfer rates between the ions, the ground- and excited-state absorption cross sections, the ionic concentration, the emission branching ratios and the lifetimes of the energy levels involved. In principle it is possible to describe the photon-avalanche excitation mechanism for Pr,Yb-doped systems with rate equation systems [11.113, 114, 117, 118, 120]. However, due to its complexity, it is not possible to predict the overall efficiency solely from knowledge of the spectroscopic parameters.

In Table 11.5 an overview of photon-avalanche pumped Pr^{3+} laser systems is given. Room-temperature avalanche-pumped laser oscillation in bulk crystals was

obtained for the Pr^3, Yb^{3+} codoped system, a so-called sensitized photon avalanche, in $YLiF_4$ (YLF) [11.156–158] and BaY_2F_8 (BYF) [11.121]. The principle scheme of the Pr-Yb system is shown in Fig. 11.39 [11.159–163]. The excitation around 840 nm corresponds to a very weak ground-state absorption process (very probable into a phonon tail of the Yb^{3+} absorption), followed by energy transfer (process r in Fig. 11.39) from Yb^{3+} to Pr^{3+} $(^2F_{5/2}, {}^3H_4) \rightarrow (^2F_{7/2}, {}^1G_4)$. The ESA process $(^1G_4 \rightarrow (^1I_6, {}^3P_1))$, followed by fast phonon de-excitation $[(^1I_6, {}^3P_1) \rightarrow {}^3P_0]$ feeds the ${}^3P_0$ level (i.e., the emitting level). The cross-relaxation process s $(^3P_0, {}^2F_{7/2}) \rightarrow (^1G_4, {}^2F_{5/2})$ followed again by the transfer process r re-feeds the reservoir level. In this way, at each step, an increase of the population in the $^1G_4$ level is obtained and consequently a strong population will be build up in the ${}^3P_0$ level (because of the strong $^1G_4 \rightarrow (^1I_6, {}^3P_1)$ ESA process). The upconverted emission excitation spectrum and the excited-state absorption spectrum are shown in Fig. 11.40 indicating the good match between these two spectra. The peak excited-state absorption cross section of the $^1G_4 \rightarrow (^1I_6, {}^3P_1)$ transition is about 1.5×10^{-19} cm^2.

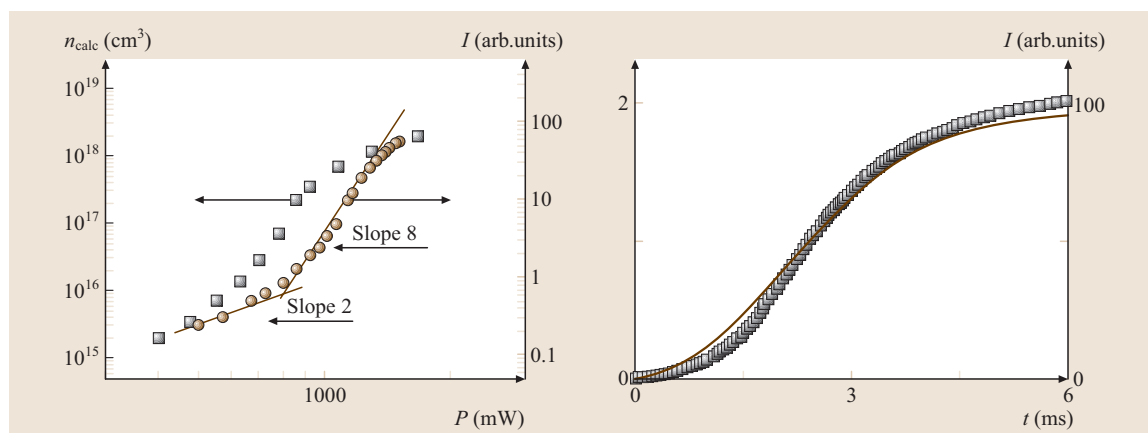
The laser input–output curves for Pr,Yb:YLF and Pr,Yb:BYF under Ti:sapphire pumping are shown in Fig. 11.41; the results are summarized in Table 11.5. The realization of diode pumping using commercially available infrared laser diodes is under investigation in several research groups. However, at the moment ion-doped fibers as materials for upconversion and avalanche pumped lasers are more efficient, because they allow waveguiding of both the pump and the laser beam.


Fig. 11.38 Characteristics of the photon-avalanche excitation mechanisms. *Left*: pump-power dependence of the upconverted emission intensity (experiment, *open circles*) and ${}^3P_0$ population (calculated, *filled squares*). *Right*: temporal evolution of the upconverted emission intensity (*solid line*: experiment, *squares*: rate equation model). Therefore high pump intensities over a long distance are possible, increasing the overall efficiency of the avalanche pumping mechanism, see the section on visible fiber lasers in Sect. 11.2.2.

Er^{3+} *lasers.* The problem for the realization of directly pumped visible Er^{3+} lasers is the lack of efficient pump sources that have a good spectral match to the absorption lines of the Er^{3+} ion. Therefore most visible Er^{3+} laser schemes have been realized by upconversion pumping in the near-infrared spectral range, as shown in Fig. 11.42. Table 11.7 summarizes a few results of direct pumping of Er^{3+} obtained with Xe lamps and a dye laser.

The energy-level schemes of Erbium-doped crystals such as $LiYF_4$ and $LiLuF_4$ [11.127, 128] offer the feasibility of realizing an upconversion laser emitting in the green spectral region ($^4S_{3/2} \rightarrow {}^4I_{15/2}$ transition). As shown in Fig. 11.42 the upconversion excitation of the upper laser level $^4S_{3/2}$ requires sequential two-photon absorption (STPA) either at 810 nm or 970 nm. With a pump wavelength of 810 nm, the ground-state absorption (GSA) $^4I_{15/2} \rightarrow {}^4I_{9/2}$ is followed by nonradiative decay to the $^4I_{11/2}$ level. From there, population is taken to the $^4F_{5/2}$ level by excited-state absorption (ESA). Finally, the $^4S_{3/2}$ level is populated by nonradiative decay. With a pump wavelength around 970 nm, the upconversion excitation scheme of the upper laser level is very similar, however, it involves the GSA process $^4I_{15/2} \rightarrow {}^4I_{11/2}$ and the ESA process $^4I_{11/2} \rightarrow {}^4F_{7/2}$.

Using a Ti:sapphire laser for excitation, various rare-earth-doped fluoride crystals have shown room-temperature CW upconversion lasing in the visible spectral range, e.g., Er^{3+}:$LiYF_4$ [11.181] and Er^{3+}:$LiLuF_4$ [11.182]. Diode pumping of a green erbium-doped upconversion laser in Er^{3+}:$LiLuF_4$ [11.183] and in the mixed fluoride crystal Er^{3+}:$LiKYF_5$ [11.184] has been demonstrated. In the latter case, however, laser operation could only be achieved under chopped excitation with a duty cycle of 20%.

Table 11.8 presents an overview Er-based upconversion lasers in different crystals and at various wavelengths.

Besides $YAlO_3$ most of the interesting candidates are fluorides, due to their relatively small phonon energies and correlated long lifetimes of intermediate states. Rare-earth-doped $LiLuF_4$ exhibits a larger splitting of the manifolds by the crystal field compared to $LiYF_4$ and $LiGdF_4$, which tends to produce more-favorable thermal occupation factors of both the upper and lower laser levels [11.185, 186]. A reasonable overlap between GSA and ESA enables two-step excitation to the $^4S_{3/2}$ level of Er^{3+} using just a single pump wavelength. The emission cross section σ_{em} at 552 nm (π polarization) is $\sigma_{em} = 3.5 \times 10^{-21}$ cm^2. This value as well as the GSA cross sections around 970 nm are slightly larger than the corresponding cross sections in Er^{3+}(1%):$LiYF_4$. The lifetime τ of the upper laser level $^4S_{3/2}$ $[\tau(^4S_{3/2}) = 400 \, \mu s]$ is slightly longer in $LiLuF_4$ than in $LiYF_4$.

A multipass pumping setup has been used in order to increase the absorbed pump power (Fig. 11.43). Both end faces of the 1.6 mm-long Er^{3+}(1%):$LiLuF_4$ crystal have been prepared with directly coated dielectric mirrors [11.183]. One of these mirrors is highly trans-
Fig. 11.41 Input–output curves of Pr,Yb:YLF [11.157, 158] (*left*) and Pr,Yb:BYF (*right*) under avalanche pumping with a Ti:sapphire laser

mitting for the pump wavelength and highly reflecting for the laser wavelength, while the other mirror is highly transmitting for the laser wavelength and highly reflecting for the pump wavelength (Fig. 11.43, coatings L and P, respectively). An additional concave mirror with a hole drilled slightly off axis is used to realize up to four passes of the pump radiation through the active volume of the laser crystal. The collimated pump beam

Fig. 11.42 Energy-level scheme of Er^{3+}:LiLuF$_4$ [11.127, 128] with two possible upconversion excitation routes of sequential two-photon absorption (STPA) at 810 nm or 970 nm [11.182, 183] and emission at 552 nm

is focused through the mirror hole into the crystal. With respect to single-pass pumping significant improvement of the performance of the Er^{3+}:LiLuF$_4$ upconversion laser could be achieved under Ti:sapphire laser excitation by using this setup. The maximum CW output power was 213 mW at an incident pump power of 2.6 W. The slope efficiencies with respect to incident and absorbed pump power were 12% and 35%, respectively. When replacing the Ti:sapphire laser by a 3 W diode, it was possible to realize laser-diode-pumped CW operation of this erbium-doped upconversion laser at room temperature for the first time [11.183]. The maximum output power was 8 mW at an incident pump power of 2.5 W. The absorbed power under four-pass pumping was small and estimated to be between 10% and 12%. The slope efficiency with respect to the absorbed pump power was 14%. Pumped with an optically pumped semiconductor laser operating at 970 nm, continuous-wave laser oscillation at 550 nm with Er^{3+}:LiLuF$_4$ has been achieved with an output power of 500 mW and a slope efficiency of about 30% [11.127, 128, 182, 183].

Other 4f–4f divalent and trivalent rare-earth ion lasers. Besides visible lasers based on 4f–4f transitions of Pr^{3+} and Er^{3+} several other lasers with 4f–4f transitions in the visible spectral region have been realized as shown in Table 11.6. When compared to Pr^{3+} and Er^{3+} lasers, the laser performance of all listed systems in Table 11.6 is worse. However, at least the upconversion pumped Tm^{3+} and Ho^{3+} lasers seem to have some potential for improvement of laser performance in the visible spectral region.

Table 11.8 Visible Er^{3+} lasers (ETU: energy transfer upconversion, STPA: sequential two-photon absorption, CT: cooperative transfer, PA: photon avalanche, CW: continuous wave, p: pulsed, SP: self-pulsed, QS: Q-switched, ML: mode-locked, IR-fl: infrared flashlamp, OPS: optically pumped semiconductor, RT: room temperature)

Blue upconversion laser emission in Tm-doped crystals can be achieved with STPA pumping. The energy levels and upconversion pump mechanisms in Tm^{3+} are illustrated in Fig. 11.44.

Figure 11.44a shows a pure STPA-pumped upconversion laser scheme, whereas in Fig. 11.44b, upconversion pumping also requires an additional cross-relaxation step between two Tm^{3+} ions. This cross-relaxation process populates the intermediate $^3F_4$ state which is the starting level for the second step of the STPA process.

In sensitized upconversion lasers a donor ion D (the sensitizer) absorbs the pump light and transfers its excitation energy to an acceptor ion A. In many cases Yb^{3+} has been used as the donor D for trivalent rare-earth-ion activators A. Through an upconversion energy transfer (ETU), two donor ions transfer their excitation energy successively to an acceptor. Finally the excitation energy of the donor is higher than the energy of an excited Yb^{3+} ion.

Figure 11.45 shows a system with $D = Yb^{3+}$ and $A = Tm^{3+}$. In this case a three-step STPA process is also possible, yielding a variety of laser transitions in the visible region.

Figure 11.46 illustrates the STPA and ETU upconversion mechanisms in Ho^{3+} and in the donor–acceptor system Yb^{3+}–Ho^{3+}. Laser emission can be generated near 750 nm and 550 nm, originating from the metastable $^5S_2$, $^3F_4$ states.

It can be seen in Table 11.6 that, besides STPA and ETU pumping, photon avalanche (PA) pumping has also been used in a few cases (Nd^{3+} and Tm^{3+}).

In Table 11.9 other rare-earth-ion lasers in the visible spectral range based on 4f–4f transitions are listed. The data are taken from [11.213].

Visible fiber lasers

A different and very promising approach to realize efficient upconversion room-temperature laser oscillation is the use of rare-earth-ion-doped fibers. The geometry of the fiber provides waveguiding of both the pump radiation and the stimulated emission, thus long interaction lengths can be realized, yielding high intensities over a long distance, a critical requirement for upconversion lasers. This is one advantage of the fiber concept (for a detailed description of the fiber concept, see the description of Yb fiber lasers in Sect. 11.2.2) compared to bulk materials. Another requirement for visible upconversion lasers is the existence of metastable intermediate levels to act as initial levels for an excited-state absorption or an energy transfer process. Like in crys-

tals, fluoride materials are preferred because of their low phonon energies and generally larger bandgaps. The fiber material of choice is the fluorocirconate glass ZBLAN ($ZrF_4 - BaF_2 - LaF_3 - AlF_3 - NaF$). Another advantage of fibers compared to bulk crystals is that the transitions in glass are broadened and therefore the possibility for resonant transitions or energy transfer is enhanced. An overview of visible fluoride fibers is given in [11.214].

Nearly all rare-earth-ion-doped fluoride fiber lasers can be pumped in the $0.63-1.2\,\mu m$ region and thus take advantage of the mature semiconductor technology, e.g., AlGaInP ($0.63-0.69\,\mu m$), GaAlAs ($0.78-0.88\,\mu m$) and InGaAs ($0.90-1.2\,\mu m$) and of the highly developed solid-state laser technology, e.g.,

Nd^{3+} and Yb^{3+} lasers in the near-infrared spectral region.

Visible Pr^{3+} fiber lasers. As in crystals, the praseodymium ion is very attractive for visible fiber lasers because of its energy-level scheme (see Fig. 11.33) and the possibility of upconversion pumping by two-step absorption, photon avalanche or energy transfer processes. Laser oscillation at room temperature has been achieved in the red, orange, green and blue spectral ranges. Some of these transitions have even been operated simultaneously [11.223]. Laser oscillation at room temperature originates from the $^3P_0$, $^3P_1$ and $^1I_6$

levels, which are thermally coupled. In Pr^{3+}:ZBLAN, the lifetime of these coupled multiplets is in the range $40-50\,\mu s$ [11.224, 225]. Recently, *Richter* et al. obtained

laser oscillation of a Pr^{3+}-doped ZBLAN fiber under direct pumping with a blue semiconductor laser [11.226]. Output powers of 94 mW and a slope efficiency of 41.5% at 635 nm were obtained.

In Table 11.10 the results to date with Pr^{3+}-doped ZBLAN fibers are summarized. The best results obtained thus far, at the most efficient wavelength of 635 nm, are output powers up to 2 W and slope efficiencies up to 45% [11.234]. The efficiencies in the green and blue wavelength regions are about one order of magnitude smaller.

Generally, a double-clad fiber can be used to couple highly divergent pump radiation of near-infrared high-power laser diodes into the large-numerical-aperture inner cladding and propagate it along the fiber axis. On its way down the fiber, the pump radiation is gradually absorbed in the embedded small-numerical-aperture active core. Since the number of transverse radiation
Fig. 11.47 Experimental setup of the Pr^{3+},Yb^{3+}-doped up-conversion ZBLAN fiber laser [11.162]. M1 denotes the dichroic mirror, C1 an aspheric lens, M2 the dielectric resonator mirror, and C2 a collimator

modes supported in a cylindrical fiber core depends only on the wavelength of the radiation, the core diameter, and its numerical aperture, the geometry and material of the active fiber core can be chosen to support just one or a few transverse modes of the radiation generated in the active core by near-infrared pumping. Thus, an upconversion double-clad fiber with a suitably chosen rare-earth-ion-doped active core can be used to convert the highly multimode radiation of high-power near-infrared laser-diode arrays into single-mode or few-mode visible laser emission with excellent beam quality. The best results in terms of upconversion laser output power, however, have been achieved when the pump radiation of a high-beam-quality laser source was launched directly into the active core of the described fiber. This is due to the high pump intensities required locally for photon-avalanche upconversion, which can

Fig. 11.48 Input–output characteristics of the Pr^{3+},Yb^{3+}-doped up-conversion ZBLAN fiber laser [11.162]

be best provided by diffraction-limited pump radiation focused onto the fiber end face and guided in the rare-earth-ion-doped active core.

For example, Fig. 11.47 shows a demonstration of high-power upconversion laser operation under pumping with two dichroic coupled Ti^{3+}:Al_2O_3 lasers tuned to pumping wavelengths near 850 nm [11.162]. The maximum upconversion-laser output power was 1020 mW at an incident near-infrared total pump power of 5.51 W (Fig. 11.48). The overall slope efficiency with respect to the incident pump power was 19% [11.162].

Also, near-infrared high-power diode-laser bars with beam-shaping optics have been used to pump a Pr^{3+},Yb^{3+}-doped ZBLAN fiber with the common single-clad structure and a large-area multimode active core. In this case, 4.5 W of pump power were launched into the fiber core, generating red output powers in excess of 2 W at 635 nm [11.234]. In the blue spectral range, a Pr^{3+},Yb^{3+}-doped ZBLAN-based upconversion fiber laser has been demonstrated at an emission wavelength of 491 nm ($^3P_0 \rightarrow {}^3H_4$ transition of Pr^{3+}). The pump source was a single-mode diode laser emitting at a wavelength of 840 nm. The maximum blue output power was 8 mW at an incident pump power of 200 mW [11.236].

Other visible fiber lasers. Laser oscillation in the visible spectral range has also been obtained with other rare-earth ions in ZBLAN. In Table 11.11 an overview of these laser systems is given. A detailed description of these systems and their prospects is given in [11.214].

11.2.3 Near–Infrared Rare Earth Lasers

Nd lasers
most intensively investigated class of solid-state lasers is based on Nd^{3+}-ion-doped materials. The Nd^{3+}-ion offers various groups of laser lines in the near-IR spectral region.

Energy–level scheme. Figure 11.49 shows transitions from the $^4F_{3/2}$ upper laser level into the $^4I_{13/2}$, $^4I_{11/2}$, and $^4I_{9/2}$ manifolds. The specific absorption and emission wavelengths depend on the crystal field, which influences the splitting within a manifold and between different manifolds. As shown in Fig. 11.49 the splitting between the ^4I (and also between ^4F) manifolds is dominated by LS coupling of the 4f electrons and is only affected to second order by covalency effects caused by the crystal field. The energetic splitting between the ^4F

and ^4I levels is dominated by Coulomb interaction of the 4f electrons, which is also only effected to second order by covalency effects of the crystal field. Therefore, the transition wavelengths of Nd-doped crystals vary in a certain range near the values given for Nd:$Y_3Al_5O_{12}$ (Nd:YAG) in Fig. 11.49. The strongest and most commonly used laser transition $^4F_{3/2} \to\, ^4I_{11/2}$ emits near 1060 nm (Fig. 11.49).

Figures 11.50 and 11.51 show as an example the absorption and emission spectra of Nd:YAG, measured at 300 K. The strongest absorption is located near 808 nm and the strongest laser transition at 1064 nm.

Longitudinal and transversal diode pumping. Nd lasers are usually pumped by lamps or diode lasers. The first generation of Nd-doped solid-state lasers were pumped with CW krypton or pulsed xenon lamps. These lamps have high electrical-to-optical efficiencies of about 70% and are available at reasonable costs. Unfortunately, the overlap of their emission spectra with the narrow 4f–4f absorption spectra of Nd-doped solid-state laser materials is usually poor; thus the electrical to optical pump efficiency is low – typically a few percent.

In modern Nd lasers, diode lasers at 808 nm are employed as pump sources. Laser diodes typically have efficiencies of about 50% and offer several advantages over lamp pumping. Diodes emit spectrally narrow-band radiation ($\approx 1–5$ nm). Therefore, a much better overlap with the 4f–4f absorption spectra of Nd can be achieved.

Because of the good spectral match, the total pump efficiency of diode pumping is much higher than for lamp pumping. In addition the transfer efficiency of pump light into the crystal is much better in the case of diode pumping, so that a total efficiency of 10% to 30% for the conversion of electrical power into laser power is achievable.
Fig. 11.49 Level scheme, pump and laser transitions of Nd^{3+} in YAG
Fig. 11.50 Absorption spectrum of Nd(1%):YAG and absorption cross sections

The selective spectral pumping with diodes also leads to reduced heat deposition in the laser crystal with reduced thermal lensing effects, giving rise to improved beam quality. Diffraction-limited beams can be realized easier.

However, there are also disadvantages of diode lasers. Because of their small active laser cross-sectional area and their relatively large refractive index, laser diode beams have a large divergence. Their beams also possess large beam-quality differences in the transversal and sagittal directions since the active area dimensions are usually $\approx 1\,\mu m \times 100\,\mu m$ and confinement is given only in one dimension. For power scaling, bars or arrays of diodes must be used. This can lead to output powers of up to several tens of watts. Unfortunately, combination of many single diode stripes also broadens the emission spectrum, while the beam quality of the combined radiation is further decreased. So, sophisticated pump optics such as beam shaping must often be employed [11.265].

Several pump geometries can be used with diode laser excitation. The common geometry to pump lasers, which are capable of generating several watts of output power with excellent beam quality, is end pumping (Fig. 11.52). In this geometry, pump radiation is focused into the laser crystal along the laser resonator axis. A very good overlap of pump and laser modes can be provided. Gain media of small volume and with short absorption lengths can be used, and high population inversions at low pump power levels can be achieved. Because most of the pump power is deposited within the volume of the TEM_{00} laser mode, higher-order modes usually cannot oscillate. Excellent beam quality is therefore inherent. However, scaling of end-pumped lasers to output powers above 20 W is difficult to achieve due to
Fig. 11.51 Emission cross section spectra of Nd:YAG

possible thermally induced fracture of the laser crystal within the small volume of pump absorption.

An alternative diode pumping method is side pumping (Fig. 11.53, [11.266]). In this approach, the pumping geometry is principally similar to the arrangement for lamp pumping. One or several linear pump diode bars are positioned around the side surface of the laser crystal. Pump radiation is then usually imaged into the crystal perpendicular to the laser resonator axis. The crystal is relatively homogeneously pumped throughout its total volume, and a smaller excitation density is usually realized than in diode laser end pumped systems. Because of the use of larger gain media, however, more energy can be deposited into the laser crystal and therefore higher output powers can be achieved. Since a larger laser mode is present inside the crystal, higher-order modes also usually oscillate in these lasers. Therefore beam quality is often rather low.

Nd-doped fiber lasers can also be operated in specific configurations, see for example [11.267–278], and are used in many applications. For high-power laser generation, double-clad fibers are usually used. Basic aspects are described below in this chapter (page 650/651).

The most important Nd *lasers.* The most important Nd-doped laser materials feature relatively high emission cross sections, a relatively long upper-state lifetime of Nd^{3+}, a high damage threshold, high mechanical and chemical stability, good thermal conductivity and very good optical quality, see Table 11.12. Many host crystals have been investigated, including yttrium aluminium garnet (YAG), yttrium aluminium perovskite (YAP or YALO), yttrium lithium fluoride (YLF) and yttrium vanadate (YVO). Very efficient and compact diode-pumped lasers with slope efficiencies of over 60% have been demonstrated in many Nd-doped laser materials.

Nd:YAG is still regarded as the most important solid-state laser. Due to their very good optical and mechanical properties, diode-pumped Nd:YAG lasers are robust and reliable. They are in use in many applications. Within the last few years Nd:YAG have also become available as ceramics with high optical quality.

The vanadates Nd:YVO and Nd:GVO emit polarized radiation and exhibit large cross sections and gain.

Nd *laser wavelength and materials.* A variety of Nd lasers have been reported so far. Tables 11.13, 14, 15 list laser materials and their laser wavelengths which have been observed at 300 K on the transitions $^4F_{3/2} \rightarrow {}^4I_{9/2}$, $^4I_{11/2}$ and $^4I_{13/2}$. The tables also list Nd-doped ceram-
Fig. 11.52 Diode end-pumping scheme

ics, which have been developed with very good optical quality and low scattering losses. So, the efficiency of ceramic lasers can be as high as for crystals.

If not specified otherwise, the references for the laser materials can be found in [11.213].

Yb lasers
Coherent oscillation of Yb^{3+} was first observed in YAG at 77 K [11.279]. In 1991 the first realization of a diode-pumped Yb:YAG laser [11.280] at room temperature initialized an intensive renaissance of research on Yb-doped laser materials for laser diode pumping at 300 K. Yb^{3+}-doped solid-state lasers feature several important advantages compared with other rare-earth lasers:

1. Yb^{3+} ions have only two states, the ground state $^2F_{7/2}$ and the excited state $^2F_{5/2}$, which are separated by an energy of about $10\,000\,cm^{-1}$. Thus, there is no excited-state absorption of the pump and laser radiation (Fig. 11.54).
2. The quantum efficiency of Yb^{3+} is close to unity.
Fig. 11.53 Diode side (transversal) pumping scheme [11.266]

Table 11.12 Important host materials for Nd^{3+} [11.285]

Host	YAG	YAlO (FAP)	YVO	GVO	YLF

[a] The published data of heat conductivities of the vanadates YVO and GVO differ considerably [11.281–284]

3. Due to the small Stokes shift and the related small quantum defect (typically $500\,cm^{-1}$) heat generation in the lasing process of Yb^{3+} is small and makes it a suitable ion for high-average-power lasers.
4. The small ionic radius of Yb^{3+} compared to that of other rare-earth ions favors its incorporation into Y-based host crystals such as YAG, allowing higher dopant concentration and thus shorter gain elements such as discs.
5. Yb^{3+} ions exhibit a relatively broad emission band which leads to tunability and the generation of ultrashort pulses.
6. The radiative lifetime of the laser level ranges in different crystals from a few hundred microseconds to a few milliseconds, which implies greater energy storage efficiency, especially for Q-switched operation with diode pumping.

One disadvantage of Yb^{3+}-doped lasers is that they operate in a quasi-three-level scheme with temperature-dependent reabsorption at the laser wavelength. This leads to an increased threshold compared to a four-level scheme, because the pump must bleach the reabsorption losses (see the section on basic spectroscopic properties in Sect. 11.2.1).

Figures 11.55 and 11.56 show as an example the absorption and emission cross section spectra of Yb:YAG [11.286]. When pumped near the absorption

peaks at 940 nm or 970 nm, the Stokes shift to the lasing wavelength at 1030 nm corresponds to less than 10%, which allows in principle a slope efficiency of more than 90%.

Yb^{3+} *thin-disc lasers*. In connection with the power scaling of diode-pumped Yb lasers *Giesen* et al. [11.310] invented the thin-disc laser concept as a pump and resonator design for high-power lasers (Fig. 11.57).

The active medium is a thin circular disc, which is coated for both the pump and laser wavelengths with a highly reflecting (HR) dielectric mirror on the rear side and with an antireflection coating on the front side. The disc is then bonded with the rear HR side to a heat sink. The resonator is formed by the coated crystal and an output coupler. The pump light is provided by fiber-coupled laser diodes which are focused onto the crystal. Since the thin crystal disc only absorbs a small fraction of the pump light during one pass through the crystal, the pump light is reflected back into the disc several times by a parabolic mirror and the folding prism [11.311]. Up to a total of 32 pump light passes may be used.

Due to the geometrical setup a nearly one-dimensional thermal gradient along the laser axis can

be reached within the crystal. This setup minimizes the formation of thermal lenses, and therefore yields better beam quality at high powers compared to a rod laser. Multiple passes of the pump radiation through the crystal increase the absorption efficiency and also the effective pump power density in the crystal. Therefore, the thin disc design is suitable for quasi-three-level systems such as Yb^{3+}. Figure 11.58 shows the input versus output power of a thin-disc Yb:YAG laser [11.311]. CW output

powers in the kilowatt range from one disc are possible. Further power scaling with several discs in the cavity is also possible [11.311].

Yb *fiber laser.* Fiber lasers present another approach for the generation of high powers with diffraction-limited beam quality. Since the introduction of the double-clad fiber more than two decades ago and with the recent technological advances in the fields of fiber fabrication and beam-shaped high-power diode lasers, the performance of diode-pumped fiber lasers has dramatically improved. Today, fiber lasers can compete with their corresponding bulk crystalline systems in certain applications, especially when fundamental-transverse-mode continuous-wave (CW) laser operation at output powers in the milliwatt to kilowatt range is required.

Basic aspects of fiber lasers. The invention of the double-clad fiber geometry and the holey fiber concept has accelerated the scaling of the output power and hence the success of high-power Er, Nd and Yb fiber lasers. For more-detailed reading a comprehensive introduction to the field of rare-earth-doped fiber lasers can be found in [11.388].

The choice of the fiber material involves a number of considerations: The maximum phonon energy, environmental durability, the drawability and the rare-earth solubility. The maximum phonon energy of the glass sets the overall infrared transparency range of the fiber and the multiphonon relaxation rates that influence the quantum efficiency of radiative electronic transitions by nonradiative decay. The important physical properties of the popular glasses used for optical fibers are shown in Table 11.16.

- Silicate glass. This glass is the most important material used for optical fiber production [11.388, 389]. However, the maximum phonon energy is high ($\approx 1100 \, \text{cm}^{-1}$) and has so far limited the emission wavelength for infrared fiber lasers using this material to approximately $2.2 \, \mu\text{m}$ [11.390]. Silica is robust and fibers fabricated from this material involve the very effective modified chemical vapor deposition (MCVD) technique. Reducing the OH^- content in the glass, which has two main absorption peaks in the range $1.3–2.0 \, \mu\text{m}$, reduces the background absorption of fibers [11.391].
- Fluoride glass. These glasses, especially the heavy-metal fluorides [11.392, 393], are used as host materials for mid-infrared fiber lasers. The most widespread fluoride fiber material is ZBLAN [11.394] with a mixture of 53 mol % ZrF_4, 20 mol % BaF_2, 4 mol % LaF_3, 3 mol % AlF_3, and 20 mol % NaF. Since it can be readily drawn into single-mode optical fiber [11.395] it is particularly important to mid-infrared fiber lasers [11.396] and allows for high infrared transparency up to $\approx 6 \, \mu\text{m}$. Nonradiative decay by multiphonon relaxation, however, becomes significant for transitions at wavelengths longer than $\approx 3 \, \mu\text{m}$. In addition to mid-infrared applications, ZBLAN is mostly also used for upconversion fiber lasers which need metastable intermediate pump levels with low multiphonon relaxation rates. An overview of the spectroscopic properties of rare-earth ions doped into ZBLAN is given in [11.397].
- Chalcogenide glasses. Chalcogenides are composed of the chalcogen elements S, Se and Te [11.398,
Fig. 11.54 Level scheme of Yb^{3+}: free-ion state (one 4f hole $4f_h^1$), electron–electron interaction (H_{ee}), splitting by spin–orbit interaction H_{SB}, and crystal field H_c. Pump and laser transitions are indicated by *arrows*

399]. When rare-earth ions are doped into these glasses [11.400], the radiative transition probabilities, and therefore the absorption and emission cross sections, are high as a result of the high (≈ 2.6) refractive index and the high degree of covalency of the glass. Small phonon energies of $300–450 \, \text{cm}^{-1}$ produce low rates of multiphonon relaxation for mid-infrared transitions. The low thermal conductivity (Table 11.16) is, however, an important factor
Fig. 11.55 Absorption spectrum of Yb:YAG at 300 K

to be considered in the design of chalcogenide-based lasers. So far, the most important glasses are the sulfide glasses GaLaS (GLS) [11.401] and GeGaS [11.402] because of the reasonably high rare-earth solubility.

Fiber, pump and resonator geometries. As bulk lasers, fiber lasers can be operated continuous wave, pulsed (including Q-switching) and mode-locked. These operation modes have been investigated intensively for the common laser transitions near 1 μm in Nd^{3+} and Yb^{3+}, and near 1.5 μm in Er^{3+}. However, the small fiber diameter limits the peak power by the damage threshold intensity and, hence, crystalline lasers in bulk geometries are mostly preferred when high-energy short pulses are needed. In an analogous way to the optical excitation of bulk gain media (see the section on longitudinal and transversal pumping in this Sect. 11.2.2), doped optical fibers can be either end pumped (core pumped) or side pumped

(cladding pumped). The former method is less scalable since it relies on the use of expensive high-beam-quality pump sources because core areas are usually $< 100 \, \mu m^2$. On the other hand, the larger cladding area ($> 10^4 \, \mu m^2$) allows for high-power diode-array pumping [11.408–411]. We will here describe the cladding-pumping technique, which is one of the most important developments in high-power fiber-laser technology.

- Fiber designs for cladding pumping. In the design of cladding pumping, the core of the fiber is generally made to guide a single transverse LP_{01} mode. The shape of the multimode pump cladding (Fig. 11.59), however, can be shaped with a number of geometries. The pump cladding, which in turn is surrounded by a low-refractive-index transparent polymer or glass, provides a high numerical aperture (NA) of typically 0.3–0.55. Photonic crystal structures can be also used to improve cladding pumping [11.412] for the operation of fiber lasers at the multi-hundred-watt level. There are three main double-clad-fiber layouts: circular, circular with offset core, and rectangular, as shown schemat-

Table 11.16 Properties of popular fiber materials

Fiber material	Max. phonon energy (cm^{-1})	Infrared transparency (μm)	Propagation losses (λ at minimum) (dB/km)	Thermal conductivity (W/Km)
Silica	1100 [11.403]	< 2.5	0.2 (1.55 μm)	1.38 [11.404]
ZBLAN	550 [11.397]	< 6.0	0.05 (2.55 μm)	0.7−0.8 [11.405]
GaLaS	425 [11.406]	< 8.0	0.5 (3.50 μm)	0.43−0.5 [11.407]

ically in Fig. 11.59. In the case of circular pump cladding [11.53] a portion of the launched pump light is skew to the fiber axis and produces an inner pump beam caustic that never crosses the core. Asymmetric configurations significantly improve the pump beam absorption in the core [11.413, 414]. Double-clad pump schemes have been demonstrated with holey or photonic crystal fibers [11.415]. In such fibers single-mode guiding and very large mode areas are possible [11.416].

- Fiber-laser resonators. Typical free-running fiber-laser resonators are shown schematically in Fig. 11.60. In the simplest resonator (Fig. 11.60a), the pump light passes through a dichroic mirror that is highly reflective for the oscillating laser light. Fresnel reflection at the cleaved output end facet of the fiber can provide sufficient feedback for laser oscillation, although with an output-coupler mirror at the output end of the fiber the optical efficiency can be maximized. In an alternative arrangement, the pump light can be launched into the output end of the fiber (Fig. 11.60b). In order to scale the output power, each end of the fiber can be pumped (Fig. 11.60c). Due to its geometry, the fiber provides potentially high pump- and signal-beam intensities without the
Fig. 11.59a–d Principal double-clad fiber geometries which include (**a**) circular-shaped pump cladding with axially positioned core, (**b**) circular-shaped pump cladding with off-axially positioned core, (**c**) rectangular-shaped pump cladding and (**d**) D-shaped pump cladding

drawbacks of significant thermal and thermo-optical effects. Its large surface-area-to-volume ratio means that the heat generated in the core is dissipated effectively by radiation and convection from the outer surface of the fiber.

High-power Yb fiber lasers. Yb-doped fiber-lasers have been operated at CW and average output powers in excess of 10 W [11.421–426], in excess of 100 W [11.427–433] and above 1 kW [11.434]. Also, a 30 μm Yb-doped large-mode-area fiber has been used for the amplification of Q-switched Nd:YAG pulses at repetition rates between 3 and 50 kHz with average output powers up to 100 W. Pulse energies as high as

4 mJ with diffraction-limited beam quality have been obtained in this case [11.435].

Yb^{3+} crystalline lasers. The properties and laser parameters of Yb:YAG are listed in Table 11.17. In the meantime, besides Yb:YAG, a lot of Yb-doped laser materials have been explored and tested in CW, Q-switched and mode-locked operation. Table 11.18 shows an overview of Yb-doped laser crystals.

Er lasers at 1.5 μm ($^4I_{13/2} \rightarrow {}^4I_{15/2}$)

For many years Er^{3+}-doped materials have been widely investigated for laser applications in the spectral range around 1.6 μm [11.436]. This laser transition ($^4I_{13/2} \rightarrow {}^4I_{15/2}$, see Er^{3+} energy-level scheme depicted in Fig. 11.61) is used for eye-safe lasers for medicine, telecommunication, remote sensing and light detecting and ranging (LIDAR). Suitable erbium-doped materials for the 1.6 μm laser transition should be at first characterized by a high phonon energy, which enables fast depopulation of the pump level $^4I_{11/2}$ via nonradiative decay in order to prevent excited-state absorption (ESA, $^4I_{11/2} \rightarrow {}^2H_{11/2}, {}^4S_{3/2}$) and upconversion [UC1, ($^4I_{11/2}, {}^4I_{11/2}) \rightarrow ({}^4I_{15/2}, {}^4F_{7/2})$] from the $^4I_{11/2}$ level and to populate efficiently the $^4I_{13/2}$ upper laser level (Fig. 11.61). The second important condition is that the ESA transition $^4I_{13/2} \rightarrow {}^4I_{9/2}$ should not spectrally overlap with the range of stimulated emission around 1.6 μm and that the upconversion process [UC2, ($^4I_{13/2}, {}^4I_{13/2}) \rightarrow ({}^4I_{9/2}, {}^4I_{15/2})$] is weak. Additionally, a significant splitting of the ground-state multiplet is advantageous to achieve a quasi-four-level system. These conditions are best fulfilled by Er^{3+}-doped glasses and fibers, which are to date the most efficient lasers at this transition. However, glasses suffer from poor thermal and mechanical stability, thus Er^{3+}-doped crystalline matrices are still being intensively investigated in order to find suitable crystals for this laser transition.

For most applications of Er^{3+}-doped laser materials, laser diodes operating in the wavelength range around 975 nm (the $^4I_{15/2} \rightarrow {}^4I_{11/2}$ transition) are used as a pump source, thus enabling all-solid-state laser systems. With Ti:sapphire pump lasers in general better laser results are obtained, however, the overall efficiency is low. Another possible pump wavelength lies around 1.5 μm, i.e., directly into the upper laser multiplet. However, for this wavelength region high-power laser diodes are not yet available, therefore usually Er–glass lasers as pump sources are used. In any case, the Er absorption at these wavelengths is rather small, because the absorption cross sections are in the order of 1 to 2×10^{-20} cm^2 (Figs. 11.62, 63). Doping levels higher than 1 to 2% are critical, because of increased reabsorption losses and higher rates for energy transfer processes, which depopulates the upper laser level ($^4I_{13/2}, {}^4I_{13/2}) \rightarrow ({}^4I_{15/2}, {}^4I_{9/2}$). Therefore, to keep the Er^{3+} concentration low but achieve higher absorption, the usual approach is to codope the Er^{3+}-doped laser material with Yb^{3+}, which can be very efficiently pumped around 975–980 nm. Then, the energy transfer process ($^2F_{5/2}, {}^4I_{15/2}) \rightarrow ({}^2F_{7/2}, {}^4I_{11/2}$) is exploited (Fig. 11.61). The main task for the optimization of Er lasers around 1.55 μm is thus to find the optimum concentration for both dopant ions.

Crystals. The absorption spectra of Er^{3+}:YVO$_4$ for the $^4I_{15/2} \rightarrow {}^4I_{11/2}$ and $^4I_{15/2} \rightarrow {}^4I_{13/2}$ transitions are shown in Figures 11.62 and 11.63, respectively [11.437]. The peak absorption cross section for the $^4I_{15/2} \rightarrow {}^4I_{11/2}$ transition around 970 nm is up to 2×10^{-20} cm^2, for the $^4I_{15/2} \rightarrow {}^4I_{13/2}$ transition around 1500 nm cross sections are higher, approximately up to 4×10^{-20} cm^2. The emission spectrum is shown in Fig. 11.63. The peak emission cross sections of the $^4I_{13/2} \rightarrow {}^4I_{15/2}$ emission in Er^{3+}:YVO$_4$ are up to 2×10^{-20} cm^2, in the long-wavelength tail, where the laser oscillation occurs, the peak cross sections are around 0.5×10^{-20} cm^2. These values are typical for Er^{3+}-doped crystals, e.g., the peak emission cross section around 1550 nm is 0.31×10^{-20} cm^2 for
Fig. 11.61 Energy-level diagram of Er^{3+} and Yb^{3+} in a YVO$_4$ crystal

Er:YAlO$_3$ [11.436], 0.33×10^{-20} cm^2 for Er:Y$_2$SiO$_5$ [11.438], 0.45×10^{-20} cm^2 for Er:YAG [11.436], 0.42×10^{-20} cm^2 for Er:YLF [11.436], and 0.59×10^{-20} cm^2 for Er:LaGaO$_3$ [11.439].

From the absorption and emission spectra the gain coefficient curves (Fig. 11.64) can be calculated by

$$g = N[P\sigma_{em} - (1-P)\sigma_{abs}] \,,$$

where N is the ion concentration and P is the inversion coefficient, defined as the ratio between the populations in the $^4I_{13/2}$ and the $^4I_{15/2}$ levels. It can be seen that for Er^{3+}:YVO$_4$ already for an inversion coefficient of $P \approx 0.2$ laser oscillation should be possible within a spectral range from approximately 1530 nm to 1610 nm.

In Fig. 11.65a the input–output characteristics of Ti:sapphire-pumped Er^{3+}:YVO$_4$ crystals with 0.5% Er and 1% Er doping, operating at 1604 nm, are shown. The slope efficiency with respect to the incident power is about 7–8%. It should be noted that with respect to the absorbed power the 0.5% Er:YVO$_4$ crystal exhibits a higher slope efficiency. This indicates that for the more highly doped sample (1% Er) the aforemen-

tioned loss mechanism of reabsorption and upconversion already take place. The laser threshold is below 200 mW of incident power and below 100 mW of absorbed pump power.

These values for the slope efficiency, the laser threshold and the output power are typical for well-performing Er^{3+}-doped crystals, such as for Y$_3$Al$_5$O$_{12}$ [11.533] and LaSc$_3$(BO$_3$)$_4$ [11.534].

Recently, high-power and ultra-efficient laser operation of an Er:YAG laser near 1645 nm with approximately 60 W [11.535–538] of output power was demonstrated using a high-power fibre laser at 1532 nm as a pump source (so-called in-band pumping (Fig. 11.65b). This work demonstrates that the small Stokes shift between the pump and laser radiation (1532 nm/1645 nm) yields very efficient Er lasers with slope efficiencies up to 80%.

In Table 11.19 an overview of crystalline room-temperature Er^{3+} lasers is given. Note that lasers on the $^4S_{3/2} \rightarrow ^4I_{9/2}$ transition are also listed.
Fig. 11.62 Polarized absorption spectra at room temperature of an Er^{3+}:YVO$_4$ crystal in the spectral range of the $^4I_{15/2} \rightarrow ^4I_{11/2}$ transition. (After [11.437])
Fig. 11.63 Spectra of absorption cross sections due to the $^4I_{15/2} \rightarrow ^4I_{13/2}$ transition of Er^{3+} in YVO$_4$ crystal (*dotted lines*) and emission cross sections ($^4I_{13/2} \rightarrow ^4I_{15/2}$) (*solid lines*) for σ and π polarization. (After [11.437])

Glass. Laser oscillation in Er^{3+}-doped and Yb^{3+},Er^{3+}-codoped silicate and phosphate glasses was investigated as early as the mid-1960s [11.539–541]. The three-level behavior of the Er^{3+} system and the weak absorption of pump radiation caused by the requirement of low dopant concentration (usually approximately 2 to 5×10^{19} cm^{-3}) makes it difficult to obtain efficient laser operation in singly Er^{3+}-doped glasses. Therefore, Yb^{3+} codoping is necessary in order to absorb the pump light efficiently at wavelengths around 1 μm. Continuous-wave laser oscillation, Q-switched [11.542, 543] and quasi-CW operation with pulse energies up to 35 J and average output powers up to 20 W have been obtained [11.544–548]. The pulse duration of the Xe flashlamps is several milliseconds, thus matching the upper-laser-level lifetime of the Er^{3+} $^4I_{13/2}$ level. Also laser diodes can be efficiently applied as pump sources. *Wu* et al. [11.549] used pulsed laser diodes in a transversal excitation scheme. Using a repetition rate of 50 Hz, a pump pulse duration of 2.5 ms and a peak pump power of ≈ 1.5 kW, an average output power of 8.5 W was obtained, corresponding to an output energy of 170 mJ per pulse. A comparison and discussion of different pumping schemes is given in [11.550]. In all experiments, the main problem of glass materials compared to crystals is the low heat conductivity (for Kigre QE7 0.82 W/mK [11.547] versus 13 W/mK for YAG). Thus, the introduced heating power and therefore also the extractable output power and/or repetition rate is limited and high-power continuous-wave excitation of Er^{3+}-doped glasses is difficult. Despite this, the overall performance of the Kigre QE7 and QX glasses is better than that of Er^{3+}-doped crystals. *Obaton* et al. [11.551] obtained a slope efficiency of 21% in a diode end-pumped setup for a QX glass. *Diening* [11.552] compared Kigre QE7 glass with Er^{3+}:LaSc$_3$(BO$_3$)$_4$ and $Y_3Al_5O_{12}$ in the same setup (Fig. 11.66). The achieved output power and slope efficiency for the QE7 glass are about twice as high as for Er^{3+}:LaSc$_3$(BO$_3$)$_4$.

Fig. 11.64 Gain coefficient curves derived for both polarizations for Er^{3+}:YVO$_4$ in the spectral range of the $^4I_{15/2} \rightarrow {}^4I_{11/2}$ laser transition for four values of the inversion parameter P (larger gain values for larger P). *Arrows* denote the wavelengths for which laser oscillation was realized. (After [11.437])

Fig. 11.65 (**a**) Input–output curve of the CW laser oscillation of Er^{3+} (0.5%):YVO$_4$ crystal ($\lambda_{laser} = 1604$ nm, output mirror transmission = 1%). The slope efficiencies are given with respect to the absorbed (η_{abs}) and incident (η_{in}) power. (Results from [11.437]). (**b**) In-band pumping of Er:YAG with a fiber laser at 1532 nm and lasing at $\lambda_{laser} = 1645$ nm [11.535]

Fibers. Erbium-doped fiber lasers have been extensively studied for their potential use as sources in communication systems operation in the third communication window around 1.55 μm. All these lasers oscillate on the $^4I_{13/2} \rightarrow ^4I_{15/2}$ transition, either in continuous-wave or pulsed mode. In singly Er^{3+}-doped fibers, suitable pump wavelengths for using laser diodes are 810 nm ($^4I_{15/2} \rightarrow ^4I_{9/2}$), 980 nm ($^4I_{15/2} \rightarrow ^4I_{11/2}$) and 1480 nm ($^4I_{15/2} \rightarrow ^4I_{13/2}$). Other possible pump bands are around 660 nm ($^4I_{15/2} \rightarrow ^4F_{9/2}$), 532 nm and 514.5 nm ($^4I_{15/2} \rightarrow ^4H_{11/2}$). The pump wavelengths at 810 nm and 514.5 nm suffer from strong excited-state absorption, yielding a loss of pump photons [11.593]. The gain coefficient of Er-doped fibers is rather high (11 dB/mW [11.594]) due to the fairly high peak emission cross section of $4-7 \times 10^{-21}$ and the long lifetime of the $^4I_{13/2}$ level (8–10 ms) in silica fibers, despite the three-level laser character causing ground-state absorption at this wavelength. Like in Er^{3+}-doped crystals and glasses, concentration quenching occurs. In order to enhance the absorption efficiency without increasing the Er^{3+} concentration and/or fiber length, Yb^{3+} codoping is used, especially when diode pumping between 900 nm and 1000 nm is used. The requirement for efficient operation is – as in the crystals and glasses – efficient energy transfer from the Yb^{3+} $^2F_{5/2}$ level to the Er^{3+} $^4I_{13/2}$ level (Fig. 11.61). In Table 11.20, some of the Er-fiber lasers around 1.55 μm are summarized. For a very detailed discussion of Er^{3+}-doped fiber lasers and amplifier see [11.595]. In summary, Er^{3+}-doped fiber lasers operating around 1.55 mm are extremely efficient. Output powers in the watt range are possible.
Fig. 11.66 Results of the laser experiments with Kigre QE7 glass, Yb^{3+} (10%), Er^{3+} (0.5%): $LaSc_3(BO_3)_4$ and Yb^{3+}, Er^{3+} (0.5%): $Y_3AL_5O_{12}$. (After [11.552])

Nowadays up to 100 W of output power are commercially available [11.596]. Most efficient pumping occurs at 1480 nm, here slope efficiencies close to the quantum limit of 95% are possible. Pumping at 980 nm is less efficient due to the higher quantum defect, however, at this wavelength highly efficient and reliable high-power laser diodes are available.

Other near-infrared Er^{3+} lasers. Room-temperature laser oscillation in Er^{3+}-doped crystals in the near-infrared spectral range has also been observed at other wavelengths. In Yb^{3+}-codoped Er^{3+}:$YLiF_4$ an upconversion pumping scheme was realized for the $^4S_{3/2} \rightarrow {}^4I_{11/2}$ transition at 1234 nm, which allowed continuous-wave room-temperature Ti:sapphire- and diode-pumped laser oscillation [11.597, 598]. Under Ti:sapphire excitation around 966 nm output powers of 160 mW and slope efficiencies of up to 22% were obtained. Note, that without the Yb codoping, the output powers were an order of magnitude lower. Under diode laser pumping at 966 nm, Yb^{3+},Er^{3+}:$YLiF_4$ exhibited output powers of 80 mW and slope efficiencies of 7%.

For this transition Xe flashlamp excitation is also possible allowing room-temperature laser oscillation in $YLiF_4$ [11.599–601], $LuLiF_4$ [11.602] and $YAlO_3$ [11.603]. In $BaYb_2F_8$, the $^4F_{9/2} \rightarrow {}^4I_{13/2}$ transition at 1260 nm exhibited laser oscillation under pulsed Nd laser or Xe flashlamp excitation [11.604]. Laser oscillation on the $^4F_{9/2} \rightarrow {}^4I_{11/2}$ transition was obtained around 1.96 μm in $BaYb_2F_8$ [11.605–607] under pulsed Nd laser and Xe flashlamp excitation.

11.2.4 Mid-Infrared Lasers

Basics

The mid-infrared wavelength range $\approx 1.9–5.0$ μm is of interest for a number of applications. Mid-infrared solid-state lasers serve as light sources for spectroscopy, e.g., in remote sensing of the atmosphere, as the frequencies of internal vibrational motion of many molecules can be found in this spectral region. Other applications include medicine, e.g., microsurgery and dentistry in the region of high water absorption around 2.7–3 μm. Laser wavelengths near 2 μm are suitable for tissue welding and lithotripsy.

The first mid-infrared laser was operated in 1960, shortly after the invention of the laser itself. It was operated at 2.6 μm in a calcium fluoride crystal doped with trivalent uranium [11.608]. Pulsed excitation and cooling to low temperatures were typically required for novel laser transitions in the early years. Two years later, a Dy^{2+}-doped CaF_2 laser at 2.36 μm was also demonstrated in continuous-wave operation [11.609, 610]. Among the lasers based on trivalent rare-earth ions, the transitions near 2 μm in Tm^{3+} and Ho^{3+} were operated in $CaWO_4$ in 1962 [11.611,612]. The first observation of coherent emission near 3 μm from erbium ions was reported in 1967 [11.613]. Since those early years, a large number of new host materials has been developed and various new laser transitions in the mid-infrared spectral region have been demonstrated (for a comprehensive overview of ion–host combinations, see [11.614]). Around 1990, Tm^{3+}- and Ho^{3+}-doped solid-state laser systems in $Y_3Al_5O_{12}$ (YAG), $YLiF_4$ (YLF), YVO_4, and $Y_3Sc_2Ga_3O_{12}$ (YSGG) were shown to operate between 1.86 and 2.46 μm [11.615–618], and Er^{3+}-doped lasers in similar host systems cover the wavelength range of 2.66–2.94 μm. Short-pulse lasers at these wavelengths have been demonstrated [11.619,620].

Nowadays, mid-infrared laser transitions ranging from 1.8 μm up to 7.2 μm [11.621] are known in divalent Dy, trivalent Tm, Ho, Er, Dy, Pr, Tb, and Nd, as well as in trivalent U. The current state of the art in solid-state lasers occurring in rare-earth ions such as Tm^{3+}, Ho^{3+}, Er^{3+} and others and their population mechanisms are discussed in this section on the basis of the spectroscopic properties of these ions. Continuous-wave fundamental-mode power levels ranging from a few mW near 4 μm up to ≈ 100 W near 2 μm have been demonstrated in recent years. Power-scaling methods and their limitations, the possibilities to optimize the population mechanisms and increase the efficiencies of these lasers, as well as the prospects of future mid-infrared lasers in

a number of rare-earth ions at transitions in the wavelength range beyond 3 μm and extending to 5 μm are described.

The aspects relevant to rare-earth-ion-doped mid-infrared solid-state lasers, such as the competition between radiative and multiphonon decay and the consequent choice of host materials for these wavelengths will be introduced next. The performance of the most important mid-infrared laser transitions in the wavelength range 2–3 μm will then be discussed in detail: Tm^{3+}-doped lasers at 1.9 μm and 2.3 μm, Ho^{3+}-doped lasers at 2.1 μm and 2.9 μm, Er^{3+}-doped lasers at 2.7–2.9 μm, and Dy^{3+}-doped lasers at 2.9–3.4 μm. At wavelengths beyond 3 μm, it becomes increasingly difficult to find suitable host materials for actively doped laser systems. This statement holds true for glass fibers in the same way as for crystalline materials. The prospects for future mid-infrared solid-state lasers in this wavelength range will be discussed at the end of the section.

Introductions to the fields of mid-infrared solid-state crystalline and fiber lasers can be found in [11.641] and [11.642], respectively.

Decay mechanisms, host materials, and thermal issues

Here a few fundamental aspects of lasers are discussed with emphasis on their impact on mid-infrared solid-state lasers.

Radiative versus multiphonon decay. The choice of host material for mid-infrared solid-state lasers involves a number of considerations. The maximum phonon energy is the most important aspect. The optical transparency range relates to both the size of the bandgap and also the infrared absorption cut-off, hence to the vi-

brational frequency ν of the anion–cation bonds of the material. For an ordered structure,

$$\nu = \left(\frac{1}{2\pi}\right)\sqrt{\frac{k}{M}} \, , \qquad (11.89)$$

where $M = m_1 m_2/(m_1 + m_2)$ is the reduced mass for two bodies m_1 and m_2 vibrating with an elastic restoring force k. The relative cation–anion bond strength is intimated by the field strength Z/r^2, where Z is the valence state of the cation or anion and r is the ionic radius. Generally, materials composed of large anions and cations with low field strengths display high transparency in the mid-infrared spectral region.

Radiative decay of excited states is in competition with nonradiative multiphonon decay. The maximum phonon energy of the material sets the multiphonon relaxation rates, which influence the quantum efficiency. The rate constant of a multiphonon relaxation process decreases exponentially with the energy gap to the next lower-lying state and with the order of the process, i. e., the number of phonons required to bridge the energy gap [11.643, 646]. As an example, the multiphonon relaxation rates for the common fiber glasses as a function of the energy gap between energy levels are shown in Fig. 11.67.

The influence of multiphonon decay is stronger in oxides than in fluorides because of the smaller atomic mass m_2 of the anion and the larger elastic restoring force k (11.89), due to the stronger covalent bonds in oxides [11.644], both resulting in larger maximum phonon energies in oxides. Typically, nonradiative decay becomes dominant if five or fewer phonons are required to bridge the energy gap [11.645]. Since an energy gap of $\approx 3300\,\mathrm{cm}^{-1}$ corresponds to a transition wavelength of $3\,\mu\mathrm{m}$, radiative decay prevails for phonon energies below $\approx 600\,\mathrm{cm}^{-1}$, which is roughly the maximum phonon energy of fluorides. Fluorides are, therefore, preferred over oxides as host materials for most mid-infrared laser transitions.

In the example of Fig. 11.68, dominant laser (solid lines) and multiphonon (dotted lines) transitions from the three lowest-energy levels of Er^{3+} are indicated, together with the corresponding lifetimes of the levels in different classes of host materials. In high-phonon-energy oxide host materials, only the $1.5\,\mu\mathrm{m}$ laser transition possesses sufficiently high frequency and large energy gap, resulting in a long $^4I_{13/2}$ lifetime. On the other hand, the $^4I_{11/2}$ lifetime is significantly quenched by multiphonon relaxation and the $2.8\,\mu\mathrm{m}$ laser originating in this level is more easily operated in fluoride host materials. Finally, low-phonon host ma-
Fig. 11.67 Calculated and measured multiphonon relaxation rates as a function of the energy gap between energy levels for glasses with different maximum phonon energies. (After [11.643, 644])

terials such as chlorides are required to ensure a long $^4I_{9/2}$ lifetime in order to operate the $4.5\,\mu\mathrm{m}$ laser.

Host materials for mid–infrared lasers. Crystalline oxide materials have been the laser host materials of choice for several decades, as many oxide crystals are comparatively easy to grow, environmentally stable, and possess high heat conductivities [11.647], fracture limits, and refractive indices, the latter resulting in large absorption and emission cross sections. Most prominent is $Y_3Al_5O_{12}$ (YAG), together with other
Fig. 11.68 Radiative and laser (*solid lines*) versus nonradiative (*dotted lines*) decay of the lowest three excited states of Er^{3+} in oxide, fluoride, and chloride host materials [11.645]

garnets, but in recent years materials such as mixed garnets, the vanadates YVO_4 and $GdVO_4$, the double tungstates $KY(WO_4)_2$ and $KGd(WO_4)_2$, the sesquioxides Y_2O_3, Sc_2O_3, and Lu_2O_3 and others have shown great promise for efficient lasing when doped with various rare-earth ions. Their performance decreases significantly when lasers are operated at wavelengths above $\approx 2.5–3\,\mu m$ because of their high maximum phonon energies ($\approx 700–900\,cm^{-1}$). Silicate glass is perhaps the most important material used for optical fiber production [11.644, 648], however, in this material the maximum phonon energy of $\approx 1100\,cm^{-1}$ [11.649] is even higher and has so far limited the emission wavelength of mid-infrared fiber lasers using this material to $\approx 2.2\,\mu m$ [11.650]. Silica is robust and involves the very effective modified chemical vapor deposition (MCVD) technique for fiber fabrication. Reducing the OH^- content in the glass, which has two main absorption peaks in the range $1.3–2.0\,\mu m$ [11.651], improves the near-to-mid-infrared utility. Rare-earth ions such as Nd^{3+} and Er^{3+} which have high field strengths have low solubility in silicate glass, which can lead to clustering and microscale phase separation.

The use of fluoride crystals and glasses as host materials for mid-infrared solid-state lasers has found wide acceptance. The heavy-metal fluorides [11.652, 653] are preferred as fiber materials, especially ZBLAN [11.654, 655], a mixture of 53 mol % ZrF_4, 20 mol % BaF_2, 4 mol % LaF_3, 3 mol % AlF_3, and 20 mol % NaF. Since it can be readily drawn into single-mode optical fiber [11.656] it is particularly important to mid-infrared fiber lasers [11.657]. The large atomic weight of the zirconium atom combined with relatively weak bonding provides a maximum phonon energy for ZBLAN of $\approx 550\,cm^{-1}$ [11.658] and allows for high infrared transparency up to $\approx 6\,\mu m$. Multiphonon relaxation, however, becomes significant for transitions at wavelengths longer than $\approx 3–3.5\,\mu m$. Compared to silica, ZBLAN has a lower damage threshold. The crystal field strength is also weaker [11.659]. An overview of the spectroscopic properties of rare-earth ions doped into ZBLAN is given in [11.658]. On the crystalline side, the host materials $LiYF_4$, BaY_2F_8, and their respective isostructural relatives have become the workhorses for many mid-infrared laser transitions [11.660, 661]. Because of their fluoride content, these materials have to be grown under an atmosphere which excludes oxygen.

Among the low-phonon host materials, many compounds naturally possess low heat conductivity and are hygroscopic. This accounts for most of the halides, with increasing hygroscopicity from chloride to iodide.

On the other hand, these materials provide phonon energies in the range of $350–150\,cm^{-1}$ [11.662]. Recently, KPb_2Cl_5 and related compounds have emerged as non-hygroscopic, hence promising candidates for mid-infrared lasers [11.663–665]. Chalcogenide glasses are composed of the chalcogen elements S, Se and Te [11.666–668]. They are environmentally durable and have reasonably large glass-forming regions. When the rare-earth ions are doped into these glasses [11.669], the radiative transition probabilities and, therefore, the absorption and emission cross sections are high as a result of the high refractive index (≈ 2.6) of the glass and the high degree of covalency of the rare-earth ion with the surrounding medium. Maximum phonon energies of $300–450\,cm^{-1}$ [11.670] produce low rates of multiphonon relaxation (Fig. 11.67), and therefore high quantum efficiencies. The most important glasses are the sulfide glasses GaLaS (GLS) [11.671] and GeGaS [11.672] because of the reasonably high rare-earth solubility.

Studies into the use of ceramics as host materials for the rare-earths have recently made a lot of progress [11.673]. These ceramics are composed of nanocrystallites of materials such as YAG and can be produced in a simple cost-efficient process at relatively low temperatures. This allows the fabrication of materials with very high melting points [11.674] that are difficult to grow by other techniques such as the Czochralski method. This class of materials is also available in a fiber geometry [11.675]. Ceramic fibers combine the characteristics of crystalline materials such as high absorption and emission cross sections, large thermal conductivity, and even the possibility of doping with transition-metal ions [11.675] with the convenience of guiding the pump and signal light in a fiber. While bulk ceramics have already matured as laser host materials, the losses of ceramic fibers are still comparatively high.

Specific aspects of operating mid-infrared lasers. As higher pump powers become available from laser-diode systems, it is generally recognized that thermal and thermo-optical issues set limitations to the power scalability of end-pumped bulk laser systems. Owing to the unfavorable temperature dependence of thermal and thermo-optical parameters [11.647], the large heat load in the crystal leads, firstly, to a significant temperature increase in the rod, secondly, to strong thermal lensing with pronounced spherical aberrations, and ultimately, to rod fracture in a high-average-power end-pumped system. Thermal management will be required when

very high output powers are desired. In particular, for high-power mid-infrared operation, thermal management may be very important because of the decreased quantum efficiency and the consequently higher amount of heat dissipation [11.676].

Due to its geometry, the fiber provides potentially high pump and signal beam intensities without the drawbacks of significant thermal and thermo-optical effects. Its large surface-area-to-volume ratio means that the heat generated from multiphonon relaxation in the core is dissipated effectively by radiation and convection from the outer surface of the fiber. This is especially true for single-clad, core-pumped single-mode fibers where this ratio is highest [11.678]. The larger cladding area ($> 10^4 \, \mu m^2$) of double-clad fiber lasers allows for high-power diode-array pumping [11.408, 679–682]. On the other hand, double-clad fibers have a smaller surface-area-to-volume ratio and thermal issues need to be taken into account [11.683–685].

While bulk crystalline mid-infrared lasers matured already during the 1990s, the high costs of fabricating fibers with sufficiently low losses in the mid-infrared region of the spectrum has impeded the necessary research efforts in the field of mid-infrared fiber lasers. However, with the introduction of the double-clad fiber and recent technological advances in the fields of fiber fabrication and beam-shaped high-power diode lasers, the performance of diode-pumped fiber lasers has dramatically improved. Today, mid-infrared fiber lasers can compete with the corresponding bulk crystalline systems in certain applications, especially when fundamental-transverse-mode, CW laser operation at output powers in the milliwatt to the hundred watt range is required.

A large number of techniques for pulsed operation including Q-switching and mode locking of fiber lasers have been explored. These techniques have been investigated intensively for the common laser transitions at $1 \, \mu m$ in Nd^{3+} and Yb^{3+}, and at $1.5 \, \mu m$ in Er^{3+}, and are usually described in combination with these lasers. The small fiber size limits the peak power through the damage-threshold intensity (propagating power per core area) and, hence, crystalline lasers in bulk geometries or optical parametric processes are often preferred when high-energy short pulses are needed. This argument accounts especially for mid-infrared ZBLAN-based fiber lasers, because these fibers possess a lower damage threshold compared to silica fibers. The description of mid-infrared fiber lasers is, therefore, confined to CW operation and specific techniques for pulsed operation of fiber lasers are not discussed in this chapter.

Thulium–doped solid–state lasers at 1.9–2.0 μm and 2.3–2.5 μm

The use of the Tm^{3+} ion for mid-infrared solid-state laser applications has been widespread, partly as a result of the convenient absorption band near $0.79 \, \mu m$, which allows for direct AlGaAs diode-laser pumping. The primary luminescent transitions of Tm^{3+} relevant to mid-infrared laser emission are the $^3F_4 \rightarrow {}^3H_5$ transition at $\approx 2.3 \, \mu m$ and the $^3H_4 \rightarrow {}^3H_6$ ground-state transition at $\approx 1.9 \, \mu m$; see the energy-level scheme in Fig. 11.69. The $^3F_4$ level is excited by the $0.79 \, \mu m$ pump wavelength.

Three-level lasers at 1.9–2.0 μm. The first laser emission from Tm^{3+} ions was reported on the phonon-terminated $2 \, \mu m$ transition $^3H_4 \rightarrow {}^3H_6$ in $CaWO_4$:Tm^{3+} in 1962 [11.611]. In 1975, pulsed operation at room temperature was demonstrated in Cr^{3+}-codoped YAG and YAlO$_3$ [11.686]. Cr^{3+} codoping allowed the experimentalist to improve the absorption of flashlamp or ion-laser pump light in the visible spectral range by the active medium and subsequent energy transfer from Cr^{3+} to the Tm^{3+} lasing ions [11.687, 688]. The cross-relaxation process $(^3F_4, {}^3H_6) \rightarrow ({}^3H_4, {}^3H_4)$ can transform one pump photon absorbed in the $^3F_4$ or a higher-lying energy level into two excitations in the $^3H_4$ upper laser level of the $2 \, \mu m$ transition [11.616, 689] (Fig. 11.69), thereby enhancing the quantum efficiency of this laser by a factor of 2. Laser emission under diode pumping of the $^3F_4$ level at $780–790 \, nm$ was achieved in YAG in the late 1980s [11.690]. A single-
Fig. 11.69 Partial energy-level scheme of Tm^{3+} displaying the measured lifetimes when doped into fluoride glass [11.677], NR and CR represent nonradiative decay and cross-relaxation, respectively

frequency monolithic laser has also been reported in YAG:Tm^{3+} [11.691].

Recently, 14 W, 18 W, and 36 W of output power with high beam quality has been achieved with diode pumping at room temperature in YAG:Tm^{3+} [11.692] and in LiYF$_4$:Tm^{3+} in slab [11.693] and bulk [11.694] geometries, respectively. The latter approach could be scaled to 70 W, however currently with low beam quality [11.695]. Two research groups reported about 115 W and 120 W, respectively, of multi-mode output power from diode-pumped YAG:Tm^{3+} lasers [11.696, 697]. A microchip laser was demonstrated in GdVO$_4$:Tm^{3+} [11.698]. A thin-disc laser has also been demonstrated in YAG [11.699].

The large degree of Stark splitting of the $^3H_6$ ground state, combined with vibronic broadening of the spectrum [11.700], provides the $^3H_4 \to {}^3H_6$ transition with a very broad emission, spanning ≈ 400 nm in many hosts, which represents one of the broadest luminescent transitions available from any rare-earth ion. Accordingly, its tunability is rather large, ranging from 1.87–2.16 μm in YAG [11.701], 1.84–2.14 μm in YSGG [11.701], 1.93–2.00 μm in YAlO$_3$ [11.702], 1.93–2.09 μm in Y$_2$O$_3$ [11.703], 1.93–2.16 μm in Sc$_2$O$_3$ [11.703], 1.83–1.97 μm in CaF$_2$ [11.704], 1.91–2.07 μm in LiYF$_4$ [11.693], 1.85–2.06 μm in BaY$_2$F$_8$ [11.705], 1.86–1.99 μm in GdVO$_4$ [11.706], 1.84–1.95 μm in LuVO$_4$ [11.707], 1.79–2.04 μm in KGd(WO$_4$)$_2$ [11.708], and 1.81–2.03 μm in NaGd(WO$_4$)$_2$ [11.709]. As for many other transitions, shifts in the center emission wavelength can be achieved by substitution of host ions, e.g., from Y$_3$Al$_5$O$_{12}$ to Lu$_3$Al$_5$O$_{12}$ [11.710]. The vanadate crystals GdVO$_4$ and YVO$_4$ as well as double tungstates possess comparatively high absorption coefficients [11.698, 711, 712], allowing pumping also at 805–810 nm, where cheaper and more-reliable pump diodes than at 780–790 nm are available. Exploiting the large gain bandwidth, mode-locked operation of Tm^{3+} 2 μm lasers with pulse durations of 35 ps and 41 ps has been reported in YAG:Tm^{3+} [11.713] and YAG:Cr^{3+},Tm^{3+} [11.714], respectively. Actively [11.715, 716] or passively [11.717] Q-switched laser operation is useful in micro-surgery [11.718].

Recent progress in the fields of crystalline epitaxial growth and in-bulk refractive-index modification processes in glasses and crystals has enabled novel solid-state lasers in the waveguide geometry [11.719]. As one of the results, Tm^{3+} waveguide lasers at 2 μm have also been demonstrated in lead germanate glass [11.720], YAG [11.721] with up to 15 W of output power under high-power diode side pumping [11.722], and KY(WO$_4$)$_2$ [11.723]. The latter laser has, as yet, not shown a performance as good as for the same material in bulk geometry [11.724] or in a waveguide geometry but doped with Yb^{3+} and lasing at 1 μm [11.725]. Epitaxial layers of Tm:KLu(WO$_4$)$_2$/KLu(WO$_4$)$_2$ have also been operated with the laser cavity perpendicular to the layer in the 2 μm spectral range [11.726].

The first explorations into fiber lasers utilizing the 1.9 μm ground-state transition related to the dye-laser pumping at 797 nm of a Tm^{3+}-doped silica fiber laser [11.727]. Overlap of the main absorption band with the emission wavelength of AlGaAs diode lasers quickly resulted in diode-laser pumping of these fiber lasers based on either silica [11.728] or fluoride [11.729] glass hosts. The cross-relaxation process $(^3F_4, {}^3H_6) \to ({}^3H_4, {}^3H_4)$ and enhancement of excited ions in the $^3H_4$ upper laser level of the 2 μm transition (Fig. 11.69), is highly dependent on the overall concentration of Tm^{3+} ions and competition from multiphonon relaxation from the $^3F_4$ level. Although generally high concentrations of Tm^{3+} in low-phonon-energy glasses enable full exploitation of this beneficial process, it has been shown recently that this cross-relaxation process is resonant in a silica host and hence only moderate (2–3 wt %) Tm^{3+} ion concentrations are required to maximize the benefits of cross-relaxation [11.730].

Also in fibers, the broad emission spectrum allows a large degree of wavelength tunability [11.731]. Recently, tuning ranges of 230 nm from 1.86–2.09 μm [11.732] and 250 nm from 1.72–1.97 μm [11.733] have been demonstrated. Since the Tm^{3+} 1.9 μm transition can be favorably operated in silica fiber (with its higher peak-power damage threshold compared to ZBLAN fiber), pulses in the range of 190–500 fs have been obtained in additive-pulse [11.734] or passive [11.735] mode-locking arrangements using this broad emission spectrum. The smaller emission cross section and the three-level nature of the laser transition resulted in higher pump thresholds compared to standard Nd^{3+}-doped silica fiber lasers. Reabsorption from the ground state of the Tm^{3+} ion has to be overcome because the ground-state multiplet is the lower laser level. Reducing the population of the higher Stark levels of the ground state by cooling the fiber causes emission at shorter wavelengths. Tunability to longer wavelengths can be obtained by variation of the fiber length because of the increased level of reabsorption by the ground state with longer lengths of fiber [11.736].

Early power-scaling experiments involved the use of the convenient 1.064 μm YAG:Nd^{3+} laser which core-pumped the short-wavelength side of the ^{3}H$_5$ level [11.737]. Pumping the long-wavelength side of the ^{3}H$_5$ level with a high-power 1.319 μm YAG:Nd^{3+} laser also yielded efficient output [11.738]. In-band pumping of the transition at 1.57 μm in silica [11.739] and at 1.58−1.60 μm in fluoride glass [11.740, 741] has also been demonstrated. Whilst theoretical modeling of Tm^{3+}-doped silica fiber lasers [11.742] indicates that in-band pumping is the most efficient pump method for silica-based fiber lasers because of the high Stokes efficiency, nevertheless, the wide availability of high-power AlGaAs diode lasers at 790−800 nm and the strong level of cross-relaxation in Tm^{3+}-doped silica means that such diode-cladding-pumped systems in both standing-wave [11.736, 743] and ring-resonator [11.744] arrangements are perhaps the most practical ways of producing high output power from this ion (Fig. 11.70). With Yb^{3+} sensitization and pumping at 975 nm, 75 W of output power has been demonstrated [11.745]. Currently, the Tm^{3+}-doped silica fiber laser is the most mature of the mid-infrared fiber-laser systems primarily because of the robustness and convenience offered by the silica glass host. The maximum output power from high-power Tm^{3+}-doped fiber lasers is now ≈ 85 W [11.743], which is comparable to the equivalent diode-pumped Tm^{3+}-doped crystalline laser systems [11.697].

Four-level lasers at 2.3–2.5 μm. The mid-infrared four-level CW laser at ≈ 2.3 μm on the transition ^{3}F$_4$ → ^{3}H$_5$ has been operated in GSGG:Tm^{3+} and LiYF$_4$:Tm^{3+}, with wavelength tunability ranging from 2.2–2.37 μm [11.748] and 2.2–2.46 μm [11.749], respectively. This laser operates best at low Tm^{3+} concentrations of < 2 at % in order to avoid the aforementioned cross-relaxation, which in this case would depopulate the upper laser level (Fig. 11.69). The lifetime of the lower laser level of the ^{3}F$_4$ → ^{3}H$_5$ transition is quite short and leads to a low pump threshold.

Doping Tm^{3+} ions into a ZBLAN fiber offers an increased quantum efficiency of the ^{3}F$_4$ level [11.750–752]. Deliberately designing the fiber to have a relatively low Tm^{3+}-ion concentration reduces cross-relaxation and hence severe lifetime quenching of the ^{3}F$_4$ level. The tunability extends from 2.25 μm to 2.5 μm [11.677]. Simultaneous lasing on the ^{3}H$_4$ → ^{3}H$_6$ transition at 1.9 μm produces a two-color fiber laser [11.753]. Applications requiring highly efficient output or multi-mid-infrared-wavelength output will benefit from the use of Tm^{3+}-doped ZBLAN fibers.

Holmium-doped solid-state lasers at 2.1 μm and 2.9 μm

The use of the Ho^{3+} ion as the active dopant for solid-state lasers opens up a number of very useful mid-infrared transitions. In this section, we will concentrate on the ^{5}I$_7$ → ^{5}I$_8$ ground-state transition at ≈ 2.1 μm and the ^{5}I$_6$ → ^{5}I$_7$ transition at ≈ 2.9 μm; see the energy-level scheme in Fig. 11.71. One of the significant shortcomings of Ho^{3+}, however, is the lack of

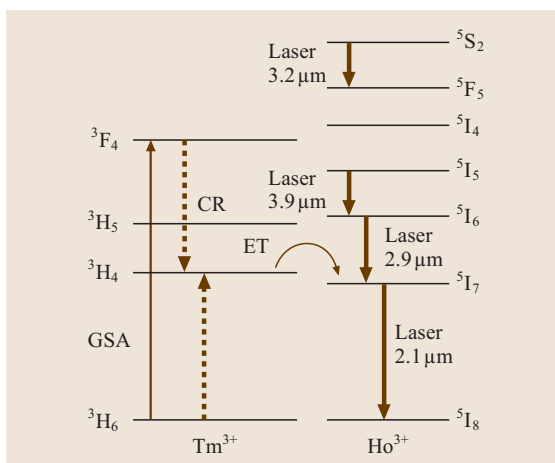
Fig. 11.70 Measured output powers from diode-cladding-pumped fiber lasers using 1.8 wt % Tm^{3+}-doped silica [11.735], 2.2 wt % Tm^{3+}-doped silica [11.746], and 3.6 mol % Tm^{3+}, 0.4 mol % Ho^{3+}-doped fluoride glass [11.747]


Fig. 11.71 Partial energy-level scheme of Ho^{3+} with a Tm^{3+} sensitizer. ET represents energy transfer

ground-state-absorption (GSA) transitions [11.754] that overlap with convenient high-power pump sources. As a result, many of the early demonstrations of Ho^{3+}-doped room-temperature crystalline CW lasers [11.616] involved sensitizing with Tm^{3+} in order to access the convenient absorption bands and the practical cross-relaxation process Tm^{3+} provides, as we have discussed in Sect. 11.3.1. Energy migration amongst the Tm^{3+} ions and a suitable $Tm^{3+}:Ho^{3+}$ concentration ratio ensures that efficient energy transfer to Ho^{3+} takes place [11.755, 756] (Fig. 11.71).

Three-level lasers at 2.1 µm. The 2 µm transition $^5I_7 \rightarrow {}^5I_8$ in Ho^{3+} ions was first demonstrated as a laser in $CaWO_4:Ho^{3+}$ in 1962 [11.612] and in Tm^{3+}-codoped $CaWO_4:Ho^{3+}$ in 1963 [11.757]. In 1971, pulsed operation at room temperature on this three-level laser transition was demonstrated in $LiYF_4$ [11.758]. CW laser emission was achieved under Kr^+-laser pumping in Cr^{3+},Tm^{3+}-codoped $YSAG:Ho^{3+}$ and $YSGG:Ho^{3+}$ in 1986 [11.759]. Like in 2 µm Tm^{3+} lasers (Sect. 11.3.1), the Cr^{3+} codopant served as a sensitizer for the absorption of pump light in the visible spectral range and excitation of Tm^{3+} ions by energy transfer. The subsequent excitation of Ho^{3+} ions by energy transfer from Tm^{3+} [11.760, 761] profits from the same Tm^{3+}-Tm^{3+} cross-relaxation as described for 2 µm Tm^{3+} lasers in Sect. 11.3.1 (Fig. 11.71). In the 1980s, laser emission at 2.1 µm in Ho^{3+} under diode pumping of the Tm^{3+} $^3F_4$ level at 780–790 nm with pump thresholds as low as 5 mW was achieved in YAG [11.762–764]. Compact, monolithic, low-threshold laser devices can be achieved in this way [11.765]. Besides many different garnet crystal systems, $LiYF_4$ also regained interest as a host material for CW diode-pumped 2 µm Ho^{3+} lasers around 1990 [11.766, 767]. An Yb^{3+}-codoped, diode-pumped Ho^{3+} laser at 2.1 µm has also been demonstrated [11.768]. Noise suppression [11.769,770], amplitude and frequency stabilization [11.771–773] of 2 µm Ho^{3+} lasers have been investigated.

Attempts to exploit the rather large gain bandwidth of Ho^{3+} near 2.0–2.1 µm by tuning the emission wavelength were reported in the early 1990s [11.774, 775]. Nowadays, tuning ranges of > 80 nm are achieved in host materials such as mixed YSGG:GSAG [11.776], $BaY_2F_8:Ho^{3+}$ [11.777], and KYF_4 [11.778]. Mode-locking experiments have resulted in 800 ps, 370 ps, and 70 ps pulse durations, obtained in YAG:Cr^{3+},Tm^{3+},Ho^{3+} [11.714], $LiYF_4:Tm^{3+},Ho^{3+}$ [11.779], and $BaY_2F_8:Tm^{3+},Ho^{3+}$ [11.780], respectively. In mixed crystals of YSGG:GSAG:Cr^{3+},Tm^{3+},Ho^{3+},

which provide an inhomogeneously broadened, and therefore smoother, gain shape, a pulse duration as short as 25 ps could be achieved [11.776]. Q-switched laser operation [11.781–783] has been investigated and applied for microsurgery [11.784].

Besides the cross-relaxation and energy-transfer processes shown in Fig. 11.71, several other energy-transfer processes can occur in Tm^{3+},Ho^{3+}-codoped materials [11.785–789], thereby making the system rather complex and introducing parasitic processes which can deplete the Ho^{3+} $^5I_7$ upper laser level, increase the laser threshold, and diminish the laser efficiency. Rather than codoping the host with Tm^{3+} ions and exciting the Ho^{3+} ions via nonradiative energy transfer from the Tm^{3+} ions, one can directly pump the Ho^{3+} $^5I_7$ upper laser level at 1.9 µm using laser diodes [11.790], the output from a 1.9 µm Tm^{3+} laser [11.791], which provided up to 15 W [11.792] and 19 W [11.694] output power from Ho^{3+}, or a $MgF_2:Co$ laser [11.793]. This approach ensures a low quantum defect and, hence, low heat generation in the laser crystal. This scheme was proven very successful by the use of a high-power Tm^{3+} fiber laser as the pump source, providing 6.4 W of output power and a slope efficiency of 80% versus incident pump power at 1.9 µm [11.794]. Also an efficient 2 µm Ho^{3+} single-frequency ring laser has been demonstrated in this way [11.795].

The first fiber laser configuration making use of this transition employed ZBLANP glass (a variant of ZBLAN) and argon-ion pumping [11.796]. A year later, this was followed by the demonstration of an argon-ion-pumped Ho^{3+}-doped silica fiber laser [11.797]. In both cases, the fiber was singly doped with Ho^{3+}, the output power < 1 mW, and each needed a relatively high pump power to reach laser threshold. Improvements in the output power and efficiency have been made recently with Yb^{3+}-doped silica fiber laser pumping of the $^5I_6$ level [11.798]; however, the output power had only increased to 280 mW because the pump fiber laser was operated at the low-efficiency 1150 nm wavelength. Using the pump wavelength of 1100 nm, which is more optimal with respect to the operation of an Yb^{3+}-doped silica fiber laser, the output power has been increased by approximately an order of magnitude [11.799].

As mentioned above, a practical method of efficiently generating laser emission on the $^5I_7 \rightarrow {}^5I_8$ transition is to codope Ho^{3+} laser ions with Tm^{3+} sensitizer ions. The first demonstration of a fiber laser operating with the Tm^{3+},Ho^{3+} system occurred in 1991 [11.800] when 250 mW was generated at a slope efficiency of 52% from a Ti:sapphire-pumped fluoride

fiber laser. A year later [11.801], this work was followed by an increase in the Tm^{3+} concentration to improve cross-relaxation and resulted in a higher slope efficiency being obtained. Demonstration of a Tm^{3+},Ho^{3+}-doped silica fiber laser soon followed [11.802, 803]; however, owing to lower Tm^{3+} concentrations which forces weaker cross-relaxation, significantly lower slope efficiencies were measured, especially when pumped at 1.064 μm [11.804]. When the concentrations are increased and the double-clad pump arrangement used, a significant augmentation of the output power to 5.4 W has been demonstrated [11.805]. To date, the highest output power of 8.8 W from a fiber laser operating on the $^5I_7 \rightarrow {}^5I_8$ transition has been produced by a diode-cladding-pumped Tm^{3+},Ho^{3+}-doped fluoride fiber laser [11.747] (Fig. 11.70). In an analogous way to recent demonstrations in bulk laser systems, tandem-pumping Ho^{3+} with a separate Tm^{3+} laser operating at 1.9 μm may also prove effective in fibers, because it similarly exploits the cross-relaxation process between Tm^{3+} ions but avoids any ETU between Ho^{3+} ions in the $^5I_7$ upper laser level and excited Tm^{3+} ions [11.789]. When sensitizing with Yb^{3+} ions, a Ho^{3+}-doped silica fiber laser at 2.1 μm has been shown [11.806] to operate at moderate efficiency levels despite the fact that the energy transfer from Yb^{3+} to Ho^{3+} is quite nonresonant (Fig. 11.72).

Four-level lasers at 2.9 μm. Laser emission at the transition $^5I_6 \rightarrow {}^5I_7$ near 3 μm in an Ho^{3+}-doped crystal was demonstrated in 1976 [11.808]. Sensitizing Ho^{3+} with Yb^{3+} ions (see the energy-level scheme in Fig. 11.72) in order to exploit the more-favorable absorption features of Yb^{3+} has been used in diode-
Fig. 11.72 Partial energy-level scheme of Ho^{3+} with Yb^{3+} sensitizer displaying the measured lifetimes of Ho^{3+} when doped into fluoride glass host [11.807]

pumped crystalline lasers for the generation of 2.9 μm output [11.809]. Recent reports on this transition include laser investigations of $YAlO_3$:Ho^{3+} [11.810], diode-pumped Yb^{3+}-codoped YGSS:Ho^{3+} with 10 mJ output energy [11.811], and Cr^{3+},Yb^{3+}-codoped YGSS:Ho^{3+} tunable in the range 2.84–3.05 μm [11.812] and in Q-switched operation [11.813]. Since the $^5I_7$ lower laser level is a metastable excited state with a longer lifetime than the $^5I_6$ upper laser level, it is difficult to achieve CW inversion on this transition. Cascade lasing on the $^5I_6 \rightarrow {}^5I_7$ and $^5I_7 \rightarrow {}^5I_8$ transitions at 3 and 2 μm, respectively [11.814, 815], may help to deplete the $^5I_7$ level radiatively, i.e., without significant heat generation. Passive Q-switching of this transition has also been demonstrated [11.813].

The combined effect of the infrared absorption cut-off wavelength of ≈ 2.5 μm for pure silica glass and the strong multiphonon relaxation quenching of mid-infrared transitions of rare-earth ions in this host means that four-level fiber lasers operating on the $^5I_6 \rightarrow {}^5I_7$ transition at ≈ 2.9 μm have only involved fluoride glass as the host material. The first demonstration of a fiber laser using this transition [11.816] produced only ≈ 13 mW when pumped at a wavelength of 640 nm. High-power cascade lasing at 2.9 μm and 2.1 μm has been employed to extend the output power to 1.3 W [11.817] by removing bottlenecking at the $^5I_7$ level [11.807] via the second laser transition at 2.1 μm. In an analogous manner to the Er^{3+}-doped fluoride glass system discussed below, the most successful arrangement to date for extracting high power from this transition has involved the use of Pr^{3+} as a desensitizer for the $^5I_7$ energy level: a maximum output power of 2.5 W was produced when the pump wavelength of 1100 nm from a Yb^{3+}-doped silica fiber laser was used [11.818].

An Yb^{3+}-sensitized Ho^{3+}-doped ZBLAN fiber could be directly pumped with diode lasers and may efficiently provide high-power 2.9 μm output without the costly requirement of an intermediate laser system. Initial spectroscopic results look encouraging [11.819], however, the many excited ion interactions that a fluoride host provides may be problematic. A recent demonstration has shown that ion–ion interactions (specifically ETU) in Ho^{3+}-doped fluoride glass are critical to the production of 2.9 μm output from singly Ho^{3+}-doped fluoride glass fiber lasers [11.820].

Erbium-doped solid-state lasers at 2.7–2.9 μm

For a long time, the development of erbium lasers operating on the $^4I_{11/2} \rightarrow {}^4I_{13/2}$ transition near 3 μm was

dominated by crystalline systems. The early success of the erbium 3 μm crystal laser has given rise to a significant amount of spectroscopic investigations. This has led to a deep understanding of the rather complex population mechanisms of this laser system and to the development of a large number of suitable host materials.

Crystalline lasers. The first observation of coherent emission near 3 μm from erbium ions was reported in 1967 [11.613]. Yttrium aluminum garnet (YAG) was demonstrated as a host for the erbium 3 μm laser [11.822] in 1975. In 1983, the first CW lasing near 3 μm was obtained in this material [11.823]. At about the same time, it was established [11.824–827] that energy transfer processes [11.828] between neighboring erbium ions in the host lattice play an important role in this laser system. Energy transfer processes can become very efficient at high excitation density [11.829] and govern the population mechanisms of the 3 μm laser at high erbium concentration. In the energy-level scheme of Fig. 11.73a, the important ETU and cross-relaxation processes are introduced. The ETU process $(^4I_{13/2}, {}^4I_{13/2}) \rightarrow (^4I_{15/2}, {}^4I_{9/2})$ leads to a fast depletion of the lower laser level and enables CW operation of a laser transition which, otherwise, could be self-terminating owing to the unfavorable lifetime ratio of the upper compared to the lower laser level. The ETU process from $^4I_{13/2}$ can be so dominant that even under direct pumping of the $^4I_{13/2}$ lower laser level and subsequent excitation of the $^4I_{11/2}$ upper laser level by ETU, 3 μm laser operation was demonstrated in several host materials [11.830].

This ETU process offers another great advantage. Half of the ions that undergo this process are upconverted to the $^4I_{9/2}$ level and, by subsequent multiphonon relaxation, are recycled to the $^4I_{11/2}$ upper laser level from where they can each emit a second laser photon, for a single pump-photon absorption. For a large number of ions participating in this process, a slope efficiency η_{sl} of twice the Stokes efficiency $\eta_{St} = \lambda_{pump}/\lambda_{laser}$ is obtained [11.831], because the quantum efficiency $\eta_{QE} = n_{laser}/n_{pump}$ of pump photons converted to laser photons increases from 1 to 2 (λ and n are the wavelengths and photon numbers of laser and pump transitions, respectively):

$$\eta_{sl} = \eta_{QE}\eta_{St} = 2\eta_{St} . \qquad (11.90)$$

This is illustrated in Fig. 11.74.

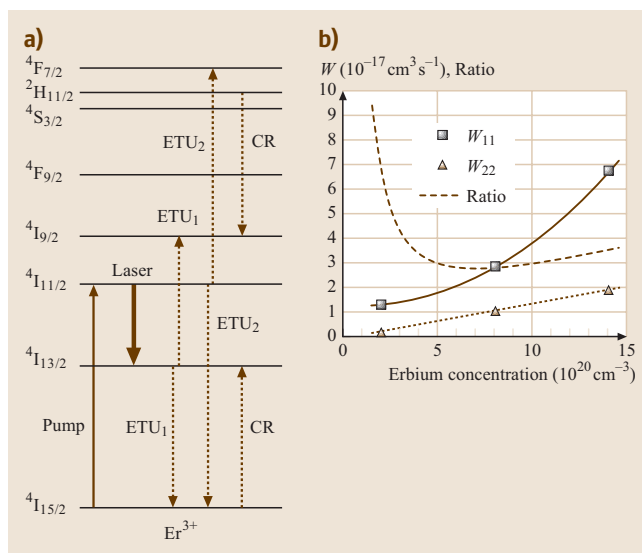
In a simple rate-equation system which includes the processes shown in Fig. 11.73a the slope efficiency is


Fig. 11.73 (a) Partial energy-level scheme of erbium indicating the pump and laser transitions, ETU_1 from $^4I_{13/2}$, ETU_2 from $^4I_{11/2}$, and cross-relaxation (CR) from the thermally coupled $^4S_{3/2}$ and $^2H_{11/2}$ levels. **(b)** Macroscopic parameters of ETU_1 from $^4I_{13/2}(W_{11})$ and ETU_2 from $^4I_{11/2}(W_{22})$ and the ratio W_{11}/W_{22} in ZBLAN:Er^{3+} bulk glasses. (After [11.821])

given by [11.831]

$$\eta_{sl} = \eta_{St} \frac{\ln(1-T)}{\ln[(1-T)(1-L)]} \left(2 - \frac{b_1^2}{b_2^2}\frac{W_{22}}{W_{11}}\right) , \qquad (11.91)$$

with T the transmission of the out-coupling mirror, L the internal resonator losses, and b_i and W_{ii}, the Boltzmann factors and ETU parameters of the upper ($i = 2$) and lower ($i = 1$) laser levels, respectively. If ETU occurs only from the lower laser level, i. e., $W_{22} = 0$, we obtain the predicted factor of two increase in slope efficiency from (11.91). The slope efficiency is reduced, however, by the resonator losses, the imperfect mode overlap, and the ETU process from the upper laser level in the case of $W_{22} > 0$. In the investigated host materials, the parameters W_{ii} of both ETU processes increase with increasing erbium concentration because of the influence of energy migration within the erbium $^4I_{11/2}$ and $^4I_{13/2}$ levels on ETU. The slope efficiency of (11.91) is optimum for a maximum ratio W_1/W_2. Spectroscopy of these processes in crystal hosts and laser experiments revealed that the maximum ratio is obtained at dopant concentrations of ≈ 12–15% in BaY$_2$F$_8$ [11.832, 833], $\approx 15\%$ in LiYF$_4$ [11.661], $\approx 30\%$ in YSGG [11.834],
Fig. 11.74 Partial energy-level scheme of erbium illustrating the process of energy recycling from the lower to the upper laser level by ETU. Indicated are the relative pump rate η_p of the upper laser level and the quantum efficiency η_{QE} which increases from 1 to 2 if a large number of ions participate in the process. (After [11.836])

and $\approx 50\%$ in $Y_3Al_5O_{12}$ [11.835]. A trend in this series is the increase of the optimum erbium concentration with phonon energy of the host material.

Energy recycling by ETU is the most efficient way to operate a CW erbium laser near 3 µm. The highest slope efficiency obtained experimentally is currently 50% in LiYF$_4$:15% Er^{3+} [11.837]. The pump wavelength that provides the highest Stokes efficiency of $\eta_{St} = \lambda_{pump}/\lambda_{laser} = 35\%$ is 980 nm, which corresponds to pumping directly into the upper laser level [11.838] (Fig. 11.73a). The highest slope efficiency obtained experimentally [11.837] is currently $\eta_{sl} = 50\%$ in LiYF$_4$:15% Er^{3+}. This result shows that energy recycling is indeed efficient and that slope efficiencies far above the Stokes efficiency can be obtained under CW pumping. Under quasi-CW excitation, the slope efficiency is strongly reduced [11.839], because the lower laser level is much less populated than in the steady-state regime and ETU is less efficient [11.840, 841]. Other operational regimes which deplete the lower laser level without recycling the energy to the upper laser level are less efficient. Consequently, neither co-lasing at the 1.6 µm transition from the lower laser level to the ground state [11.842] nor energy transfer from the erbium lower laser level to a rare-earth codopant [11.660] have reached the efficiency of the recycling regime.

Lifetime quenching of the $^4I_{11/2}$ upper laser level by multiphonon relaxation is stronger in oxide com-

pared to fluoride host materials because of the larger maximum phonon energies in oxides. With an energy gap between the $^4I_{11/2}$ upper and $^4I_{13/2}$ lower laser levels of ≈ 3400–3500 cm^{-1}, the radiative decay becomes dominant for phonon energies below ≈ 550 cm^{-1}. Since a long lifetime of the $^4I_{11/2}$ upper laser level provides a small pump threshold, fluorides are preferable host materials [11.843] for this laser transition if the pump power is not many times above threshold.

In the 1980s and 1990s, numerous host materials were investigated for CW and pulsed laser operation of Er^{3+} in the 2.7–2.9 µm region. A major role was played by the family of garnet crystals YAG, YSGG, YSAG, YGG, and GGG [11.615, 844, 845]. In the early years, Cr^{3+} codoping was used in order to improve the absorption of broadband flashlamp pump light in the visible spectral range and transfer the absorbed energy from Cr^{3+} to Er^{3+}. Typical output characteristics obtained were 2.7 W average power at a pump energy of 5 J with a repetition rate of 10 Hz [11.845]. Doping levels up to 100% substitution of Y^{3+} by Er^{3+} were tested [11.846]. A new class of host materials, fluoride crystals such as LiYF$_4$, BaY$_2$F$_8$, and others, became of importance in the late 1980s [11.847–850]. Laser thresholds as low as 5 mW were obtained under CW excitation by diode lasers [11.849].

In recent years, researchers have obtained CW and quasi-CW diode-pumped output power levels exceeding 1 W at 3 µm from fluoride [11.661] and oxide [11.851–853] crystalline host materials. A significant problem in the energy-recycling regime is increased heat generation due to the multiphonon relaxation $^4I_{9/2} \rightarrow {}^4I_{11/2}$ that follows each ETU process from the lower laser level [11.676]. Glass bulk materials [11.854] suffer from the same thermal and thermo-optical drawbacks as the crystalline bulk materials, with even decreased thermal conductivity in the glass. A possible solution is diode side pumping, which leads to lower excitation densities and correspondingly weaker ETU processes, as well as better heat removal in the slab geometry. The highest output powers of 1.8 W and later 4 W from an erbium 3 µm crystal laser [11.855, 856] have been obtained in this way. A reduced erbium concentration with correspondingly smaller parameters of the ETU processes may aid this approach. However, the efficiency of the energy-recycling regime cannot be reached in this approach.

Other special configurations include the operation of Er^{3+}-doped YAG, GGG, and YSGG lasers in monolithic cavities with output powers up to 0.5 W and tunable single-frequency output [11.857] as well as mi-

crolasers in YSGG [11.858]. Pulsed output at 3 μm has been generated from erbium-doped crystalline materials in many configurations and regimes, e.g., under quasi-CW pumping [11.839, 841], active [11.859–868] and passive [11.869–872] Q-switching, and mode-locking [11.619, 869, 873].

Fiber lasers. The erbium-doped fluoride fiber represents a promising alternative for the construction of a compact and efficient all-solid-state laser emitting at the transition at 3 μm. Due to its geometry, the fiber provides large flexibility and potentially high pump and signal beam intensities without the drawbacks of thermal and thermo-optical effects. The first erbium 3 μm fiber laser was demonstrated in 1988 [11.875]. Single-mode [11.876] and diode-pumped [11.877] operation were demonstrated shortly afterwards. Although the lifetime of the $^4I_{13/2}$ lower laser level exceeds that of the $^4I_{11/2}$ upper laser level, CW lasing can be obtained on this four-level-laser transition in ZBLAN (but also in fluoride crystals, see the paragraph on crystalline lasers) without employing special techniques to depopulate the $^4I_{13/2}$ lower laser level, because the lower laser level is not fed significantly by luminescent decay or multiphonon relaxation from the upper laser level [11.878]. In addition, the Stark splitting of the laser levels contributes to population inversion, because the laser transition occurs between a low-lying Stark component of the upper and a high-lying Stark component of the lower laser level [11.836]. During the relaxation oscillations at the onset of lasing, a red-shift of the lasing wavelength is often observed in erbium 3 μm laser systems [11.879–882], because the excitation energy is accumulated in the long-lived $^4I_{13/2}$ lower laser level and the character of the lasing process changes from four-level to three-level lasing [11.836]. For the same reason, the tunability range of a 3 μm CW laser [11.883] is narrowed and red-shifted with increasing pump power.

Pump excited-state absorption (ESA), which is present in Er^{3+} at almost all available GSA wavelengths [11.884], has a major influence on the performance of low-doped, core-pumped erbium 2.7 μm ZBLAN fiber lasers because of the significant amount of ground-state bleaching and excitation of the laser levels under these conditions [11.885]. Pumping at 980 nm directly into the upper laser level provides the highest Stokes efficiency of $\eta_{St} = \lambda_{pump}/\lambda_{laser} = 35\%$ [11.838]. However, ESA at 980 nm from the $^4I_{11/2}$ upper laser level [11.886] is detrimental to lasing. Experimentally, the best pump wavelength [11.885] is near 792 nm, at the peak of ESA from the $^4I_{13/2}$ lower laser level [11.874];

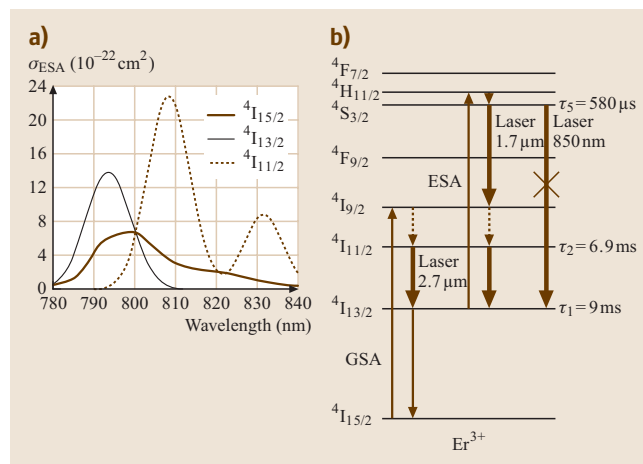
see the measured GSA and ESA cross sections in Fig. 11.75a. Depletion of the lower laser level by ESA favorably results in a redistribution of its population density and overcomes the bottleneck that results from the long lower-level lifetime. However, slope efficiencies obtained in this way were < 15%. Moreover, saturation of the output power at 2.7 μm was observed and the highest reported output powers were in the 20 mW region [11.887, 888]. The excitation of the metastable $^4S_{3/2}$ level (lifetime ≈ 580 μs [11.821]) led to inversion with respect to the $^4I_{13/2}$ level. A second laser transition at 850 nm repopulated the $^4I_{13/2}$ lower laser level of the 2.7 μm transition (Fig. 11.75b), causing the 2.7 μm laser to saturate at low output powers [11.885]. Significant improvement in the performance of this laser system was obtained by deliberately operating a third laser transition $^4S_{3/2} \rightarrow {}^4I_{9/2}$ at 1.7 μm, thereby suppressing the competitive laser at 850 nm and recycling the excitation energy accumulated in the $^4S_{3/2}$ level into the upper laser level; see the energy-level scheme in Fig. 11.75b. The slope efficiency of the 2.7 μm transition increased significantly to 23% [11.889], close to the Stokes efficiency limit of 29% under 800 nm pumping. An output power of 150 mW was demonstrated experimentally [11.889]. Also a three-transition-cascade


Fig. 11.75 (a) Absorption cross sections in ZBLAN:Er^{3+} near 800 nm: GSA $^4I_{15/2} \rightarrow {}^4I_{9/2}$ and ESA $^4I_{13/2} \rightarrow {}^2H_{11/2}$, $^4I_{11/2} \rightarrow {}^4F_{3/2}$, and $^4I_{11/2} \rightarrow {}^4F_{5/2}$ (After [11.874]). **(b)** Partial energy-level scheme of erbium indicating the processes relevant to the ZBLAN:Er^{3+} cascade laser: *lower loop* with GSA to $^4I_{9/2}$, multiphonon relaxation, laser transition at 2.7 μm, luminescent decay, and *upper loop* with ESA to $^2H_{11/2}$, thermal relaxation, laser transition at 1.7 μm, multiphonon relaxation, laser transition at 2.7 μm. Competitive lasing at 850 nm is suppressed in the cascade regime

lasing regime with additional lasing at the transition $^4I_{13/2} \rightarrow {}^4I_{15/2}$ near 1.6 μm was demonstrated [11.890].

In ZBLAN fibers with higher dopant concentrations of typically 1–5 mol % (≈ 1.6–8×10^{20} cm^{-3}) and with the double-clad geometry, ESA is much less important, because the reduced pump intensity with low-brightness diode lasers leads to smaller excitation densities. Currently, the most successful approach towards a high-power erbium 2.7 μm fiber laser is codoping of the fiber with Pr^{3+} [11.891, 892]. This idea was reported already in [11.887, 893, 894] and was proposed for the double-clad fiber laser in [11.895]. In this approach, the Er^{3+} 2.7 μm transition is operated as a simple four-level laser; see the energy-level scheme in Fig. 11.76a. The $^4I_{13/2}$ lower laser level is depopulated by the energy transfer process ET$_1$ to the Pr^{3+} codopant and fast decay to the ground state by multiphonon relaxation within Pr^{3+}. The energy-transfer process ET$_2$ from the $^4I_{11/2}$ upper laser level to the Pr^{3+} codopant is weak [11.821]. The strong lifetime quenching of the $^4I_{13/2}$ lower laser level significantly reduces ground-state bleaching and excitation of the laser levels, thus making the influence of ESA negligible, but

similarly preventing energy recycling by ETU [11.896]. Each pump photon can at best produce one laser photon in the Er^{3+},Pr^{3+}-codoped system. The theoretical limit of the slope efficiency is given by the Stokes efficiency, which is 29% under 800 nm pumping. Experimentally, a slope efficiency of 17% and an output power of 1.7 W were obtained [11.891] (Fig. 11.76b). Other researchers [11.897] reported output powers of 660 mW. Since ESA from both laser levels is negligible, the system can alternatively be pumped near 980 nm, which provides a Stokes efficiency of 35%. In this way, the experimental slope efficiency could be increased to 25% [11.898]. With improvements in diode-laser technology and an optimized fiber design, an output power of 5.4 W at 2.7 μm with a slope efficiency of 21% could recently be demonstrated from an Er^{3+},Pr^{3+}-codoped ZBLAN fiber laser [11.892, 899].

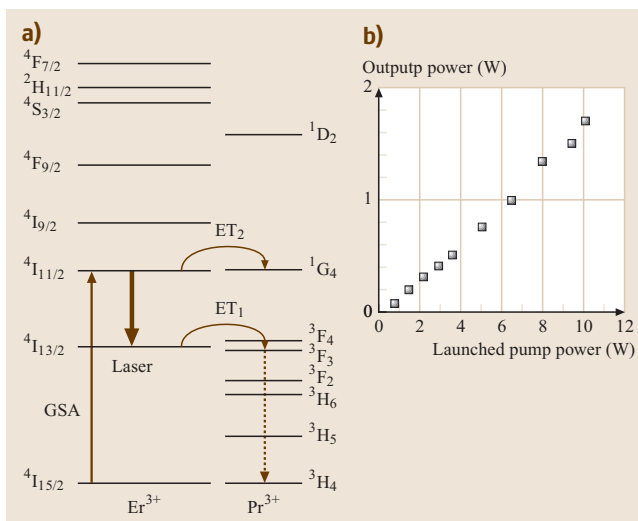
The first steps toward pulsed output from erbium 3 μm ZBLAN lasers [11.882, 900, 901] were unsatisfactory in terms of output energies and average powers. There have also been attempts to operate the ZBLAN fiber laser in the energy-recycling regime. The parameters W_{ii} of both ETU processes in ZBLAN bulk glasses [11.821] versus Er^{3+} concentration are shown in Fig. 11.73b. The criterion for optimization of the slope efficiency in (11.90) is maximizing the ratio W_{11}/W_{22}. For Er^{3+} concentrations of > 2–3 mol % at which ETU processes become important, this ratio is ≈ 3, see the *dashed line* in Fig. 11.73b, a more favorable value than reported for LiYF$_4$:Er^{3+} [11.851]. Energy recycling by ETU at high Er^{3+} concentrations [11.902] might lead to output powers at 3 μm on the order of 10 W. In early attempts, two research groups tried to exploit energy recycling [11.903, 904], however the slope efficiencies in these experiments did not exceed the slope efficiencies obtained in Er^{3+},Pr^{3+}-codoped fibers pumped at corresponding pump wavelengths [11.891, 892, 898]. In fibers with relatively large core diameters and therefore transverse multimode operation, singly Er-doped with concentrations smaller than those required for efficient energy recycling, 3 W of output power was obtained [11.905]. With further increase of the core diameter to 90 μm, the highest pulsed output of > 0.5 mJ could be demonstrated by the same researchers. Recently, 8 W of output power with a slope efficiency of 24.4% were demonstrated from a highly Er-doped (60 000 ppm) ZBLAN fiber when dual-end-pumping the fiber with 25 W of launched pump power at 975 nm. This result represents the highest output obtained by the end of 2005 from a fiber laser near 3 μm. Again, the achieved slope efficiency of 24.4% is very similar to


Fig. 11.76 (a) Partial energy-level scheme of erbium indicating the processes relevant to the ZBLAN:Er^{3+} lifetime-quenching laser: GSA at 980 nm to the $^4I_{11/2}$ upper laser level (or at 790 nm to the $^4I_{9/2}$ pump level and subsequent multiphonon relaxation to $^4I_{11/2}$), laser transition to the $^4I_{13/2}$ lower laser level, and relaxation to the ground state via energy transfer ET$_1$ to the Pr^{3+} codopant. The energy transfer ET$_2$ from the $^4I_{11/2}$ upper laser level to the Pr^{3+} codopant is weak. **(b)** Output power at 2.7 μm under 792 nm pumping. (After [11.891])

that of 25% obtained with the same pump wavelength in a Er^{3+},Pr^{3+}-codoped fiber [11.898]. Therefore, it must be concluded that efficient energy recycling with correspondingly improved slope efficiency similar to the result of 50% in a crystalline host material [11.837] is still lacking.

Dysprosium-doped solid-state lasers at 2.3–2.4 μm and 2.9–3.4 μm

The search for new mid-infrared laser transitions depends entirely on the structure of the energy-level diagram of the rare-earth ions. The Dy^{3+} ion offers a rather dense energy-level scheme in the infrared spectral region, resulting in a range of absorption peaks, as well as a four-level laser transition at 2.3–2.4 μm and a phonon-terminated 3 μm laser transition. The transition at 2.3–2.4 μm was among the first laser transitions reported and the first to be demonstrated in continuous-wave operation [11.609, 610]. Because of the dense energy-level scheme of Dy^{3+}, multiphonon relaxation is an issue of concern in this ion, hence low-phonon host materials may improve its laser performance. Recently, room-temperature laser emission at 2.43 μm was reported in the low-phonon host materials $CaGa_2S_4:Dy^{3+}$ and $KPb_2Cl_5:Dy^{3+}$. At the 3.4 μm transition, room-temperature laser oscillation from Dy^{3+} in $BaYb_2F_8$ has been reported [11.906]. The 1100 nm output from a Yb^{3+}-doped silica fiber laser has been successfully used to pump a Dy^{3+}-doped fluoride fiber laser [11.907]. In this case, a maximum output power of 275 mW was generated with a slope efficiency of only $\approx 5\%$, however, when the pump wavelength was increased to ≈ 1.3 μm using a YAG:Nd^{3+} laser, the slope efficiency is approximately quadrupled to $\approx 20\%$ [11.908]. Reduced levels of pump ESA are believed to cause this augmentation in the slope efficiency. Future Dy^{3+}-doped fluoride fiber lasers may benefit from further increases in the pump wavelength to 1.7 μm or 2.8 μm.

Before turning our attention to rare-earth-ion-doped solid-state lasers in the wavelength range beyond 3 μm, it should be noted that solid-state lasers based on the actinide ion U^{3+} have also attracted attention in the recent past [11.909, 910].

Solid-state lasers at wavelengths beyond 3 μm

Laser wavelengths longer than typically 3 μm are generally difficult to achieve in solid-state host materials by direct generation from rare-earth or transition-metal ions, because the energy gap between the upper and lower laser level is necessarily small and all the common oxide and fluoride host materials possess maximum

phonon energies, which lead to fast multiphonon relaxation of the excitation of the upper laser level. Therefore, many of the laser transitions reported in the literature require cooling of the active device. On the other hand, the attractiveness of this wavelength range for a number of applications has inspired the search for host materials with maximum phonon energies below ≈ 300 cm^{-1}.

In crystalline hosts, a flashlamp-pumped, cooled Er^{3+} laser at 4.75 μm [11.614], a CW diode-pumped, cooled Er^{3+} laser at 3.41 μm [11.911], and a pulsed diode-pumped room-temperature Er^{3+} laser at 4.6 μm [11.912] have been operated. A room-temperature $BaY_2F_8:Ho^{3+}$ laser was operated at 3.9 μm [11.913]. Due to its dense energy-level scheme, Dy^{3+} offers a large range of possible mid-infrared transitions. Recently, room-temperature lasing of Dy^{3+} transitions in the low-phonon host materials $CaGaS_2$ and KPb_2Cl_5 was demonstrated [11.914], in the former material even at 4.31 μm. The longest-wavelength lasers shown to operate in a solid-state material are room-temperature 5 μm and 7 μm lasers in $LaCl_3:Pr^{3+}$ [11.915, 916].

The operation of lasers at wavelengths of 3.22 μm [11.917] and 3.95 μm [11.918] has been obtained from Ho^{3+}-doped ZBLAN fiber and at 3.45 μm [11.919] from Er^{3+}-doped ZBLAN fiber. It was, however, necessary to cool the ZBLAN fiber for the 3.45 μm and 3.95 μm transitions. These two laser transitions span five or six maximum phonon energies in ZBLAN, therefore the lifetime of the upper laser level for each of these transitions is short and engenders an increase in the pump threshold compared to other ZBLAN fiber lasers operating at the shorter mid-infrared wavelengths. In addition, the lower laser levels of these transitions possess quite long lifetimes and some saturation of the output power has been observed [11.920]. This problem (while it can be mitigated with cascaded lasing), combined with the use of inconvenient pump sources has impeded the full utilization of these laser transitions. The 3.95 μm wavelength emitted from the cooled ZBLAN fiber laser is currently the longest laser wavelength that has been generated from a fiber laser.

Generating wavelengths longer than 3 μm from fiber lasers is a task that tests the limits of current glass technology. The need for lower phonon energies has to be balanced with acceptable mechanical, chemical, and thermal properties. Since the highly developed ZBLAN glass is only useful for laser transitions up to 3–3.5 μm, glasses such as the chalcogenides [11.921] will need to fill the gap. It is because these glasses have to

be drawn into low-loss fiber that has prevented long-wavelength emission to the extent that is possible in crystalline-based solid-state lasers. Creating efficient, high-power mid-infrared fiber lasers with output wavelengths $> 3\,\mu m$ is at the forefront of current fiber-laser research efforts.

As mentioned above, fiber lasers operating on laser transitions that have wavelengths $> 3\,\mu m$ will need to use glasses, which have very low phonon energies. While rare-earth-ion-doped heavy-metal oxides [11.925] have been studied for $2-3\,\mu m$ mid-infrared emission; to date, there has been no report of laser action for a fiber laser comprised of such a glass. Heavy-metal oxides do not seem to be suitable for lasers at wavelengths beyond $3\,\mu m$, because their maximum phonon energies are comparable to fluoride glasses and are too high for laser transitions beyond $3\,\mu m$.

The chalcogenide glasses have been doped with a number of rare-earth ions including Ho^{3+} [11.924], Tm^{3+} [11.923], Tb^{3+} [11.923], Dy^{3+} [11.922], Pr^{3+} [11.926], and Er^{3+} [11.927, 928] for studies into $> 3\,\mu m$ mid-infrared luminescence (Table 11.21). Fiber-laser action has been reported, however, only for an Nd^{3+}-doped GLS glass operating at a wavelength of $\approx 1\,\mu m$ [11.929]. Recent demonstrations of fabricating Bragg gratings [11.930], single-mode fibers [11.931] and holey fibers [11.932] with chalcogenide glass highlight the utility of this glass for fiber-based applications; however, the purity and toxicity of the starting materials and the difficulty of making ultralow-loss fiber currently impede the widespread use of chalcogenide glass for mid-infrared fiber-laser applications. Once these obstacles have been overcome, future $> 3\,\mu m$ fiber lasers will most likely involve the rare-earth ions Pr^{3+}, Nd^{3+}, Dy^{3+}, and Ho^{3+} doped into chalcogenide glass, because most of the important mid-infrared transitions relevant to these ions can be accessed with pump-photon wavenumbers $< 10\,000\,cm^{-1}$. Judicious choice of the overall dopant-ion concentration and the use of particular sen-

sitizer and quenching ions will enable the production of efficient $> 3\,\mu m$ output some time in the future.

Conclusions

In the roughly four decades since the demonstration of the first mid-infrared solid-state lasers, thousands of scientific papers have been published which have reported on lasing in novel host materials, replacement of flashlamps by ion-laser and later diode-laser pump sources, ever-growing output powers, higher efficiencies, larger tunability ranges, shorter pulse durations and the like. A general tendency is that, the shorter the wavelength, the better the laser performance. When we approach longer wavelengths in the mid-infrared spectrum, we find that the quality and durability of the required low-phonon-energy host materials decline, Stokes and slope efficiencies decrease, whereas the thermal problems increase. While many crystalline host materials and the corresponding laser techniques have matured during the 1990s, the fast development of high-power, fundamental-mode fiber lasers, which could be witnessed in the $1\,\mu m$ spectral range, has now also reached the mid-infrared spectral region. However, the assumption that, due to its large surface-to-volume ratio, the fiber geometry might avoid all thermal problems has been questioned by several recent high-power fiber-laser experiments in the near- and mid-infrared spectral region. These phenomena are, in principle, not much different from the situation found in crystalline lasers. Nevertheless, there remain distinct differences between these two host categories. When flexibility of the resonator design, short pulses, and high peak powers are required, crystalline lasers have advantages. On the other hand, fiber lasers are preferred when high beam quality or low pump threshold combined with medium CW output power are desired. The low pump threshold of fiber lasers is an invaluable advantage when cascade-laser operation is required to depopulate the long-lived terminating level of one laser transition by a second laser transition. The comparatively low dopant concentrations that are useful in fiber lasers due to the long interaction lengths can minimize energy dissipation by interionic processes but, equally, limit the exploitation of these processes as a tool to optimize the population mechanisms of a certain laser system, as has been done successfully in several of the mid-infrared crystalline laser systems discussed above. Although still a great challenge with respect to fabrication process and durability, low-phonon crystalline and fiber host materials have the potential to revolutionize CW mid-infrared lasers in the wavelength range between $3-5\,\mu m$.

11.2.5 Transition–Metal–Ion Lasers

Basics

In this chapter an overview of transition-metal-ion lasers will be given. The main focus lies on the laser characteristics and results, a more spectroscopically oriented overview is given in [11.933]. Transition metals are elements of the third, fourth and fifth row of elements in the periodic table. Laser oscillation has so far only been obtained with ions of the transition metals of the third row (the Fe row; Ti to Cu). Due to the strong coupling between the electronic levels of the transition-metal ion with the surrounding field established by the crystalline environment, transition-metal-ion lasers are usually tunable over a wide spectral range up to several hundred nanometers. These lasers are of interest for a wide field of applications, e.g., in scientific research, in medicine, for measurement and testing techniques, ultrashort-pulse generation, and communication. They can also be used as coherent light sources for second-harmonic generation, for optical parametric oscillators, and for sum- and difference-frequency generation.

The energy-level scheme and thus also the spectroscopic and laser characteristics of a transition-metal ion in a crystalline field is strongly dependent on the valence state of the ion, the number of ligands (i. e., the coordination number) and the strength and symmetry of the surrounding crystalline field. Therefore it is not possible to draw some kind of Dieke diagram for the transition-metal ions, as it is possible for the trivalent rare-earth ions (see the section on 4f–4f transitions in Sect. 11.2.1). The energy-level schemes of the transition-metal ions in crystalline hosts are in principle described by the so-called Tanabe–Sugano diagrams [11.934–936]. These diagrams are distinguished by the number of electron within the 3d electron shell. In these diagrams the energy of a specific level of the transition-metal ion is depicted as a function of the crystal field strength. We will not describe the quantum-mechanical background to obtain these diagrams, which would be beyond the frame of this handbook. The reader is referred to the appropriate literature [11.937–942].

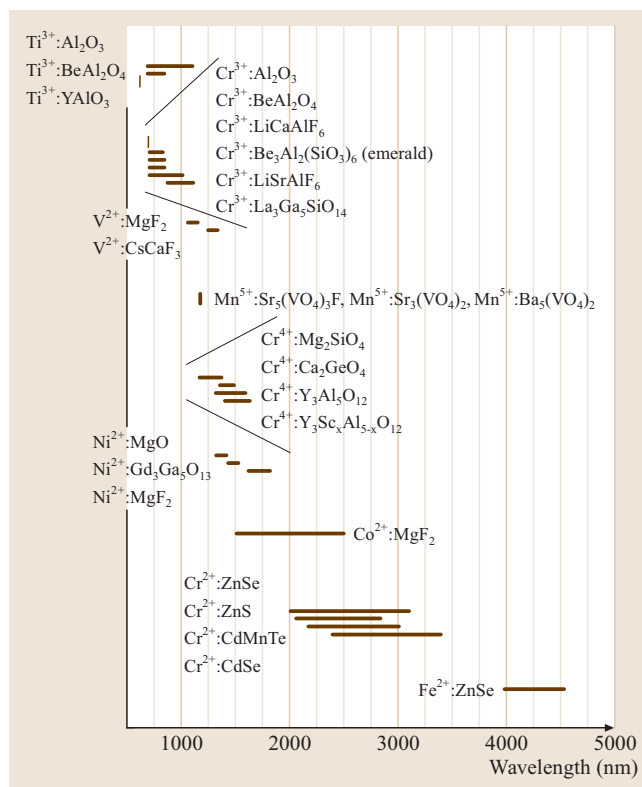
In comparison to laser systems based on the 4f↔4f transitions of trivalent rare-earth ions, lasers based on 3d↔3d transitions are in general more affected by a higher probability of excited-state absorption, a higher probability of nonradiative decay, and a higher saturation intensity, leading to higher laser thresholds. Often laser oscillation cannot be obtained at all. In the following section, the focus is on specific transition-metal-ion lasers, ordered according to their laser wavelength from visible


Fig. 11.77 Overview of tunable solid-state lasers based on transition-metal-ion-doped crystals

over the near-infrared to the mid-infrared. This overview includes Ti^{3+} lasers, especially $Ti^{3+}:Al_2O_3$, Cr^{3+} lasers, Cr^{4+} lasers and finally Cr^{2+} lasers. At the end of this section, other transition-metal-ion lasers are presented, including Co^{2+} and Ni^{2+} lasers. Finally, some general comments about transition-metal-ion lasers will be given in the last section. In Fig. 11.77 an overview of lasers based on 3d↔3d transitions of transition-metal ions is given. It can be seen that almost the whole spectral range between 650 nm and 4500 nm is covered.

Overview of Transition–Metal–Ion Lasers

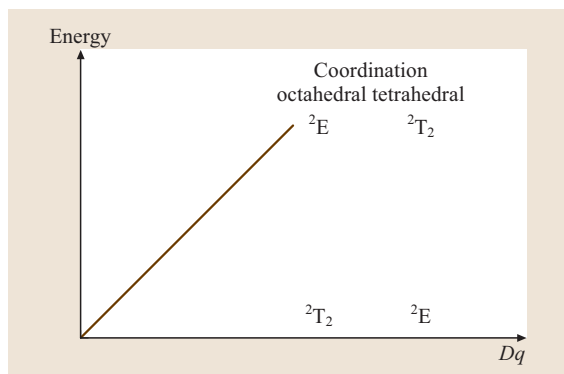
Ti^{3+} *lasers.* Ti^{3+}-doped Al_2O_3 (Ti:sapphire) has been intensively investigated as a tunable laser material since the first laser operation was reported [11.943, 944]. Efficient laser oscillation was obtained in Al_2O_3 in pulsed [11.943, 945, 946] and continuous-wave [11.945, 947, 948] operation, for further references see [11.213]. The tuning range covers more than 400 nm and spans approximately 670–1100 nm [11.949]. It has a relatively high emission cross section of approximately


Fig. 11.78 Basic energy-level schemes of $3d^1$ ions in octahedral and tetrahedral coordination

4.1×10^{-19} cm^2 [11.950] at the maximum of the emission spectrum. A slope efficiency of 62% has been reported [11.951], which is close to the quantum limit in that experiment of 78% (pump wavelength 589 nm, emission wavelength 750 nm). This indicates the low intrinsic losses of the system.

The Ti^{3+} ion belongs to the $3d^1$ configuration, which is very favorable with respect to laser application because of its simple energy-level scheme (see Figs. 11.78, 11.79). There are only two $3d^1$ energy levels, which diminishes the possibility of excited-state absorption of the laser radiation, a process that limits
Fig. 11.79 Schematic diagram of the Jahn–Teller effect for octahedrally coordinated d^1-systems. ^2E, $^2T_2$ and CT (charge transfer) are the energy levels, GSA, ESA, and em are ground-state absorption, excited-state absorption, and emission, respectively. nr represents the nonradiative decay via tunneling between the excited state and the ground state. ΔE_{JT} is the Jahn–Teller stabilization energy

the tuning range and efficiency of other transition-metal-ion-doped lasers. The orbital degeneracy of the d levels is removed due to the Jahn–Teller effect, which yields the large absorption and emission bandwidths. The room-temperature absorption and emission spectra are shown in Fig. 11.80. Excited-state absorption transitions occurs to energy levels correlated to charge transfer and conduction-band levels and between the two Jahn–Teller-split components of the upper (^2E) d level. In Ti:sapphire, excited-state absorption was not observed in the spectral range of emission [11.952]. In Table 11.22 the laser-relevant parameters of Ti:sapphire are listed. Besides the favorable spectroscopic and laser characteristic, the Al$_2$O$_3$ host material offers a variety of advantageous properties: a high thermal conductivity, as well as mechanical and chemical hardness.

To date, Ti^{3+}:Al$_2$O$_3$ is the most common and commercially available tunable solid-state laser. Nowadays, it can be pumped with frequency-doubled Nd lasers at wavelengths around 532 nm, thus efficient all-solid-state laser operation is possible. Formerly, Ar$^+$-ion laser pumping was applied. In commercial systems, overall efficiencies as high as 30% are obtained.

Besides the broad tuning capability of the Ti:sapphire laser, its ability for ultrashort-pulse generation and amplification is especially exploited. In mode-locked operation, pulses as short as 5 fs [11.953–957] and octave-spanning spectra (e.g., 600 nm to 1200 nm [11.957]) have been obtained.

Laser oscillation with reasonable efficiency has also been reported for Ti^{3+}:BeAl$_2$O$_4$ [11.958–961]

Table 11.22 Overview of Ti^{3+}:Al$_2$O$_3$ laser-relevant parameters [11.948, 950]

Index of refraction	1.76
Absorption cross section	6.5×10^{-20} cm^2 ($E \parallel c$)
Fluorescence lifetime	3.2 μs
Fluorescence bandwidth (FWHM)	≈ 200 nm
Peak emission wavelength	790 nm
Peak stimulated emission cross section	4.1×10^{-19} cm^2 ($E \parallel c$)
	2.0×10^{-19} cm^2 ($E \perp c$)
Quantum efficiency	$\approx 0.9 - 1$
Saturation fluence	0.9 J/cm^2
Dopant concentration	0.1% (weight)
Growth	Czochralski, heat exchange
T_m	2050 °C
Thermal conductivity	28 W/mK
Thermal lens (dn/dT)	12×10^{-19} K^{-1}

(Table 11.23). However, the efficiency as well as the tuning range is smaller than $Ti^{3+}:Al_2O_3$, thus this laser has no commercial application. In $Y_3Al_5O_{12}$ [11.962] and $YAlO_3$ [11.963, 964] crystals doped with Ti^{3+} the observed efficiencies are very low (Table 11.23). The main reason for this is excited-state absorption in the spectral region of emission and absorption [11.952, 965]. In Ti^{3+}-doped systems nonradiative decay processes due to phonon-assisted tunneling between the Jahn–Teller-split excited and ground states also occur, which prevent efficient laser oscillation, e.g., in $Ti^{3+}:Y_3Al_5O_{12}$ [11.966, 967].

Cr^{3+} lasers.

Basics. The Cr^{3+} ion is almost always found in octahedral coordination and its energy-level scheme is described by the Tanabe–Sugano diagram shown in Fig. 11.81. In low crystal fields, the first excited state is the $^4T_2$ level, whereas in strong crystal fields the ^2E level is the first excited state. This means, that either broadband emission ($^4T_2 \rightarrow {}^4A_2$) or narrow-line emission ($^2E \rightarrow {}^4A_2$) occurs. The absorption spectra are dominated by quartet–quartet transitions, whereas the excited-state absorption spectra are dominated either by quartet–quartet or doublet–doublet transitions depending on the total spin of the lowest excited state.

Laser characteristics. The first laser was realized in 1960 with ruby, i.e., Cr^{3+}-doped Al_2O_3 [11.968]. In ruby – due to the strong crystal field experienced by the Cr^{3+} ion – the laser oscillation occurs on the $^2E \rightarrow {}^4A_2$ transition. Thus, ruby is a three-level laser and not tunable over a wide range. Ruby is still a commercially available pulsed laser system with peak output powers in the MW range used for applications in measurement and pulsed holography. Ruby has remarkable thermo-mechanical properties which allows high peak power operation, especially in the Q-switched regime. In 1976, *Morris* et al. [11.969] realized with Cr^{3+}-doped $BeAl_2O_4$ (alexandrite) the first tunable laser based on the Cr^{3+} ion. The laser transition is $^4T_2 \rightarrow {}^4A_2$ and terminates in the higher vibronics of

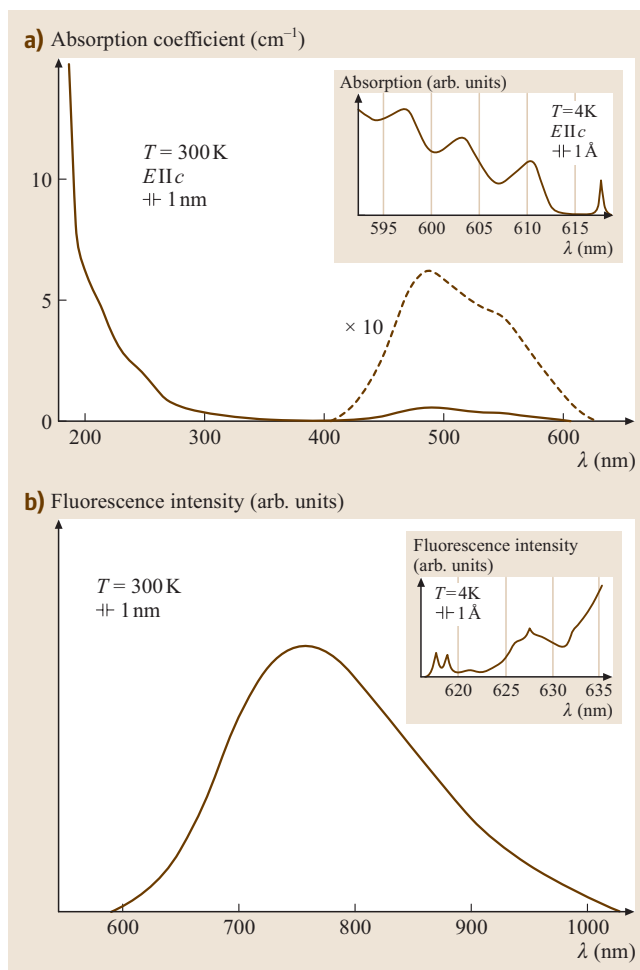
the ground state. Therefore, a four-level laser system is realized. To date, the alexandrite laser has found significant commercial applications in industry (e.g., marking, writing and printing), scientific research (e.g., fluorescence dynamics, fluorescence imaging, LIDAR), and


Fig. 11.80a,b Absorption (**a**) and emission (**b**) spectra at room temperature and at 4 K of Ti:sapphire. (After [11.948])

Table 11.23 Overview of other Ti^{3+}-laser materials

medicine (e.g., hair and tattoo removal,). Its advantages are its tunability between 700 nm and 820 nm, the high heat conductivity of 23 W/mK, which allows high-power pulsed operation, and its high slope efficiency of up to 51% [11.970, 971]. Even broader laser tuning ranges with similar efficiencies were achieved with the Cr^{3+}-doped colquirite crystals $LiCaAlF_6$, $LiSrAlF_6$, and $LiSrGaF_6$ [11.972] (Table 11.25). However, these crystals suffer from poor thermo-mechanical properties (Table 11.24), which allow only relatively low pump and laser powers. The broad tuning range is exploited for mode-locked operation with pulse lengths down to 9 fs for Cr^{3+}:LiCAF [11.973]. The crystals also offer the possibility of efficient laser-diode pumping with laser diodes at wavelengths around 670–690 nm. Thus compact, mode-locked laser systems in the low-power range are possible [11.974–976]. It is interesting to note that the highest slope efficiency ever obtained with a Cr^{3+}-based laser was achieved with Cr^{3+}:$Be_3Al_2(SiO_3)_6$ (emerald). Also here, however, the thermo-mechanical properties are poor and, furthermore, the emerald crystal is very difficult to grow in laser quality. For the most efficient Cr^{3+} laser materials the relevant laser and materials parameters are listed in Table 11.24. Laser oscillation with Cr^{3+}-doped systems has been realized in

more than 30 materials. In Table 11.25 an overview of reported laser systems is given [11.103, 977]. In general the tuning ranges for Cr^{3+} lasers are not as broad as for Ti^{3+}:Al_2O_3 lasers, however, they exhibit the advantage of direct diode-laser pumping around 670 nm, i.e., in the spectral region of the $^4A_2 \rightarrow {}^4T_2$ absorption.

For Cr^{3+} laser systems excited-state absorption (ESA) plays a very important role and is the main reason for the observed large differences in the laser efficiencies. Due to its energy-level scheme (Fig. 11.81), spin-allowed ESA transitions are expected either between the quartet states (for low-crystal-field hosts) or between the doublet states (in strong-field hosts). These transitions cover a wide spectral range, due to the strong electron–phonon coupling. Thus, in general, these ESA transitions overlap with the absorption and emission bands. The influence of the ESA is strongly dependent on the host lattice, i.e., on the crystal field experienced by the Cr^{3+} ion. In general, it is observed that crystals with a medium crystal field for the Cr^{3+} ion are favorable. Furthermore, in some crystals (e.g., the colquirites, alexandrite, emerald etc.) the polarization-dependent selection rules can be exploited. Cubic hosts are generally more strongly affected.

Summary and perspectives for Cr^{3+} lasers. Cr^{3+} lasers are generally interesting for laser applications. High-efficiency diode-pumped and broadly tunable continuous-wave and mode-locked laser oscillation have been obtained in a variety of crystals. Some laser systems are commercially available. However, all of these crystals have specific drawbacks: they have poor thermal mechanical properties, the growing process is difficult or the tuning range is small. Therefore Cr^{3+} lasers are at this time in general not competitive with the Ti^{3+}:Al_2O_3 laser, which offers a broader tuning range, allows shorter pulses in the mode-locked regime and has better thermo-mechanical properties. Ti^{3+}:Al_2O_3 cannot be pumped directly with diode lasers; however, advances in the frequency-doubling technique of neodymium lasers has led to efficient all-solid-state pump lasers which replaced the argon-ion laser as pump. Additionally, pump laser diodes in the spectral region between 630 nm and 700 nm with high beam quality and output power are currently not available in a satisfactory manner. Concerning the research for new Cr^{3+} laser systems one has to take into account that the Cr^{3+} ion has already been investigated in a large number of systems. In principle, new host materials with the perspective of efficient laser operation should have a medium crystal field for the Cr^{3+} ion and polarization-dependent optical prop-

erties that could help to avoid or at least significantly reduce excited-state absorption in the spectral region of the emission. Furthermore, good thermo-mechanical properties are required.

Cr^{4+} lasers.

Basics. Cr^{4+}-doped crystals have been of interest as tunable, room-temperature laser materials since the late 1980s. In a variety of materials laser oscillation in different operation schemes has been achieved, see Table 11.26 and Table 11.28, where an overview of the obtained laser results is given. The energy-level scheme of the Cr^{4+} ion in crystals can be described with the Tanabe–Sugano diagram shown in Fig. 11.82. The absorption spectra are dominated by the three spin-allowed transitions between the $^3A_2$ ground state and the $^3T_2(^3F)$, $^3T_1(^3F)$, and $^3T_1(^3P)$ excited states. Usually, the energy levels are strongly crystal field dependent and split, thus the absorption spectra of different materials differ significantly. In all materials investigated thus far, broadband emission due to the transition between the

$^3T_2$ excited state and the $^3A_2$ ground state is observed. Referring to the Tanabe–Sugano diagram and the indicated area of crystal field values for the Cr^{4+} ion, one would expect – at least in some materials – narrow-line emission. However, due to lattice relaxation and crystal field splitting of the excited state, the $^3T_2$ or one of its crystal field components becomes lower than the ^1E level.

The most efficient laser oscillation of Cr^{4+}-doped materials was realized in Mg$_2$SiO$_4$ and Y$_3$Al$_5$O$_{12}$ (YAG). The laser data and main spectroscopic data of these materials are listed in Table 11.26 and Table 11.27. A variety of further host materials for the Cr^{4+} ion were also investigated, but with either low efficiency (Table 11.28) or without realization of laser oscillation. A detailed overview of Cr^{4+}-doped systems is given in [11.933].

In all Cr^{4+}-doped materials investigated thus far, there are two main drawbacks for efficient laser oscillation or laser oscillation at all: excited-state absorption and nonradiative decay. Investigation of excited-state

absorption has been performed on garnets [11.978–980], forsterite [11.981–984], cunyite [11.985], silicates [11.982] and Wurtzite-type crystals [11.984, 986, 987]. The nonradiative decay via multiphonon relaxation leads to quantum efficiencies far below 100% at room temperature; see the overview given in [11.933]. The preparation of Cr^{4+}-doped crystals requires for most materials special conditions before, during or after the growth process. The Cr^{4+} ion is not as stable in its va-

lence state as Cr^{3+}. Therefore, there is the tendency for incorporation of chromium ions in different valencies in the crystals, especially for materials that do not exhibit an appropriate tetravalent tetrahedrally coordinated lattice site. This is, e.g., the case for Y$_3$Al$_5$O$_{12}$, therefore here additional codoping with divalent cations (Mg, Ca) is necessary. But also in Mg$_2$SiO$_4$, Cr^{3+} is incorporated into the Mg lattice. No traces of Cr^{3+} were observed in these materials, which do not exhibit an ap-

propriate lattice site for the Cr^{3+} ion, e.g., Ca_2GeO_4 and Y_2SiO_5. However, the laser results obtained with $Y_3Al_5O_{12}$ and Mg_2SiO_4 indicate that the laser efficiency is not necessarily affected by the presence of Cr^{3+}.

Laser characteristics. In Table 11.26 an overview of the laser results obtained with Cr^{4+}:YAG and Cr^{4+}:Mg_2SiO_4, the materials in which the most efficient laser operation has been obtained, is given. In YAG, the highest slope efficiency obtained thus far in the continuous-wave regime is 42% [11.1085]. The corresponding input–output curve is shown in Fig. 11.83a. Attempts to improve the laser efficiency by changing the crystals composition, i. e., by substituting Lu for Y on the dodecahedral site or Sc for Al on the octahedral site were not successful [11.1086, 1087]. The efficiency de-

creased significantly. The reason is mainly excited-state absorption, but the lower crystal quality and increased nonradiative rate also contribute [11.1125]. A remarkable characteristic – on first sight – is that the Cr^{4+}:YAG laser oscillates polarized parallel to one of its main crystallographic axes. The laser output was highest when the pump beam of a Nd:YAG laser operating at 1064 nm and propagating along the [001]-axis of the Cr^{4+}:YAG crystal is polarized parallel to one of the crystallographic < 100 >-axes of the Cr^{4+}:YAG crystal, and was lowest when its polarization was parallel to one of the < 110 >-axes (Fig. 11.83b). The Cr^{4+}:YAG laser output is polarized and maintains its polarization while rotating the pump beam polarization. When the pump beam polarization is parallel to one of the < 110 >-axes, the Cr^{4+}:YAG laser polarization

tals from the forsterite group the attempts to obtain better laser results by substituting the constituent ions of the host lattice were also not successful. A variety of crystals were investigated [11.1142–1144] (see the overview given in [11.933]) but only for Ca_2GeO_4 was laser oscillation obtained. For Ca_2GeO_4 excited-state absorption on the laser wavelength is detrimental [11.985].

Laser oscillation was also obtained for Cr^{4+}-doped Y_2SiO_5, $LiGeNbO_5$, $CaGd_4(SiO_4)_3O$, and $SrGd_4(SiO_4)_3O$. The low efficiencies are probably due to excited-state absorption and the high nonradiative decay rate.

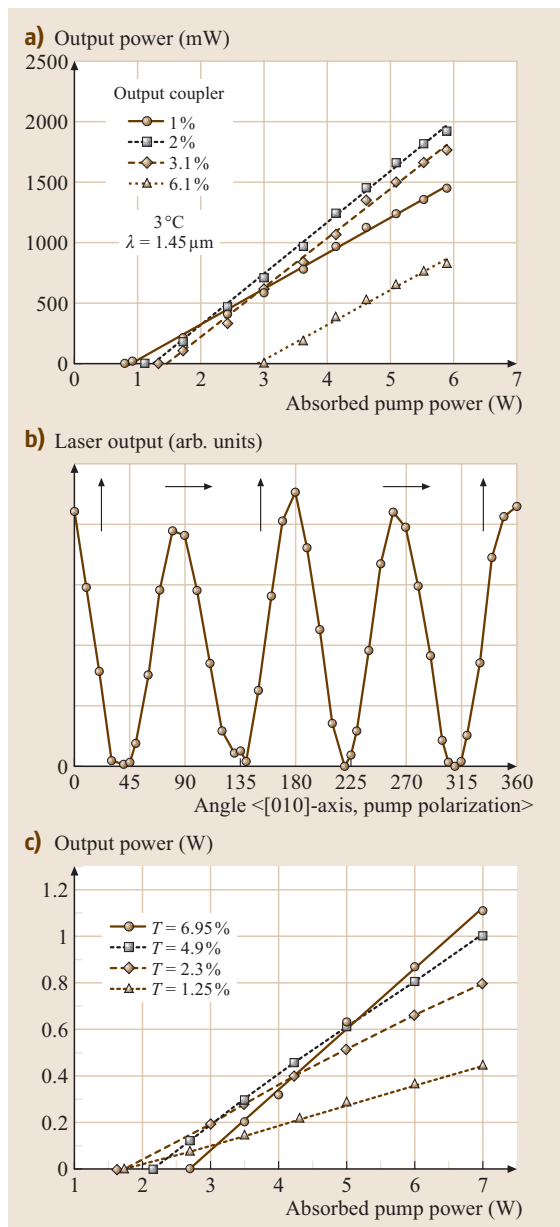
Summary and outlook for Cr^{4+} lasers.
Cr^{4+}:YAG and Cr^{4+}:Mg_2SiO_4 are efficient and broadly tunable laser systems for the infrared spectral range including the very interesting region for telecommunication applications around $1.3\,\mu m$ and $1.55\,\mu m$. Mode-locked operation with pulse lengths as short as 20 fs for Cr^{4+}:YAG [11.1096] and 14 fs for Cr^{4+}:Mg_2SiO_4 [11.1123] were obtained. Also direct diode-pumped laser operation was realized, however, with lower efficiencies [11.1094, 1097]. For both systems, power handling is a problem and the ion


Fig. 11.83 (a) Input–output characteristic of a Cr^{4+}:YAG-laser (after [11.1085]), **(b)** Polarization dependence of a Cr^{4+}:YAG laser (after [11.933, 1084]), **(c)** Input–output characteristic of a Cr^{4+}:Mg_2SiO_4 laser (after [11.1103])

concentration in both materials is rather low, yielding a low absorption efficiency of the pump light.

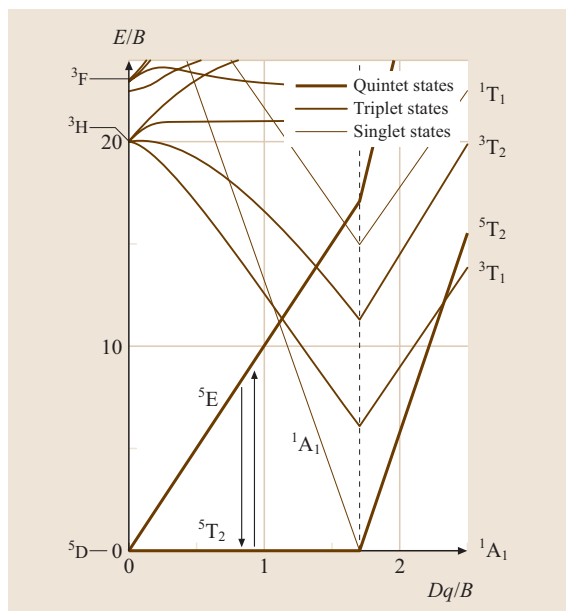
The main obstacle for Cr^{4+} laser materials is excited-state absorption at the emission wavelength, which


Fig. 11.84 Tanabe–Sugano diagram for tetrahedrally coordinated ions with $3d^4$ configuration, $C/B = 4$

is present in practically all crystals. Its influence is small in systems with an advantageous energy-level scheme and/or a crystal structure that supports strong polarization-dependent selection rules. A second but less

Fig. 11.85 σ_{GSA} (*dashed line*), σ_{SE} (*dotted line*), $(\sigma_{GSA} + \sigma_{SE} - \sigma_{ESA})$ (*thin solid line*), and $(\sigma_{SE} - \sigma_{ESA})$ spectrum (*thick solid line*) of Cr^{2+}:ZnSe at room temperature. The sharp structure beyond 2500 nm is attributed to the water absorption in air and the following normalization process. (After [11.1145])

important point concerning Cr^{4+} laser materials is the nonradiative decay rate. To decrease this rate, crystals with low-energy phonons and/or small electron–phonon coupling should be used as host materials, e.g., those in which silicon is substituted by germanium or aluminum is substituted by gallium. However, attempts in this direction have not been successful thus far.

Cr^{2+} lasers.

Basics. The energy-level scheme of tetrahedrally coordinated Cr^{2+} is shown in Fig. 11.84. The Cr^{2+} ion experiences a low crystal field, e.g., in ZnSe the value of Dq/B is about 0.9. Thus, the $^5T_2$ level is the ground state and the ^5E level is the first excited state, whilst all higher-lying levels are triplet and singlet states. In consequence, the $^5E \rightarrow {}^5T_2$ emission is a spin-allowed transition, while all interionic excited-state transitions are spin-forbidden. Such systems are in general very promising for the realization of efficient tunable laser oscillation, because even in the case of a spectral overlap between stimulated emission and excited-state absorption, the transition probabilities for the latter are expected to be about a factor of 10 smaller.

Cr^{2+}-doped chalcogenide crystals have been shown to be efficient and broadband tunable solid-state lasers for the infrared spectral range between 2 μm and 3 μm. Pulsed, continuous-wave, mode-locked and diode-pumped laser operation have been demonstrated in recent years. Possible applications of these mid-infrared lasers include scientific research, remote sensing, trace-gas analysis, medicine, biology, materials processing, and ultrashort-pulse generation.

Materials. The choice of host materials for the Cr^{2+} laser ion is limited due to special conditions. First, the materials have to exhibit a tetrahedrally coordinated lattice site. A divalent lattice site is also preferably, because otherwise a charge-compensation mechanism would have to be established in the lattice. Furthermore, host crystals with low phonon frequencies have to be chosen in order to decrease the possibility of nonradiative decay via multiphonon relaxation. Chalcogenide crystals, with their tetrahedrally coordinated divalent cation lattice sites and with phonon energies lower than $400\,cm^{-1}$, are thus very suitable with respect to the realization of efficient broadband emission in this mid-infrared spectral range. In Table 11.29 some material parameters of the investigated chalcogenide crystals are given in comparison to the data for Al_2O_3. The thermal conductivities of the chalcogenides are rather high and comparable to the values for Al_2O_3. However, the

Table 11.29 Materials parameter of some chalcogenide crystals suitable for Cr^{2+}. The data for $Y_3Al_5O_{12}$ are given for comparison. (*: for CdTe). (After [11.1146–1148]) w: Wurtzite, z: Zincblende

Transmission range (μm)	w: 0.4–17 z: 0.4–14	0.5–18	1–28*	0.8–18	0.2–10

main disadvantages of the chalcogenide crystals are the growth techniques, which are Bridgman or vapor transport, which usually lead to a lower crystal quality than in the case of growth by the Czochralski method, and the high values for dn/dt, which lead to strong thermal lensing during laser operation, especially in the case of high-power operation.

Spectroscopy. The spectroscopy of Cr^{2+} ions in chalcogenide crystals has been thoroughly investigated in the past [11.1154–1162]. Tetrahedrally coordinated Cr^{2+} ions exhibit a broad band in the absorption spectrum due to the $^5T_2 \rightarrow {}^5E$ transition in the infrared spectral range with a maximum around 1.7–1.9 μm. The emission

spectrum due to the $^5E \rightarrow {}^5T_2$ transition is also broad and occurs between 2 μm and 3 μm. The absorption and emission cross sections for the Cr^{2+}-doped chalcogenides are on the order of $\approx 10^{-18}$ cm^2; these are values expected for tetrahedrally coordinated transition-metal ions and are larger than those for Ti^{3+}:Al_2O_3 [11.948]. The room-temperature absorption and emission spectra are shown in Fig. 11.85. The emission lifetimes at room temperature are on the order of several μs and the emission quantum efficiencies are close to unity. The $\sigma_{em}\tau$ product gives an indication of the expected laser threshold, because $P_{thr} \propto (\sigma_{em}\tau)^{-1}$. The values for the Cr^{2+}-doped chalcogenides are higher than in the case of Ti^{3+}:Al_2O_3, so that generally lower laser thresholds

for the Cr^{2+}-doped materials are expected. The ratio between the emission bandwidth and the central emission wavelength, $\Delta\lambda/\lambda_{peak,em}$, is a measure for the principle ability to generate ultrashort pulses in the mode-locked regime; the higher this value, the shorter the pulses. The values for Cr^{2+}-doped crystals are comparable to those of $Ti^{3+}:Al_2O_3$, for which laser pulses shorter than 5 fs have been realized. However, one has to keep in mind that bandwidth is not the only important parameter for ultrashort-pulse generation. Other important parameters are the nonlinearities of the material and the thermal lensing introduced by the high peak power, which occurs in the mode-locked regime. Only recently Sorokina et al. [11.1163] obtained mode-locking in the fs regime, after a lot of work was spent in order to understand the mechanisms behind the pulse-forming processes and how they can be controlled. In Table 11.30 the main spectroscopic data for the Cr^{2+}-doped chalcogenides are summarized in comparison to the data for $Ti^{3+}:Al_2O_3$.

For the tetrahedrally coordinated Cr^{2+} ion strong ESA transitions due to inner-shell 3d transitions are not expected, because all possible transitions are supposed to be spin-forbidden. This assumption was proven by ESA measurements [11.1145, 1164] (Fig. 11.85). Neither in the spectral region of the ground-state absorption nor in the emission region is ESA observed. Tunability up to and beyond 3 μm was predicted for $Cr^{2+}:ZnSe$ [11.1145]. This prediction was later proven with laser experiments, where laser oscillation was observed up to 3100 nm [11.1165].

Laser results. Laser materials based on the Cr^{2+} ion as the active ion have been investigated since the mid 1990s. Nowadays, Cr^{2+} lasers are operating in a variety of different operation schemes and under different excitation sources. In Table 11.31 an overview of the obtained laser results is given.

The best laser results were thus far obtained for $Cr^{2+}:ZnSe$. In different setups using different pump sources (Tm^{3+} lasers, $Co^{2+}:MgF_2$ lasers, diode lasers between 1.54 μm and 2.0 μm, erbium-doped fiber amplifiers) slope efficiencies up to 73%, output powers up to 7 W, thresholds lower than 100 mW, a tuning range of 2000–3100 nm and mode locking with pulse durations as short as ≈ 100 fs were obtained (Table 11.31). *McKay* and coworkers [11.1166] reported results of a thin-disc laser setup for a $Cr^{2+}:ZnSe$ laser, a setup that was successfully applied to Yb-doped laser materials [11.1167]. This setup appears to be favorable also for $Cr^{2+}:ZnSe$, because *Wagner* et al. [11.1168] reported on thermal rollover in the case of high-power pumping. In McKay's

experiment, a *Q*-switched Tm,Ho:YLF laser operating at 2.05 μm with a repetition rate of 10 kHz was used as the pump source. An output power of 4.27 W with a slope efficiency of 47% with respect to the absorbed pump power was obtained. The other possibility is to use a rather large pump beam radius of 260 μm ($1/e^2$ radius), as was done by *Alford* et al. [11.1169]. Using a 35 W $Tm^{3+}:YAlO_3$ as the pump laser, a continuous-wave output power of 7 W at 2.51 μm was achieved.

Besides ZnSe, other chalcogenide and mixed chalcogenide host materials for the Cr^{2+} ion are also suitable for efficient laser oscillation. For Cr^{2+}-doped ZnS, the spectroscopic characteristics are very similar to those of $Cr^{2+}:ZnSe$. From the material point of view, ZnS even seems to have some advantages over ZnSe as ZnS has a higher bandgap energy (3.84 eV for ZnS, 2.83 eV for ZnSe), a higher hardness, a higher thermal conductivity [27 W/mK for ZnS (cubic phase), 19 W/mK for ZnSe] and a lower dn/dT (46×10^{-6} 1/K for ZnS, 70×10^{-6} 1/K for ZnSe) (Table 11.29). However, ZnS is much more difficult to grow and many different structure types exist. Thus far, the obtained laser results for $Cr^{2+}:ZnS$ are not as good as the results for $Cr^{2+}:ZnSe$ (Table 11.31). The highest output power obtained was about 700 mW at an absorbed pump power of 2.65 W from an Er-doped fiber laser [11.1170, 1171]. The thresholds are around 100 mW and are thus comparable to those observed for $Cr^{2+}:ZnSe$. The widest tuning range obtained so far is 2110–2840 nm. The highest slope efficiency in CW regime is about 40%. Direct diode pumping has also been realized, with an output power of 25 mW at an absorbed pump power of 570 mW [11.1170]. However, in the same setup a $Cr^{2+}:ZnSe$ laser showed better results. Investigations revealed that the passive losses of the $Cr^{2+}:ZnS$ crystal (14%/cm) were much higher than the losses from the $Cr^{2+}:ZnSe$ crystal (4%/cm), indicating the larger problems with crystal growth and crystal quality in the case of $Cr^{2+}:ZnS$ compared to $Cr^{2+}:ZnSe$.

Compared to ZnSe and ZnS, the thermal properties and material parameters of $Cd_{0.55}Mn_{0.45}Te$ are much worse, i. e., the dn/dT is higher and the thermal conductivity is lower (Table 11.29). Therefore, efficient laser operation was only achieved under pulsed pumping [11.1153]. An output power of 170 mW with a slope efficiency of 64% was realized for a repetition rate of 2 Hz; the tuning range was 2.17–3.01 μm [11.1153]. *Mond* et al. [11.1172] reported diode-pumped CW operation with an output power of 6 mW and a slope efficiency of 4%. A thermal rollover at higher pump powers was observed, indicating the strong thermal lens-

ing problems. The threshold pump power was only 120 mW. This low value is expected from the spectroscopic parameters. Under diode pumping at a duty cycle of 1:4, the thermal rollover is not observed at the pump powers available. Then the highest output power is 15 mW with a slope efficiency of 5% and a threshold of $\approx$ 100 mW.

Cr^{2+}:CdSe exhibits a similar behavior to Cr^{2+}:$Cd_{0.55}Mn_{0.45}Te$, as expected from the material parameters and spectroscopic characteristics. Thus also strong thermal lensing and power-handling problems are encountered in the laser experiments. CW laser operation has not yet been reported, however, the laser results under pulsed pumping are very promising. Using a Q-switched Tm,Ho:YAG laser operating at 2.05 µm with a repetition rate of 1 kHz, a maximum output energy of 0.5 mJ per pulse and a slope efficiency of 50% was obtained [11.1177]. The highest average output power

was 815 mW [11.1184] while the largest tuning range achieved thus far is 2.4–3.4 µm [11.1179].

Outlook for Cr^{2+} systems. Cr^{2+}-doped materials are highly efficient lasers in a very interesting wavelength range for application; see the overview in Table 11.31. In all materials investigated, the material parameters are still a large problem, i.e., the quality of the crystals, the strong thermal lensing, the high nonlinearity, yielding a strong tendency for self-focusing, and the relatively low damage threshold. All these problems are most severe for CdMnTe and CdSe. Therefore, the thin-disc setup may be a way to overcome some of these problems. Another alternative is the use of larger pump and laser modes. As far as ultrashort-pulse generation is concerned, *Sorokina* et al. recently realized mode locking in the fs regime [11.1163]. Thus far, only a few materials have been investigated for laser applications. Therefore,

there is the possibility to look for different host materials for the tetrahedral Cr^{2+} ion, e.g., $ZnGa_2S_4$, $ZnGa_2Se_4$, $CaGa_2S_4$, and $CaGa_2Se_4$.

Other transition–metal–ion lasers.

V^{2+} lasers. The V^{2+} ion is isoelectronic to the Cr^{3+} ion. Therefore, its energy-level scheme can also be described with the Tanabe–Sugano diagram shown in Fig. 11.81. The absorption spectra of octahedrally coordinated V^{2+} is similar to that of Cr^{3+}, but red-shifted due to the lower valence of the V^{2+} ion. The spectra are dominated by the three broad spin-allowed bands due to transitions between the $^4A_2(^4F)$ ground state and the $^4T_2(^4F)$, $^4T_1(^4F)$, and $^4T_1(^4P)$ excited states. The emission spectra consist of a broad band due to the $^4T_2(^4F) \rightarrow {}^4A_2(^4F)$ transition, also shifted to longer wavelengths compared to the emission spectra of Cr^{3+}. Laser oscillation with V^{2+} on the $^4T_2(^4F) \rightarrow {}^4A_2(^4F)$ transition was realized only in MgF_2 [11.1200–1202] and $CsCaF_3$ [11.1203, 1204]. An overview of the obtained laser results is given in Table 11.31. The laser efficiencies are very low. *Payne* et al. [11.44, 1205] and *Moncorgé* et al. [11.1206] found that ESA is the dominant loss mechanism for laser oscillation. In some materials nonradiative decay also competes with the emission, leading to small emission quantum efficiencies.

Ni^{2+} lasers. The energy-level scheme of octahedrally coordinated Ni^{2+} in crystals can be described with the Tanabe–Sugano diagram shown in Fig. 11.86. In the absorption spectra, three bands according to the spin-allowed transitions from the $^3A_2(^3F)$ ground state to the $^3T_2(^3F)$, $^3T_{1a}(^3F)$, and $^3T_{1b}(^3P)$ excited states are observed. The laser transition of Ni^{2+} lies in the infrared spectral range due to the $^3T_2(^3F) \rightarrow {}^3A_2(^3F)$ transition. Its spectral position is strongly wavelength dependent (Table 11.33). The emission lifetime is typically on the order of ms and the emission quantum efficiency is near unity at room temperature in most materials.

Despite these advantageous spectroscopic data, laser oscillation with Ni^{2+} was obtained only at temperatures below 240 K and only in a few materials (Table 11.33). The absence of laser oscillation at room temperature can be explained by excited-state absorption (ESA), which overlaps with the spectral range of emission. Detailed
Fig. 11.86 Tanabe–Sugano diagram for the d^8 electron configuration. The *dashed area* corresponds to the Dq/B values of Ni^{2+}

measurements of the ESA for several Ni^{2+}-doped crystals were performed by *Koetke* et al. [11.1207, 1208]. With increasing temperature the excited-state absorption and ground-state absorption bands become broader and thus overlap to a larger extent with the stimulated emission. As a result, the spectral region where $\sigma_{eff} = \sigma_{se} - \sigma_{ESA} > 0$ becomes narrower. Furthermore, the losses due to ground-state absorption increase. However, at low temperatures output powers up to 10 W and slope efficiencies up to 57% were obtained [11.1202].

Mn^{5+} lasers. The Mn^{5+} ion incorporates into crystals mainly at tetrahedrally coordinated lattice sites. Its energy-level scheme can be described with the Tanabe–Sugano diagram shown in Fig. 11.82. Compared to Cr^{4+}, the crystal field is higher due to the higher valence state, thus the Mn^{5+} ion exhibits narrow-line emission due to the $^1E(^1D) \rightarrow {}^3A_2(^3F)$ transition. Optical properties of Mn^{5+} ions in solids have been under investigation for more than 30 years [11.1209–1217].

Mn^{5+} laser operation at room temperature was demonstrated by *Merkle* et al. in $Ba_3(VO_4)_2$, $Sr_3(VO_4)_2$, and in $Sr_5(VO_4)_3F$ [11.1218–1220]. The laser transition is realized between the $^1E(^1D)$ excited state and the $^3A_2(^3F)$ ground state, thus these lasers are three-level systems. The efficiency is rather low (laser output energy $\sim \mu J$, $\eta_{sl} \leq 1.6\%$) and laser oscillation from other Mn^{5+} systems has not been reported. The major drawback for these lasers is the excited-state absorption at the stimulated-emission wavelength. Investigations of the excited-state absorption and gain were performed in detail by *Verdún* [11.1217], *Merkle* et al. [11.1218], *Manaa* et al. [11.1221] and *Kück* et al. [11.933, 1222].

To obtain a four-level system, one should search for crystals with low crystal field strengths or with large energy-level splittings. Then the $^3T_2(^3F)$ or one of its crystal field components would be the lowest-

energy level. However, thus far Mn^{5+} systems exhibiting broadband emission are not known.

Co^{2+} **lasers.** The Co^{2+} ion in octahedral coordination exhibits laser oscillation in the mid-infrared spectral region between $1.5\,\mu m$ and $2.5\,\mu m$. Its energy-level scheme can be described with the Tanabe–Sugano diagram for the $3d^7$ electron configuration shown in Fig. 11.87. Three broad and spin-allowed transitions between the $^4T_{1a}$ ground state and the $^4T_2$, $^4A_2$ and $^4T_{1b}$ excited states exist. In MgF_2, these transitions are located around $7000\,cm^{-1}$, $15\,000\,cm^{-1}$, and $20\,000\,cm^{-1}$, respectively [11.1233]. The emission occurs between $1.5\,\mu m$ and $2.5\,\mu m$, according to the $^4T_2 \rightarrow {}^4T_{1a}$ transition. At low temperatures, the lifetimes are on the order of several ms, while at room temperature the emission is strongly quenched due to nonradiative decay via multiphonon relaxation, yielding very low quantum
Fig. 11.87 Tanabe–Sugano diagram for the d^7 configuration (after [11.36])

efficiencies [11.1234]. Excited-state absorption overlaps with the $^4T_{1a} \rightarrow {}^4T_2$ absorption band, which is the main pump band for laser operation. In the region of stimulated emission, the excited-state absorption is negligible [11.1233].

Laser oscillation was obtained in the continuous-wave regime only at cryogenic temperatures, while pulsed laser operation was also realized at room temperature for Co^{2+}-doped MgF_2 and $KZnF_3$. An overview of the laser results for Co^{2+} laser systems is given in Table 11.35. The best laser results were obtained for

Co^{2+}:MgF_2, which is also a commercial laser system. With Co^{2+}:MgF_2 an overall tuning range of 1.5–2.5 µm was realized with output powers up to 4.2 W, output energies up to 1.6 J and slope efficiencies as high as 65%. As the pump source, Nd:YAG or Nd:glass lasers around 1.3 µm are usually used, however, laser oscillation has also been realized under flashlamp pumping, argon-ion laser excitation and oxygen–iodine laser excitation. Operation regimes are CW, pulsed, Q-switched and mode-locked.

Fe^{2+} lasers. The Fe^{2+} ion has a $3d^6$ electron configuration that is complementary to that of Cr^{2+}. The ^5D free-ion state also splits into a $^5T_2$ and a ^5E state, however, for the Fe^{2+} ion ^5E is the ground state and $^5T_2$ is the first excited state. Consequently, there is just one spin-allowed absorption ($^5E \rightarrow {}^5T_2$) and emission ($^5T_2 \rightarrow {}^5E$) transition. As for the Cr^{2+} ion, all excited-state transitions are spin-forbidden. Thus, one might expect similar laser characteristics for Fe^{2+}-doped lasers as for Cr^{2+} lasers. However, the energy gap between the $^5T_2$ excited state and the ^5E ground state is smaller, thus the emission is at longer wavelengths and the nonradiative decay rate is higher, leading to lifetime shortening and low quantum efficiencies at elevated temperatures. For Fe^{2+}:ZnSe, the emission lifetime first increases from 12 to 120 K from 33 µs to 105 µs and then decreases to about 5 µs at 250 K due to thermally activated multi-phonon decay [11.1235, 1236]. At 14 K, the $^5E \rightarrow {}^5T_2$ absorption band is between 2.5 µm and 3.75 µm, and the $^5T_2 \rightarrow {}^5E$ emission band is between 3.7 µm and 4.8 µm.

Laser oscillation of Fe^{2+} was obtained in ZnSe [11.1235–1239] and in n-InP [11.1240]. For Fe^{2+}:ZnSe, room-temperature tunable laser oscillation was recently reported in a gain-switched

mode [11.1237]. The pump source was the second Stokes output of a Nd:YAG laser at 2.92 μm. The output pulse energy was about 1 μJ. The highest output power and slope efficiency of 12 μJ and 8.2%, respectively, were obtained at lower temperatures. In this case, the Fe^{2+}:ZnSe laser was pumped by a pulsed Er^{3+}:YAG laser operating at 2.698 μm [11.1235, 1236]. The laser wavelength is tunable with temperature from 3.98 μm at 15 K to 4.54 μm at 180 K. In n-InP, Fe^{2+} laser oscillation was obtained at 2 K at 3.53 μm, i. e., at the zero-phonon transition [11.1240].

Summary

In this chapter an overview of transition-metal-ion-doped crystals as solid-state laser materials is given. It was shown that they are efficient (usually tunable) laser sources covering a wide spectral range (Fig. 11.77). However, compared to lasers based on $4f^n \rightarrow 4f^n$ transitions of trivalent rare-earth ions, they play only a small role as far as commercialization is concerned. In principle only the Ti^{3+}:Al_2O_3 and – with limitations – the Cr^{3+}:$BeAl_2O_4$ laser can be mentioned. These lasers are mainly used in the field of scientific research. The main reason for this is that their advantages, i. e., their tunability and their capability to generate ultrashort pulses, are not relevant for most industrial applications. They exhibit lower output power than lasers based on $4f^n \rightarrow 4f^n$ transitions of trivalent rare-earth ions (e.g., Nd^{3+}:YAG, Yb^{3+}:YAG) and are more expensive and less efficient than diode lasers. Direct diode-laser pumping is either

inefficient or – in the case of Cr^{3+} and Cr^{2+} lasers – requires laser diodes that are not yet available at a satisfactory price and quality on the market.

Transition-metal-ion and especially tunable laser systems exhibit a stronger coupling of the electronic levels to the vibrating lattice of the crystal. This leads to higher possibilities for ESA and nonradiative decay processes compared to the $4f^n \rightarrow 4f^n$ transitions of trivalent rare-earth ions in crystals.

The main problem in realizing efficient laser oscillation is the excited-state absorption from the metastable upper laser level. From (11.87) and (11.88) its effect on laser threshold and slope efficiency becomes clear. It occurs in principle for every electron configuration, either as intra- or interconfigurational transitions or as a transition to charge transfer or conduction-band-related levels. The electron configurations are in general favorable, when intraconfigurational excited-state absorption transitions are not possible, e.g., in the d^1 and d^9 configuration, or are less strong due to selection rules, e.g., in the d^4 and d^6 configurations. Other configurations exhibit more-complex energy-level schemes, therefore intraconfigurational ESA transitions occur with high probability in the spectral regions of emission and excitation. The influence of ESA, however, can even in this case be reduced, e.g., by taking advantage of polarization-dependent transition rules, which result in higher stimulated-emission cross sections than ESA cross sections, as it is the case, e.g., for Cr^{3+}:LiSrAlF$_6$ and Cr^{4+}:Y$_3$Al$_5$O$_{12}$.

The role of nonradiative decay for the realization of efficient laser operation is less important, although not negligible. It affects to a first approximation only the laser threshold, which is increased (11.84). However, a nonradiative rate leads to a temperature increase

in the pump channel, which also affects the overall laser characteristics. Thus, its general influence depends strongly on the material parameters of the laser system, i.e., mainly of the host material. Materials with a high thermal conductivity and mechanical strength are favored. As an example, Cr^{4+}:Y$_3$Al$_5$O$_{12}$ can be given. Here, the quantum efficiency is less than 20%, whereas laser operation with a slope efficiency close to 40% was realized.

Table 11.36 gives an overview of the transition-metal ions in octahedral and tetrahedral coordination investigated to date. They are listed according to their corresponding energy-level diagram (i.e., Tanabe–Sugano diagram). The laser-active transition-metal ions are indicated. Almost all transition-metal ions with different valence states and ligand coordinations have been investigated thus far. Efficient room-temperature laser oscillation was only obtained for Ti^{3+} and Cr^{3+} in octahedral and for Cr^{2+} and Cr^{4+} in tetrahedral coordination. Whether efficient laser operation will also be obtained for other ions depends very much on the host material chosen. For example, the Ti^{3+} ion exhibits efficient laser operation only in Al$_2$O$_3$. Therefore, other ions cannot a priori be excluded as efficient laser ions.

11.2.6 Overview of the most Important Laser Ions in Solid–State Lasers

Research on laser materials has created a number of compact, efficient solid-state laser sources for a large variety of applications. Laser materials have been developed for various wavelengths (near-infrared, visible, UV) and power regimes (mW to multi-kW). Special geometries of the active material (microchip, rod,

disc, fiber) strongly correlate with the active ion concentrations and cross sections of absorption and gain transitions.

The values of the cross sections depend on the quantum numbers of the final and initial states as well as on the local environment of the active-ion site in the material. The lifetimes of the states are influenced by radiative and nonradiative transitions. So, the microscopic crystal properties play an important role for static and dynamic processes in the laser crystal.

In the near-infrared spectral region high efficiencies have been achieved with diode-pumped oxide- and fluoride-based laser materials doped with the rare-earth ions Nd^{3+}, Tm^{3+}, Ho^{3+}, Er^{3+}, and Yb^{3+}. For high-average-power operation Nd^{3+}- and Yb^{3+}-doped crystals are of greatest interest. Especially the Yb^{3+} ion exhibits very small Stokes losses and minimum heat generation, which reduces thermal lensing and improves beam quality. Transition-metal-doped crystals based on the ions Ti^{3+}, Cr^{2+}, Cr^{3+}, and Cr^{4+} offer broadly tunable radiation within the spectral region 680–3000 nm. In the visible region Er^{3+}-, Tm^{3+}-, and Pr^{3+}-doped laser materials operate at several red, green, and blue transitions with laser diode upconversion and/or direct pumping. So far Ce^{3+} is the only ion with reasonable direct laser performance in the UV.

The following wavelength data provide a rough guide to the spectral range of the various laser ions.

Near–IR rare–earth lasers.

Nd^{3+}	0.9, 1.06, 1.3 µm
Yb^{3+}	1−1.1 µm
Tm^{3+}	2 µm, 1.5 µm (upconversion)
Ho^{3+}	2 µm
Er^{3+}	1.6, 3 µm, 0.85 µm (upconversion)

Visible rare–earth lasers.

Pr^{3+}	0.64 µm (diode-pumped)

11.3 Semiconductor Lasers

11.3.1 Overview

In crystalline solids the interaction between *atomic energy levels* generates energy bands. A quantum-mechanical treatment provides, in the single-electron approximation, energy bands which overlap which each other or are separated by bandgaps from each other. In semiconductors, we find between the energetically highest band, which is fully occupied by electrons at $T = 0\,\text{K}$, the valence band (VB), and the energetically lowest band, which is completely empty at $T = 0\,\text{K}$ the conduction band (CB) an energy range, in which we find no allowed energy states, disregarding energy states originating from dopants. This bandgap, E_g, is the energy difference between the lower conduction-band edge E_C and the upper valence-band edge E_V. For laser operation an extreme deviation from thermal equilibrium (nonthermal carrier distribution) is required: carrier inversion. In the CB close to E_C carrier inversion means

a much higher density of electrons than holes and in the VB close to E_V a much higher density of holes than electrons. This extremely nonthermal condition is generated by strong electrical or optical pumping of the laser-active material. The electrical carrier injection in most cases is obtained by a p–i–n heterojunction made of III/V semiconductor materials. Choosing InP as a typical example, Fig. 11.88 displays a planarization (projection into 2-D space for simplification) of the real 3-D zinkblende crystal structure with the corresponding band structures below. From the left to the right p-InP, intrinsic i-InP and p-InP are shown.

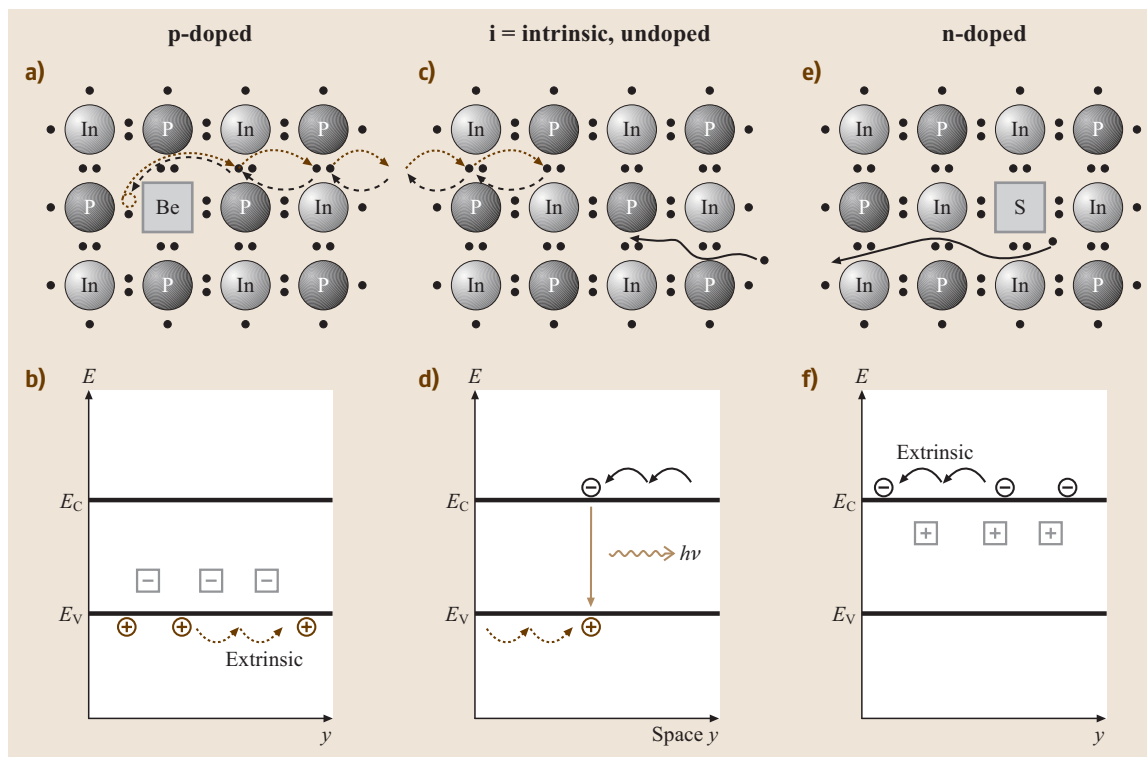
In the highly p-doped InP bulk regions, at room temperature nearly all acceptors have released their holes into the valence band. Well away from the pn junction the hole field current (drift current) dominates the carrier transport. At the left edge of the device, holes are generated under the p contact. At the right edge of the device, electrons are injected through the n contact.


Fig. 11.88a–f Schematic of a planarized lattice structure of p-doped, undoped and n-doped InP **(a,c,e)**. *Below* are the corresponding band structures in space **(b,d,f)**. The dopants are indicated by *squares*, the *full lines* indicate the movement of electrons, the *broken line* the movement of defect electrons (=holes) in space and the *dotted line* the movement of holes on the VB

Well away from the pn junction the electron field current dominates the carrier transport there. The bandgap E_g nearly equals the energy of the photons generated in the central intrinsic region. However, such a homojunction p–i–n structure (Fig. 11.88) suffers from enormous carrier leakage and the lack of a medium guiding the generated light. To enable operation at room temperature and considerably reduce the threshold currents at least a double heterostructure (heterojunction p–i–n structure) is required (Fig. 11.89). This Nobel-prize-winning idea by *Koemer* and *Alferov* [11.1257, 1258] enables carrier confinement and optical confinement by a single important modification: using higher-bandgap E_g materials for the p and n regions compared to the central intrinsic active layer. Thus, for semiconductor lasers at least two different materials are required, as shown in space $z(x, y)$ (Fig. 11.89a) and in the band structure $E(y, z)$ in space (Fig. 11.89b) for an undoped and unbiased structure. The central layer (material 1) has a lower E_g than the embedding bulk layers (materials 2) and therefore

electrically confines electrons in the CB and holes in the VB, which is visualized by the band edge. Since for semiconductors decreasing E_g in nearly all cases increases the refractive index n we fortunately obtain an optical waveguide: a central higher-n material embedded in a lower-index material (Fig. 11.89c). Thus, the laser-active layer is the core layer of the waveguide at the same time. By a proper design, essentially of the refractive index differences and dimensions, we can efficiently guide the generated light in a fundamental mode (see the profile in Fig. 11.89c) similar to a single-mode optical fibre. Considering an edge-emitting laser, the structure is now p–i–n doped and forward-biased (Fig. 11.89d), enabling the carrier transport described above: hole injection from the left and electron injection from right. The band structure (Fig. 11.89e) of the doped and biased laser structure visualizes the operation of the p–i heterointerface acting as a border (electrical confinement) for the electrons. The small potential barrier at the i–n heterointerface is no real obstacle. The

electrons can tunnel through or thermally jump across. In analogy, the p–i heterointerface is no real obstacle for the holes, whereas the n–i heterointerface provides the required border (electrical confinement). Modern semiconductor lasers, however, include quantum wells (QWs, a 2-D carrier system) [11.1259] or quantum dots (QDs, a 0-D carrier system) [11.1260] as the laser-active medium, instead of a 3-D laser-active region in bulk

lasers (Fig. 11.89e). In Fig. 11.89f two QWs are depicted as an example, providing the emission energy as the difference between the energetically lowest bound states in the wells (note that the ordinate indicates the electron energy).

Finally, electrical and optical confinement in the y-direction (Fig. 11.89c) has to be completed by electrical and optical confinement in the x-direction (Fig. 11.90). Note that this figure is rotated by 90° with respect to Fig. 11.89. In Fig. 11.90 the active material is embedded in the x-direction by semi-insulating (si) material to force the current to move mainly in the active layers (lateral electrical confinement). The si material is chosen to have a higher bandgap, and thus a lower refractive index, than the active material (lateral optical confinement). Also in this case, wave guiding is applied in the x- and z-directions. This is shown in the two insets by the two cross sections A and B, showing the refractive-index profiles and light-intensity profiles. Here, waveguiding in fundamental mode is shown for the case of bulk 3-D active layers.

11.3.2 Resonator Types and Modern Active Layer Materials: Quantum Effects and Strain

Modern optoelectronic semiconductor devices are based on a sequence of materials of different composition. Embedding a film of lower E_g between a material of larger E_g, we obtain quantization effects if the film thickness L_y is on the order of the electron wavelength or below (QW) [11.1259]. Using the Schrödinger equation, we obtain at least one bound state in the CB and VB potential wells, respectively. The electrons and holes are still fully mobile in the x- and z-directions. This means that a wavevector $k_{||}$ parallel to the heterointerfaces exists. The motion in the y-direction is considerably restricted and statistically described by quantum mechanics. Figure 11.91 displays the VB structure in k-space [$E(k_{||})$] obtained by a theoretical model calculation [11.1261] based on the Schrödinger equation for four different Ga(In)As/(Al)GaAs QWs ($k_{||}$ is oriented parallel to the heterointerfaces).

In most cases in addition the QWs and the barriers in the active layer are additionally strained [11.1262]. Usually, the wells are compressively strained, which means
Fig. 11.91 Valence-band structure $E(k_{||})$ of various Ga(In)As/AlGaAs QWs [11.1261]

that the lattice constant of that layer is compressively reduced in the x- and z-directions to match that of the substrate a_o. In many cases, the barriers are in tension, which indicates that the lattice constant of the barriers is increased in the x- and z-directions by tensile strain to be identical to the substrate lattice constant a_o.

Strain and quantization effects in the active layers of semiconductor lasers are used to improve the device properties. For the laser it is beneficial to make the effective masses of electrons and holes as similar as possible, to increase material gain, to reduce threshold, to tailor the density of states and to increase differential gain. This can be obtained by applying strain and/or quantization. In Fig. 11.92, the energy dependence of the density of states is shown for 3-D material to be root-like, and to be constant for 2-D material.

Figure 11.93 depicts examples of InAs [11.1263] and CdSe [11.1264] QDs. Schematically, Fig. 11.93a shows the QD formation in a cross section of the crystal structure. We see the three upper monolayers of the GaAs substrate. During the self-organized QD formation

the intentionally integrated strain (detailed explanation below) of the InAs versus GaAs plays an important role. For thermodynamical and elastomechanical reasons, two monolayers of strained InAs are first formed. Continuing the growth, for total-energy reasons, it is of considerable advantage for the semiconductor surface to continue by a localized island-like growth. In this case a possible geometric shape is a pyramid with a base plane directly joined to the top of the InAs monolayers. Experimentally, this phase can be directly studied using an atomic force microscope (AFM) [11.1260]. Figure 11.93b displays in a top view a typical AFM surface profile. In the next process step the QDs are overgrown by GaAs and thereby embedded. Experimentally the final layer sequence can be studied by transmission electron microscopy (TEM) after cleaving. In order to increase the number of QDs in the direction perpendicular to the substrate interface, the whole InAs process is repeated as often as desired after a defined GaAs spacer layer thickness. This provides layered QD arrangements. Figures 11.93c, d show TEM micrographs for two different spacer-layer widths: 40 nm ad 20 nm. We observe a vertical correlation of the dots for the smaller separation. At very high magnification Fig. 11.93e shows QD formations in the II/VI semiconductor system CdSe/ZnSe; note the different scales in the subfigures. This high TEM magnification resolves the individual crystal layers. The CdSe QD is contrasted dark against the surrounding brighter ZnSe.

However, quantization is not limited to a single direction. If we limit the carrier movement in another direction (e.g., in the z- and y-direction as in Fig. 11.92), we obtain a 1-D carrier system and, thus, a quantum wire [11.1265] with hyperbolically shaped density of states branches. Limitation of carrier movement in all three space directions results in quantum dots [11.1260, 1261, 1263–1272], i.e., a zero-dimensional (0-D) carrier system with a δ-like density of states (Fig. 11.92d). For many physical properties of the semiconductor (e.g., carrier mobilities, carrier capture in quantized states and spontaneous or stimulated emission of light), the density of states plays an important role. Using dimensionality and strain efficiently during the design of lasers enables one to enhance desired and suppress undesired properties. Here, modern epitaxy [e.g., metal organic chemical vapour deposition (MOCVD) and molecular beam epitaxy (MBE)] are powerful tools. To date 2-D and 0-D structures have been used successfully for laser devices. 1-D structures have not yet had a breakthrough due to their disadvantageous dynamic properties. QDs are grown today using self-organization in the Stranski–Krastanow growth mode [11.1263,1265,1267,1271]. By growing a large number of QDs with identical quantized energy levels in the laser-active layer, we would benefit from a strongly reduced temperature sensitivity and a very high differential gain and, thus, extremely high bit rates in optical communication. Although many QD lasers have been implemented, the pyramid-like QDs suffer from strong fluctuations in size and thus in their energy levels.

On the basis of these QDs, however, the aforementioned improvements in device properties have not yet be demonstrated. On the other hand, the strong fluctuation causes a strongly spectrally broadened gain profile,
Fig. 11.94 Bandgap energy E_g (*left*) and bandgap wavelength (*right*) as a function of the lattice constant a

which is beneficial for other applications, e.g., short-pulse generation by mode locking or wide spectral tuning of the laser device. However, we should also remember that 10 years were necessary after implementing the first QW lasers to demonstrate that QW lasers were superior to bulk lasers. Similarly, QD lasers will require time before their final breakthrough. However, we believe that QW and QD lasers will share the application area in the future, depending on the specific requirements.

Figure 11.94 shows the dependence of the bandgap on the lattice constant for various III/V and II/VI semiconductors. The brown area corresponds to the quaternary $Al_zGa_{1-x-z}In_xN$. The grey area describes the quaternary $Ga_{1-x}In_xAs_{1-y}P_y$. For high laser efficiencies in interband lasers, active materials with a direct bandgap are required, disregarding for the moment some intraband lasers. Note that simple bulk Si has an indirect band structure and does not provide efficient radiative recombination. Modified Si structures have demonstrated strong luminescence, LED operation or laser oscillation, e.g., from Si/Ge superlattices, QDs in Si and Si-based Raman laser structures [11.1273]. All compound semiconductors, located on one of the grey vertical lines (Fig. 11.94) that indicate the lattice constant of important semiconductor substrate materials, can be lattice-matched to the respective substrate. According to Fig. 11.94 the ternary compounds $Al_{0.48}In_{0.52}As$

($E_g = 1.43 \text{ eV}$) and $Ga_{0.47}In_{0.53}As$ ($E_g = 0.75 \text{ eV}$) have the same lattice constant as InP ($E_g = 1.34 \text{ eV}$), which is available in wafers today up to a diameter of 150 mm.

QW widths (or QD dimensions), effective masses [more precisely the $E(k)$ functions], and bandgaps of well and barrier materials energetically determine the quantized states and, thus, the spectral gain profile of the laser, i. e., the possible range of laser emission. Figure 11.94 shows that a very large wavelength range can be covered for different applications. Some examples are red and blue lasers which are used for data storage in digital versatile and blue-ray discs, respectively. Emission at about 850 nm is used for short-range optical fibre communication and CD devices, 980 nm lasers for pumping Er-doped fibre amplifiers, while between 1.25 and 1.65 μm the lasers are applied in ultrahigh-bit-rate long-haul optical fibre communication. Visible and infrared wavelengths are very attractive for optical sensing. The range between 0.8 and 1 μm is used for direct laser applications (welding, drilling, cutting and soldering) since it includes lasers with extremely high output power, highest wall-plug efficiencies and lowest price per watt of optical power.

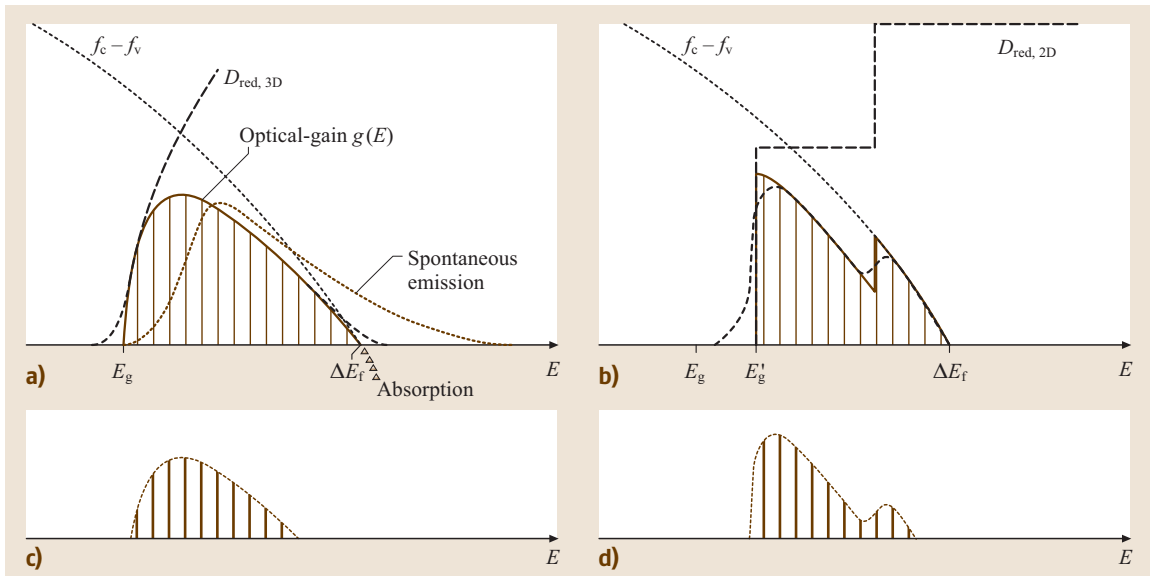
Stimulated emission and optical gain (Fig. 11.95) are essentially determined by the product of the reduced electronic density of states and the Fermi factor ($f_c - f_v$). This Fermi factor originates from $f_c(1 - f_v) - f_v(1 - f_c)$, namely the *probability of processes photon-*


Fig. 11.95a–d Profile of optical material gain, spontaneous emission, Fermi factors and the density of states as a function of energy for (**a**) 3-D und (**b**) 2-D materials. Corresponding net gain profiles in (**c**) and (**d**)

generating photons (emission), i. e., the probability that the CB states are occupied by electrons and VB states are not occupied by electrons $f_c(1 - f_v)$ *minus* the *probability of processes destroying photons (reabsorption)*, i. e., the probability of VB states occupied by electrons and CB states not occupied by electrons $f_v(1 - f_c)$. The full lines in Fig. 11.95a, b schematically show the spectral material gain profile of 3-D and 2-D semiconductors, respectively. Gain ranges spectrally from the bandgap E_g to the difference between the two quasi-Fermi levels ΔE_F. In reality there are additional effects such as Fermi-level filling, profile broadening [11.1261] (bold broken line) or many-body effects. Material gain minus loss provides net gain (Fig. 11.95c, d). If these laser-active materials are placed in a Fabry–Pérot (FP) laser

Fig. 11.96 Different geometries of lasers with horizontal (*left*) and vertical resonators (*right*)

the net gain can support the modes (vertical lines) as indicated. In Fig. 11.95 the spontaneous emission is shown by the thin broken lines, revealing a different spectral profile, which is important, e.g., for LEDs.

Figure 11.96 depicts a classification summary of the most important semiconductor laser geometries. Most of them will be treated in detail below. Generally, the heterointerfaces are located horizontally. We distinguish between horizontal (left) and vertical (right) resonator structures, which is indicated by the orientation of the broad brown double arrow. Thus, we have horizontal cavity lasers (in-plane lasers) and vertical cavity (VC) lasers.

First case: Fabry–Pérot (FP) structures. Here the optical reflection (feedback) is provided by the borders of the resonator (facets). In many cases, the high refractive index difference between the semiconductor and the air is already sufficient, providing an optical reflection coefficient of about 30%. By additional facet coatings this coefficient can be tailored continuously between 0% (antireflection) and 100% (perfect reflection). The resonator modes are given by

$$m_{FP}\left(\frac{\lambda_B}{2n_{eff}}\right) = L . \tag{11.92}$$

Intuitively, the resonator length L has to be a positive integer multiple of half of the wavelength of light in the medium, where n_{eff} is the effective refractive index (eigenvalue of the Helmholtz equation, see below) of the waveguide. In the second case, in so-called structures with distributed feedback (DFB), the optical reflection is extended over the whole resonator. A very efficient feedback occurs at the Bragg wavelength λ_B, which is correlated with the DFB grating period Λ via the Bragg condition:

$$m_{DFB}(\lambda_B/n_{eff}) = 2\Lambda . \tag{11.93}$$

m_{DFB} is a positive integer and describes the grating order. An example: for a DFB laser emitting at $\lambda_B = 1.55\,\mu m$ having a first-order grating ($m_{DFB} = 1$) and an effective refractive index $n_{eff} = 3.27$, a grating period of $\Lambda = 237\,nm$ is required. Intuitively, an integer multiple of the wavelength in the medium has to correspond, according to (11.93), to the double grating period. Note that the mathematical structure of (11.92) and (11.93) is identical. In lasers with a typical length of $200\,\mu m$ we obatin for FP laser modes within the gain profile a very large m_{FP} (on the order of 1000) while for DFB lasers in most cases m_{DFB} is 1 (for a first-order grating).
As expected, light is emitted in horizontal directions for edge-emitting lasers (Fig. 11.96). Surface emitters can be implemented by etching an out-coupling mirror inclined at 45° or by a second-order DFB grating (note the doubled grating period in the figure). In a second-order grating the light field is reflected back horizontally (180°) and coupled out vertically. If the Bragg condition is exactly fulfilled, the emission occurs exactly perpendicular to the surface (90°). However, the larger the deviation in (11.93) in the (>)-direction or (<)-direction, the larger or smaller the angle, respectively. If the grating is interrupted we have a distributed Bragg reflector (DBR) structure. Typically, a central grating-free section is embedded between two DBR sections. In the DFB and DBR structures the horizontally propagating light field alternatively passes two virtual *quasi-layers* of slightly different refractive index. For DBR resonators with *real layers* (see Sect. 11.3.4 or the next section) these operation principles become more evident.

Second case: VCSELs. They are also based on DBR structures, which in contrast to the first case consist of real multiple layers having a very high refractive-index difference. The central cavity has no grating and is embedded between two DBR mirrors, thus also forming an FP-like structure. However, feedback is distributed over the two DBR structures. In most cases the thickness of a single period (equivalent to a pair of neighboring layers) is chosen to equal half the wavelength of light in the medium for the design wavelength. This corresponds to a first-order grating according to (11.93). Since the resonator is oriented perpendicularly and the emission occurs perpendicular to the main chip surface (oriented parallel to the substrate area), this laser is called a vertical-cavity surface-emitting laser (VCSEL). The two mirrors must have a very high reflectivity to reach the laser threshold, since the laser-active layer is relatively thin and has a weak overlap with the light field in the resonator.

Edge-emitting lasers as well as VCSELs will be treated in detail in the following sections. On the basis of both cases (A and B), it is possible to implement lasers with external resonators, as indicated in the last row of Fig. 11.96.

11.3.3 Edge-Emitting Laser Diodes with Horizontal Resonators

As already mentioned, the population inversion between the valence and conduction bands, which is necessary for the coherent amplification of radiation [11.1274],

can be obtained by an injection of electrons and holes via a forward-biased pn junction (see Figs. 11.89, 90). The electrons injected into the n semiconductor as well as the holes injected into the p semiconductor diffuse to the pn junction and can recombine there radiatively and generate a photon with energy $\hbar\omega$ (Fig. 11.88). If the external voltage is increased and the carrier density exceeds a critical value in the range of 10^{18} cm^{-3}, the rate of photon emission becomes higher than the absorption rate, so that an incident wave can be amplified coherently due to stimulated emission. The condition for this population inversion is that the separation between the quasi-Fermi levels E_{f_c} and E_{f_v}, which describe the filling of the conduction and valence bands, is larger than the bandgap E_g (Bernard–Durafourg condition):

$$E_{f_c} - E_{f_v} \geq \hbar\omega \geq E_g \, . \tag{11.94}$$

In this case the semiconductor material is transparent for the generated wave with the wavelength defined by the bandgap. The resulting gain values are very high (in the range of 10^3 cm^{-1}) due to the high carrier density. Lasing occurs if the additional losses of the optical resonator providing the feedback are compensated.

Double-Heterostructure Lasers

The active region, where population inversion is achieved, is very thin in homojunction lasers and the threshold current is very high, since only a small portion of the injected carriers is utilized for the lasing process. Lower threshold currents and continuous operation at room temperature can be achieved with double-heterostructure lasers, where the low-bandgap active layer is sandwiched between n- and p-doped cladding layers with a higher bandgap epitaxially grown on a substrate (Fig. 11.89). The technical realization of these structures is possible if the lattice mismatch between the different layers of the material system does not exceed a critical value. Double heterostructures [11.1257] have three main advantages with respect to laser operation:

- The bandgap difference between the layers is distributed between the valence and conduction bands and creates potential barriers for the injected electrons and holes. For an appropriate choice of doping and applied voltage, a nearly rectangular-shaped potential well can be achieved (Fig. 11.89), which efficiently confines the carriers in the low-bandgap active layer if the potential difference is higher than the thermal activation energy $k_B T$. The width of the active layer d_{act} is defined by the heterostructure geometry. The carriers injected via the pn junction are

captured in the potential well and confined to a small volume, thus decreasing the injection current, which is necessary to achieve inversion.

- There is no reabsorption of the radiation emitted from the active layer in the surrounding layers due to the difference in bandgap energies.
- In the material systems used for semiconductor lasers, the low-bandgap active layer has a higher refractive index than the surrounding cladding layers. Therefore, the double heterostructure acts as a dielectric planar slab waveguide, confining the generated optical field to the active region due to the refractive-index difference between the layers. The number of modes supported by this optical waveguide for a given wavelength depends on the thicknesses and the refractive indices of the layers. By a proper choice of the design parameters, a single transverse (perpendicular to the pn junction) mode can be selected, which concentrates the photon density for stimulated emission in the gain region.

Thus, a double heterostructure enables the confinement of carriers and generated photons in the active layer. For bulk active layers, the de Broglie wavelength of the carriers is small compared to the thickness of the active layer, leading to a high degree of carrier confinement. The wavelength of the photons, however, is comparable to the dimension of the structure, so that only a portion of the optical intensity is confined to the active region. The transversal distribution of the light intensity in the double heterostructure is given by the solution of the wave equation of a planar slab waveguide supporting TE and TM modes with an effective index n_{eff} as the respective eigenvalue. Figure 11.89c shows the optical intensity of the fundamental TE mode in a double heterostructure as a function of the transversal coordinate y, revealing the incomplete confinement of the optical field in the active region. The fraction of the mode intensity within the active layer is called the optical confinement or the filling factor Γ_{act}, which is an important design parameter for a semiconductor laser:

$$\Gamma_{act} = \frac{\int_0^{d_{act}} |E(y)|^2 \, dy}{\int_{-\infty}^{+\infty} |E(y)|^2 \, dy} \,, \tag{11.95}$$

where $E(y)$ is the electric field. If the light is also confined in the lateral direction of the laser, the definition has to be modified accordingly.

The dependence of the optical confinement factor of the guided modes on the thickness d for a layer structure is shown in Fig. 11.97. For increasing thickness of
Fig. 11.97 Dependence of the optical confinement factor Γ on the thickness d of an InP/InGaAsP/InP layer structure

the waveguide, the confinement factor approaches 1 and additional modes are supported.

An optical mode with an effective refractive index n_{eff} experiences an effective gain g_{eff} in a waveguide with an active layer, which provides the material gain g_{act} and has a refractive index n_{act}

$$g_{eff} = \frac{n_{act}}{n_{eff}} \Gamma_{act} g_{act} \,. \tag{11.96}$$

The correction factor n_{act}/n_{eff} takes into account the waveguiding effect on the modal gain [11.1275].

Laser Structures

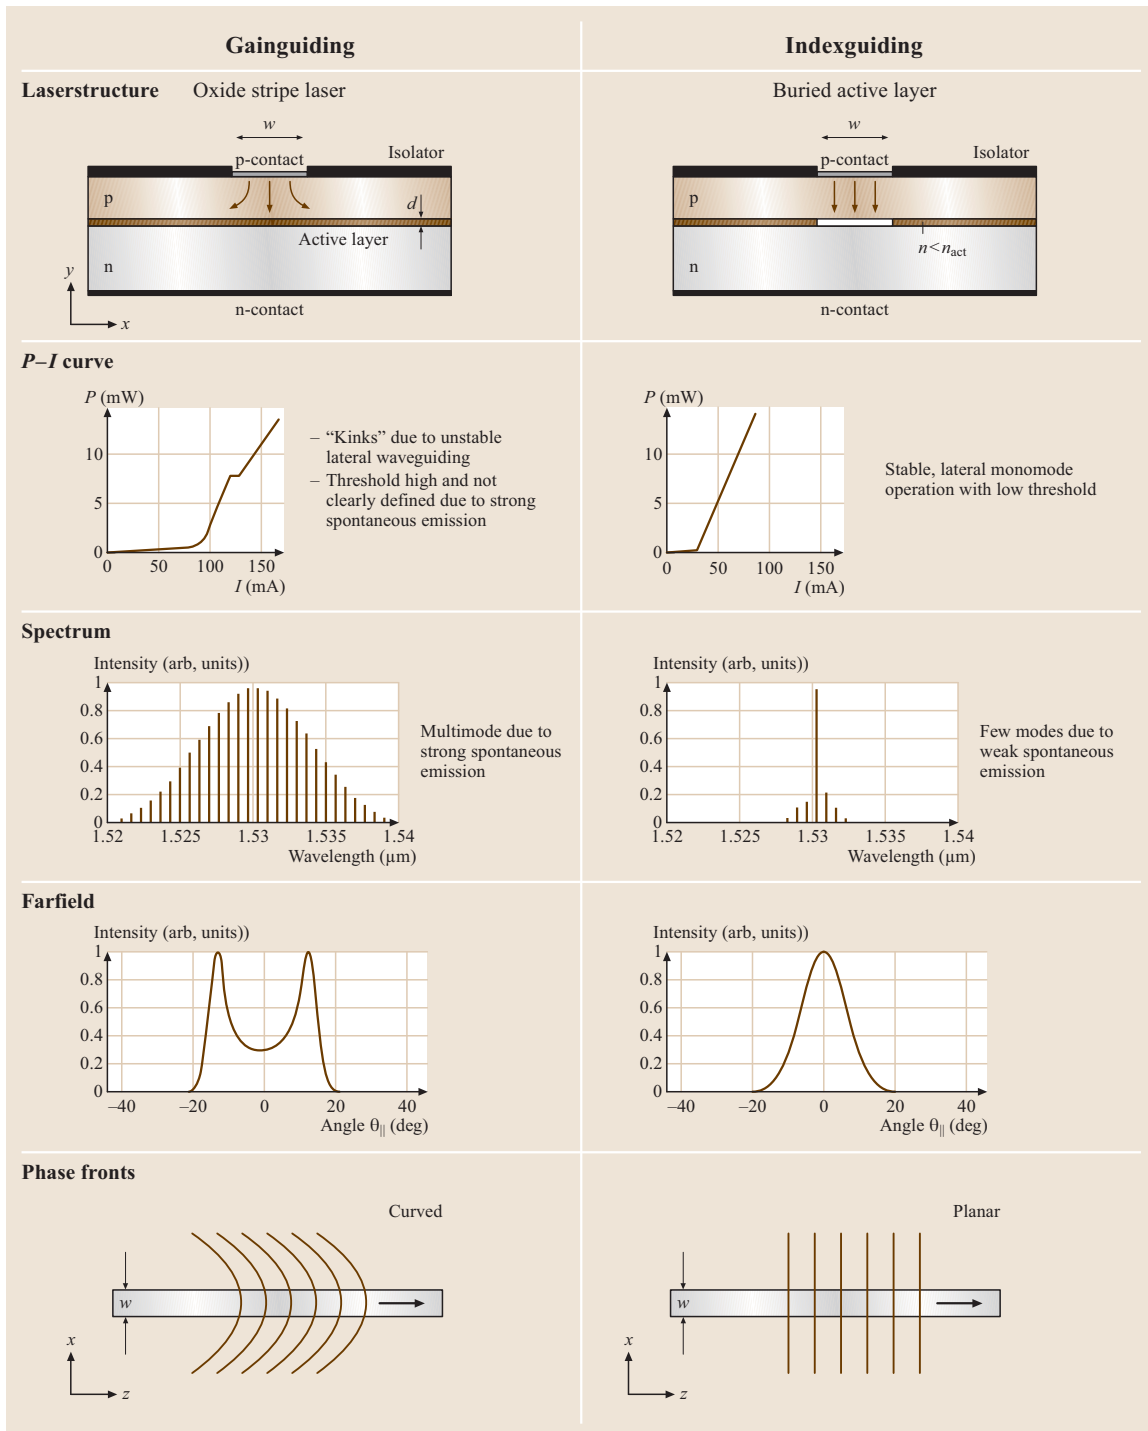
Using modern epitaxial growth methods it is possible to realize semiconductor multilayer structures very precisely so that stable, transverse single-mode operation can be obtained using dielectric waveguiding [11.1276]. For most applications, however, lateral (parallel to the pn junction) patterning of the laser structure is also required to obtain lateral carrier and photon confinement, which is important to obtain stable and efficient laser operation with high spectral purity and good coupling efficiency into a fibre. In addition, lateral confinement of the injection current is necessary to avoid leakage currents bypassing the active region. The confinement of photons, carriers and current has been implemented in many ways, reflecting the specific purpose of the device. Semiconductor lasers can be classified according to the mechanism of lateral waveguiding as gain-guided or index-guided, depending on whether it is the lateral variation of the optical gain or the refractive index that confines the mode. Index-guided lasers can further be subclassified as weakly or strongly index-guided, depending on the magnitude of the lateral refractive-index


Fig. 11.98 Comparison of gain-guided and index-guided laser structures

step. In a gain-guided laser structure (oxide stripe laser, Fig. 11.98, left) the current is injected via a stripe contact (width $w \approx 5\,\mu m$) in a laterally unpatterned active layer. The optical field is mainly guided by the resulting variation of the gain. The lateral waveguiding is weak, so that even small variations of the refractive index, e.g., due to temperature changes or carrier injection lead to unstable operation. In an index-guided laser structure (buried laser structure, Fig. 11.98, right) the active layer ($w \approx 2\,\mu m$) is laterally embedded into a material with a lower refractive index ($n < n_{act}$), higher bandgap and higher electrical resistivity to facilitate stable lateral waveguiding, carrier confinement and current confinement. The typical features of index- and gain-guided laser structures are summarized in Fig. 11.98. The power–current characteristic ($P–I$ curve) of gain-guided lasers is characterized by a high threshold current (typical 50–100 mA) and kinks originating from the unstable lateral waveguiding. The optical spectrum is multimodal due to the enhanced spontaneous emission. The phase-fronts are curved in the resonator and the far field shows the characteristic twin lobes caused by the laterally inhomogeneous gain distribution. The main advantage of gain-guided lasers is the simplicity of their fabrication. For very large stripe widths (50–100 μm) a so-called broad-area laser results, in which the current is injected laterally and homogeneously via a large contact. Since there is no lateral waveguiding in broad-area lasers, the threshold current is very high (typical a few A) and the multimode emission cannot be coupled efficiently into a fibre. Due to the high output power, broad-area lasers are used, e.g., for optical pumping of solid-state lasers.

Index-guided lasers show stable, lateral single-mode emission with a low threshold current (typical 10 mA) and a $P–I$ curve without kinks. The spontaneous emission in each mode is significantly smaller, resulting in a spectrum with a few dominating modes. The phase-fronts are planar and the far field has a smooth shape, enabling a high coupling efficiency into a single-mode fibre.

Weakly index–guided laser structures. In weakly index-guided lasers the thickness of the waveguiding layer is varied, thus resulting in a lateral waveguiding structure. Lateral single-mode emission can be obtained by a proper choice of the thickness and width of this variation. The lateral index step has to exceed the carrier-induced reduction of the refractive index ($\Delta n \approx 5 \times 10^{-3}$) so that index-guiding is dominating. Weakly index-guided laser structures can be divided into

two categories: ridge waveguide lasers and channeled substrate lasers.

In ridge-waveguide lasers, a rib waveguide is defined by etching a narrow stripe ($\approx 3–5\,\mu$m) down near to the active layer (at a typical distance of 200 nm). In the case of a metal-clad-ridge waveguide (MCRW) laser in
Fig. 11.99 Weakly index-guided laser structures

the material system GaAlAs (Fig. 11.99a) a CrAu electrode is deposited, which gives an electrically conductive contact on the p^+ top layer of the rib and an insulating contact on the p-GaAlAs layer with lower doping along the rib. Thus, the current injection is focused in the region of the active layer below the rib. This current confinement can also be realized by additional isolating layers, e.g., SiO$_2$ (Fig. 11.99b). The lateral waveguiding is accomplished by the higher refractive index of the semiconductor material compared to the surrounding SiO$_2$ and air. The etch depth has to be carefully controlled (e.g., by using etch-stop layers) in order to select one lateral mode and minimize current bypass.

The first step in the processing of channeled substrate lasers is the etch of a 2–3 μm-wide and 1 μm-deep channel into the substrate (Fig. 11.99c). In the subsequent epitaxy (e.g., liquid-phase epitaxy) this channel is

nearly planarized, thus generating a lateral waveguiding structure, since the active layer has a higher refractive index. Current bypass can be reduced by guiding the injection current using, e.g., localized Zn diffusion.

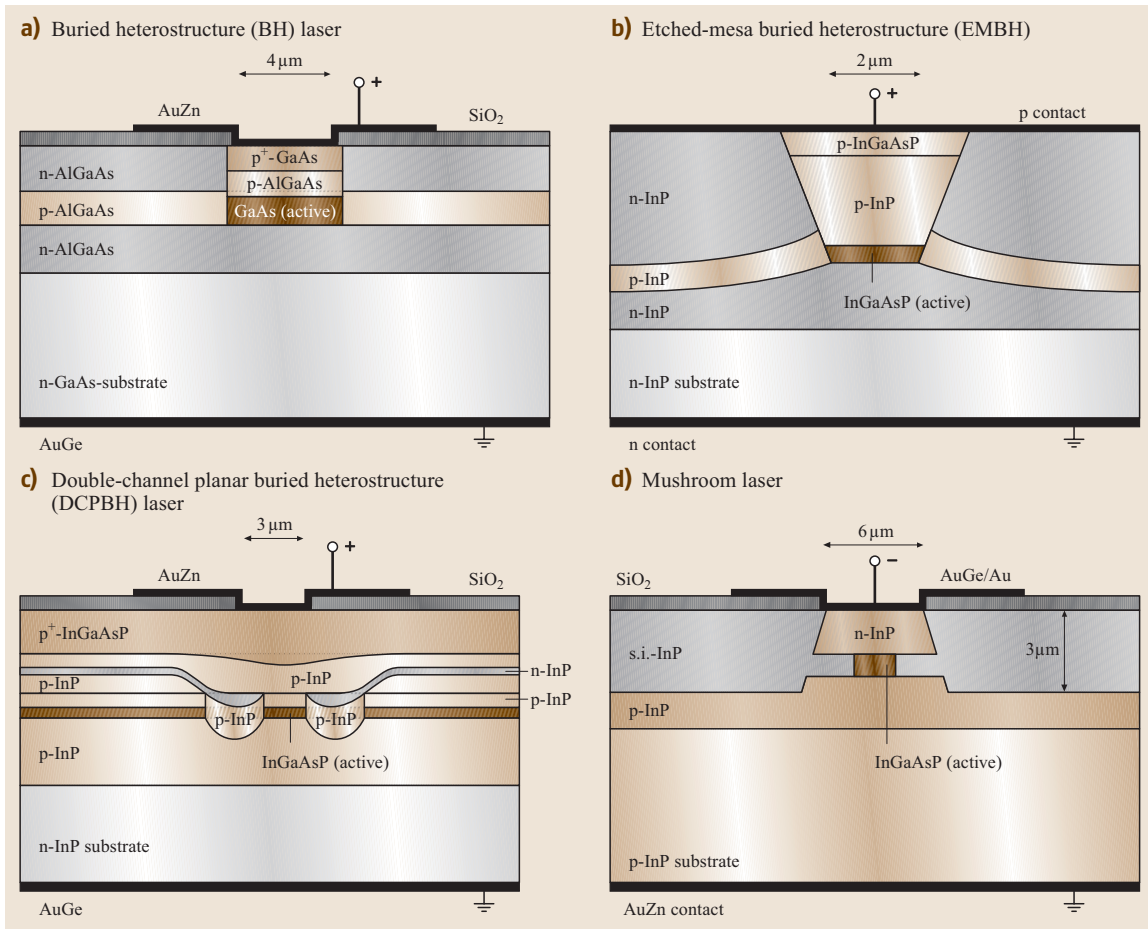
Weakly index-guided lasers are suitable to obtain low threshold currents of typically 20–40 mA and high output powers with lateral single-mode emission. The weak waveguiding allows for broader active layers compared to buried laser structures, which has a positive effect, e.g., on the series resistance. The low current leakage in ridge waveguide lasers usually results in good linearity of the P–I curve. The emission is more complex than in buried lasers, since index- and gain-guiding are important and even small changes of the refractive index by temperature or current injection can influence the performance. The active layer in weakly index-guided lasers is not affected during processing, so that lateral


Fig. 11.100 Buried heterostructure lasers

carrier diffusion in the active layer cannot be avoided, but on the other hand, the unpatterned active layer is advantageous for the reliability of the device. Since only one epitaxial growth step is needed, the fabrication of these lasers is significantly easier than buried semiconductor lasers.

Strongly index–guided laser structures. Strong index-guiding can be accomplished by buried laser structures, where a small stripe of the active layer material with a high refractive index is embedded into semiconductor material with lower refractive index and larger bandgap. For this purpose, the active layer has to be patterned and epitaxially regrown afterwards. Lateral single-mode operation is possible, if the resulting stripe width of the active layer does not exceed a critical value defined by the cut-off for the higher lateral modes [11.1277].

Figure 11.100 shows some examples for strongly index-guided laser structures. In the case of a buried-heterostructure (BH) laser structure in the material system GaAs/GaAlAs (Fig. 11.100a) the GaAs active layer is surrounded by AlGaAs, which has a larger bandgap and a lower refractive index. The active layer is grown in the first epitaxial step and structured into $1-2\,\mu$m-wide stripes. Using liquid-phase epitaxy (LPE), which planarizes the structure, the regions alongside the stripe are refilled with alternating n- and p-doped AlGaAs layers. This reverse-biased diode structure prevents the current from bypassing the active region. In a similar way, a BH structure can be realized in the long-wavelength material system InGaAsP/InP (Etched-mesa buried heterostructure laser, Fig. 11.100b). The reduction of leakage current using alternating n- and p-doped layers, however, leads to a significant increase of the parasitic electrical capacity of the laser, which degrades the high-frequency response of the device. Alternatively, electrically isolating regions for the current confinement can be fabricated using semi-insulating material (e.g., Fe-doped InP) or by proton implantation. In Double-channel substrate planar buried heterostructure (DCPBH) lasers (Fig. 11.100c) the first epitaxial growth step produces the active InGaAsP-layer and a p-InP cap layer on the n-InP substrate. Then, a double-stripe structure embedding the active region is created by etching. In the subsequent LPE step the generated channels are refilled with p-InP/n-InP and the epitaxial growth of the laser structure is finished up to the InGaAsP top layer. The processing of the mushroom laser (Fig. 11.100d) begins with the etching of $6\,\mu$m-wide mesa in the layer structure, which cuts through the active layer grown in the first epitaxy [11.1278]. Using a selective wet chem-

ical etching process the width of the active region is reduced up to $1-2\,\mu$m to obtain lateral single-mode operation. The resulting undercut area is epitaxially refilled afterwards, e.g., using vapor phase epitaxy (VPE) with semi-insulating InP [11.1279].

In addition to this strongly index-guided laser structures with a planar active layer, which are useful for integration with a DFB grating, there also exist buried laser structures utilizing nonplanar active layers based on the regrowth of, e.g., V-grooves or mesas.

Using strongly index-guided structures, a very stable and lateral single-mode laser operation with very low threshold currents (< 10 mA) and excellent high-speed characteristics can be obtained, since stable optical waveguiding, carrier confinement and current confinement are combined. The fabrication of these devices, however, is complicated due to the additional epitaxy step.

Edge–emitting Fabry–Pérot laser diodes

In Fabry–Pérot (FP) lasers, the cleaved facets of the semiconductor crystal form the optical resonator, which enables laser operation by providing the optical feedback of the stimulated amplified radiation. This resonator selects the photons generated by stimulated emission with respect to direction and wavelength. The light wave traveling perpendicularly to the facets is amplified if the wavelength matches a longitudinal mode of the resonator [(11.92), Figs. 11.90, 95, 96, 103a]. The lasing process starts if the gain experienced during one round-trip in the cavity equals the losses caused by absorption, scattering and the light output through the facets.

Lasing condition. The length L of the resonator is typically a few hundred micrometers. The intensity reflection and transmission coefficients of the end facets can be estimated using the Fresnel equations, neglecting the transversal and lateral structure of the waveguide with the air ($n = 1$) assumed to be outside the cavity:

$$R = \frac{(n_{\text{eff}} - 1)^2}{(n_{\text{eff}} + 1)^2}, \quad T = \frac{4n_{\text{eff}}}{(n_{\text{eff}} + 1)^2}, \quad (11.97)$$

where n_{eff} is the effective refractive index of the waveguide mode considered.

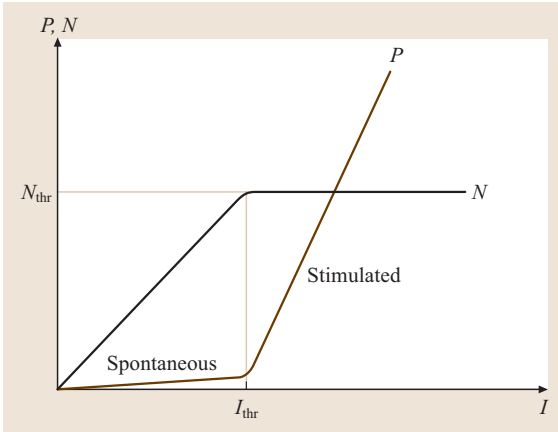
In this one-dimensional model plane waves with electric field amplitude $E(z)$ travel in the longitudinal direction (z) of the FP resonator, experiencing the modal intensity gain g due to stimulated emission. The threshold for laser operation is defined by a round-trip condition requiring that in a stationary state the optical wave remains unchanged after one complete round-trip


Fig. 11.101 Dependence of the output power (P) and carrier density (N) on the injected current

Fig. 11.102 Scheme of a DFB laser structure with an integrated rectangular Bragg grating (duty cycle w/Λ) including the corresponding transversal intensity distribution $I(x)$

in the cavity. This round-trip condition gives the mirror losses of the FP resonator

$$g = \alpha_\mathrm{m} = \frac{1}{2L}\ln(R_1 R_2)\,, \qquad (11.98)$$

where R_1 and R_2 denote the intensity reflection coefficients of the end facets. Since the net gain g in the cavity is composed of the material gain of the semiconductor g_eff and the waveguide losses α_s, the lasing condition can be written as

$$g_\mathrm{thr} = \frac{n_\mathrm{act}}{n_\mathrm{eff}}\Gamma_\mathrm{act}g_\mathrm{act}(N_\mathrm{thr}) = \alpha_s + \alpha_\mathrm{m} \qquad (11.99)$$

if the contribution of spontaneous emission is neglected and N_thr denotes the carrier density at threshold. The optical losses of the waveguide are caused by optical scattering from imperfections in the bulk media or at interfaces and free-carrier absorption in the active and cladding layers.

The longitudinal distribution of the photon density $s(z)$ in the active FP resonator is given by the sum of the forward and backward traveling photon densities, which grow exponentially due to the gain g. For a symmetric resonator ($R = R_1 = R_2$) the total photon density $s(z)$ is given by a cosh function (Fig. 11.103a) with a minimum in the middle of the resonator. For a laser diode with as-cleaved facets ($R = 0.28$), the intensity distribution is relatively flat, whereas for antireflection-coated facets a strongly inhomogeneous photon distribution results.

The round-trip condition also gives the optical frequencies of the longitudinal modes of the FP resonator according to $\nu_q = qc/(2Ln_\mathrm{eff})$, where $q = 1, 2, 3 \cdots$ and c denotes the vacuum speed of light. The frequency

separation $\Delta\nu$ of adjacent modes is influenced by the dispersion of the waveguide, which is taken into account by the group refractive index n_g

$$\Delta\nu = \frac{c}{2Ln_\mathrm{g}} \qquad (11.100)$$

with

$$n_\mathrm{g} = n_\mathrm{eff} + \nu\frac{\mathrm{d}n_\mathrm{eff}}{\mathrm{d}\nu}\,. \qquad (11.101)$$

For a typical FP laser diode the group index of $n_\mathrm{g} \approx 3.5{-}5$ is higher than the effective index $n_\mathrm{eff} \approx 3{-}3.5$. The separation of the equidistant mode frequencies is about 150 GHz for a 300 μm-long cavity, which is small compared to the width of the gain curve of
Fig. 11.103 Schematic structural cross sections (*left*) and the corresponding emission spectra (*right*) for various diode lasers

the semiconductor ($\approx 5\,\text{THz}$). Thus, longitudinal multi-mode operation can be expected above threshold for an FP laser diode.

For many applications the degree of single-mode emission is important; it can be quantified by the side-mode suppression ratio (SMSR):

$$\text{SMSR} = 10 \log_{10}(P_1/P_2) , \tag{11.102}$$

where P_1 and $P_2 \le P_1$ denote the output power of the two strongest modes in the optical spectrum. Typical FP laser diodes achieve a maximum SMSR of approximately $20\,\text{dB}$.

Rate equations. The fundamental static and dynamic properties of semiconductor laser diodes can be modeled using a set of rate equations [11.1280] describing the interaction of electron–hole pairs and photons in the active layer. We consider a strongly index-guiding double heterostructure supporting a single optical mode traveling as a plane wave axially in the cavity. The current I is assumed to be uniformly injected into the active layer with volume V and recombines there, completely neglecting leakage currents. The carrier density within the active layer is treated as homogeneous in the transversal and lateral direction, since the corresponding inhomogeneities of photon density are small and the resulting gradients in carrier density are smoothed out by diffusion. In FP lasers with a sufficiently high mirror reflectivity, the axial variations of the photon density s and the carrier density N can be neglected and the rate equations can be written as:

$$\frac{\mathrm{d}N}{\mathrm{d}t} = \frac{I}{eV} - \frac{N}{\tau_{\text{nr}}} - BN^2 - CN^3$$
$$\qquad - v_\text{g} \frac{n_{\text{act}}}{n_{\text{eff}}} g_{\text{act}}(N, s)s + \frac{F_N(t)}{V} , \tag{11.103}$$

$$\frac{\mathrm{d}s}{\mathrm{d}t} = v_\text{g} \left[\Gamma_{\text{act}} \frac{n_{\text{act}}}{n_{\text{eff}}} g_{\text{act}}(N, s) - g_{\text{thr}} \right] s$$
$$\qquad + \frac{\Gamma_{\text{act}} \left[R_{\text{sp}} + F_s(t) \right]}{V} , \tag{11.104}$$

$$\frac{\mathrm{d}\Phi}{\mathrm{d}t} = \frac{1}{2} \alpha_\text{H} v_\text{g} \Gamma_{\text{act}} \frac{n_{\text{act}}}{n_{\text{eff}}} g_{\text{act}}(N, s) + F_\Phi(t) , \tag{11.105}$$

where $v_\text{g} = c/n_\text{g}$ is the group velocity of the waveguide, e the electron charge, g_{act} is the material gain of the active layer, Γ_{act} is the optical confinement factor of the active layer and $1/\tau_{\text{nr}}$, B and C are the parameters describing nonradiative, bimolecular and Auger recombination, respectively. Φ is the phase of the complex electric field E, which is connected with the photon

number $S = sV/\Gamma_{\text{act}}$ via

$$E(t) = \sqrt{S(t)} \exp[i\Phi(t)] , \tag{11.106}$$

R_{sp} is the time-averaged rate of spontaneous emission into the lasing mode; $F_s(t)$, $F_N(t)$ and $F_\Phi(t)$ represent Langevin noise sources taking into account the statistic nature of the spontaneous emission and the shot-noise character of the carrier recombination and generation. The Langevin forces leading to fluctuations of carrier density and photon density are correlated and have zero mean [11.1280].

The longitudinal excess factor K_z accounts for the enhancement of the spontaneous-emission noise due to the axial dependence of the complex electric field $E(z, t)$

$$K_z(t) = \frac{|\int_0^L |E(z, t)|^2 \,\mathrm{d}z|^2}{|\int_0^L E^2(z, t)\,\mathrm{d}z|^2} . \tag{11.107}$$

In the case of a transversely single-mode index-guided FP laser the factor K_z is given by [11.1281]

$$K_z^{\text{FP}} = \left(\frac{(\sqrt{R_1} + \sqrt{R_2})(1 - \sqrt{R_1 R_2})}{\sqrt{R_1 R_2} \ln(1/R_1 R_2)} \right)^2 . \tag{11.108}$$

The first rate equation (11.103) can be formally derived from the quantum-mechanical density-matrix formalism. It can be interpreted as a balance of carriers that are injected as a current I and contribute to stimulated emission or are lost for the lasing process via the different recombination processes. The second and third equations (11.104, 105) can be derived from the Maxwell equations with the rotating-wave and slowly varying amplitude approximations.

For semiconductor lasers with a bulk active layer, the dependence of the gain on the carrier density $g_{\text{act}}(N)$ can be approximated as linear [11.1282]

$$g_{\text{act}}(N) = \frac{\mathrm{d}g}{\mathrm{d}N}(N - N_{\text{tr}}) , \tag{11.109}$$

where $\mathrm{d}g/\mathrm{d}N$ is the differential gain and N_{tr} is the transparency carrier density. In quantum well structures (Figs. 11.91, 92) this dependence is usually described by a logarithmic function [11.1283, 1284]

$$g_{\text{act}}(N) = \frac{\mathrm{d}g}{\mathrm{d}N} N \ln \frac{N}{N_{\text{tr}}} \quad \text{for} \quad g_{\text{act}} \ge 0 . \tag{11.110}$$

The influence of the photon density on the gain is taken into account by introducing a nonlinear gain coefficient ε according to:

$$g_{\text{act}}(N, s) = \frac{g_{\text{act}}(N)}{1 + \varepsilon s} . \tag{11.111}$$

This nonlinear gain compression is caused by spectral hole burning and carrier heating, which is significant if the time constant of stimulated emission becomes comparable to the intraband relaxation time.

Refractive index change. In semiconductors the real part of the refractive index depends on the carrier density because of various physical mechanisms. With increasing injection the band-to-band absorption is reduced due to band-filling effects. In addition, the absorption increases due to the reduction of the bandgap (bandgap renormalization resulting from many-body effects) and absorption also increases due to the increasing absorption of free carriers. The resulting total change of the real part of the refractive index, which is related to the gain spectrum via the Kramers–Kronig relation, depends on the wavelength relative to the gain maximum. In the case of 1.5 μm InGaAsP the refractive index decreases with injection. The dependence of the refractive index on the carrier density is theoretically described by the effective line width enhancement or Henry factor α

$$\alpha = \frac{\partial n_{\text{eff}}}{\partial \gamma_{\text{eff}}} \,, \tag{11.112}$$

where the complex effective refractive index is defined by $n_{\text{eff}} - i\gamma_{\text{eff}}$. The change of the effective index with carrier density can be written as

$$\delta n_{\text{eff}} \cong \Gamma_{\text{act}} \frac{n_{\text{act}}}{n_{\text{eff}}} \delta n_{\text{act}} = -\Gamma_{\text{act}} \frac{n_{\text{act}}}{n_{\text{eff}}} \frac{\alpha\lambda}{4\pi} \frac{\partial g_{\text{act}}(N)}{\partial N} \delta N \,. \tag{11.113}$$

The line width enhancement factor is important for the treatment of line width and frequency chirp under modulation [11.1281]. Typically it ranges from 3 to 5, decreasing from the long-wavelength to the short-wavelength side of the gain curve [11.1282].

Steady-state characteristics. The single-mode rate equations can be used to analyze the steady-state behavior of a semiconductor laser. Setting the time derivative to zero in (11.104), we obtain an implicit expression for the photon number S in the case of continuous-wave (CW) operation:

$$S = \frac{R_{\text{sp}}}{v_g[g_{\text{thr}} - \Gamma_{\text{act}}g_{\text{act}}(N, s)]} \,. \tag{11.114}$$

The number of photons increases as the gain value asymptotically approaches the losses g_{thr}. The small gain difference is compensated by spontaneous emission, which provides the noise input amplified by stimulated emission. Below threshold the photon density is

small and (11.103) gives a linear increase of the carrier density according to $N \propto I/eV$. Above threshold the gain is approximately clamped at $g(N_{\text{thr}}) = g_{\text{thr}}$ and the corresponding threshold current, which is defined in the limiting case of vanishing spontaneous emission ($R_{\text{sp}} = 0$), becomes

$$I_{\text{thr}} = eV \left(\frac{N_{\text{thr}}}{\tau_{\text{nr}}} + BN_{\text{thr}}^2 + CN_{\text{thr}}^3 \right) \,. \tag{11.115}$$

Using (11.103) the photon number above threshold can then be written as $S = (I - I_{\text{thr}})/ev_g g_{\text{thr}}$. Since the carrier density is clamped at threshold, all injected carriers in excess of the threshold current contribute to stimulated emission and the number of photons increases proportionally to $(I - I_{\text{thr}})$. The total output power $P = v_g \hbar \omega \alpha_{\text{m}} S$ emitted from both facets becomes

$$P = \frac{\hbar\omega}{e} \eta_i \frac{\alpha_{\text{m}}}{g_{\text{thr}}} (I - I_{\text{thr}}) \,, \tag{11.116}$$

where we assume that only a fraction η_i of the external drive current reaches the active region and the remaining fraction $(1 - \eta_i)$ is lost via leakage current or nonradiative recombination. Thus, the P–I curve of a semiconductor laser diode is a straight line (Fig. 11.101) above threshold with a slope defined by the external quantum efficiency η_{ext}:

$$\eta_{\text{ext}} = \frac{\text{d}P}{\text{d}I} \frac{e}{\hbar\omega} = \eta_i \frac{\alpha_{\text{m}}}{g_{\text{thr}}} \,, \tag{11.117}$$

which can be interpreted as the ratio of the number of emitted photons to the number of injected electrons per time. The sharpness of the transition from the spontaneous emission below threshold to the stimulated emission above threshold depends on the amount of spontaneous emission into the lasing mode. Leakage currents, thermal effects and spectral hole-burning neglected so far lead to bending of the P–I curve.

Characteristic temperature. The threshold current of a semiconductor laser depends on the temperature T, which can be described phenomenologically by

$$I_{\text{thr}}(T) = I_0 \exp \frac{T}{T_0} \,, \tag{11.118}$$

where T_0 is the characteristic temperature, which typically ranges between 40 K and 90 K for semiconductor lasers emitting around 1550 nm.

Single-Mode Laser Structures
Transmitters used, e.g., in optical-fibre communication systems should emit light predominantly in a single

longitudinal mode since the presence of side modes limits the transmission capacity due to pulse broadening caused by the chromatic dispersion of the fibre. Semiconductor lasers with an FP resonator usually exhibit multimode operation since the gain spectrum is wider than the longitudinal mode spacing and the broadening of the gain profile, which due to spectral hole burning is not perfectly homogeneous, offers several modes with sufficient gain to oscillate. The techniques to achieve reliable longitudinal mode control even under high-bit-rate modulation can be categorized into two main groups:

Short lasers. The discrimination against side modes in FP resonators can be enhanced by reducing the cavity length L. If the mode spacing $\Delta \nu \propto L^{-1}$ becomes comparable to the width of the gain curve, only one mode will oscillate near the gain peak. To obtain stable single-mode operation, however, the lasers must be extremely short. This requires a very good reflectivity of the end facets to overcome the high mirror losses $\alpha_m \propto L^{-1}$, leading to high threshold current densities. The problems of fabricating very short semiconductor devices can be solved using a vertical-cavity surface-emitting laser (VCSEL) structure (Fig. 11.96).

Frequency–selective feedback. The second method to obtain single-mode operation is to incorporate a frequency-selective element in the resonator structure. This can be realized by using coupled cavities, an external grating or a Bragg grating:

Coupled cavities. If one or more additional mirrors are introduced in the FP resonator, the boundary conditions added due to the reflections at each interface severely limit the number of longitudinal modes. To achieve single-mode operation, however, it is often necessary to tune the resonator by changing the drive current or the temperature. Usually the single-mode regime is small so that such structures can only be modulated over a limited current range without mode jumps. In addition, the reproducible fabrication of nearly identical devices turns out to be difficult since the spectral properties strongly depend on the exact lengths of the sections.

External grating. Frequency selection can also be realized by an external grating outside the resonator. The mechanical stability of such lasers, however, is a critical point since the grating is not integrated on the wafer. Consequently, lasers with external gratings are expensive devices (Fig. 11.110a).

Bragg grating. The method most frequently used to achieve single-mode emission is to incorporate a Bragg grating, which creates a periodic variation of the complex refractive index and distributes the feedback throughout the cavity. Dynamic single-mode operation is achieved if the threshold gain for the oscillating mode is significantly smaller than the threshold gain for the other modes. Devices employing Bragg gratings can be classified roughly into three categories: distributed Bragg reflector (DBR), distributed feedback (DFB) (Figs. 11.96, 102, 103, section on Fabry–Pérot structures in Sect. 11.3.2, and Sect. 11.3.6) and gain-coupled (GC) lasers.

In DBR lasers the Bragg grating is etched into passive regions near the cavity ends. The index grating (the variation of the real part of the refractive index) acts as an effective mirror with wavelength-dependent reflectivity and surrounds the central part of the cavity which is active and remains uncorrugated. The longitudinal mode with a wavelength located near the reflectivity maximum of the grating is selected. Since a DBR laser is formed by replacing the mirrors by passive gratings, the properties can be described by an effective mirror model. The transition between the active section and the passive gratings usually complicates the technological realization of in-plane DBR lasers. An important advantage of DBR lasers is that the wavelength can be changed if the grating regions are equipped with separate electrodes that can tune the Bragg frequency via the carrier-induced refractive index change. Thus, DBR gratings are often used in tunable lasers.

In DFB lasers the index grating covers the entire resonator length. At the wavelength corresponding to the corrugation period of the grating, the forward- and backward-traveling waves created by the Bragg scattering are confined in the central part of the cavity so that the mirror losses become a function of the wavelength. The longitudinal mode with the lowest mirror losses corresponding to the most effective concentration of photons in the resonator is selected.

In gain-coupled devices a periodic variation of gain or loss is used to favor a longitudinal mode of the FP resonator. In the ideal case, there is no Bragg scattering at the gain grating, and the longitudinal photon distribution as well as the mirror losses are unchanged compared to the FP cavity. The overlap with the loss or gain grating, however, varies between the different longitudinal modes of the FP resonator. The mode experiencing the largest overlap with the gain grating (or minimum overlap with a loss grating) is selected.

DFB lasers. The spectral properties of DFB lasers [11.1285] are essentially determined by the integrated Bragg grating. The waveguiding in such periodic structures can be analyzed by the coupled mode theory [11.1286], which yields approximate analytical solutions describing the light propagation in waveguides with a periodic variation of the complex refractive index by counter-propagating modes exchanging energy by scattering. The strength of the interaction and the amount of feedback in the grating structure are determined by the complex coupling coefficient

$$\kappa = \pi \Delta n/\lambda_0 + \mathrm{i}\Delta g/4 \,, \tag{11.119}$$

which is proportional to the variation of the refractive index step Δn, the gain variation Δg and the number of corrugations per length in the grating. The Bragg wavelength λ_B is given by the effective index, the corrugation period Λ and the order m_{DFB} of the grating according to (11.93). For an axially homogeneous first-order grating ($m_{DFB} = 1$) with length L and a perfect antireflection coating on the facets ($R_1 = R_2 = 0$) the theory reveals the following solutions

- In the case of pure index coupling ($\Delta n_{eff} \neq 0$, $\Delta g = 0$) the transmission spectrum turns out to be symmetric with respect to the Bragg wavelength $\lambda_B = 2n_{eff}\Lambda$ where oscillation is forbidden. For a small coupling coefficient, the mode spacing approximately takes the value of an FP resonator $\Delta\lambda = \lambda^2/2n_{eff}L$ but, in contrast to an FP cavity, the threshold gain of the modes is wavelength dependent and increases with growing distance from the Bragg wavelength. A strong coupling produces a transmission stop-band with width $\Delta\lambda \cong \kappa\lambda_B^2/(\pi n_{eff})$ centered at the Bragg wavelength, in which transmission is strongly damped. The two modes with the lowest threshold gain $g \cong 2\pi^2/(\kappa^2L^3)$ are located at the edges of the stop-band symmetrical to the Bragg wavelength.
- In the case of pure gain coupling ($\Delta g \neq 0$, $\Delta n_{eff} = 0$) the mode degeneracy is removed, which means that the mode with the lowest threshold gain oscillates at the Bragg wavelength symmetrically surrounded by the other modes with higher threshold gain values. The mode spacing is $\Delta\lambda = \lambda^2/2n_{eff}L$ and no stop-band occurs since there is no backscattering at index steps in the grating. The mode selection is due to the different overlap of the standing waves in the FP resonator with the gain grating.

In second-order gratings ($m_{DFB} = 2$) additional scattering occurs in the transversal direction, leading to higher losses. In addition, the coupling coefficient of second-order gratings depends more sensitively on the exact shape of the grating so that it becomes more difficult to control. That is why first-order gratings predominate although the corrugation periods are smaller ($\Lambda \cong 240$ nm for $\lambda = 1.55\,\mu$m). Due to the scattering perpendicular to the optical axis (Fig. 11.96), second-order gratings can be utilized for the vertical emission of light from edge-emitting laser diodes [11.1287, 1288].

Basic properties of index-coupled DFB lasers. The spectrum of an index-coupled DFB laser mainly consists of two degenerate lasing modes at the edges of the stop-band (Fig. 11.103b). This mode degeneracy in index-coupled DFB laser structures is usually removed by incorporating a $\lambda/4$ phase shift in the grating. This can technologically be implemented by inserting an additional section of length $\lambda_0/(4n_{eff}) = \Lambda/2$ in the middle of the grating. The introduction of the $\lambda/4$ phase shift selects the Bragg mode in the middle of the stop-band, revealing the lowest mirror losses so that single-mode operation with an SMSR of > 40 dB can be obtained (Fig. 11.103c).

The axial distribution of the light intensity in the cavity is connected to the mirror losses α_m via the round-trip condition. Thus, a decrease of the mirror losses for the longitudinal modes in a DFB grating is equivalent to increasing longitudinal optical confinement, which means that the photons are concentrated inside the cavity and only a small fraction of the light intensity leaves the resonator through the end facets. The typical longitudinal photon distribution for a DFB laser with and without a $\lambda/4$ phase shift is shown in Fig. 11.103, revealing the pronounced maximum in the middle of the resonator even for moderate coupling coefficients. This strong inhomogeneity of the photon density distribution in DFB lasers leads to an inhomogeneous carrier density distribution above threshold due to the recombination by stimulated emission. With increasing injection the carrier density is depleted in places with a high photon density. This phenomenon is called longitudinal spatial hole burning (LSHB) and has several important consequences for the static and dynamic behavior of DFB lasers above threshold. First, the mode discrimination is influenced since a variation of the carrier density distribution changes the round-trip gain of the various modes having different photon density distributions. Thus, the side-mode suppression can degrade with increasing output power due to LSHB. Second, the mode wavelengths change, even above threshold, since the inhomogeneity of the carrier density caused by LSHB leads to an inho-

mogeneous axial distribution of the effective refractive index. This effect is utilized in several types of tunable DFB lasers.

Various DFB lasers with a more complex grating structure have been developed in order to obtain a high yield of single-mode devices and a flat axial photon distribution with reduced LSHB. Some examples are:

- $2 \times \lambda/8$ phase shifts. The distance between the phase shifts, however, must be optimized to achieve a high yield [11.1289].
- Corrugation pitch modulation (CPM). The DFB grating is divided into three sections. The corrugation period in the central section is slightly higher than in the outer sections so that the phase shift is quasi-continuously distributed along the cavity [11.1290].
- Axial variation of duty cycle by using, e.g., a holographic double-exposure technique [11.1291].
- Axial variation of coupling coefficient by variation of the etch depth [11.1292] or sampled gratings [11.1293].
- Bent waveguides superimposed on homogeneous grating fields can be used to obtain quasi-continuously and arbitrarily chirped gratings with high spatial resolution [11.1294].
- Axially inhomogeneous injection using a three-electrode structure. Spatial hole burning can be

compensated for if the injected current density is higher in the central section near the peak of the photon density, thus reducing the gain of the side-modes suffering from the lower current in the outer section [11.1295].

The phase relation between the grating and the end facets is difficult to control during the cleaving process of DFB lasers, since the corrugation period for a first-order grating ($\lambda = 1.55 \, \mu\text{m}$) is typically 240 nm. Experimental and theoretical investigations show that all static and dynamic optical properties of as-cleaved DFB lasers are strongly influenced by this phase relation between the grating and facet. The mirror losses of the various longitudinal modes, the mode discrimination, the intensity distribution, the optical spectra and the dynamic and noise characteristics vary considerably as a function of the end facet phases [11.1296]. Since these end facet phases are distributed randomly after the cleaving process, the yield of good DFB devices is limited. The problem of the uncertain end facet phases can be reduced by appropriate antireflection coatings.

Gain-coupled lasers. In gain-coupled laser structures, a longitudinal mode of the FP resonator is selected by implementing an axial gain or loss grating. In contrast to index-coupled DFB lasers, there is almost no reflection of the light wave in a gain grating. Therefore, the longitudinal intensity distribution and the spectral positions of the various modes are equal to those of an FP resonator. The mode selection is caused by the different overlap of the longitudinal modes with the gain grating. The mode, whose longitudinal field distribution exhibits the largest overlap with the gain grating or the smallest overlap with the loss grating, is selected.

Gain coupling can be realized in different ways:

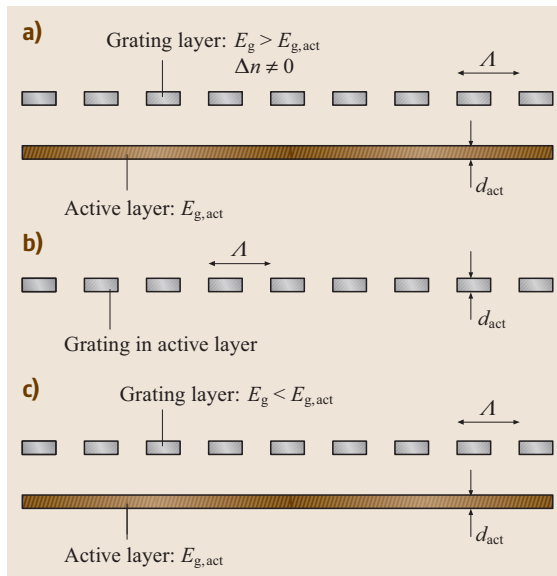
- The grating structure can be etched directly into the active layer and regrown afterwards with a semiconductor material [11.1297] that is transparent to the laser emission (Fig. 11.104b). The resulting gain coupling in this grating structure is accompanied by a strong index coupling due to the high refractive-index difference between the active layer and the regrown material. With respect to the phase difference between the index and gain grating one distinguishes between in-phase and anti-phase gratings.
- A current blocking pnp layer structure above the active layer is corrugated and regrown, so that a periodic variation of the current density injected into the active layer is achieved [11.1298]. The parasitic index coupling can be kept very small in this type of


Fig. 11.104a–c Various types of Bragg gratings. **(a)** Index coupling; **(b)** gain coupling; **(c)** loss coupling

gain grating. Due to the Kramers–Kronig relations, however, the gain grating is inevitably accompanied by an index grating.

Loss coupling is obtained if the grating is etched into an additional layer that is separated from the active layer and is absorbing for the emission (Fig. 11.104c). This grating acts as a saturable periodic absorber for the laser emission from the active layer [11.1299]. In contrast to index coupling (Fig. 11.104a) the bandgap E_g of the grating is smaller than the bandgap of the active layer $E_{g,act}$. Usually, the absorbing grating layer has a different refractive index than the material used for the regrowth, so that considerable index coupling occurs. Alternatively, the loss grating can be integrated into a metallization at the surface of the device, so that no epitaxial regrowth is required [11.1300].

There are significant differences between the characteristics of gain- and loss-coupled semiconductor lasers compared to index-coupled DFB lasers:

- In contrast to index-coupled devices, there is almost no reflection of the light wave in an ideal gain grating. Thus, the interference of the reflected wave inside the grating and at the facets is avoided, so that the influence of the end facet phases is strongly reduced compared with index-coupled DFB lasers. Therefore, a high single-mode yield can be obtained without the necessity to use an antireflection coating of the end facets.
- The longitudinal photon distribution is, in the case of a small parasitic index coupling, similar to that of an FP resonator. Thus, the strongly inhomogeneous photon distribution in DFB lasers and the resulting problem of longitudinal spatial hole burning is reduced in gain-coupled devices.

Basics of Lasers
with High Modulation Bandwidth

For the highest-bit-rate fibre-optic data communication $(1.26-1.68 \, \mu m)$, the ultrafast conversion of the data from the electronic bit sequence into the appropriate optical bit pattern takes place by means of semiconductor lasers. This is done either with a CW laser combined with a subsequent ultrafast optical modulator or via direct modulation of the laser (intensity or frequency modulation). As the simplest example the intensity modulation of the laser is described. The bit pattern available as a sequence of ultrashort current pulses is translated by the laser into the appropriate sequence of ultrashort light pulses, which then propagate e.g. via a fibre towards

the receiver. The photodetector retranslates the light pulses back to the electronic bit sequence. Seen in terms of a two-language dictionary, the laser translates ultrafast from electronics into optics and the photodetector ultrafast from optics into electronics.

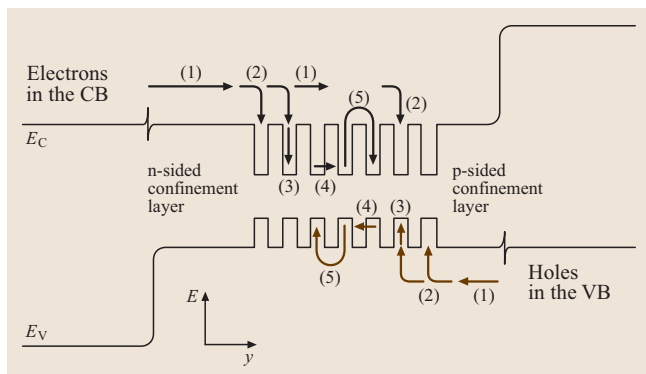
For this purpose, the electrons injected through the n contact in the semiconductor laser must arrive as fast as possible at the most deeply bound energy states of the conduction-band QWs and the holes injected through the p contact as fast as possible into the ground states of the valence-band QWs (Fig. 11.105). Several retarding physical transport and relaxation processes are involved, whose combined time delay effect can however be minimized [11.1301, 1302]. Owing to the very high doping in the long conduction paths, which start at the contacts, very short dielectric re-
Fig. 11.105 Schematic representation of the direct modulation of a semiconductor laser, translation of an electronic bit pattern (*left*) via a corresponding temporal carrier distribution in the QWs (*center*) into an optical bit pattern (*bottom*)


Fig. 11.106 Schematic representation of the charge carrier dynamics close of the active region (here seven QWs) in the band structure in space for an asymmetric laser structure [11.1302] (enlargement of Fig. 11.105 in the area indicated by the ellipse)

laxation times arise there. This can be visualized by means of a pipe completely filled with ping pong balls (high doping throughout the length of the conduction path). A ball injected at one end of the pipe, causes another to be ejected from the other end of the pipe. In this manner, a *current pulse* is transferred to the other end of the pipe almost without delay in heavily doped semiconductors.

In order to reduce optical losses through reabsorption, the confinement layers should be undoped or only slightly doped. Retarding effects arise as a consequence of the charge-carrier transport (number 1 in Fig. 11.106). Using the analogy of the balls and pipe above, a ball in an empty pipe (undoped) must go through the entire length of pipe (the length of a confinement layer) before finally exiting from the other end. Further retarding effects arise from the charge carrier capture (2), relaxation (3) in the respective QW ground states, by the reconciliation of charge carrier inhomogeneities between the individual pots, through tunneling (4) and thermal reemission (5). Since the mobility of the electrons is substantially higher than that of the holes, in asymmetrical laser structures [11.1302] the p-side confinement layers are reduced in thickness in favor of the n side. This favors the transfer of the less-mobile holes. In addition, this asymmetric laser structure design takes into account the different capture probabilities: the capture of holes into the QWs is much more efficient than that of electrons. Thus, a smaller p-sided confinement layer (reservoir of uncaptured electrons giving rise to bit interfering) is beneficial. In today's fastest laser diodes (largest modulation bandwidth) $-3\,\mathrm{dB}$ modulation frequencies of up to $40\,\mathrm{GHz}$ can be obtained.

Tunable Lasers

Wavelength tuning of an edge-emitting DFB semiconductor laser can be obtained according to (11.93), in the simplest case, by varying the effective refractive index via the injection currents in different sections, either thermally or by using plasma effects (carrier density variations). In these cases rising injection currents lead

1. to increasing emission wavelengths (red shift) via thermal effects and
2. to a blue shift via the plasma effect.

A superposition of both effects is found in multi-section DFB lasers [11.1305] since gain, tuning and DFB grating exist in all sections (Fig. 11.107a). In order to increase the total tuning range it is necessary to separate gain and tuning [11.1306, 1307]. In the three-section DBR laser (Fig. 11.107b) this is done longitudinally by using a gain section (*right*, the active region is shown in black), a grating-section (*left*) and a phase section

(*center*) [11.1308]. The phase section only includes the brown waveguide layer(s) and is used to match the phase of the standing light wave after one round-trip. The gain is controlled, e.g., via the current between the top right contact and the bottom contact. In contrast, a vertical separation is used in the tunable twin guide (TTG) laser [11.1306, 1307, 1309] (Fig. 11.107c). A current from the left-side contact to the top contact only controls the carrier density in the brown waveguiding layer. The gain is controlled via the current between the left side contact and the bottom contact. In the three-section DBR and the TTG laser the tuning is based on the plasma effect, if only forward biasing is used.

Another very important tuning principle is based on two mode combs of slightly different mode spacing. In analogy to a vernier based on two scales [11.1306, 1307], a small detuning of the combs can address individual modes separated widely in the spectrum: only those modes which exactly occur in both combs can oscillate since only this situation provides sufficient reflectivity

Table 11.37 Tuning characteristics of different 1.55 μm laser types, DFB: distributed feedback, DBR: distributed Bragg reflector, TTG: tunable twin guide, SSG: superstructure grating, SG: sampled grating, GAC: grating-assisted coupler, GCSR: grating-assisted co-directional coupler laser with rear sampled grating reflector. The tuning occurs either thermally (t), via the plasma effect (p), via the co-directional coupler (CC) grating or via Vernier effect (V). TR: tuning range

Laser type	Control currents	Tuning (exp.) ($\Delta\lambda$/nm)	Tuning (max. continuous)	Tuning principles	Miscellaneous	Ref.
3 sect. DFB	2	3	3	t, p	Continuous TR	[11.1305]
3 sect. DFB	2	5.5	3	t, p	Bent waveguide, quasi contiunuous TR	[11.1294, 1304, 1312]
3 sect. DBR	3	10	7	p, (t)	Quasi continuous TR	[11.1313]
3 sect. DBR	3	22	7	p, t	Incl. both polarities, quasi continuous TR	[11.1314]
3 sect. DBR	3		7	p	Mode-hop-free, really continuous TR	[11.1315]
TTG	2	7	13	p, (t)	Continuous TR	[11.1306, 1309]
TTG	2	13	13	p, t	Incl. both polarities, continuous TR	[11.1306]
Y	4	51		V, p	No continuous TR	[11.1303]
SSG/SG	4	95		V, p	Quasi contiunuous TR, gaps in the total TR	[11.1310, 1311]
SSG/SG	11	38-50		V, p	Quasi contiunuous TR, *without* gaps in the total TR	[11.1316]
GAC	3	50-70		CC, p	No continuous TR	[11.1262, 1317, 1318]
GCSR	4	100		CC, p	Quasi continuous TR, *without* gaps in the total TR	[11.1319]
GCSR	4	50-114		CC, p	Quasi contiunuous TR, gaps in the total TR	[11.1320]
SSG/SG TTG	3	30-50		V, p	Quasi contiunuous TR	[11.1321]
MG-Y	4-5	46		V, p	Quasi contiunuous TR	[11.1322]

and, thus, sufficient net gain. This principle is applied in the (C^3) laser, Y laser, Mach–Zehnder interferometer laser, superstructure grating (SSG) DBR laser and sampled grating (SG) laser. Two FP cavities of different length and, thus, *two FP mode combs* are used in the Y laser (Fig. 11.108a) and the C^3 laser (two coupled FP lasers of slightly different length, not displayed). Two superstructure mode combs are shifted against each other in the SSG laser [11.1310] and SG DBR laser [11.1311] (Fig. 11.107e). The codirectional coupling in the grating assisted coupler (GAC) laser between two waveguides realizes an additional spectral filter which can be shifted spectrally in a controlled way against an FP mode spectrum. The two waveguides can be laterally or vertically (Fig. 11.107d) coupled. Depending on the size of the grating period, a grating can reflect light (inversion of the propagation wave vector, contra-directional coupling grating, short grating period, e.g., Fig. 11.107a,b,c,e) or change the magnitude of the propagation vector (maintaining propagation direction, codirectional coupling grating, long period, shown in Fig. 11.107d below the center contact). Table 11.37 includes a comparison of different tunable laser types with respect to important device characteristics and properties.

Generally the types discussed up to now cannot provide excellent characteristics in all features such as simple tuning (low number of control parameters), high SMSR, wide tuning, continuous tuning and high efficiency. This motivates the search for promising combinations of the above principles. Using a GAC to select a mode from an SG yields the grating-assisted codirectional coupler laser with rear sampled grating reflector (GCSR) [11.1319, 1320] (Fig. 11.107f). Another laser with 11 sections combines a SSG or a SG with many DBR sections of different grating period each [11.1316]. SSG or the SG laser and the TTG laser has been proposed [11.1321]. Combining the SSG laser and the Y laser yields the modulated grating Y laser [11.1322]. For comprehensive details of tunable lasers we refer to [11.1306, 1307]. Finally, coupled Mach–Zehnder interferometers or arrayed waveguide (AWG) structures can also be used as filter structures in lasers, e.g., in the digitally tunable ring laser using a ladder of ring-resonator filters [11.1323, 1324].

DFB lasers with an axially varying grating period are very attractive to tailor specific device properties. Using bent waveguides on homogeneous DFB gratings ($\Lambda_z = $ const.) enables to generate a local effective pitch length $\Lambda(z)$ that exceeds Λ_z the more, the larger the local tilt angle of the bent waveguide deviates from a vertical intersection of the pitches i.e., the larger the local tilt angle $\vartheta(z)$ is. Figure 11.108b schematically shows a bent waveguide covering a homogeneous grating. Choosing appropriate bending functions $x(z)$ generates chirped DFB gratings with a varying effective pitch length $\Lambda(z) = \Lambda_z / \cos(\vartheta(z))$, as shown in the inset to Fig. 11.108b [11.1294]. The fabrication method is indicated in Fig. 11.108c, which shows two chirped DFB lasers formed after cleaving the structure in Fig. 11.108b in the x-direction in the center of the side of the device oriented in the z-direction. Since the light is strongly guided along the bent w-direction, the light sequentially passes quasi continuously varying pitch lengths $\Lambda(w)$, as displayed in Fig. 11.108c. Since ϑ is largest in the center of Fig. 11.108b, the two chirped DFB lasers have the largest pitch at the center facets. Various applications of chirped DFB gratings have been demonstrated [11.1294, 1304, 1312, 1325], including axially distributed phase shifts, higher SMSR, enhanced single-mode stability and lower line widths. In addition, chirped three-section DFB lasers (Fig. 11.108d) have demonstrated enhanced tuning ranges [11.1294, 1304, 1325] (Table 11.37). The mushroom-type laser structure (Fig. 11.100d) is applied in the chirped three-section DFB laser (Fig. 11.108d), which shows a modulation bandwidth of up to 26 GHz [11.1302].

Further Laser Types with Horizontal Resonators

In the bipolar lasers considered so far the light emission in the active layer takes place through the recombination of an electron in the conduction band with a hole in the valence band (band–band transition or *inter-band* transition). In unipolar lasers the radiative recombination takes place within a single band between two bound states of a potential well (*intra-band* transition, in Fig. 11.109 shown for the conduction band). Through so-called electron recycling, this process is cascaded in stages (explaining the name quantum cascade laser, Fig. 11.109). The band edges are accordingly tilted by the applied voltage (electric field). The multiple-QW structure [11.1326] shown here is based on a uniform QW composition and a different uniform barrier composition. However, there are in each case six different QW widths (the lower sequence of numbers) and barrier widths (the upper sequence of numbers) involved.
Fig. 11.109 Principle of a quantum cascade laser [11.1326]

Through tailored dimensioning, we ensure that in the case of resonance (for a certain applied voltage) each of the four narrowest QWs exhibits a bound state, and that these four states are energetically identical (i.e., they line up exactly horizontally). Furthermore, the widest QW is dimensioned in such a way that the highest state of the three bound states, marked with a 3 in Fig. 11.109, deviates only insignificantly from the four identical levels mentioned above. Due to the thin barriers and the resulting tunneling processes, an electron injected from the left tunnels horizontally into the excited level 3. After a radiative transition it falls down to level 2. Due to the very thin barriers, the wave functions are generally strongly delocalized. By optimizing the QW geometries the relaxation time from state 2 to state 1 is designed to be very small, so that the maxima of the wave function of state 2 lies on the left and that of state 1 on the right of both of the wider QWs.

This tunneling process proceeds in a stair-like cascade, which is illustrated with just two stages in Fig. 11.109. This example also illustrates very successful recent complex QW structures, which are based on a variety of different quantum cascade structures. Quantum cascade lasers are very successful to produce laser emissions in the mid infrared ($3.5 - 10\,\mu\text{m}$, in some cases even up to $60\,\mu\text{m}$), where there are very few suitable semiconductor materials with extremely small bandgaps for the construction of bipolar lasers.

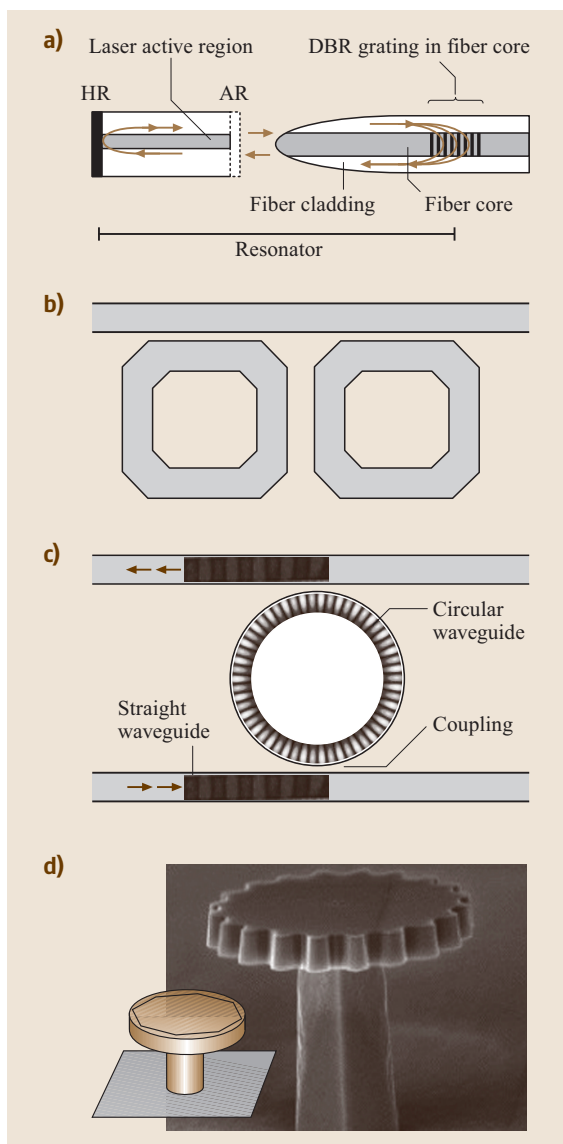
A very elegant way to obtain a longitudinal single-mode oscillation of an FP laser is to use one highly reflecting (HR) and one antireflection (AR) coated facet, with a piece of fibre optically coupled to the latter (Fig. 11.110a) including a DBR grating with a period ((11.93)) such that it filters exactly one single oscillating mode from the spectral amplification profile. This laser design is called a (semiconductor-)fibre laser. In


Fig. 11.110a–d Various designs of lasers with horizontal resonator. (**a**) FP laser with an external fibre mirror, (**b**) double ring resonators coupled to a straight waveguide, (**c**) standing wave in a single ring resonator coupled to 2 waveguides, (**d**) DFB microdisc laser [11.1327]; *inset*: FP microdisc laser with *whispering-gallery* mode

contrast, the active medium for optically pumped fibre lasers is a doped fibre.

Laser designs with straight aligned resonators have been considered so far. However, in the ring laser (Fig. 11.110b, c) and the microdisk laser (Fig. 11.110d),

the beginning and end of the resonator merge into one another. In the case of waveguiding (Fig. 11.110b) modal solutions result if the length of the circular optical axis is close to an integer multiple of the wavelength in the medium. Similar selection rules apply in microdisc lasers, which can also be illustrated in the ray model with multiple reflections (eight in Fig. 11.110d) at the exterior surfaces. These modes are also known as *whispering-gallery modes* after the acoustic phenomena in the gallery of the St. Paul's cathedral in London and the Gol Gumgaz mausoleum in Bijapur city in India. There, a whispered word is discernible, after multiple reflections from the inner walls of the cupola, back at the ear of the speaker.

11.3.4 Basics of Surface–Emitting Lasers with Vertical Resonators (VCSELs)

The VCSEL presents a large technological challenge in terms of the implementation of DBR mirrors with extremely high reflectivity. In contrast to the edge-emitting DFB or DBR laser, the individual layers of the DBR mirrors in the VCSEL are successively deposited (e.g., by epitaxy). In this way, layer A and the neighboring layer B together make up one period. Since the reflectivity of the DBR mirrors rises with increasing number of periods and refractive index contrast, materials with large refractive index contrast are preferable in order to reduce the total number of periods and thus device cost. The insets in Fig. 11.111 show a DBR mirror (left inset) and the light intensity reflected by the mirror as a function of the wavelength (reflection spectrum, right inset). For $\lambda = 1.55\,\mu m$, the maximum reflectivity R_{max} in the stop-band is presented in the main picture as a function of the number of periods for different material systems. The data result from theoretical model calculations with consideration of the spectral variations of the refractive indices and absorption coefficients [11.1328, 1329]. Large differences appear in the figure due to different absorption and different refractive index contrast $2(n_A - n_B)/(n_A + n_B)$. For semiconductor epitaxial layers, absorption depends on the doping concentration and is well controllable. Absorption in dielectric layers is more difficult to control and depends strongly on the technological process. Unfortunately, no large refractive index contrasts can be realized in the GaInAsP material system. To achieve a reflectivity of 99.8%, 50 periods, a number that is in practice too high, are needed. In contrast, this is achieved in AlAs/GaAs DBRs with just 20 periods. If the two dielectrics Si_3N_4 and SiO_2 are combined, then even 13 periods are suf-

ficient due to the very high relative refractive index contrast.

This enormously high reflectivity is achieved through constructive interference of the partial waves reflected at all heterointerfaces. Note that with a reflection at the interfaces from the optically thinner to the optically denser medium a phase change of π occurs, but not vice versa [11.1330, 1331]. The condition for constructive interference is fulfilled, e.g., by the combination of $\lambda/4$-thick layers A and B, as is the case in Fig. 11.111. Here, d_A and d_B are the physical thicknesses and $\lambda/4n_A$ and $\lambda/4n_B$ are the optical thicknesses. In general, the following relation applies to achieve high reflectivity using constructive interference

$$n_A d_A + n_B d_A = m\frac{\lambda}{2} \quad (\text{with } m = 1, 3, 5\ldots).$$

(11.120)

On GaAs substrates the almost lattice-matched AlAs/(Al)GaAs combination is ideal for lasers in the wavelength range 800–1300 nm. Although, as with the edge emitters, trials have been made to implement long-wavelength VCSELs on GaAs substrates, 1.55 μm VCSELs are still based on InP. This is due to the fact that the active laser layers (e.g., GaInAsP and AlGaInAs) for the spectral range close to 1.55 μm can be best implemented on InP substrates. There are different possibilities for implementing highly reflecting 1.55 μm DBR mirrors on InP substrates: a kind of pressure bonding technique (wafer fusion) of AlAs/GaAs DBRs [11.1332, 1333] to embed the GaInAsP active region, strongly lattice-mismatched so-called pseudomorphic AlAs/GaAs DBRs [11.1334], lattice-matched AlGaInAs, AlAsSb/AlGaAsSb, AlGaAsSb/InP DBRs [11.1335, 1336] or fusing of a low-period GaInAsP/InP DBR with active layers onto a AlAs/GaAs DBR [11.1337].

A resonator results from the combination of two DBR mirrors, where the volume between the DBR mirror-ends towards the center is called the cavity. If the cavity material is passive, then the setup is an optical filter, if it is active then a VCSEL results. Figure 11.112 shows schematically the structure of a VCSEL with two multiple-layer semiconductor DBR mirrors. In the illustration the upper mirror is highly reflective, so the laser light is emitted essentially downwards (brown arrow). The envelope of the vertical intensity distribution discussed below is indicated by the lateral expansion of the brown arrow (Fig. 11.96, depicted in grey-tone variations). The holes are injected from above through the upper p-doped DBR mirror into the active laser zone;
Fig. 11.111 Maximum spectral reflectivity R_{max} in the stop-band for $\lambda = 1.55$ μm as a function of the number of periods for different DBR mirror systems. *Left inset*: cross section of a DBR mirror. *Right inset*: reflectivity as a function of wavelength

the electrons are injected from below through the lower n-doped DBR mirror. The outer curved black arrows indicate the current flow. Here, it is challenging to reduce the electrical resistance of the p-doped DBR mirror by sophisticated doping (impurity concentration profiles) in order to reduce the operating voltages and the buildup of Joule heating. Figure 11.112a schematically depicts the structure of a VCSEL with two dielectric DBR mirrors. The holes and electrons are injected by means of ring contacts, whereby the current flow bypasses the electrically insulating DBR mirrors. Furthermore, of crucial importance is the lateral electrical confinement to enable the production of high electron–hole-pair densities in the central part of the active zone, and thereby very small threshold current densities. Therefore, an electrically insulating ring is built surrounding the lateral laser mode. The realization of this is technologically demanding and is achieved, e.g., by ion implantation or selective oxidation. A sufficiently high thermal conductivity of the DBR mirrors is of further importance in enabling efficient heat dissipation from the active region to the heat sink and, if necessary, of that heat generated inside the DBR mirrors.

For the VCSEL with two dielectric DBR mirrors and a cavity length of $3\lambda/2$ shown in Fig. 11.112a, the electric field of the standing light wave is computed [11.1328, 1329] and presented in Fig. 11.113 together with the entire multilayer structure. In order
Fig. 11.112a,b Schematic setup of a VCSEL with electrically insulating (**a**) and electrically conducting DBR mirrors (**b**)

Fig. 11.113 Layered structure of a VCSEL including the standing wave of the electrical field

to achieve a high gain in the laser design, the QWs are positioned at the maxima (antinodes) of the half-waves. Ideally, three QWs, three double QWs or three triple QWs should be placed in the $3\lambda/2$ cavity shown. The envelope of the standing light wave field gradually drops outwards from center due to the distributed reflecting effect of the DBR mirrors. We note again that exactly one quarter of a wavelength is allotted to each mirror layer ($\lambda/4$ layers) and that the nodes for the design wavelength lie exactly at the interfaces.

In the following, the VCSEL spectra are intuitively constructed. To derive this, we consider a semiconductor cavity between two mirrors indicated in the top left of Fig. 11.114. Based on the fixed cavity length, (11.92) leads to the three modes displayed as lines in the spectrum on the right of the figure, which become sharper

for higher mirror reflectivities. This means that a cavity of this length is suitable for each of these (laser) wavelengths if the standing wave experiences a sufficiently large optical gain at its peak (antinodes). On the contrary case, for a desired (fixed) laser wavelength λ the cavity length can be selected straight away as $\lambda/2$, $2\lambda/2$ or $3\lambda/2$. If the two mirrors are implement as DBRs (bottom left of the figure), then the line spectrum at the top right is *superposed* with the known reflection spectrum (Fig. 11.114 bottom right) of the DBR mirrors, resulting in the laser spectrum already shown in Fig. 11.103d. The stop-band of the VCSEL is substantially larger because of the higher refractive index contrast in the DBR mirrors compared to that of the DFB laser with the relatively small refractive index contrast between the quasi-layers of the DFB grating. Following from Fig. 11.103c, d the $\lambda/4$-phase-shifted DFB laser has many similarities to a VCSEL with a $\lambda/2$ cavity and two very long DBR mirrors with a small refractive index contrast.

Note that the following numerical values are strongly dependent on wavelength and material and that a thoroughly comprehensive treatment would exceed the framework of this volume. For VCSELs, optical power outputs of $< 1\,\mathrm{mW}$ (lateral single-mode operation) are typical. With a laterally expanded active region, i. e., laterally multimode VCSELs, achieve up to $120\,\mathrm{mW}$. Typical threshold currents lie around $1\,\mathrm{mA}$, with record values of about $0.06\,\mathrm{mA}$ (corresponding to $350\,\mathrm{A/cm^2}$). The highest power outputs and the lowest thresholds are achieved in the spectral range $850–1000\,\mathrm{nm}$. Compared to edge emitters the thresholds are amazingly low, but with rather moderate maximum power outputs. In broad-area edge emitters for example, over $6\,\mathrm{W}$ [11.1338] and external quantum efficiencies of

over 56% [11.1338] have been achieved. While the VCSEL has enormous advantages in the laser–fiber coupling due to the small beam divergence and the symmetric mode profile, the edge emitter incurs substantial overhead costs for light coupling due to the higher divergence and the elliptical mode profile. This is achieved in practice with aspherical lenses or with complicated tapered waveguide structures in the laser or fibre. The VCSEL offers further substantial advantages as it enables simple optical on-wafer testing similar to the testing of integrated electronic circuits. In contrary, edge emitters must be individually isolated for characterization, i. e., at least cleaved into bars, or additionally for surface out-coupling, a 45° mirror (Fig. 11.96) must be implement in combination with etched mirrors.

The modulation bandwidths of VCSELs are typically around 1 GHz (the record being 10 GHz), compared with typical values of 15 GHz (the record being 40 GHz) for edge emitters. If one compares the laser line widths of devices without external resonators, then VCSELs typically attain 200 MHz (the record being 50 MHz) while edge emitters typically attain 1 MHz (the record being 10 kHz). Edge-emitting semiconductor lasers exist in the range between 350 nm and 12 μm, while in the green and mid-IR spectral regions there are as yet either no devices exist or the component lifetimes are not sufficient for practical applications. Electrically pumped VCSELs exist so far within a spectrally much smaller range (420 nm to 2.05 μm) [11.1339–1341]. In VCSELs wavelength tuning is particularly difficult using charge-carrier-induced (current-induced) or thermal refractive index changes. A typical tuning range of 1 nm is attained in VCSELs compared to 80 nm in single-mode edge emitters. Finally we present a tuning concept for optoelectronic devices with vertical resonators which permits ultrawide wavelength tuning on the basis of only one control parameter.

Micromechanical Tunable Filters and VCSELs

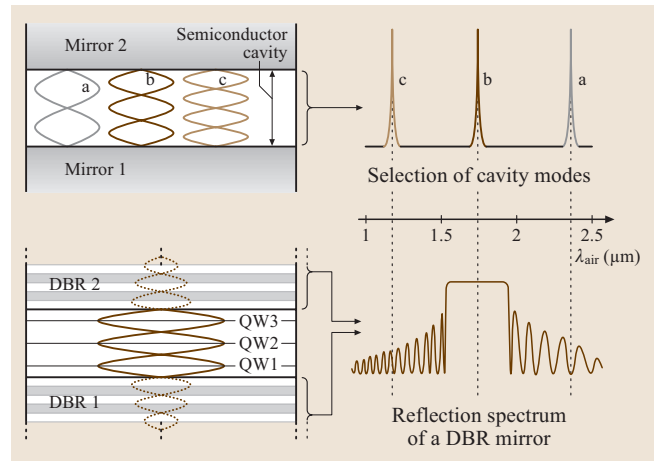
A perpendicular light wave (wavelength λ_D) incident on a highly reflecting DBR mirror is up to 99.9% reflected. The period is normally selected in such a way that λ_D lies at the center of the stop-band (Fig. 11.114 bottom right). When a second identical mirror is positioned parallel at a distance, say, $1.5 \times \lambda_D$ from the first one, as shown in Fig. 11.114, it is experimentally observed that the first mirror does not reflect the wavelength λ_D any more. Although at first sight astonishing, the arrangement of the two DBR mirrors is now almost 100% transparent for λ_D.


Fig. 11.114 Characteristic spectral components of a VC resonator. Three standing waves in the cavity ((*a–c*) *above left*) cause, as marked by the *bracket*, the build up of the FP modes (*above right*), the DBR mirrors (*bottom left*) are characterized by the reflection spectrum (*bottom right*), as indicated by the two *brackets*. With a very short cavity length only one FP mode is located in the stop band (along the *broken vertical lines*)

For λ_D in a DBR mirror, all reflected partial waves interfere constructively (99.9% reflection) on the incident side of the mirror and destructively on the opposite side. This is the result of complicated multiple reflections and complex zigzag paths (in the simple ray model) portrayed in a simplified manner occur. The light waves penetrate the mirror, but due to the perfect destructive interference, behind the mirrors, they transfer no energy. By the targeted positioning of the second mirror (and adding further boundary surfaces) all partial waves now interfere destructively on the incident side and constructively on the opposite side (behind the second DBR mirror). Furthermore, a standing wave forms in the cavity for λ_D (Fig. 11.114).

Within the stop-band, except within the range of the very sharp filter line (centered at λ_D) all wavelengths are up to 99.9% reflected. In this way extremely high-quality optical filters can be implement, e.g., for fibre-optic telecommunications based on dense wavelength division multiplexing.

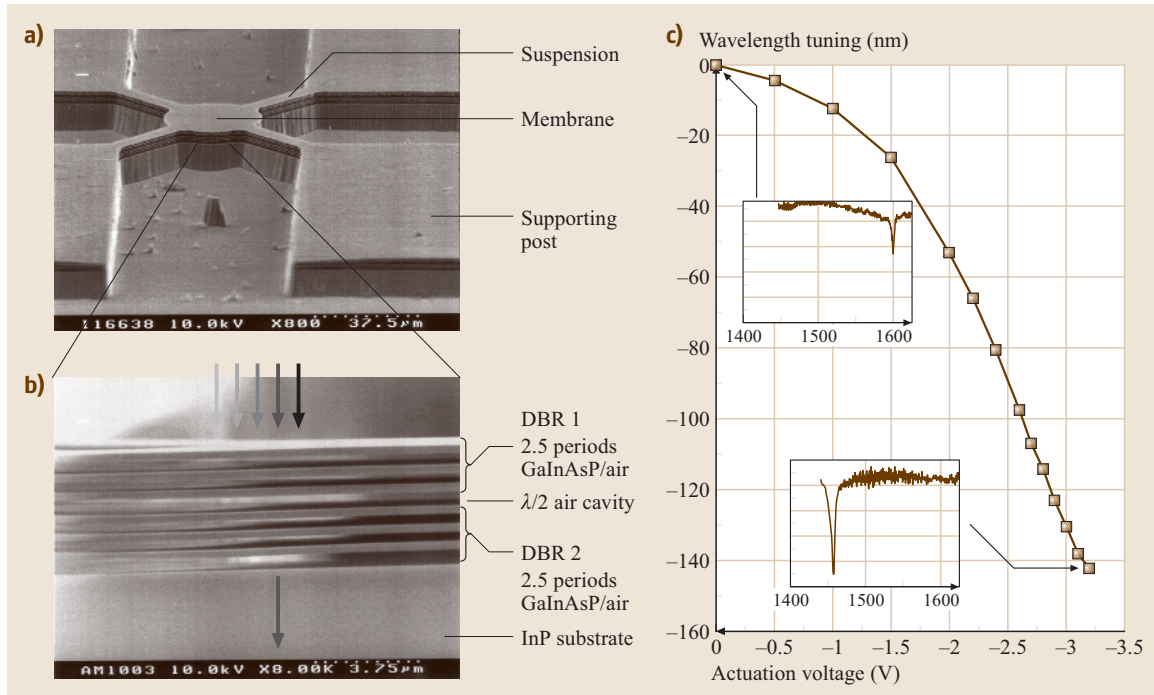
Figure 11.111 contains a further material system, so far not discussed, with an extremely high refractive index contrast ($n_{InP} = 3.2$, $n_{air} = 1$). With only four periods, a reflectivity of over 99.8% can be obtained. This unusual structure can be made, e.g., from a semiconductor multilayered structure with alternating InP and $Ga_{0.43}In_{0.57}As$ layers by selective etching of the GaInAs


Fig. 11.115a–c Micromachined filter device with vertical resonator based on semiconductor multiple air gaps [11.1342, 1343]. Electron micrograph of the cross section of a filter (**a**), details in (**b**), corresponding experimental wavelength tuning as function of the actuation voltage in (**c**)

layers (micromechanical sacrificial-layer technology). Lattice-matching already exists through epitaxy on an InP substrate and, if necessary, an outstanding compatibility with 1.55 μm GaInAsP laser-active layers is available. Figures 11.115a,b show a filter structure with six InP membranes, each of which is fixed to the supporting posts at four points. If a reverse-bias voltage is applied between the upper p-doped and the lower n-doped DBR mirrors the membranes including the sandwiched air cavity can be electrostatically actuated. The cavity length and thus the filter wavelength can be varied in this way with only one control parameter (voltage). With such an optical filter, an enormous continuous wavelength tuning range of 142 nm (Fig. 11.115c) was experimentally achieved with only 3.2 V [11.1328, 1329, 1342, 1343]. In other structures of the same type, a continuous tuning range of as much as 221 nm has been obtained [11.1342]. The same tuning principle occurs in Figures 11.116c,d showing a VCSEL with InP/multiple-air-gap DBR mirrors, GaInAsP laser-active QW layers and an InP substrate.

In conclusion, based on Fig. 11.116 a very interesting parallel between quantum electronics and quantum photonics (Fig. 11.116c,d) can be drawn. In order to tailor the electronic levels for electrons and holes, semiconductor heterostructures of predetermined composition and thickness are implemented. If the layer thickness of the material with the smaller bandgap is on the order of the magnitude of the electron wavelength, a quantization occurs that leads to defined quantized energy levels in the QWs. These quantized energy levels (eigenvalues) and the corresponding electronic wave functions (eigenfunctions, i.e., modes) are solutions of the Schrödinger equation. The materials, stress and layer thicknesses are set up in this example with the 10 AlGaInAs QWs (Fig. 11.116b) in such a way that the optical emission is at 1.55 μm. These QWs serve as the laser-active medium of an ultrafast semiconductor diode laser (Fig. 11.116a) [11.1302, 1344]. In a very simplified depiction, the multiple QWs define a resonator for electron waves.

The electron microscope micrographs on the right show the exact analogy for photons. In order to select a defined mode in the resonator of a VCSEL, taking into account the refractive indices, layer thicknesses in the order of magnitude of the photon wavelength

are chosen. A kind of quantization also arises in this case. The effective refractive indices (eigenvalues) and the corresponding photon wave functions (eigenfunctions, i.e., modes) are solutions of the Helmholtz equation. From the mathematical point of view, the space-dependent parts of the Schrödinger and Helmholtz equations have equivalent behavior. The strong refractive index contrast of InP/air-gap multi-membrane structures is again used in Fig. 11.116d to implement highly reflective DBR mirrors for a 1.55 μm VCSEL (Fig. 11.116c) [11.1342, 1343]. Analogously the periodic refractive index variation defines a resonator for photon waves.

Further analogies in this area are offered by periodic 2-D quantum-dot fields and 2-D photonic crystals, or photonic band structures and electronic band structures.

11.3.5 Edge-Emitting Lasers and VCSELs with Low-Dimensional Active Regions

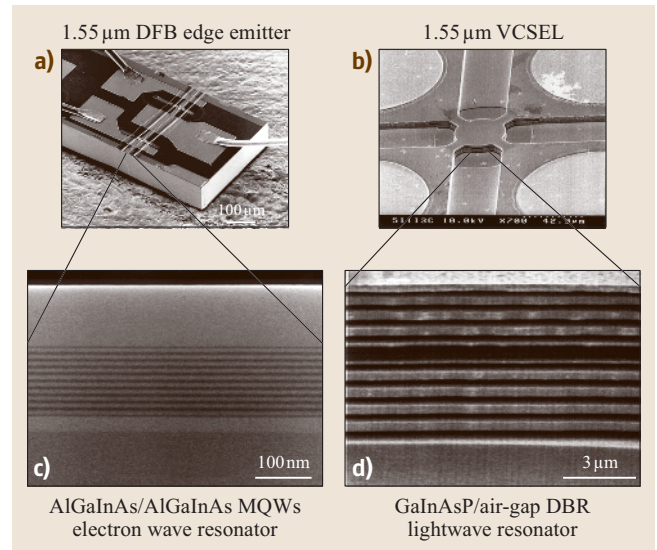
In commercial semiconductor laser diodes, bulk semiconductor materials (3-D) were exclusively used for the active zones for 25 years. Starting from 1990 edge emitters with QWs (2-D) were implement in research labs and continuously improved. Only after a further five years QW lasers were commercialized and subsequently surpassed the 3-D lasers with lower threshold current densities, higher power outputs, higher characteristic temperatures T_0 and higher bit rates due to more-favorable gain profiles and better electronic confinement. Although quantum wire (1-D) lasers should exhibit even better characteristics, they have so far not been very successful due to technological and geometrical constraints. In particular long carrier-transport and carrier-capture times substantially limit the bit rates in quantum wire lasers. Quantum dot QD (0-D) laser structures [11.1263–1272] are a lot more promising. However, a problem at the moment is the strongly varying size of QDs (Fig. 11.93). The theoretically very sharp density-of-state profiles are strongly inhomogeneously spread, so that the predicted high differential gain dg/dn does not arise in practice. Compared with the 3-D and 2-D structures so far no spectrally narrower and higher-gain profile has been obtained. Particularly broad gain profiles can be of advantage however for extremely widely tunable lasers (see the section on tunable lasers in Sect. 11.3.3 and that on micromechanical tunable VCSELs in Sect. 11.3.4). However, as already mentioned, additional research and


Fig. 11.116 (a) Tunable, edge-emitting three-section laser with axially varying DFB grating known as a chirped DFB grating [11.1294], **(b)** strain-compensated multiple QW structure with tensile-strained AlGaInAs barriers and compressively strained AlGaInAs wells[11.1344], **(c)** VCSEL based on multiple InP/air membranes (*centre*), each of which is supported by four suspensions connected to the square supporting posts [11.1343], **(d)** cross section of the vertical resonator, consisting of the laser-active GaInAsP QW region, which is embedded between two InP/air-gap DBR mirrors [11.1342]

development effort is expected to provide excellent QD lasers.

11.3.6 Lasers with External Resonators

Both edge emitters and VCSELs can be implemented, as shown in Fig. 11.96, with an external resonator mirror, in contrast to Figs. 11.115 and 11.116c, which involve a relatively large air gap. This can serve several purposes:

1. the extension of the resonator length to achieve narrower line widths,
2. wavelength tuning by inserting a wavelength-selective, rotating element (prism, etalon, grating),
3. mode coupling for the generation of periodic sequences of ultrashort pulses and
4. wavelength conversion by insertion of an optically nonlinear crystal.

Examples of the last of these are lasers in which a frequency-doubling crystal in the air gap of the res-

onator transforms the IR light, which is emitted from an edge emitter with one side antireflection-coated or a half-

cavity VCSEL (active region plus one DBR mirror), into the yellow, green and blue range.

11.4 The CO$_2$ Laser

The CO$_2$ laser is one of the most important lasers for industrial, medical and scientific applications. Applications include high-precision material processing, cutting and welding of sheet metal, marking of plastics, cutting of paper and fabrics, surface treatments for steel hardening or medical applications such as tissue coagulation.

CO$_2$ lasers use a gas mixture of helium, nitrogen and carbon dioxide as the active medium, which is usually excited by an electrical gas discharge. The key characteristics are emission in the mid-infrared at wavelengths around 10 μm and a continuous-wave output power ranging from a few watts for sealed-off miniature laser modules to more than 10 kW for high-power CO$_2$ lasers with fast gas flow. While most CO$_2$ lasers operate in a CW mode with quite fast power modulation enabled by electrical excitation, there are also pulsed systems based on Q-switching or the so-called tranversal-excited atmospheric-pressure (TEA) laser. The beam quality is often excellent and in many cases nearly diffraction-limited. This is important for applications such as precision cutting or remote welding. The mid-infrared emission implies that standard glass lenses and glass fiber-optic waveguides cannot be used because of the high infrared absorption of silica-based glasses. Transmitting optics such as focussing lenses or partially reflecting mirror substrates are commonly made of zinc selenide, silicon or germanium. For beam guidance moving-mirror systems mounted on linear and swivel axes are used. Besides the most common emis-

sion wavelength of 10.6 μm, special tunable CO$_2$ lasers can generate laser light at dozens of distinct emission lines between roughly 9.2 μm and 11 μm. Such lasers are used for scientific applications such as molecular spectroscopy and optically pumping of far-infrared gas lasers.

The physical principles and the technical realizations of typical CO$_2$ lasers are described in the following sections.

11.4.1 Physical Principles

Basic CO$_2$ Laser Tube Principles

Laser action in a CO$_2$ gas was first described by *Patel* in 1964 [11.1345, 1346]. The basic physical principles have changed little since then. An excellent and detailed discussion of CO$_2$ laser fundamentals is given in [11.1347] while additional general laser fundamentals are described in [11.1348] and [11.1349]. Figure 11.117 shows a sketch of a basic longitudinally direct current (DC)-excited CO$_2$ laser. The laser gas is usually a mixture of CO$_2$, N$_2$ and He in a ratio of 1:2:8, for example. The total gas pressure in such a DC-excited laser is a few tens of hPa. The gas is excited by an electrical gas discharge, for example by a steady longitudinal DC glow discharge inside a quartz glass tube. Typical required voltages are 15 kV per meter of discharge length, with a DC current of a few tens of mA. The voltages needed to start the discharge can be considerably higher. To maintain a stable α-type glow discharge [11.1350]
Fig. 11.117 Basic longitudinally DC-excited CO$_2$ laser

an external ballast resistor R_b is required in series with the high-voltage power supply. This compensates for the differential negative impedance characteristic of the gas discharge and limits the discharge current in order to prevent arcing. Alternatively, power supplies with fast voltage- and current-regulating electronics can be used. Typical lengths of the gas discharge are on the order of one meter, depending on the desired output power.

Such laser tubes can be filled once with the laser gas mixture and are then sealed-off for the lifetime of the laser tube. Other lasers are provided with a gas inlet and outlet to maintain a gas flow through the laser tube. This improves the laser power as fresh laser gas is provided to the laser but also requires additional peripherals such as gas reservoirs and vacuum pumps. Optical windows to seal off the tube can be realized by plane transparent plates at the Brewster angle with respect to the beam axis. One polarization state of the laser light can pass through the Brewster window without unwanted reflections. Thus, the Brewster window also acts as a polarization-selecting element inside the laser resonator.

The CO$_2$–N$_2$ molecule mixture can be excited inside the gas discharge by collisions with free electrons [11.1351]. The excited roto-vibrational states provide optical gain at certain wavelengths in the infrared. A simple plano-concave stable optical resonator with two mirrors located at each ends of the discharge tube can be used to provide continuous laser oscillation. The totally reflecting mirror is often made of copper, optionally with additional gold or protective dielectric layers to enhance lifetime and reflectivity. The output coupler can be made of zinc selenide (ZnSe), germanium or silicon, as these materials have good transparency in the mid-infrared, in contrast to common silica-based glasses. The required reflectivity is provided by dielectric coatings on the mirror substrate. As the optical small-signal gain of the active CO$_2$ gas medium is quite high compared to a helium–neon (HeNe) gas laser and is in the range of $1 \, \mathrm{m}^{-1}$, reflectivities of output couplers may range from 20% to 90%. Optimum output coupler reflectivities for a maximum laser power are often determined experimentally. Alternatively, they can be calculated by a so-called Rigrod analysis if parameters such as the small-signal gain and the saturation intensity of the medium are known [11.1352, 1353].

Typical efficiencies η_E, defined as the ratio of the extracted optical laser power P_L to the applied electrical power P_E into the discharge, are in the range of 10%. The largest part of the electrical excitation power is dissipated as thermal energy inside the gas volume. To avoid a high thermal population of the lower laser energy levels, the CO$_2$ laser gas must be kept cool at temperatures of $400–500 \, \mathrm{K}$, depending largely on the different CO$_2$ laser types. A simple method for cooling is a second glass tube, which acts as a cooling jacket coaxial to the laser gas tube with a continuous water flow, as shown in Fig. 11.117.

A rough estimate for these diffusion-cooled DC excited lasers is an output power per discharge length of $80 \, \mathrm{W/m}$. This cannot be scaled by using larger cross sections of the laser tube since this would reduce the amount of thermal energy that can be removed from the middle of the gas discharge by diffusion cooling to the walls. The overheating of the gas and the resulting thermal population of the lower energy level of the laser transition would reduce the optical gain. In fact, for optimized cooling the glass tube should be as small as possible without introducing significant aperture losses by truncating the free-space laser beam. Typical diameters are $5–10 \, \mathrm{mm}$, depending on the tube length and the optical resonator design [11.1354].

Vibration and Rotation of the CO$_2$ Molecule

The emission wavelengths of the CO$_2$ laser are determined by the vibrational and rotational energy levels of the CO$_2$ molecule, which are discussed in more detail in [11.1355, 1356] or [11.1357]. All data in the following sections are given for the naturally most abundant isotopologue $^{16}\mathrm{O}^{12}\mathrm{C}^{16}\mathrm{O}$. Figure 11.118 shows the three fundamental vibrational modes: the symmetric stretch mode v_1 along the molecule axis, the bending mode v_2 with motion of the C atom in a plane perpendicular to the molecule axis, and the asymmetric stretch mode v_3. The bending mode is twofold degenerate because of the pos-
Fig. 11.118 Vibrational modes of the CO$_2$ molecule
Fig. 11.119 Some of the lowest vibrational energy levels of the CO_2 molecule. The Fermi resonance couples energy levels as indicated by the *dashed lines*

sible bending motions in the two orthogonal coordinates of the plane.

In the classical model of the unperturbed harmonic oscillator each mode has an associated vibrational frequency:

$$f_1 = 40.51\,\text{THz}, \quad f_2 = 20.15\,\text{THz},$$
$$f_3 = 71.84\,\text{THz}. \tag{11.121}$$

In the quantum-mechanical model the energy of any vibrational state of the molecule can only have discrete values called the vibrational energy levels. Using the integer vibrational quantum numbers n_1, n_2 and n_3 that describe the degree of excitation of the vibrational modes, the total vibrational energy W_v of the molecule can be written as a sum over the single vibrations:

$$W_v = hf_1\left(n_1 + \frac{1}{2}\right) + hf_2(n_2 + 1)$$
$$+ hf_3\left(n_3 + \frac{1}{2}\right). \tag{11.122}$$

Even if there is no vibrational excitation present (all $n_i = 0$) and the molecule is in its ground state there is energy stored inside the molecule that cannot be exchanged. Thus, this zero-point energy is neglected in all further energy formulas and diagrams.

To characterize the vibrational state completely another quantum number l is required to define the distribution and the phase of the bending vibration quanta in v_2 into the two orthogonal coordinates. For each number n_2 there are $n_2 + 1$ values for the angular momentum l:

$$|l| = \begin{cases} n_2,\ n_2 - 2,\ n_2 - 4,\ \ldots,\ 0\,; & n_2 \text{ even} \\ n_2,\ n_2 - 2,\ n_2 - 4,\ \ldots,\ 1\,; & n_2 \text{ odd}. \end{cases} \tag{11.123}$$

For example for $n_2 = 2$ the value $l = 0$ describes a linear bending motion, and $l = -2$ or $l = 2$ describes circular motions of the C atom in opposite directions in the plane perpendicular to the molecule axis. A vibrational state of the CO_2 molecule is labeled with the common Herzberg notation $(n_1 n_2^l n_3)$, for example (00^00) for the ground state or (12^20) for a state with simultaneous excitation of several vibrational modes [11.1355].

Figure 11.119 shows the energies of some of the lowest vibrational states. The energy levels observed by emission and absorption of radiation, as shown in Table 11.38, are slightly different than those calculated using the simple-harmonic-oscillator theory (11.122). More-precise calculations using anharmonic corrections and considering the mutual coupling of the three vibrational modes are therefore required.

The so-called Fermi resonance is of particular importance for the laser process in the CO_2 laser. Vibrational states with equal values of the term $2n_1 + n_2$ and $l = 0$ have almost the same energy and are strongly coupled. Due to this Fermi resonance the (10^00) state is shifted up

Table 11.38 Labeling, symmetry/parity classification and energies of some low-lying vibrational states of the CO_2 molecule [11.1358]

State			Frequency and energy		
Herzberg	**AFGL**	**Type**	$\bar{\nu}$ **(cm^{-1})**	f **(THz)**	W **(meV)**

Fig. 11.120 Rotation of the CO_2 molecule
and the (02^00) state is shifted down in energy. The population densities of these states are quickly exchanged by collisions with each other. Also the quantum-mechanical wave functions and the vibrational motion of the two resulting levels are a strong mixture of the unperturbed vibrational states. In the CO_2 laser literature the resulting levels are sometimes labeled (I) for the more (10^00)-like state and (II) for the more (02^00)-like state. Spectroscopic databases, which are an excellent reference for accurate absorption and emission wavelengths of the CO_2 molecule, often use a different labeling scheme than the simple Herzberg scheme, for example the so-called AFGL (Air Force Geophysics Lab, USA) notation, which gives a better treatment of the Fermi resonance [11.1359, 1360].

Superimposed onto the vibration is the rotational motion of the CO_2 molecule, as shown in Fig. 11.120. Only the rotation around an axis perpendicular to the molecule axis has a significant moment of inertia and is considered further. The discrete energy levels in the rigid-rotator model are given by

$$W_r = B \cdot J(J+1), \tag{11.124}$$

where B is the rotational constant and J is the quantum number for the rotational state. The higher the value of J the faster would be the rotation of the molecule in the classical mechanical model. For the (00^01) vibrational state, for example, B has a value of

$$B = 48.0 \text{ meV} = h f_r = h \, 11.6 \text{ GHz} . \tag{11.125}$$

More precise calculations show that the rotational constant B is slightly dependent on the vibrational state because of the anharmonicity and also dependent on the rotational quantum number J itself because of centrifugal forces.

The total internal energy $W = W_v + W_r$ of the CO_2 molecule is the sum of the vibrational and the rotational energies. The energy stored in the rotational motion is usually much smaller than in the vibration motion. Thus, the rotational energy levels can be thought of as superimposed on each vibrational level.

Emission Lines of the CO₂ Laser

Absorption, spontaneous and stimulated emission of light can occur when the energy of a photon $W_p = h f_p$

equals the energy difference $\Delta W = W_2 - W_1$ between two given energy levels of the respective atom or molecule. Additionally, selection rules based on the conservation of the spin or angular momentum and due to symmetry properties of the wave functions have to be considered. Based on the formalism of vibrational matrix dipole elements only certain transitions are allowed [11.1357]. The strongest allowed CO_2 laser emission lines result from the vibrational transitions $(00^01) \rightarrow (10^00)$ centered at wavelengths around $10.4 \,\mu m$ ($10 \,\mu m$ band) and $(00^01) \rightarrow (02^00)$ around $9.4 \,\mu m$ ($9 \,\mu m$ band). For these regular transitions the following selection rule for the rotational quantum numbers of upper and lower energy levels apply:

$$\Delta J = J_2 - J_1 = \pm 1 . \tag{11.126}$$

For a given lower rotational state J_1 there are two different possibilities for the emission of photons, as shown in Fig. 11.121. Transitions are named after the rotational quantum number of the lower state. Additionally, the transitions are labeled P (the P branch) for $\Delta J = -1$ and R (the R branch) for $\Delta J = +1$. For
Fig. 11.121 Examples of names for allowed roto-vibrational transitions of the regular bands. The rotational distribution is calculated for $T = 400 \text{ K}$
Fig. 11.122 Calculated relative small-signal gain for the regular bands of the CO_2 laser at $T = 500$ K

example one of the strongest emission lines of the CO_2 laser is labeled 10P(20), indicating a transition from the $10\,\mu m$ band with the lower rotational state $J = 20$ and $\Delta J = -1$. Different transitions have different energy differences ΔW and thus different emission frequencies f or wavelengths λ because of the non-equidistant rotational energies in (11.124). This is the origin of the multitude of possible emission lines of the CO_2 laser.

Figure 11.122 shows the calculated relative gain of the regular bands of a typical CO_2 laser. Both vibrational transitions have characteristic R and P branches due to the superimposed rotational energy levels and the selection rules. Exact line positions are listed in [11.1347] based on [11.1361], or in spectral databases such as [11.1359], which also lists transition dipole moments that are useful for the calculation of the absorption and gain of a transition [11.1362]. Note that in Fig. 11.121 only rotational states of even order J are present for the lower states (10^00) and (02^00). The odd states are missing because of the symmetry properties and parity rules (Σ_g^+) of these states in the $^{16}O^{12}C^{16}O$ isotopologue [11.1356]. Similar considerations are valid for the upper state of the regular band (00^01) $(\Sigma_u^+$ state), which only has odd rotational quantum numbers J.

Table 11.39 Possible vibrational lasing transitions

Vibrational band	Comment
$(00^01) \rightarrow (10^00)$	Regular band, $10\,\mu m$
$(00^01) \rightarrow (02^00)$	Regular band, $9\,\mu m$
$(01^11) \rightarrow (11^10)$	Hot band
$(01^11) \rightarrow (03^10)$	Hot band
$(00^02) \rightarrow (10^01)$	Sequence band
$(00^02) \rightarrow (02^01)$	Sequence band

Besides of the regular bands, there are other vibrational transitions with slightly shifted wavelengths that can be operated as lasers: the so-called hot band and sequence band. Table 11.39 shows a summary of vibrational transitions. For laser emission in the sequence or hot bands, lasing in the regular bands must be suppressed, for example by passive absorption cells filled with hot CO_2 gas inside the resonator [11.1347]. Almost all technical lasers operate in the regular bands.

The optical small-signal intensity gain per unit length g_0 of a given transition is proportional to the population density difference of the upper and the lower states, weighted with the respective degeneracy factors:

$$g_0 \sim \left(N_{n_2 J_2} - \frac{2J_2 - 1}{2J_1 - 1} N_{n_1 J_1} \right) . \tag{11.127}$$

The population densities N_{nJ} are the numbers of molecules per unit volume in the roto-vibrational energy level n and J. Within each vibrational state n with a total population of N_n the distribution of the molecules in the different rotational states N_{nJ} is described by a thermal Boltzmann distribution, weighted by the total rotational partition sum and the degeneracy factor for each J:

$$N_{nJ} = N_n \left(\frac{2B}{kT} \right) (2J+1) \exp\left(-\frac{W_r}{kT} \right) , \tag{11.128}$$

with the translational gas temperature T and the Boltzmann constant k. The rotational level at the maximum of this distribution at a given temperature can be approximately calculated as

$$J_{max} \approx \sqrt{\frac{kT}{2B}} - \frac{1}{2} . \tag{11.129}$$

For typical gas temperatures of $T = 400$ K the levels around $J = 19$ have the strongest population. In CO_2

lasers without any further wavelength-selective elements normally only one transition around the 10P(20) line at a wavelength of 10.59 μm will lase, as this one has the strongest gain (Fig. 11.122). Typical values for the small signal gain g_0 are in the range from $0.5\,\text{m}^{-1}$ to $1.5\,\text{m}^{-1}$.

Even under lasing conditions the rotational distribution will maintain its thermal Boltzmann shape because of fast population exchange between the rotational levels by molecule collisions. Thus, almost all rotational states within the upper vibrational level can contribute to a single lasing transition rather than just the population of the particular upper level, for example the $J = 19$ state of the (00^01) vibrational level. This affects mainly the saturation intensity I_s of the optical gain, which is much larger than expected form the population N_{nJ} of a single rotational level J itself. The saturation intensity I_s is in the range from $100\,\text{W cm}^{-2}$ for sealed-off large-bore DC-excited lasers to over $1000\,\text{W cm}^{-2}$ for fast-flow systems.

Electrical Excitation and Gas Composition

Without any excitation and in thermal equilibrium the population of the vibrational states is given by a Boltzmann distribution. As the energies of the lower vibrational levels are almost of the same order as the thermal energy $kT = 25.5\,\text{meV}$ at 296 K, the thermal population of levels above the ground state cannot be neglected. The population N_n of a given vibrational level n is given by:

$$N_n = N_0 \frac{\exp\left(-\frac{d_n W_n}{kT}\right)}{Q_{\text{vib}}}, \qquad (11.130)$$

where N_0 is the total density of CO_2 molecules, d_n is the degeneracy factor and W_n the energy of level n, and Q_{vib} is the vibrational total partition sum. Without ex-

citation the population of the upper laser state (00^01) is always smaller than the lower laser levels (10^00) or (02^00). This is the normal case for passive media, which show absorption lines on the respective transition wavelengths.

To achieve an inversion, and thus optical gain, in an active medium an electrical gas discharge is usually used to excite the CO_2 laser. Accelerated electrons inside the discharge collide with the molecules and lose part of their kinetic energy. This energy can be transformed into vibrational excitation energy of the molecules or into kinetic energy by a pure translatory motion. How effective a certain vibrational state of the molecule is excited is described by the excitation cross section, which is dependent on the energy of the electrons. For inversion of the regular CO_2 laser lines, a selective population of the upper laser state (00^01) is required. This is barely possible in a pure CO_2 gas discharge as the cross sections for excitation of the different vibrational states are of the same order of magnitude.

Therefore, nitrogen (N_2) is added to the laser gas [11.1351]. As a molecule with two atoms it only has one vibrational mode. As a homonuclear molecule it has no electric dipole moment and hence, no radiative decay of excited vibrational states. Thus, nitrogen can efficiently store energy in its vibrational excited states. More than 50% of all N_2 molecules can be excited to higher vibrational levels inside a gas discharge. The first excited vibrational state, $n = 1$, has nearly the same energy (289 meV) as the upper laser level (00^01). Due to resonant collisions between excited nitrogen atoms vibrational energy is readily transferred to the desired CO_2 state

$$\begin{aligned} N_2(n) + CO_2(00^00) \\ \rightleftharpoons N_2(n-1) + CO_2(00^01) + \Delta W. \end{aligned} \qquad (11.131)$$
Fig. 11.123 Energy-level diagram of the CO_2 laser process with excitation and decay paths

The energy difference $\Delta W = -2.2\,\text{meV} \ll kT$ is easily available from the thermal kinetic energy of the molecules.

Figure 11.123 shows the energy-level diagram of the CO_2 laser process. Accelerated electrons from the gas discharge excite nitrogen molecules to higher vibrational levels by collisions. These excited nitrogen molecules transfer their energy to the upper laser level (00^01) of the CO_2 molecule and provide a significant population inversion compared to the lower laser levels. From there, two strong lasing transitions by stimulated emission of photons are possible, the $9\,\mu\text{m}$ band with (02^00) as the lower laser level and the $10\,\mu\text{m}$ band with (10^00).

To maintain a large inversion thermal population of the lower laser levels must be avoided by efficient cooling of the laser gas. Therefore, helium (He) is added to the laser gas. Helium is the gas with the largest thermal conductivity. It also plays an important role for the population decay of the (02^00) and (01^10) levels by vibrational–translational (V–T) relaxation. Thereby, vibrational energy of the CO_2 molecule is transferred to kinetic energy, the translatory motion of the molecules. Radiative decay by spontaneous emission is also possible for the (02^00) and (01^10) levels, but not for the (10^00) level, which shows no change in the dipole moment during vibration. It can reduce its population by V–T relaxation directly to the (01^10) level, but also by the Fermi resonance via collisions and energy exchange with the (02^00) state. In fact, the degree of vibrational excitation of these two vibrational modes is almost the same due to this Fermi coupling. After relaxation to the ground state (00^00) the CO_2 molecule is available for excitation and the laser process again.

Within one vibrational mode, for example v_1 of the CO_2 molecule, there is a strong interaction of the vibrational levels by vibrational–vibrational (V–V) relaxation and excitation processes during collisions:

$$CO_2(n_1') + CO_2(n_1'')$$
$$\rightleftharpoons CO_2(n_1'+1) + CO_2(n_1''-1) + \Delta W \,, \quad (11.132)$$
where the small energy difference ΔW coming from the anharmonic forces can almost be neglected. By this fast thermalization the population distribution of the vibrational levels within one mode v_i can be described by a Boltzmann distribution similar to (11.130) with a specific vibrational temperature T_i for this particular mode. Three vibrational temperatures T_1, T_2, and T_3 are required to describe the three vibrational modes of the CO_2 molecule. Together with the vibrational temperature of the nitrogen T_N and the physical gas temperature T they form the so-called five-temperature model of the CO_2 laser. This model can be used to quantify the degree of vibrational excitation in a given laser system and to calculate the optical gain of different transitions [11.1347, 1363, 1364].

Note that the vibrational temperatures inside a gas discharge can be significantly higher than the usual physical gas temperature T which describes the translatory kinetic energy. For typical laser conditions the temperatures T_3 and T_N can be in excess of $1000\,\text{K}$, even if the physical gas temperature T is only $450\,\text{K}$, for example. This describes the desired high level of excitation of these modes for a strong inversion, especially if there is no laser action to reduce the population in (00^01) by stimulated emission. The vibrational temperatures T_1 and T_2 are almost equal because of their coupling and are slightly larger than the physical temperature, because their population decay to the ground state takes place with a finite rate. Here, as low as possible vibrational temperatures are desired for a low population of the lower laser levels. Of course, no vibrational temperature can be lower than the physical gas temperature T. It is also the temperature T that is valid for the rotational population distribution.

Thus, a gas mixture for a CO_2 laser could be $\text{He}:\text{N}_2:\text{CO}_2 = 8:2:1$, with large individual variations between specific laser designs, which are often experimentally defined for maximum laser output. The gas pressure p is typically a few tens of hPa for longitudinally DC-excited lasers, in the range of $100\,\text{hPa}$ for lasers with a transversal RF discharge or can equal the atmospheric pressure in so-called TEA (transversaly excited atmospheric pressure) lasers with a pulsed transversal discharge. The gas pressure influences the stability of the gas discharge and the electric field strengths required to start and maintain a stable discharge at the different excitation frequencies and geometries. Together with the applied electric field E inside the discharge the gas pressure p affects the electron energy distribution function (EEDF). For efficient excitation of the desired vibrational nitrogen states electrons with energies of $2-3\,\text{eV}$ are required, where the effective cross section for vibrational excitation of N_2 has a maximum [11.1347].

Dissociation and Gas Additives

The complex-shaped electron energy distribution function (EEDF) in such a laser gas discharge always has a tail extending to quite high electron energies. These electrons can start unwanted chemical dissociation processes of the CO_2 molecule inside the gas discharge, for

example

$$CO_2 + e^- \rightleftharpoons CO + O^- , \Delta W = -3.85 \, eV , \tag{11.133}$$

$$CO_2 + e^- \rightleftharpoons CO + O + e^- , \Delta W = -5.5 \, eV . \tag{11.134}$$
This is the origin of the complex gas chemistry that leads to a reduced CO_2 concentration and the formation of a significant CO concentration inside the laser gas tube [11.1367]. By the law of mass action a typical equilibrium ratio of 1 : 1 between CO_2 and CO is established if no means to reduce the dissociation are present. Clearly this reduces the overall laser output power and efficiency.

In lasers with a steady gas exchange by a gas flow the laser gas can be replaced by fresh gas from a premix bottle or can be partially regenerated by forced circulation through catalysts to prevent too high a degree of dissociation. Naturally, the gas dissociation is more crucial for sealed-off lasers without any gas exchange. To decrease dissociation processes and maintain a high output power, many different gas additives to the basic mixture have been studied [11.1347]. Table 11.40 shows the composition of some commercial laser gas premixes for high-power CO_2 lasers.

Xenon (Xe) is without doubt the most efficient and most widely used additive for sealed CO_2 lasers [11.1368–1370]. Xe has a first ionizing potential of 12.1 eV, which is some eV less than the other gases. Hence, the same current density in the discharge can be maintained at a lower applied electric field. This in turn shifts the EEDF towards lower energies, which are more efficient for vibrational excitation, and there are fewer fast electrons to cause dissociation processes. On the other hand, Xe with its heavy atomic weight has a very low thermal conductivity. Also it is a very rare and expensive noble gas. Sealed laser mixtures typically contain a few percent of Xe.

Water vapor (H_2O) and molecular hydrogen (H_2) have also been extensively studied [11.1347, 1371]. Both gases react inside the gas discharge, for example with oxygen radicals to form hydroxyl radicals OH. This hydroxyl radical is an efficient catalyst for oxidizing CO back to CO_2. On the other hand, water vapor with its multitude of vibrational states rapidly deexcites the upper laser state (00^01) and quenches the desired population densities of this level. The reported water vapor concentrations for optimum catalysis and yet low vibrational quenching are quite low [11.1347] and were found to be hard to control in real laser systems. In other laser systems no clear proof of an optimum water vapor content was found at all [11.1372, 1373]. As a rule of thump the dew point of the laser gas should be below $-40\,°C$, equivalent to a water vapor partial pressure of 0.13 hPa. Creeping of water from the cooling system has to be avoided. However, some laser gas premixes may contain small amounts of hydrogen, as deemed appropriate by the manufacturer of the laser system.

Other gas premixes include carbon monoxide (CO) or oxygen (O_2). By the law of mass action both additives can shift the equilibrium of the dissociation reactions (11.133) and (11.134) towards the left. Too high an O_2 concentration has a detrimental influence on the discharge stability and the EEDF, as it is a strongly electronegative gas. CO as a diatomic molecule has similar vibrational energy levels to nitrogen and can also transfer vibrational energy by resonant collisions to the upper laser state of the CO_2 molecule (Fig. 11.123). Another benefit of adding CO and O_2 initially to the gas premix for filling the laser is that the gas is already near its equilibrium composition for the dissociation process, so no overshoot or undershoot of the laser power occurs when the laser is operated for the first time after filling. However, CO is not as effective as nitrogen for vibrational excitation. The energy difference from the CO:($n = 1$) vibrational level to the CO_2:(00^01) level is 25.5 meV and is thus larger than with nitrogen. Additionally, CO has allowed dipole transitions to the ground state by spontaneous emission, which

Table 11.40 Some commercial gas premixes for different industrial CO_2 laser types [11.1365, 1366]

Premix name / (Maker)	Composition							Laser type, model series
	He	N$_2$	CO$_2$	CO	O$_2$	Xe	H$_2$	
Lasermix ® 322 (Linde AG)	65.5	29	5.5					Fast axial-flow, Trumpf TLF Series
Lasermix® 690 (Linde AG)	65	19	4	6	3	3		Diffusion-cooled sealed-off, Rofin Slab DC 0XX
Lasal™ 81 (Air Liquide)	80.8	15	4				0.2	DC excited slow-flow, FEHA SM Series

decreases vibrational excitation compared to nitrogen. Also CO is the only toxic gas of the species discussed here. Care has to be taken when handling such gas mixtures.

Materials for CO_2 Lasers

Materials for the laser tube have to be chosen properly. All common rules for building and preparing vacuum systems apply. Materials with low out-gasing and low vapor pressure must be used. This normally inhibits the application of plastics and polymer-based glues in CO_2 laser tubes. Additionally, the UV radiation of the gas discharge will degrade most organic compounds rapidly. There are only a few epoxy-based adhesives that may be used.

Many low-power sealed-off lasers and even high-power lasers with slow or fast gas circulation use quartz glass tubes to confine the laser gas. Quartz (SiO_2) glass is thermally stable, chemically inert, robust against UV radiation and has low dielectric losses. However, silica-based glasses have high infrared absorption, even for grazing incidence of light to the surface. Thus, the diameter of the quartz glass tube needs to be considerably larger than the laser beam formed by the resonator mirrors. For waveguide lasers (see Sect. 11.4.2) tubes made from other materials must be used. Alumina (polycrystalline Al_2O_3 ceramics) is often used. It is a dense and vacuum-tight ceramic material, which is also dimensionally and thermally stable. Its infrared absorption is lower than quartz glass, making it suitable for hollow dielectric waveguides. Also it has very low dielectric losses at radio frequencies, making it an ideal material for transversal capacitively coupled RF discharge excitation.

Good material choices to confine the gas volume are also inert passivated metals such as stainless steel [11.1374] and passivated aluminium. Steel can easily be welded, both with conventional techniques or with lasers, to built a vacuum-tight laser tube. Welding of aluminum is more difficult. On the other hand, aluminum has a far better thermal and electrical conductivity and a higher infrared reflectivity. This makes aluminum a very good material for waveguide plates and electrodes for transversal RF discharges [11.1375].

Electrolytic copper or oxygen-free high-conductivity (OFHC) copper can also be used because of their excellent thermal and electrical conductivity and infrared reflectivity. On the other hand, copper can be oxidized by oxygen radicals from the dissociation process inside the gas discharge. Copper does not form stable, inert oxides on its surface but rather absorbs and binds

the oxygen in the volume. This shifts the equilibrium of the dissociation towards lower CO_2 content in the tube. Therefore, uncoated copper is not well suited as a material in direct contact with the gas discharge. Away from the discharge, however, copper is an excellent material for mirrors. Copper mirrors can be cooled effectively by water channels from the rear side. This is important for resonator and deflecting mirrors inside high-power lasers. For example, with an output coupler reflectivity of 50% the circulating light power inside the resonator is twice the rated laser power of the system. Even if the infrared reflectivity is very high, this can lead to considerable warming and mechanical stress if the mirrors are not cooled. Copper can be electroplated with nickel (Ni) and then coated with gold (Au). This makes the copper surface more stable against oxidation.

Catalysts and Gas Analysis

Much research was carried out to find proper catalysts to reduce the dissociation of CO_2 and to maintain a high output power. In lasers with a gas flow, the laser gas can be circulated through external catalysts. Common catalysts such as hot platinum [11.1376] or platinum on metallic oxides such as tin oxide with a large surface area [11.1377, 1378] can be used. However, fast-flow systems require gas replenishment of a few liters per hour to compensate for residual vacuum leaks or material contamination. As the price of the laser gas mixture is rather low compared to the costs of installing a catalyst, they are usually not applied in fast-flow systems.

For sealed lasers without any gas flow the situation is quite different. The dissociation reactions inside the gas discharge are fast and equilibrium is reached in a tenth of a second within the discharge. On the other hand, diffusion time constants to a nearby gas reservoir are in the range of minutes. Thus, any catalytic surfaces need to be in close contact with the discharge itself. For example, catalytic active platinum cathodes [11.1371] and distributed platinum [11.1379] or sputtered gold coatings on the inside of a longitudinal discharge tube [11.1380] have been reported. For waveguide lasers, gold-coated electrodes were found to be effective in some reports [11.1381, 1382]. The catalytic activity and the advantages for laser output power of these approaches depend on the preparation of the catalytic surfaces, the gas composition and the laser geometry itself, leaving open many questions and an impression of alchemy. Some commercial laser designs embody some sort of

these techniques, as deemed best for the given laser design.

To study the effects of catalysts on the gas composition or, more generally, to have more data about the active medium such as rotational and vibrational temperatures various methods can be applied. Mass spectrometers are commonly used for gas analysis. However, short-lived species from the discharge cannot be easily measured. The required pressure reduction from some tens of hPa down to 10×10^{-7} hPa tends to change the original gas compositions. Special techniques in experimental laser systems have been used to measure gas compositions directly from the gas discharge, and have given insight into the complex gas chemistry [11.1367, 1384].

Another method is to study the visible and UV spontaneous emission from electronically excited states inside the gas discharge [11.1385]. This can even be done with the naked eye. Figure 11.124 shows an example spectrum. A gas discharge without much CO appears pink or redish-purple because of vibronic nitrogen emission lines in the red and blue visible spectrum. With a significant carbon monoxide content there are additionally some CO emission lines spread over the visible and a strong emission band in the blue–UV spectral region. Thus, a gas discharge with a higher degree of dissociation looks more blueish-white. The color change can be observed in slow-flow DC-excited gas lasers with glass tubes from the gas inlet to the gas outlet, for example. For quantitative studies fiber-coupled spectrometers with fast readout can be used to gain time-resolved concentration data [11.1383]. With high-resolution spectroscopy, for example of the UV nitrogen emission band, the rotational temperatures of the gas can be measured. Using an imaging system, spatially resolved data for these parameters have even been measured in the discharge gap of an RF-excited high-power slab laser [11.1386].

Absorption spectroscopy with tunable diode lasers is also very effective for measuring species concentrations and roto-vibrational temperatures directly inside the laser tube or gas discharge. To do this, a wavelength-tunable diode laser is adjusted to the various absorption transitions of the relevant molecules (i. e., CO_2, CO, N_2O, NO). By aiming the diode-laser beam through the gas volume and measuring the relative intensities of several rotational and vibrational transitions an accurate diagnostic of the active medium is possible [11.1387–1391]. Recently, the catalytic activity of special gold coatings on electrodes for RF-excited slab lasers was verified using this technique [11.1392].
Fig. 11.124 Visible spectrum the sidewards spontaneous emission of a CO_2 laser gas discharge (after [11.1373, 1383])

Output Spectra and Line Broadening

Due to the fast population relaxation between the rotational levels only the rotational transition with the largest gain is usually observed. A similar competition as for the rotational lines is also given for the two regular vibrational transitions. As both have the same upper laser level (00^01), and the population levels of the lower states (10^00) and (02^00) are coupled by the Fermi resonance and have similar decay rates, only the vibrational transition with the largest gain will survive. Typically this is the 10P(20) transition or one of its neighbors for many lasers.

Every roto-vibrational transmission line is broadened by several broadening mechanisms. At gas pressures above 10 hPa collisional or pressure broadening dominates over Doppler broadening. The collision-broadened line shape is described by a Lorentzian function having a line width (FWHM) Δf_L proportional to the total gas pressure p:

$$\Delta f_L = 2p \left(\psi_{CO_2} b_{CO_2} + \psi_{N_2} b_{N_2} + \psi_{He} b_{He} \right) \times \left(\frac{300}{T} \right)^n \tag{11.135}$$

where the ψ_i are the fractions of the respective gases and T is the gas temperature. The temperature exponent n is 0.58 for constant pressure [11.1393], with values ranging from 0.5 to 0.7 also found in the literature. The b_i are the pressure-broadening coefficients resulting from collisions with species i and are given in [11.1393] to
Fig. 11.125 Homogeneous saturation of a Lorentzian gain profile leads to lasing of a single longitudinal resonator eigenfrequency

be:

$$b_{CO_2} = (3.40 - |m| \cdot 0.0272)\, \text{MHz hPa}^{-1} \quad (11.136)$$

$$b_{N_2} = (2.35 - |m| \cdot 0.0127)\, \text{MHz hPa}^{-1} \quad (11.137)$$

$$b_{He} = (1.77 - |m| \cdot 0.00083)\, \text{MHz hPa}^{-1}\,,$$

$$(11.138)$$

where $m = -J$ for the P branch and $m = J + 1$ for the R branch. For example, the most common 10P(20) line at 100 hPa and 500 K in Lasermix 322 from Table 11.40 has a Lorentzian line width (FWHM) of 284 MHz. The Doppler line width at this temperature would be $\Delta f_D = 36.2$ MHz and can be considered if a Voigt line shape instead of a pure Lorentzian is used [11.1394].

Within this line width one or more longitudinal resonator eigenfrequencies f_q may be located. For an example length for a CO_2 laser resonator of $L_{res} = 2$ m a spacing of the eigenfrequencies $\Delta f_q = c/2L = 75$ MHz results. As the collision-broadened line saturates homogeneously, only the eigenfrequency closest to the center frequency of the transition can lase in the steady state after saturation, as shown in Fig. 11.125. Thus, CO_2 lasers are typically longitudinally single-mode lasers.

Efficiency, Output Power and Cooling

The theoretical limit for the efficiency of a laser is the internal quantum efficiency η_q. For the CO_2 laser this is the ratio of the energy of the laser photons to the energy of the upper laser level (00^01) and is roughly 40%. This is quite high for a gas laser. Real technical lasers

have significantly lower efficiencies for several reasons. The electrons inside the gas discharge do not only excite the required vibrational states of the molecules but also other states. Also a significant part of the kinetic electron energy is transferred into pure translatory motion of the molecules and thus transferred into heat. Additional energy is lost in the ionizing processes required to maintain the gas discharge and in chemical dissociation processes. Also not every vibrationally excited molecule contributes to the laser process. Vibrational energy decays by vibrational–translational relaxation, which produces heat again and by radiative decay by spontaneous emission of excited states. Finally, optical energy is dissipated in absorption losses of the mirrors and waveguides or by limited aperture diameters.

Typical electrical efficiencies η_E, defined as the ratio of the extracted laser power P_L to the electrical power P_E applied directly to the discharge tube, are in the range of 10% for slow-flow DC-excited laser, up to 15% for RF-excited waveguide lasers and up to 20% for fast-flowing systems. The overall wall-plug efficiencies η_{tot} as a ratio of laser power P_L to mains supply power P_{mains} are always lower than η_E. This is due to conversion losses in the electronic power supplies to provide the required DC high-voltage or RF power. A considerable amount of energy is also dissipated in the gas circulating system of fast-flow lasers.

The output power of a given CO_2 laser can be roughly estimated by simple thermodynamics. If all aspects of optical design, electrical excitation and gas composition are optimized, electrical efficiencies η_E as discussed above can be assumed. From this point, the laser power is finally limited by the cooling and heat removal capacity of the laser system. The power dissipated by the electric excitation P_{diss} should not heat the laser gas above a certain temperature, for example 450 K.

In diffusion-cooled lasers no forced gas flow contributes to the heat removal. The thermal conductivity of the gas mixture and the diffusion of excited vibrational states to the housing walls determine the thermal transport processes. For a given tolerable temperature rise ΔT of the laser gas in the discharge area, the maximum applicable dissipated thermal power P_{diss} can be calculated by solving the differential heat-transfer equation for the given geometry. For fast-flowing systems the amount of heat removal is given by the specific heat capacity c_P of the gas and the mass flow $\dot{m}$.

With the assumption that almost all electrical excitation power P_E is finally dissipated into heat P_{diss}, the maximum permissable excitation power $P_{E,max}$ for the given temperature rise ΔT is thus known. The maximum

possible output power $P_{L,max}$ of this laser system can then be calculated with the assumed electrical efficiency η_E. This exaggerates the importance of the cooling methods for high-power lasers. Different approaches will be discussed in the next section on technical lasers.

11.4.2 Typical Technical Designs

Although CO_2 lasers with a longitudinal DC discharge inside a glass tube as described in Sect. 11.4.1 are still being used and sold because of their simplicity, many other types and realizations of the CO_2 laser have been developed over the last decades. They can by systematically categorized according to various characteristics, as below.

Gas flow inside the laser.
- No gas flow, sealed-off
- Quasi-sealed-off, periodic gas exchange
- Slow gas flow axial to the laser beam
- Fast gas flow axial to the laser beam
- Fast gas flow transversal to the laser beam

Gas cooling.
- Diffusion-cooled, cooled walls of the gas discharge
- Fast gas flow with external heat exchanger

Electrical excitation.
- Longitudinal DC discharge, continuous
- Transversal DC discharge at high gas pressure, pulsed
- Capacitively coupled transversal RF discharge
- Inductively coupled RF discharge
- Microwave-excited gas discharge

Optical resonator.
- Stable optical resonator
- Unstable optical resonator
- Free-space propagation between the mirrors
- Optical waveguide between the mirrors
- Combinations of these in different planes

In principle, almost any of these characteristics could be combined to give specific advantages. The three axes of the optical laser beam, the gas flow and the exciting electrical field can be mutually parallel or orthogonal in general. Some of the most important designs with their specific technical characteristics are discussed further in the next sections. Commercial manufacturers of CO_2 lasers often have quite different approaches, also depending on their own intellectual property and patents.

General design aspects are: as efficient a heat removal as possible, a compact optical resonator for a small footprint even at very high power levels and a rugged and robust design for maintenance-free long-term industrial operation.

More-exotic laser types such as optically pumped CO_2 lasers, black-body radiation-pumped lasers, lasers with electron-beam sustained gas discharges and gas-dynamic CO_2 lasers are not further considered in detail here.

DC-Excited Fast-Axial-Gas-Flow Lasers
Longitudinally DC-excited lasers have the advantage of a rather simple and cost-effective design. Modern DC-excited lasers use sophisticated electronically regulated high-voltage (HV) supply circuits with both voltage and current control to omit the ballast resistor shown in Fig. 11.117. This reduces ohmic losses in the HV circuit. Vacuum-tube-based or more modern semiconductor-based current regulators and switched-mode voltage converters are applied.

For high-power lasers a fast axial gas flow can be used to cool the gas. Lasers with a power in the kW range [11.1396, 1397] were demonstrated in the late 1970s. Figure 11.126 shows an example of a modern DC-excited fast-flow high-power laser. The gas discharge in the gas tube is divided into four independent sections to keep the required high-voltage levels moderate. Two of the discharge and flow tubes shown can be used in parallel, with a U-shaped folded light path and resonator to double the length of the active medium. This is because the output power scales with the length of the gain medium.
Fig. 11.126 Longitudinally DC-excited high-power CO_2 laser with fast axial gas flow [11.1395]

As discussed in Sect. 11.4.1, the maximum output power of a CO_2 laser is also largely determined by its heat removal capacity. A fast gas circulation can be driven by a turbo blower. From thermodynamic considerations, the maximum laser power $P_{L,max}$ of a fast-flow laser can be calculated with a given electrical efficiency η_E:

$$P_{L,max} = \eta_E P_{E,max} = \left(\frac{\eta_E}{1 - \eta_E} \right) P_{th}$$

$$= \left(\frac{\eta_E}{1 - \eta_E} \right) \dot{m} \, c_p \, \Delta T \,, \qquad (11.139)$$

where $P_{E,max}$ is the maximum applicable electrical power, P_{th} is the thermal power dissipated in and removed from the discharge, $\dot{m}$ is the mass flow, c_p is the specific heat of the gas mixture, typically $2500 \, \text{J} \, \text{kg}^{-1} \, \text{m}^{-3}$, and ΔT is the maximum gas temperature rise that can be tolerated, typically $250 \, \text{K}$. It can be seen clearly that the laser power scales with the mass throughput and thus with the flow velocity, which is limited by the onset of turbulence and the speed of sound. For an assumed efficiency of $P_E = 15\%$, one yields an approximate required mass flow of $0.1 \, \text{kg/s}$ per kW of laser power. The heat dissipated in the gas is removed by a heat exchanger after the gas has passed the discharge

sections. The additional heat resulting from the gas compression by the turbo blower is removed by pre-coolers before the gas enters the discharge tube again.

Besides the fast gas flow there is also a permanent slow gas exchange with a fresh gas mixture, for example at a rate of 371 (standard pressure and temperature) per hour in a ratio $\text{He} : N_2 : CO_2 = 25 : 12 : 2$ for a particular commercial system. Longitudinally DC-excited lasers up to several kW laser power are available. Depending on the laser power and the application, such laser systems can emit a mixture of an ideal TEM_{00} mode and a hybrid TEM_{10}^* donut-shaped mode.

RF-Excited Gas Discharges

Radio-frequency (RF) excitation of the gas discharge is widely used in CO_2 lasers. In this context RF means a frequency range of roughly $1-500 \, \text{MHz}$. Figure 11.127 shows cross sections of typical geometries found in CO_2 lasers. In capacitively coupled RF (CCRF) discharges the electric field is applied by two metallic electrodes with the gas volume in between. The electric field E in the volume of the gas is sufficiently high to start and maintain a self-sustained glow discharge [11.1350]. The RF voltage U_{RF} and the RF electric field E are typically applied transversely to the laser beam. Thus, much lower voltages U_{RF} are required compared to longitudinally excited discharges. U_{RF} is roughly $100 \, \text{V}$ per mm discharge gap width d, depending largely on the gas pressure.

The electrodes can be electrically insulated from the discharge by a dielectric material, for example a glass or alumina tube as shown in Fig. 11.127a. No direct contact of the gas with the electrodes is necessary. The current flow is closed by the displacement current, which is $\sim \partial E / \partial t$ according to Maxwell's laws.

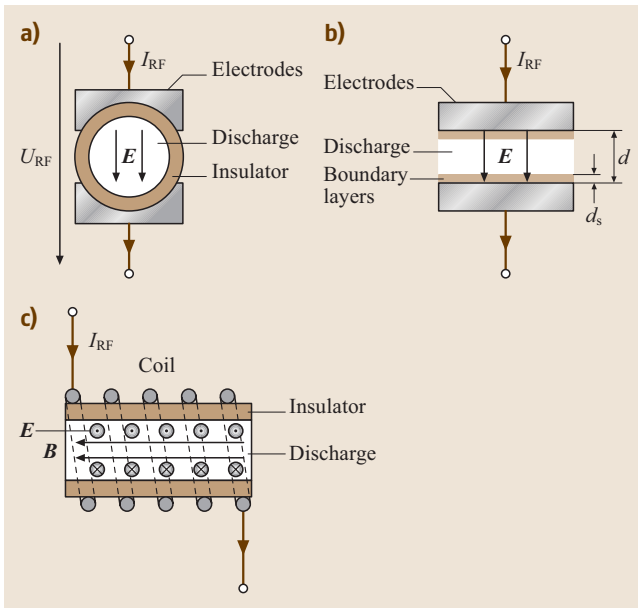
Alternatively, the metallic electrodes can be placed in direct contact with the gas volume (Fig. 11.127b). In this case the surface regions on both electrode boundaries have reduced free-electron densities and are called ion sheaths. In these ion sheaths no efficient excitation of vibrational states takes place. Power dissipated in the sheaths does not contribute to the laser power. The width of the sheaths d_s is inversely proportional to the excitation frequency $d_s \sim 1/f$ and is, for example, $0.35 \, \text{mm}$ at $f = 125 \, \text{MHz}$ at a pressure of $p = 90 \, \text{hPa}$ [11.1398]. The electrode separation must be significantly larger than this value to ensure sufficient excitation of the gas volume. On the other hand, this reduces the efficiency of diffusion cooling for heat removal from the gas to the electrodes. For small gaps and efficient cooling, excitation frequencies in the $100 \, \text{MHz}$ range are often chosen.


Fig. 11.127a–c Geometries for RF excitation with current I_{RF} and electric field E: **(a)** capacitively coupled RF discharge, insulated electrode, **(b)** capacitively coupled RF discharge, non-insulated electrodes, **(c)** inductively coupled RF discharge

An optimized value for the electrode separation d is typically 2 mm under these conditions.

With insulated electrodes a so-called dielectric barrier discharge has been reported, which allows efficient excitation at much lower frequencies around 1 MHz while still maintaining a stable discharge with efficient vibrational excitation and good cooling of the gas [11.1400].

The α-type RF discharge is a volume discharge with all ionizing and electron-collision processes taking place throughout the entire gas volume. No ionizing processes at the electrodes are required. Such RF discharges are hence called electrodeless discharges. However, in the case of non-isolated electrodes (Fig. 11.127b) there is also an onset of a γ-type discharge at higher current densities, where surface ionizing processes play an important role [11.1350]. This is usually not the desired discharge type for laser excitation.

RF gas discharges can also be inductively coupled (Fig. 11.127c). The RF current I_{RF} through a coil generates a time-varying magnetic field $\boldsymbol{B}$ which is accompanied by an electric field $\boldsymbol{E}$ according to curl $\boldsymbol{E} = -\partial\boldsymbol{B}/\partial t$. Inductively coupled discharges are not commonly used for CO$_2$ lasers because the gas cooling and electrical field geometry are not as favorable as for CCRFs.

RF-excited discharges have several advantages. One advantage is that such an electrodeless discharge shows no material sputtering from the cathode or anode and no resulting contamination of the laser gas or degradation by material ablation. Very high energy densities can be applied to the gas volume while still maintaining a stable glow discharge without arcing. Higher gas pressures can be used, typically around 100 hPa. Thus, more active medium and more laser power is available per volume. The required voltages are lower than for DC excitation. Insulation of electric wires and components on the air-pressure side is easily done by sufficient large air gaps or common dielectrics. The impedance of the gas discharge, which can be modeled as a strongly lossy capacitor [11.1401], can be matched to the RF generator impedance with almost lossless reactive components (LC matching circuit). No ohmic ballast resistors are required to stabilize the discharge.

However, there are also some issues to be properly considered in the design of RF-excited lasers. One of those is voltage and discharge homogeneity along the RF electrodes. At a frequency of 100 MHz the vacuum wavelength λ_0 is 3 m. Wave propagation effects and waveguide theory must be applied if structures with one dimension ℓ larger than $\lambda_0/10$ are used. This is often the case for the length of typical RF-excited waveguide lasers. Therefore, regularly spaced inductors parallel to the electrodes are used [11.1369, 1402, 1403]. Figure 11.128 shows an example for an electric circuit model of the electrodes with a gas discharge.
Fig. 11.128 Homogenization of the RF voltage distribution $U_{RF}(z)$ on long electrodes with parallel inductors [11.1399]

The electrical wave propagation along the electrodes is described by a characteristic impedance Z_ℓ and the propagation constant of a lossy transmission line γ. Parallel inductors L_i are used to compensate for the capacity per unit length of the electrodes to homogenize the voltage distribution. The higher the RF frequency, the more inductors in a shorter distance l_i must be used. Also shown is an impedance-matching network to match the complex impedance of the laser Z_{laser} to the system impedance Z_0 of $50\,\Omega$ of common RF generators.

Alternatively, an array of segmented electrodes much smaller than the wavelength can be used. This can be problematic if the electrodes also act as waveguides for the laser light. Mechanical misalignment of the electrode segments may then cause excessive optical losses.

RF power generators are somewhat more complex than DC high-voltage supplies. They must provide roughly ten times the nominal laser power as electrical power at RF frequencies. For low- and medium-power CO_2 lasers up to $500\,W$, solid-state RF power generators based on semiconductor transistors [mostly metal–oxide–semiconductor field-effect transistors (MOSFETs)] are available at the required frequencies. Such RF generators can be integrated directly into the laser system housing with air or water cooling of the power supply.

For an RF power beyond this level electron-tube-based generators are required. Coaxial power tetrodes, as installed in amplitude-modulation (AM) short-wave radio transmitter stations, are used. This is a mature and reliable technique to generate RF powers of tens of kilowatts in the desired frequency range. Tubes can tolerate large reflected power levels from badly matched loads without permanent damage. Electron tubes are more robust against overvoltage and current transients than transistors. A drawback is that the tubes itself need a high-voltage DC power supply and that they dissipate

additional power for cathode heating. The lifetime of such tubes is on the order of 10 000 hours. However, costs for replacement tubes are moderate.

Finally, issues of electromagnetic compatibility (EMC) have to be considered. Therefore, many RF-excited lasers operate in the ISM (Industrial Scientific and Medical) bands of $13.6\,MHz$, $27\,MHz$ or $40.6\,MHz$, where less-stringent regulations apply. Systems at different frequencies, especially in the frequency-modulated (FM) radio bands around $100\,MHz$ need to have properly shielded housings, best made of all metal and with contact strips for all service flaps of the laser housing.

Microwave excitation at a frequency of $2.45\,GHz$ has been studied intensively [11.1404–1406]. Powerful magnetrons are very efficient microwave-generating tubes at this frequency and are available at low cost, because of their use in mass-produced products such as kitchen microwave ovens. However, the short wavelength makes it difficult to realize large-area discharges with good uniformity. Additionally, the power density required to maintain a microwave-excited gas discharge is larger than at common RF frequencies and tends to overheat the gas. Thus, microwave-excited CO_2 lasers have been realized mostly in pulsed operation [11.1407] or with a fast gas flow [11.1408]. Diffusion-cooled laser systems have also been demonstrated [11.1409]. In spite of the cost advantages of microwave generation with magnetrons, the mentioned disadvantages and the progress of RF-excited lasers has hindered the commercial success of microwave excitation to date.

Waveguide Lasers

For the laser design in Fig. 11.117 it would be desirable to reduce the diameter of the glass tube to achieve better cooling of the laser gas. This can introduce excessive optical losses by obstructing the laser beam inside the resonator. Losses from such limiting apertures with a radius of a for common Gaussian TEM modes in two-mirror stable resonators of length l are calculated
Fig. 11.129a–c Cross sections of some waveguides for CO_2 lasers with RF electrodes: **(a)** circular dielectric waveguide, **(b)** all-dielectric rectangular waveguide, **(c)** hybrid metal–dielectric waveguide

in [11.1410]. These losses rise quickly if the Fresnel number $N = a^2/\lambda l$ gets smaller than 1.

This problem can be overcome if the gas tube has waveguide properties at the optical laser frequency. A comprehensive overview of waveguide laser design is given in [11.1402]. Figure 11.129 shows the principle geometries of waveguides used in CO_2 lasers. The simplest form is a circular hollow dielectric waveguide, which is theoretically described in [11.1411]. Circular metallic waveguides are not an option because they will obviously shorten any electrical field required for the discharge excitation. Rectangular waveguides can have dielectric walls on all four sides or one pair of dielectric and one pair of metallic walls [11.1412, 1413]. Such waveguides support hybrid EH_{mn} modes at optical frequencies with very low losses. These modes can be thought of as a superposition of electromagnetic waves propagating at different angles to the waveguide axis, reflected by the walls at grazing incidence. Therefore, the materials used should have low absorption losses in the infrared. Alumina or beryllium oxide ceramics are a good choice for the dielectrics because of their high mechanical, chemical and thermal stability and their high thermal conductivity for heat removal. Aluminum or gold-plated copper surfaces can be used as metallic waveguide boundaries.

The lowest circular mode EH_{11} is very similar to the Gaussian free-space mode TEM_{00}, with a power overlap of 98%. Thus, waveguide lasers operating only in the lowest possible mode have excellent beam quality.

To build a waveguide laser, such waveguides are filled with laser gas. The excitation of the gas discharge is therefore often realized by a transversal RF discharge. A pair of metallic electrodes are placed on opposite sides of the dielectric waveguide (Figure 11.129a,b) or are part of the waveguide itself (Figure 11.129c). The optical resonator is realized by mirrors at both ends of the waveguide. Design rules for low-loss coupling and good mode discrimination are given in [11.1414]. A good solution is a mirror in a small distance d from the waveguide, which is half the radius of curvature ρ_M of the mirror. Alternatively, plane mirrors close to the waveguide can be used.

The power of a waveguide laser scales almost linearly with the length. Up to 110 W of laser power per meter length have been reported [11.1415].

Many commercial CO_2 lasers use waveguide technology. Figure 11.130 shows the cross section of a particular commercial waveguide laser [11.1416]. The resonator light path is folded in a zigzag shape three times through multiple waveguide channels formed by
Fig. 11.130 Cross section of a commercial RF excited waveguide laser with a folded resonator light path

a ceramic plate and an aluminum profile. This results in a compact laser head design with high power, as the laser power scales with the length of the waveguide. The aluminum profile serves as the RF ground electrode, as one side of the optical waveguide, as a cooling plate and as an RF- and gas-tight housing for sealed operation. The second RF electrode is on top of the ceramic plate. Regularly spaced spiral inductors homogenize the RF voltage distribution along the structure. Air or water cooling can be realized by the cooling channels on the profile. An output power of 100 W is available from a compact package size [11.1417]. Q-switching can optionally be applied to realize pulsed lasers with high peak power, especially for marking applications.

Another interesting waveguide laser structure is shown in Fig. 11.131 [11.1418]. The waveguide is formed by two pairs of metallic aluminum electrodes and two ridges from the metallic housing profile. RF power is applied to both electrodes in a push–pull mode
Fig. 11.131 Cross section of an all-metal waveguide laser

with respect to the grounded housing. That means that the RF voltage amplitude on both electrodes is the same but with a 180° phase shift relative to one other. The electrodes are separated from the ridges by small gaps which enable gas circulation in the whole structure for cooling and heat removal. The electrodes are anodized such that the oxide layer provides sufficient insulation to the grounded ridges of the housing. Additional insulators are used to hold the electrodes in the housing. A homogeneous gas discharge is formed in the middle of the structure with lateral dimensions of a few mm. In spite of the small gaps, the structure can act as an optical waveguide in all directions to form a laser beam with good beam quality.

The advantage of this all-metal structure is that no ceramic–metal joints are required. Such joints can potentially cause failure because of the mismatched thermal expansion coefficients. Both the electrodes and the housing can economically be manufactured by extruded aluminum profiles. Heat is easily removed by conduction or passive thermal convection. Without ceramics with their high dielectric constants between the electrodes, the capacitive loading of the electrical waveguide is low. Fewer inductors are thus required for voltage homogenization. The metal housing can be sealed with metal brazing to build long-living sealed-off lasers. A range of medium-power compact lasers up to 240 W is available in this technology [11.1420], partially using folded resonators for power scaling with the waveguide length.

The Slab Laser
Figure 11.132 shows the structure of an RF-excited slab laser. This design has been pioneered by several groups [11.1421–1424], accompanied by the well-known Tulip patent [11.1425]. It is formed by two

Fig. 11.132 RF-excited slab laser with hybrid waveguide-unstable resonator [11.1419]

large-area metallic electrodes separated by a small gap. The length of the electrodes can be 1 m with a width of some tens of centimeters. A typical gap height is 2 mm. An RF voltage at a frequency in the range of 100 MHz is applied between the electrodes to start a gas discharge in the laser gas mixture between the electrodes. The electrodes are provided with channels for cooling water. Thermal energy dissipated in the gas discharge is effectively removed by conductive or diffusion cooling. Gas discharges with very large areas can be operated stably with this geometry.

In a plane perpendicular to the large-area surfaces the electrode pair acts as a waveguide for optical frequencies. A low-order mode is easily obtained in this waveguide direction. In the plane parallel to the electrode surfaces free-space conditions are valid as there are no limiting boundaries on the sides of the electrodes. With such broad dimensions this would result in a strongly multimode beam profile in this direction, if common stable resonators were applied. Therefore, an unstable resonator is used which has advantages for the extraction of high-quality beams from active laser media with large transversal dimensions [11.1348, 1426]. An unstable resonator is characterized by two mirrors with radii of curvature ρ_1 and ρ_2 and a mirror separation L that do noes fulfill the stability criterion for stable Gaussian beam resonators:

$$0 \leq \left(1 - \frac{L}{\rho_1}\right)\left(1 - \frac{L}{\rho_2}\right) \leq 1 \qquad (11.140)$$

Such a resonator does not reflect a Gaussian beam backwards into itself but rather uses the partial transmission of the beam on one mirror side as the output coupling. It can be shown that the beam profile can have an almost diffraction-limited beam quality in the unstable-resonator plane. In the waveguide plane, the mirrors can be almost flat. Both mirrors can be made of solid copper and can be cooled to withstand very high power densities. By a proper design, the coupling losses between the mirrors and the slab waveguide can be minimized [11.1427].

The laser beam coming directly from this type of resonator has an elliptical shape and has different divergence angles in the waveguide and the free-space plane. This is corrected by beam-shaping optics with at least one cylindrical mirror. Additionally, a spatial mode filter is used to eliminate shadows on the beam wings in the free-space unstable-resonator direction. After that, the beam has a nearly circular shape with an excellent beam quality of $M^2 = 1.1$.
The main advantage of this structure is that the laser power can be scaled by the area A_e of the gas discharge, which extends in two dimensions. This is in contrast to tube-type or waveguide lasers where the power scales only over one dimension, namely the tube length L. From thermodynamic calculations and based on extending results from conventional waveguide lasers, the maximum laser power P_L of a slab with an electrode area A_e and an electrode separation d_e is approximately given by:

$$P_L = C\frac{A_e}{d_e}, \quad C \approx 3\frac{\text{W mm}}{\text{cm}^2}. \tag{11.141}$$

By this area scaling over A_e, very compact and yet powerful lasers can be made. As with all large RF-excited laser systems, parallel inductors are used for homogeneous RF voltage distribution along the electrodes. The efficient diffusion cooling requires no gas flow, which saves system and operating costs. Medium-power lasers can be operated completely sealed and are available at power levels up to 500 W [11.1429], partially with transistor-based RF generators. High-power slab lasers operate typically with a periodic gas exchange, for example after 72 h of continuous operation, to compensate for residual gas leaks from the large structure. Commercial slab lasers with powers up to 8 kW integrate the slab structure and the electron-tube-based self-oscillating RF generator into one compact housing with an integrated premix gas supply which lasts for approximately 12 months of continuous use [11.1419].

RF–Excited Fast–Flow CO$_2$ Lasers

The basic principle of a fast-axial-gas-flow laser as described in Sect. 11.4.2 can be combined with the advantages of RF excitation. Figure 11.133 shows such a laser system. The gas circulates through glass tubes driven by a turbo radial blower in the center of the structure. The optical resonator is quadratically folded. For an even longer discharge length and more output power, the resonator can be folded in two planes with 16 discharge sections (Fig. 11.134). Optically stable resonator configurations are used. The RF discharge is capacitively coupled with eight pairs of electrodes, two on each side. The electrodes are mutually rotated by an angle of 45° to ensure a homogeneous gain in the cross section, averaged over one resonator cycle. A heat exchanger cools the gas coming from the discharge section and a pre-cooler removes compression heat after the blower before the gas enters the discharge sections again. Typical gas pressures are in the range of 150 hPa. The power scaling with mass flow according to (11.139) is also valid for this
Fig. 11.133 RF-excited fast axial gas flow with a folded resonator [11.1428]

system. Volume flow rates are up to 500 m^3/h per kW extracted laser power with gas velocities of 100 m/s. Lasers with output powers up to 20 kW are commercially available while laser powers above 30 kW have been demonstrated experimentally [11.1430]. The beam quality is near a perfect diffraction-limited TEM$_{00}$ mode with an M^2 of 1.1 for high-quality series up to 4 kW. At the high-power end the 20 kW system still has an M^2 value as low as 5. The wall-plug efficiency of these systems is 10% including the losses in the RF power supply and the gas-circulating system. Electron-tube-based high-power RF oscillators at an industrial ISM standard frequency of 13.6 MHz are used.

Other RF–Excited CO$_2$ Laser Systems

There are many other commercial laser designs based on RF excitation and with specific resonator or cooling geometries. Some interesting designs will be discussed briefly here.
Fig. 11.134 Quadratically folded resonator in two planes [11.1428]
Fig. 11.135 Folded free-space resonator between large-area slab electrodes [11.1431]

Figure 11.135 shows a folded free-space resonator between two large-area RF electrodes. Only three mirrors are required for beam folding. The output coupler and the plane total reflector can even be integrated in one mirror with inhomogeneously reflecting coatings. Compact and robust sealed original equipment manufacturer (OEM) laser modules up to 120 W are available [11.1431].

A combination of large-area electrodes with a hybrid stable–unstable resonator is described in [11.1433] and [11.1434]. In contrast to the slab laser with its plane-parallel electrodes, the electrodes do not act as a waveguide here. Instead, they have a slightly V-shaped surface geometry along the beam propagation direction between the mirrors to select the lowest-order free-space mode in a plane perpendicular to the electrodes, whereas an unstable resonator is used in the
Fig. 11.136 RF-excited laser with fast transversal gas flow [11.1432]

free-space plane again. Sealed-off OEM modules in an all-metal design and a maximum power of 400 W can be realized [11.1435].

Large-area RF-excited gas discharges can also be combined with a fast gas flow between the electrode plates transversally to the optical resonator and the laser beam (Fig. 11.136). The gas flow is driven by a tangential blower integrated into the large-diameter cylindrical gas vessel. A folded resonator is used to extract the energy from the large active medium. Such lasers can produce 8 kW of laser power from a very compact footprint. The beam quality with $M^2 \approx 5$ is still well suited for welding and surface-treatment applications.

Coaxial laser systems with an annular gas discharge as shown in Fig. 11.137 can be thought of as slab-type lasers with an electrode pair rolled up to form coaxial tubes [11.1436]. RF power is applied to the inner tube, while the outer tube is grounded. This is similar to a coaxial cable, but with an inner-conductor diameter of approximately 10 cm and a discharge gap width of 7 mm, for example. In this design, the electrodes have no optical waveguiding properties, thus such lasers are less susceptible to power and beam-quality variations under mechanical and thermal stress. The resonator is formed by a helical mirror and an axicon mirror, bending the beam to the opposite side of the tube while slightly shifting the azimuthal angle after each pass [11.1437]. In the radial direction the optical resonator configuration is stable, while in the azimuthal direction an unstable resonator is used. The laser is diffusion-cooled by water-cooled electrode tubes. The laser can be operated quasi-sealed-off with a regularly scheduled gas exchange. Compact and robust lasers with 2 kW power can be realized [11.1438]. They are well suited for mounting on moving systems such as robots without bending mirrors for beam steering.

Pulsed TEA Lasers

All the laser designs discussed so far are continuous-wave (CW) lasers by principle. Their power can be modulated by the electrical excitation power with frequencies of a few kHz for DC excitation and up to 100 kHz for some RF-excited lasers. In contrast, the tranversal-excited atmospheric-pressure (TEA) laser is a CO_2 laser that can inherently operate only in pulsed mode, but is capable of generation very high pulse energies and peak powers that are not possible with CW CO_2 lasers. This is achieved by a high gas pressure, at atmospheric pressure or above. A homogeneous DC discharge can only be operated for a short time of 1 μs under these conditions before filamentation and arcing would

start. The required voltages at this pressure are in the order of magnitude of 100 kV per meter. Longitudinal discharges would need voltages that are not practical and would not produce stable discharges. Therefore, pulsed transversal discharges are used. Figure 11.138 shows a sketch of a simple TEA laser circuit. A high-voltage power supply (HV) charges a storage capacitor C slowly via the resistors R_{V1} and R_{V2}. When the maximum voltage at the capacitor is reached, a fast high-voltage switch, which is also capable of carrying high currents, is triggered to close the circuit quickly. The capacitor voltage is applied to the electrode pair, where a short but intense discharge transversal to the resonator axis and the laser beam starts. The discharge self-terminates when all the energy stored in the capacitor is dissipated. Afterwards the high-voltage switch resets itself to an open state and charging of the capacitor starts again before the next pulse can be triggered.

With TEA lasers pulse energies in the range of 10 J per liter of active volume and per bar of pressure can be achieved, with peak intensities in the MW range [11.1440, 1441]. Pulse repetition rates are a few 10 Hz for high-power systems and kHz for mini-TEA lasers [11.1442].

Critical design issues are the electrode profile to maintain a stable and homogeneous discharge in the cross section and also over the length of the electrodes. Often pre-ionization techniques by additional electrodes, UV light from corona discharges or even electron beams are therefore applied. The high-voltage switch is also a crucial part. Typically, triggered spark gaps or thyratrons are used, which must be replaced after a given number of pulses. Recently, progress in semiconductor technology has made it possible to replace these vacuum tubes by solid-state switches. A device called a silicon controlled rectifier (SCR) is capable of switching high currents very fast. In combination with a step-up transformer and a saturable inductor/capacitor ladder network the high-voltage level and the fast rise time required for the electrode voltage can be achieved.

Much research was done on TEA lasers in the 1980s, especially in the fields of plasma physics, LIDAR and military applications. Partially due to the success of high-power fast-flow and RF-excited systems, only a few commercial TEA lasers are available. Systems with pulse energies of 2.4 J at a repetition rate of 125 Hz are available, for example. Applications include non-metal processing such as marking and paint or rubber-compound stripping from surfaces in the automotive industry [11.1443].
Fig. 11.137 Coaxial laser with an annular gas discharge [11.1439]

Wavelength Selection and Tunable CO₂ Lasers

Without any wavelength-selective elements, a CO_2 laser emits at wavelengths around 10.6 μm in the vicinity of the 10P(20) line. Some commercial lasers are optionally available at the wavelengths of the strongest lines of the other bands, for example at 9.3 μm, 9.6 μm or 10.3 μm (Fig. 11.122). This is done by weakly wavelength-selective elements such as mirror coatings to select one of the four regular emission bands where the strongest line will start to oscillate. For example, this is interesting for plastics machining where materials can show a strong variation of absorption over wavelength.

For precise selection of a particular roto-vibrational transition, a diffraction grating is used. Figure 11.139 shows a DC-excited tunable laser in the Littrow configuration. Depending on the angle α of the incoming beam with respect to the surface normal of the grating, only a light beam at a specific wavelength λ_L is reflected:

$$\lambda_L = 2\Lambda \sin\alpha , \tag{11.142}$$

with Λ being the grating period. For this particular wavelength λ_L the grating acts as a plane reflector on axis to the second resonator mirror. This wavelength is selected
Fig. 11.138 Excitation circuit for a basic TEA laser
Fig. 11.139 Tunable CO_2 laser in Littrow configuration

Table 11.41 Emission range of a tunable CO_2 laser [11.1444]

Band	Wavelengths (μm) min – center – max	Lines min – center – max
9R	9.158 – 9.271 – 9.367	9R(44) – 9R(20) – 9R(4)
9P	9.443 – 9.552 – 9.836	9P(6) – 9P(20) – 9P(50)
10R	10.095 – 10.247 – 10.365	10R(46) – 10R(20) – 10R(4)
10P	10.441 – 10.591 – 10.936	10P(4) – 10P(20) – 10R(50)

to lase. Other wavelengths λ_x, if present, would be reflected at a different angle not parallel to the resonator axis. They would suffer significant losses from the aperture of the laser tube, which would prevent them from lasing. By rotation of the grating the angle α can be varied to select different roto-vibrational transitions one by one. Such gratings are mostly made of copper or steel with precision-ruled grooves and a gold coating to enhance IR reflectivity. The grating period Λ is chosen to be slightly smaller than the laser wavelength in order to suppress higher diffraction orders. The groove geometry can be adjusted such that the reflectivity in the desired minus-first diffraction order at a given wavelength is maximal (blazed gratings, blazing wavelength).

Table 11.41 shows for example the tuning range of a commercial tunable CO_2 laser. Note that, because of the separation of the rotational lines in the range of 30–90 GHz and the pressure-broadened line width of some 100 MHz, continuous tuning over the entire range is not possible. Within one line width, fine-tuning can be done by changing the resonator length with a piezoelectric element. An output power of 180 W can be achieved for the strongest lines and more than 20 W on the weak lines at the band edges, for example.

Applications include scientific spectroscopy, industrial trace-gas monitoring by absorption spectroscopy or optically pumping of far-infrared molecular gas lasers. By using gas mixtures enriched with special isotopologues, for example $^{13}CO_2$, emission lines at additional wavelengths can be realized. Tables of such wavelengths are given, for example, in [11.1347].

Besides longitudinally DC-excited lasers, RF-excited waveguide lasers are also good candidates for being tuned by a standard Littrow grating. Tunable slab-type lasers with their broad active medium require special grating structures for the extraction of a low-order mode. This can be realized by apodized Littrow gratings where the splitting ratio between the diffraction orders $m = 0$ and $m = -1$ is variable over direction of the grating [11.1445]. Such gratings can act as an output coupler with spatially variably reflectivity for beam forming and as line-selective element for wavelength tuning at the same time. They have been realized on copper mirror substrates with photolithography and a microgalvanic process as well as on silicon substrates with photolithography and anisotropic etching [11.1446].

11.5 Ion Lasers

Ion lasers became a success very soon after their invention in the 1960s. In the following decades, low-power air-cooled argon lasers were made in the tens of thousands for use in printing, color separa-

tion, and medical technology. Mid-power ion lasers were a staple of the entertainment industry, used in light shows, special effects, and for holography, as well as in disc mastering. Large-frame ion lasers

were ubiquitous in well-equipped chemistry and biology laboratories around the world. Ion lasers were the flagship products of the major commercial laser manufacturers.

But even in their heyday, alternatives to ion lasers were eagerly sought. There were several reasons for this, including early problems with reliability and lifetime, as well as high cost, but the major dissatisfactions resulted from the fundamental low efficiency of the devices. This poor efficiency meant ion lasers were large, of considerable weight, and needed substantial power supplies drawing large utility loads. They also had to be cooled aggressively either by air or water.

With the development of solid-state lasers in the 1990s, in particular diode-pumped lasers with frequency-doubled green output at 532 nm, many expected ion-laser technology to become obsolete. This has not happened. While not nearly at the levels they experienced in the 1980s, sales continue to be steady, ion lasers are still found in their traditional applications, and are a significant contributor to the bottom line of a number of companies, both as new systems and in the replacement market. While there are fewer types of new ion lasers available now, these systems still vary considerably in performance, size, utility requirements, and cost.

An ion-laser system consists of a power supply, control electronics, and the laser head. The laser head itself contains the plasma tube placed within a resonator (or *cavity*) structure. Control of the laser is typically through an interface included in the power supply, which itself can vary considerably in size, complexity, and cooling requirements.

Small ion lasers are air cooled, require only standard wall-plug electrical service, have a laser head roughly the size of a toaster, and are most commonly used to produce only a single blue–green output at 488 nm in the range 5–100 mW. When operated in the low-current range, these lasers can be expected to last for years in a stable environment. Tube replacement when necessary can be performed by the user and is relatively quick and inexpensive.

The greatest variety of product offerings is in the mid-range of performance of 1–5 W of laser output. These systems range from simpler models based on the original ion technology, with air cooling and ceramic plasma tubes, to specialized systems with single-wavelength output intended for specific industrial applications, to only slightly smaller versions of the sophisticated large-frame systems used in advanced laboratories.

A high-performance ion system has a laser head about a meter and half long and can weigh 100 kg. It may require 70 A per phase of three-phase electrical service at 480 V and in addition a cooling-water flow of several liters per minute. But in compensation, these lasers are capable of producing many watts of continuous laser power in a range of selectable wavelengths not available from any other commercial laser system.

Wavelengths available from ion lasers extend from the infrared well into the ultraviolet, with argon, the most common type of ion laser, emitting light primarily in the blue–green to ultraviolet range [11.1447, 1448]. Specific wavelength output is determined either by the choice of the coating for the laser output mirror, or by tuning to the desired wavelength using a Littrow prism placed in the laser resonator. The section below discussing the laser resonator will further describe control of the spectral characteristics of the ion-laser output.

Krypton is not nearly as popular an ion laser as argon, in part because of its lower power, but it remains commercially viable because, like argon, it offers significant levels of continuous output power at wavelengths not easily achieved by other means. For example, more than 1 W CW is available from a single line in the yellow, a color region where laser sources are scarce, and lines in the violet and ultraviolet have important applications as well.

The output power of an ion laser depends on two sets of variables. One set derives from the design of the laser resonator, and includes, for example, the cross-sectional area of the laser beam. This set of variables will be discussed in the section which describes the resonator. The other set of variables that determines laser power results from the physics of the laser process in the plasma created from the noble gas. These variables include the total light amplification available from the plasma.

11.5.1 Ion–Laser Physics

An energy-level diagram is used to show the wavelengths available from a laser material that has been excited into a condition of population inversion. A simplified version illustrating the transitions in singly ionized argon that produce visible laser light is shown in Fig. 11.140 [11.1449]. The transitions shown result from energetic electrons that have decayed to the 4p upper laser level from a still higher level not shown in the figure. From the upper laser level, the electrons are stimulated to fall into the 4s states. The most important individual transitions, which result in the highest output
Fig. 11.140 The visible laser transitions of ionized argon (wavelengths in nanometers)

power, are those for 488.0 nm, a blue–green color, and 514.5 nm in the green.

Having many upper laser levels transitioning to only two lower levels raises the possibility of competition for the lower states, which can limit laser output. In the case of argon, however, the lower states depopulate to the ground state very rapidly, avoiding this potential bottleneck. The lifetime of an electron in one of the upper 4p states is about 10 ns, while the lower 4s states make their transition to the ground state in a favorable 0.5 ns. With a proper choice of mirror coating, *all-lines* visible operation can produce laser power from most of these visible lines simultaneously, and the power present in any one of the lines will not be much less than that obtained from single-line operation.

An energy-level diagram can also illustrate problems or requirements in the design of a specific laser system. Figure 11.141 shows the 4p and 4s laser levels of ionized singly argon in relation to the argon ground state. The energy needed to ionize the argon to start the population inversion is about 16 eV, and an additional 20 eV is required to reach the states that decay to the upper laser level. Comparing this total energy input of 36 eV to the energy emitted by the laser transition itself, about 2 eV, it is evident that the efficiency of an argon ion laser will be low. In addition, the temperature of the gas discharge needed to produce electrons with sufficient kinetic energy to achieve the required level of ionization is in the vicinity of 3000 K. This, combined with the low efficiency, indicates that heat management is a primary concern in ion-laser design [11.1450].

Ion lasers use an electric discharge to energize the gas. As can be seen in Fig. 11.141, two collisions with free electrons are required to excite an electron in an
Fig. 11.141 The two-step ion-laser excitation. One electron collision ionizes neutral argon and a second pumps the ion to an excited state from which it decays to the upper laser level

argon ion to the upper level of visible lasing transitions. The gain available from the ionized gas therefore varies as the square of the current density, up to the point where the gain saturates (i. e., other gas-phase processes begin to limit the gain) [11.1451].

The optimum gas pressure that produces the maximum laser output is a balance between competing factors. High pressure provides a greater number of potential ions to stimulate laser emission, while low pressure allows the voltage drop along the plasma more time to accelerate the free electrons to a greater energy between collisions. Different wavelengths have different optimum pressures, and the final choice for a laser designed to operate at multiple wavelengths is a compromise. In general the optimum is in the low-pressure regime. Argon plasma tubes have a fill pressure on the order of 1 Torr [11.1452].

Performance is improved by a magnetic field directed along the length of the plasma discharge, which helps confine the discharge towards the center of the plasma tube [11.1450]. The benefit is greatest for lasers operating at high current. Again, different wavelengths have different optima, and a compromise value of magnetic field strength is employed. Air-cooled lasers typically do not use magnets, as the benefit of a magnetic field for low powers does not justify the added expense,

and the addition of magnets would complicate the flow of cooling air.

If the argon is doubly ionized (i. e., stripped of two electrons), a new set of transitions become available that produce ultraviolet laser light [11.1453]. The ground state of Ar^{2+} is about 43 eV above that of the neutral atom, compared to the Ar^+ ground-state difference of 16 eV mentioned, so operating in the ultraviolet can be expected to be even less efficient. Once above a higher threshold current, UV output rises more rapidly than the visible output does.

The energy diagram for krypton is similar to that for argon, with laser transitions shifted to somewhat lower photon energies in the visible from the upper 5p to the lower 5s bands [11.1454]. Important lines are at 647.1 nm in the red, corresponding to the green 514.5 nm argon line, and at 568.2 nm in the yellow, corresponding to the blue–green line at 488 nm in argon. Unlike argon, however, in krypton these strong lines do experience competition for the same lower state, and so all-lines operation in krypton does not produce the power that might be expected judging from single-line output.

Argon and krypton can be mixed together in the same laser tube to produce a laser offering a dazzling variety of visible wavelengths. A compromise must be reached in the parameters such as fill pressure and magnetic field that allows for the differences in the optimization for each type of laser. Such a mixed-gas laser using broadband mirror coatings has even been used to produce a *white-light* laser, but the argon–krypton mixture becomes unbalanced fairly quickly due to the difference in gas sputtering rates, and the white-light balance is lost as the component wavelengths change in relative strength of output.

11.5.2 Plasma Tube Design

The heart of the ion laser is the plasma tube, which amplifies laser wavelengths available from a low-pressure noble gas by confining a high-current discharge within a narrow bore. The demands placed on the tube structure are extreme, resulting from the need to confine and sustain a discharge as high as 70 A for hours at a time. The bore of the tube must withstand the bombardment of high-energy ions (sputtering) and the heat from the discharge, which can exceed 50 kW under some operating conditions. This heat must be efficiently removed from the tube or tube components will melt or rupture.

Early tube designs relied on cylinders of the ceramic beryllia, or BeO, about 1–2 cm in diameter with a centrally drilled hole of about 1 mm to form the bore. Beryllia cylinders about 10 to 15 cm long are still in use today in lower-power ion lasers, particularly for air-cooled argon. Figure 11.142 shows a cross section of an air-cooled plasma tube. However beryllia proved incapable of sufficiently withstanding the sputtering from the plasmas of high-power or ultraviolet ion lasers, and alternative designs were sought.

Years of intensive research and development have resulted in sophisticated designs for high-current tubes that replace beryllia with a tube structured of composite materials [11.1452, 1455]. These complex (and more expensive) designs can withstand high current densities for an extended period, thus making practical the operation of ion lasers at higher powers or less-efficient
Fig. 11.142 Design of an air-cooled plasma tube
Fig. 11.143 Design of a water-cooled plasma tube

wavelengths. The description that follows is based on the segmented-bore technology used by Spectra-Physics in the manufacture of its water-cooled ion lasers. The overall design is illustrated in Fig. 11.143.

The exterior of the plasma tube is a long, hollow thin-walled ceramic pipe or sleeve a few centimeters in diameter. Inside this sleeve, spaced about one centimeter apart, are many thin discs brazed to the interior of the ceramic. The discs are copper with a central tungsten ring with a hole a few millimeters in diameter. The bore of the plasma tube is defined by the diameter of the hole in the tungsten segments (Fig. 11.144).

The tungsten bore segments are extremely resistant to sputtering action and can withstand the high temperatures of the discharge. The copper discs to which they are bonded conduct the heat of the discharge from the tungsten to the thin ceramic wall of the exterior sleeve, which is bathed outside by a cooling water flow of several liters per minute. The flow of this cooling water is designed to prevent local thermal stresses affecting the tube.

The plasma tube must ensure uniform gas pressure along the length of the bore. In arc discharges in low-pressure gases, the ions lose their momentum in frequent collisions with the tube walls. In contrast, the electrons lose little momentum, so an imbalance is created in the net momentum in the gas. As a result, the neutral gas atoms are driven to the anode end of the plasma tube. To equalize the gas pressure along the length of the tube, holes in the copper discs provide a return path to the cathode end, which also allows the copper discs to help cool the gas in the return flow.

The design of the bore where it opens to the cathode, the so-called *throat* region, is critically important to achieve good laser lifetime. Damage to the bore from sputtering is maximum in the throat. The diameter of the bore segments (or, in lower-power tubes, the conically shaped opening drilled in the beryllia to form the throat) is tapered to match the contour of the electrical field as it enters the bore.

The design of the cathode element itself is also critical. The cathode is helical and is made from a spongy material formed of tungsten powder. It may also include some admixture of calcium, aluminum, barium, and strontium. These additives reduce the work function of the cathode surface so that the temperature needed to produce electron emission is reduced [11.1455].

The efficiency of laser amplification is a function of the gas pressure in the discharge. However ionic sputtering not only erodes the tube materials, but also over time embeds a significant amount of gas in the tube walls and components. Low-power lasers compensate for this effect by widening the body of the plasma tube to form a reservoir, so that the gas lost from sputtering action is a small fraction of the total volume in the tube. Mid- and high-power designs incorporate an active fill system to replenish the gas as it is lost.

To determine when the gas must be replenished, a microprocessor compares the operating voltage of the laser to values stored in a look-up table, taking into account the current, magnetic field and warm-up time. When the voltage indicates that the tube pressure is low, a high-pressure reservoir automatically injects a small quantity of gas into a plenum. A separate valve then

Magnet
Water
Ceramic envelop
Copper heat web
Tungsten disk
Bore
Fig. 11.144 Segmented bore design

opens to allow the plenum to add a precise quantity of gas to the plasma tube. Since this fill process briefly disturbs laser operation, the fill system may be manually disabled for short periods to ensure that critical experiments are not effected.

For air-cooled lasers, which do not employ a magnetic field, copper cooling fins are brazed onto the exterior of the beryllia cylinder that forms the plasma tube. Cooling air is forced over the fins at a rate of a few hundred cubic feet per minute (about $10\,m^3$ per minute). Care must be taken that heat removal is evenly distributed so that the tube does not warp and move the laser beam (the laser output mirror is attached directly to the tube), and the air flow should not induce vibrations in the fins which might translate into motion of the beam.

For larger lasers, the entire plasma tube is encased in a large electromagnet which also forms the confining wall for the water flowing next to the tube. The field chosen for the magnet depends on the diameter of the bore and the details of how the laser is operated, but is usually in the neighborhood of 1000 G. The magnetic field is particularly important for ultraviolet output, which requires stronger magnetic fields for optimum performance.

The ends of the plasma tube are sealed with optics that allow the laser light to exit the tube. These optics are either laser mirrors with dielectric coatings, used in essentially all low-power and some mid-power lasers, or quartz windows oriented at Brewster's angle. Tubes are constructed with Brewster windows to polarize their output, generally oriented vertically. Mirror-sealed tubes will have an internal optic to achieve polarization.

The light emitted from the discharge of high-current tubes poses a challenge for optics. The transitions from the lower laser levels back to the ground state of neutral argon shown in Fig. 11.141 emits a highly energetic photon around 80 nm. This vacuum UV radiation is very deleterious to optical materials. The coatings on the mirrors that seal low-power and some mid-power tubes are made of many alternating layers of dielectric materials, such as silica and alumina, that are capable of withstanding this radiation. Brewster windows used to seal mid-power lasers are typically made of fused silica.

The levels of the vacuum ultraviolet of high-current discharges present a greater problem for the Brewster window seals of these tubes [11.1456, 1457]. Fused silica cannot be used because, when exposed to these radiation levels, it forms color-center defects which then absorb even more radiation in a runaway effect that will degrade laser action. To meet the challenge of sealing high-current plasma tubes, manufacturers use crystalline quartz, carefully cut and oriented on the tube so that the crystalline axis of the two windows on each end of the tube are in alignment.

11.5.3 Ion−Laser Resonators

To complete the ion-laser structure, the plasma tube must be placed between suitable mirrors that provide light feedback for amplification by the discharge. These mirrors are a high reflector at one end of the laser, and a partial transmitter or output coupler that allows a portion of the circulating light to exit the laser. These mirrors, together with the structure that holds them in position, form the laser resonator [11.1458]. For small ion lasers and some mid-frame systems, this resonator structure is very simple: the mirrors are bonded onto the plasma tube itself.

Air-cooled ion lasers sacrifice flexibility for simplicity. Except for the power level, their output characteristics cannot be changed. A mirror position is fixed at manufacture by the plastic deformation of the thin metal tube to which the mirror is bonded. The output wavelength, mode structure of the beam, and so on
Fig. 11.145 Open resonator design

remain fixed. For many applications this is acceptable, even desirable, but other applications benefit greatly by retaining the flexibility of output that is a hallmark of the ion laser.

The external or open resonator commonly employed with mid- and large-frame systems retains this flexibility. This design requires the use of Brewster-window seals for the plasma tube, as discussed in the preceding section. The resonator mirrors are held in place by a rigid structure that frames the plasma tube (hence the use of *mid-frame* or *large frame* as an indication of laser size). While it outwardly appears simple, the design of the resonator is critical to the performance of the laser.

The resonator frame, as shown in Fig. 11.145, must keep the mirrors aligned to each other and pointing through the laser bore within a very tight tolerance over the entire range of operating and environmental conditions. The choice of materials affects the stability of the resonator. The ideal material has both a low thermal expansion coefficient and a high ability to distribute heat evenly. Graphite and low-expansion compounds such as iron–nickel alloys are typically used for the long rods that form the length of the frame.

Stability also depends on the rigidity of the resonator. Jitter impressed on the laser output due to the microphonic movement of the mirrors can be caused by cooling-water flow, vibration of the resonator structure, and acoustic noise. Isolation of the resonator from both the plasma tube, the magnet, and the cover of the laser head helps reduce jitter.

The mechanical design of the structure is also critical to stability. The most stable configuration is an arrangement of three resonator rods in an equilateral triangle. As a practical matter, this ideal structure does not leave sufficient room for the plasma tube and magnet. As one of the angles of the resonator triangle increases, the resistance to flexure is reduced. The closer the design can be to the ideal equilateral triangle, the better will be the

mechanical stability provided for stable power and beam pointing [11.1459].

A significant advantage that modern large-frame lasers have over their forerunners is the use of active mirror positioning. The output coupler is mounted on three-point piezoelectric positioner that provides small corrections to the mirror alignment in response to changes in laser output power, most commonly experienced when the laser is warming up. This active resonator also allows for a more aggressive optical design to extract power from the plasma tube.

With active mirror positioning, the cross-sectional area of the beam, and therefore the volume of the plasma discharge used to provide laser amplification, can be increased by enlarging the bore and using a longer-radius output coupler (Fig. 11.146). This is especially beneficial for wavelengths with lower gain. However active control alone cannot provide all of the stability required by this design: the use of long-radius optics requires an extremely rigid resonator structure.

The open resonator allows the user to employ different mirrors to obtain different wavelength output. To obtain *all-lines* argon-ion output in the visible, for example, mirrors are used with coatings that reflect over about 70 nm in the blue and green. A prism on a rotatable mount placed before the high reflector allows the laser to be tuned to single-line output throughout the all-lines range. (The dispersion of the prism directs only one wavelength at a time to the high reflector.) A similar arrangement using different optics enables the same operation for all-lines ultraviolet output.

The open resonator also allows the spatial mode of the beam to be controlled. An adjustable aperture placed between the Brewster window and the output coupler, where the beam is large, provides a variable amount of loss to the edges of the beam while it is inside the resonator. The aperture, when opened to allow the highest power output, will permit a number of transverse modes, or if reduced will result in TEM_{00} mode operation. An aperture diameter between 1.5 and 2 times the TEM_{00} mode diameter is used to achieve this [11.1460].

The spectral content of the laser output may also be changed by insertion of an etalon into the laser resonator. An etalon is a thin optical cavity, such as a plate of glass. When inserted into the resonator, the internal reflections from its surfaces act to narrow the frequency content of the laser output, its *line width*. The resonator produces standing waves of light between its mirrors, called longitudinal modes, many of which have frequencies that fall within the bandwidth of the laser amplifier. The etalon acts as a bandpass filter that introduces variable loss and
Fig. 11.146 Active mirror positioning allows resonators to extract more power from the discharge

Spherical output coupler · Additional mode volume · Flat high reflector · Plasma tube bore · Short center of curvature · Long center of curvature
Fig. 11.147 Using an etalon to narrow the spectrum of the laser output

favors oscillation on only one of the longitudinal modes (Fig. 11.147).

Active mirror positioning may also be used to stabilize the line width further, resulting in an even narrower spectral output. The coherence length – the distance over which the output beam maintains a fixed phase relationship – is inversely proportional to the line width. When the laser output is changed from single line to single frequency, the coherence length increases from about 50 mm to 20 m.

A drawback of the open resonator is that the space between the mirrors and the Brewster windows is not vacuum-sealed. Laser performance strongly depends on keeping these optical surfaces clean. In addition, the vacuum UV light from the arc discharge, transmitted by the Brewster windows, converts oxygen to ozone, which is deleterious to the laser optics. This intracavity space must be sealed and its atmosphere controlled to maintain cleanliness and avoid optical damage. Lasers producing short-wavelength UV may employ a nitrogen purge to avoid ozone production. Longer-wavelength lasers can use a simpler technique of placing a catalyst in the enclosed space that converts ozone back into oxygen.

11.5.4 Electronics

A variety of electronic subsystems are required to operate an ion laser, as shown in the block diagram of a large-frame system in Fig. 11.148. Typically packaged in the laser head along with the plasma tube are the start circuit and the light pick-off. Lasers that are not sold as OEM components for a larger system are required to have an interlock switch that will reliably terminate laser operation if the head cover is opened. For water-cooled lasers, the laser head will usually also contain the flow- and temperature-control circuits for the cooling water, and the fill circuitry to monitor and replenish the gas in the plasma tube.

The start circuit provides a high-voltage spark to initiate the discharge. Typically, a pulse of several kV is injected in series with the tube by a pulse transformer or a spark-gap circuit. The light pick-off is the sensor for the feedback loop that measures and regulates the laser output power, and usually consists of a beam splitter with a silicon photodetector. Since an ion laser may be capable of producing a wide spectrum of wavelengths over a considerable range of powers, multiple preamplifier ranges are usually used in the feedback loop, as well as wavelength sensitivity correction color filters or electronic gain modification.

The power supply that drives the plasma tube is almost always packaged as a separate unit. This is because the supply itself is roughly the same volume as the laser head, and separating it from the laser allows much greater flexibility in positioning the laser system. The drive current for the plasma tube is delivered to the laser head through a robust umbilical. Since the power supply also serves as the control interface for the laser, cables

that carry monitoring and control signals are typically bundled in the umbilical as well.

Ion-laser power supplies show the same range of variation in size and design as the laser heads. The power supplies of small air-cooled argon units can be as small about 15 cm on a side, while supplies that drive large-frame systems are roughly 0.7 m on a side and weigh almost 100 kg. These larger units may require cooling water. Table 11.43 displays typical service requirements and loads for the three main classes of ion lasers.

The electrical characteristics of the arc discharge are such that it essentially requires a constant-current supply in order to be sustained [11.1458]. The heart of an ion-laser power supply is the plasma current regulator.

Table 11.43 Power supply characteristics of typical ion-laser systems

Ion-laser type	Maximum laser power	Electrical input	Plasma discharge	Discharge power requirement
Air-cooled	20 mW	115 V_{AC} single phase	90 V 8 A	0.7 kW
Small frame	5 W	208 V_{AC} three phase	240 V 55 A	13 kW
Large frame	25 W	480 V_{AC} three phase	550 V 65 A	36 kW

The plasma current needs to be well regulated in order to prevent line ripple and other variations from being impressed on the laser output. The plasma current may be regulated by a linear transistor passbank, or more efficiently by various switching-type power supplies.

In the patented regulator used by Spectra-Physics, a switched resistor regulator consisting of a pulse-width modulator (PWM) controlling a switch transistor is connected to a low-impedance high-power water-cooled resistor. This resistor is connected to the plasma load. The PWM varies the percent of the time that the transistor is turned on and the resistor is conducting current. A parallel capacitor provides a current path to the load when the transistor is off. This regulator looks like a variable resistor that can vary from infinity down to the minimum resistance of the circuit. A shunt regulator is used to provide ripple rejection and high-speed small-signal regulation.

The power supply must power the electromagnet when an axial magnetic field is employed. The electromagnet requires about 10–25% of the power supplied to the arc discharge. Thus a large-frame supply is really two supplies: a 36 kW plasma supply and a regulated 8 kW magnet supply. The power supply must also provide power to heat the tungsten cathode in the plasma tube. Typically a filament transformer provides 15–25 A at about 4 V_{AC} for this purpose.

11.5.5 Ion–Laser Applications

The operator interface to control power and the basic on/off function is through the power supply. In inexpensive models of air-cooled systems, the control interface typically consists of hand-wired knobs and switches on the front panel of the supply. The next step in sophistication is a hand-held system controller with a visual display that attaches to the power supply with a long flexible cable. Upon turn-on, all functions of the laser can be accessed from the system controller. High-end models offer a fully functioning computer interface for automated remote operation and monitoring of the laser.

Ion lasers operate in either current mode or power mode (also called light mode). Current mode holds the plasma discharge current at a fixed value and allows the laser output to vary. Power mode, a much more common method of operating the laser, adjusts the plasma current as necessary to match the output power to a user-requested value. When the current can no longer be increased to achieve the power set-point, it may be time to replace the plasma tube.

Like many modern laser systems, most ion lasers are designed for hands-free operation. Air-cooled argon systems in particular are intended to provide a constant laser source available from a simple flip of a switch. Large-frame systems in laboratory applications in contrast trade on the flexibility they provide the user.

Small air-cooled systems continue to be economical and reliable sources of coherent, polarized. TEM_{00} blue–green laser light. They are usually operated at a power significantly derated from their maximum, which can extend their useful lifetime for years. Biological and medical applications for these lasers include cell sorting. Desoxyribonucleic acid (DNA) sequencing, bacterial analysis, confocal microscopy, and hematology. Many of the dyes used in these applications were originally developed for argon-laser wavelengths.

These lasers are also used in many applications related to producing text and images. The blue beam is valuable for exposing printing plates for high-speed printing, and to provide the color separation required for full-color printing. Similar applications are found in photoprocessing and other photographic sources.

Mid-frame systems are used in many of the same applications as lower-power lasers. In addition, they are used in entertainment, especially for laser light shows, and have laboratory applications in Raman spectroscopy or as a pump sources for tunable laser systems such as a Ti:sapphire. In ophthalmology, the beam can be focused on the retina to repair diabetes – induced retinal detachment, for instance.

The deep-blue and UV outputs of ion lasers have been used in the semiconductor industry for wafer inspection and lithography. The ability of the output to expose photoresist is also used in producing masters for compact discs, which then serve as the molds in the injection-molding manufacture of high-volume CD production.

11.6 The HeNe Laser

The HeNe laser is an electrically pumped continuously emitting gas laser. Its basic principle is a gas discharge in a glass tube filled with a mixture of helium and neon under low pressure. The gas discharge is set up by a cathode and an anode placed at opposite sides of the glass tube. The laser mirrors are usually fixed to the end of the tubes.

The HeNe laser was one of the first lasers to be realized. It was developed in 1960 as the first laser emitting light continuously [11.1461]. However, this was not the well-known bright red line (632.8 nm) that has been discovered, the first laser emitted light at 1.15 μm, which is one of the strongest lines of the HeNe laser. Red laser emission was achieved shortly after, in 1962 [11.1462]. Though other possible transitions delivering light in the visible had been found theoretically, it took a certain time to demonstrate this practically. Improvements in resonator design and the performance of the mirrors had to be achieved. Especially the well-known 543.3 nm line, with its low gain, needed several attempts by researchers until it was demonstrated for the first time in 1970 [11.1463].

Shortly after its first demonstration, the HeNe laser found more and more applications and became the most common laser worldwide with millions of units sold, until laser diodes appeared on the market. More than 40 years after its first appearance the HeNe laser is still of great importance in the worldwide laser market. Around 44 000 units were sold in 2005 [11.1464].

The HeNe laser has been used for adjusting and positioning but also, because of its excellent optical properties, in interferometers, sensors or spectrometers. It was applied in the first scanner tills and even the first CD players were equipped with HeNe lasers. Although these applications have been taken over completely by diode lasers, HeNe lasers still find their use in many fields of analytics, instrumentation, sensor technology, science and education.

Its advantages are excellent beam quality, long lifetime and an unbeatable price–performance ratio. Because of the mature technology and the still large sales numbers manufacturing costs have decreased continuously. Against the trend for shorter product lifetime the HeNe laser has asserted itself for 40 years and is still a competitive product. Many OEM manufactures still choose the HeNe laser for there new products, irrespective of the competition from diode lasers and solid-state lasers. Considering especially the laser diodes we see that, in fact, the diode itself is a rather cheap compo-

nent. To achieve a beam quality comparable to the HeNe laser, however, requires considerable effort and additional cost, which compensates for the higher costs of a HeNe laser. For example, the strongly elliptical beam of the diode has to be made circular and, in order to avoid wavelength drift, temperature stabilization has to be provided. Another advantage is the longer coherence length of a HeNe laser compared to that of standard diodes.

Further advantages of the HeNe laser are:

- Excellent mode purity, typical $> 95\%$ Gaussian TEM_{00}
- A favorable relation between resonator length and resonator width (diameter)
- A nearly diffraction-limited beam
- High beam-pointing stability
- High reproducibility in manufacturing

11.6.1 The Active Medium

Energy–Level Diagram

The most detailed energy-level diagram which we could find in the literature is given in [11.1465]. Nowadays, however, the green and yellow laser lines are of much more importance than the infrared ones, so it was necessary to add these new visible lines to the diagram. It can be seen that neutral helium is excited by electron collisions and transfers its energy by nearly resonant inelastic atomic collisions to the excited states of neon. This means that the lasing atom is the neon, helium is only necessary for energy transfer from the gas discharge to the upper neon levels. The energy transfer from the lower laser levels 3p and 2p ends at the 1s level due to spontaneous emission and the 1s level is depopulated by wall collisions to the ground state of neon. For this reason it is necessary to have a small-diameter discharge tube, in order to secure a quick emptying of the 1s level. It should be mentioned that the rare ^{3}He isotope is used and not ^{4}He. The reason is that the lighter ^{3}He isotope has a higher velocity difference to neon, resulting in better energy transfer to the upper laser levels [11.1466] and consequently a higher gain and output power (about 25% better at 633 nm).

It is known that electron collisions and stimulated absorption of visible light can cause transitions from the 1s to the 2p level, resulting in a higher lifetime of this lower laser level (2p). This leads to a higher inversion for the 3.39 μm laser line as for the other lines, since it has the 3p level as the lower laser level.

Table 11.44 Typical laser transitions

Wavelength (in air) (nm)	Transition	Gain (m^{-1})	Typical power (mW)
543.3	$3s_2-2p_{10}$	0.03	0.5–3.0
594.1	$3s_2-2p_8$		2.0
611.8	$3s_2-2p_6$	0.1	2.0
632.8	$3s_2-2p_4$	0.5	0.5–50
640.2	$3s_2-2p_2$		
1152.3	$2s_2-2p_4$		2.0
1523.1	$2s_2-2p_1$	4	1
3391.3	$3s_2-3p_4$	100	10

Table 11.44 lists the commercially available laser lines and some typical parameters. The gain [11.1465, 1467] depends strongly on the inversion and the noted values should only give an impression of how the gain changes with wavelength ($g_0 \sim \nu_0^{-3}$). This illustrates that the most difficult laser to build is the green one (543.3 nm).

Another difficulty in making a green laser is that, within each group of energy levels (2s, 3s, 2p, 3p, and so on), the energy distribution of the sublevels (e.g., $2p_1$ to $2p_{10}$) is determined by thermic Ne–Ne collisions, resulting in a Boltzmann distribution, which means that the population rises with falling energy. Thus, the lower laser level for the 543.3 nm line ($2p_{10}$) has a much higher population as the $2p_4$ level for the red line. In order to achieve population inversion for this laser line it is necessary to reduce the number of Ne–Ne collisions by reducing the neon pressure. The consequence is a lower output power at this line and a lower lifetime for green lasers (about 10 000 h) compared to red lasers (> 20 000 h).

Table 11.44 lists only the most important laser lines. A good compilation of laser lines at different elements is given in [11.213], which also contains references to the original literature. Sometimes in an experiment one may have unwanted light from scattering from the discharge tube itself (not laser light). Such discharge lines can be found in [11.1468].

Gas Discharge

The gas discharge is the most important process in the laser, since it has to transform the electrical energy of the power supply into the laser light. This process determines the laser power, power stability, optical noise and lifetime of the laser. Hence, the key know-how of a laser manufacturer is not the resonator design but how to optimize the discharge.
Fig. 11.149 Energy-level diagram of the HeNe laser

As shown in Fig. 11.149 the HeNe laser tube is filled with a helium–neon gas mixture, having a total pressure of about 4–7 mbar and a neon content of about 10%. The operating DC current is in the range of 3.5–11 mA and the corresponding tube voltage is about 1–5 kV. This is a cold-cathode glow discharge, where the active laser medium is formed by the positive column of the discharge, which is located in a capillary of diameters of 0.5–2 mm. Since such a glow discharge has a decreasing voltage–current characteristic curve (see Fig. 11.151),
Fig. 11.150 Electrical scheme of the laser
Fig. 11.151 Characteristic voltage–current curve of a HeNe laser

a ballast resistor R of about $60-100\,\mathrm{k}\Omega$ is used to bring the whole system to an increasing voltage–current curve.

In Fig. 11.151 the black curve shows the electrical behavior of the discharge tube and the brown line the corresponding ballast resistor. After switching on the laser, the power supply has to raise voltage to the ignition point ($U_I \approx 10\,\mathrm{kV}$). After the ignition, the power supply switches to its normal fixed-current operating mode. The corresponding voltage is determined by the crossing point of the discharge curve and the resistor line (voltage at the tube U_T). It is important to choose the resistor in such a way that only one crossing point exists.

Whereas in the tube design a small metal anode is used, the cathode is considerably larger, and is mostly made of aluminium because the cathode has to deliver the electrons for the discharge and to transfer the heat of the cathode fall, the region where the electrons are accelerated from zero to the colliding velocity, outside the laser tube. The capability of the cathode to emit elec-

trons depends on the properties of the cathode surface. Normally the current density at the cathode surface is constant, so the cathode surface must be large enough for the applied operating current, otherwise sputtering occurs and the tube is quickly damaged. The typical cathode size is in the range of some $10\,\mathrm{cm}^2$. In order to avoid sputtering, at the surface a nanometer-scale layer of Al_2O_3 is formed. Normally this oxide layer withstands sputtering for some $10\,000\,\mathrm{h}$. If this layer is destroyed, the laser fails within a few hundred hours.

11.6.2 Construction and Design Principles

Construction of a HeNe Laser

Figure 11.152 shows a cross-sectional view of a modern HeNe laser. The principal setup is very similar for all major manufactures of HeNe lasers and differs in details only. The laser tube consists of a glass tube (8) which is melted at both ends to metal end caps (3, 10). To these end caps the laser mirrors (1, 12) are connected using a metal–glass soldering technique. These metal–glass connections provide long-term vacuum sealing of the laser tube. Inside the laser tube the cathode (6) and the gas discharge capillary (7) are located. The glass of the capillary is melted to the glass of the outer tube (8), so the discharge is concentrated inside this capillary. If the mirror (1) is a flat mirror and mirror (12) is concave, the end of the capillary (9) acts as a mode field aperture. If linear polarized laser radiation is required, a Brewster window (2) is placed inside the laser. A favorable position for this window is near the flat mirror, because at this position the beam diameter is the smallest in the tube and there is no angular displacement between the laser beam and the window (the beam is always perpendicular to the mirror surface). The tube is evacuated and filled using the pipe (4), which is sealed after filling the tube by means of a cold soldering process. The spring (13) centers the capillary end. At the mirror holders (3, 10)
Fig. 11.152 Sectional view of a HeNe laser tube (LASOS Lasertechnik GmbH), see text for explanation

a region of reduced material thickness is formed (5, 11). This is used for the alignment of the mirrors by means of plastic deformation of the metal.

The setup according to Fig. 11.152 represents the basic design of commercial laser tubes up to about 25 mW output power which has been used for about three decades with minor changes only. It provides long-term gas stability, clean optics over the whole lifetime of the laser and a long lifetime of the laser.

In contrast to the present design, early HeNe lasers were not sealed by the mirrors but by a Brewster window at each end. Thus, they used an external resonator, mostly made of mirrors hold on invar rods. This older design is used today only in high-power HeNe lasers (> 35 mW), because such lasers need a very long cavity (> 1 m). Here, the external resonator allows a better stability of the mirror alignment, and the capillary (which suffers from bending due to their own weight) can be aligned too.

Resonator Design

The design goal of a HeNe resonator is mainly to achieve a Gaussian beam profile. The calculation of all beam parameters can be easily done by means of the *ABCD* matrix formalism [11.1469]. In this case, every optical element in the laser is described by a matrix, as described below.

The matrix of a mirror with curvature *r*

$$M = \begin{pmatrix} 1 & 0 \\ -2/r & 1 \end{pmatrix} . \tag{11.143}$$

The matrix for the free-space propagation of distance *s*

$$S = \begin{pmatrix} 1 & s \\ 0 & 1 \end{pmatrix} . \tag{11.144}$$

Starting at the output mirror all single matrices for every element are multiplied for one complete round-trip (RT), resulting in the following calculation:

$$RT = S\, M_2\, S\, M_1 = \begin{pmatrix} A & B \\ C & D \end{pmatrix} . \tag{11.145}$$

In a last step, the $1/\mathrm{e}^2$ beam radius (w) and the wavefront curvature (R) are calculated from this matrix:

The beam radius at the output mirror is

$$w = \sqrt{\frac{\lambda}{\pi} \frac{2|B|}{\sqrt{4 - (A+D)^2}}} . \tag{11.146}$$

Fig. 11.153 Laser tube with fixed mirrors (LASOS Lasertechnik GmbH)

The wave-front curvature at the output mirror is

$$R = \frac{2B}{D - A} . \tag{11.147}$$

Using the well-known formalism for Gaussian beam propagation, the beam diameter can be calculated at any desired position.

The complex parameter q is defined as:

$$\frac{1}{q} = \frac{1}{R} - \mathrm{i}\frac{\lambda}{\pi w^2} . \tag{11.148}$$
Fig. 11.154 35 mW laser tube with external resonator (LASOS Lasertechnik GmbH)

The propagation of a Gaussian beam through an optical system described by the *ABCD* matrix yields

$$q_{\text{out}} = \frac{A q_{\text{in}} + B}{C q_{\text{in}} + D} \ . \tag{11.149}$$

The beam diameter at the position of the mode field aperture is important for the laser design (Fig. 11.155). The ratio between this aperture and the beam diameter has to be chosen in such a wa, that the losses for the TEM_{00} mode are low but high enough for the first higher-order transversal modes, e.g., TEM_{01}, in order to suppress the higher modes. This ratio depends on the laser gain and can be calculated theoretically. The practical experience for a common 633 nm laser leads to a ratio between the aperture diameter and beam radius of about 3.5 : 1. For high-power HeNe lasers, this value must be reduced, whereas for the low-gain 543 nm laser it has to be increased.

In practical designs the above formalism is used to balance the resonator design between the beam diameter, required by the application (the beam waist is normally located at the surface of the output mirror), and the laser power, which determines the laser length on one hand, and the available mirror curvatures as well the available aperture diameters and aperture positions on the other.

Scaling Relations

Scaling relations are very useful for the practical design of new lasers. The most important scaling relations are described below. Firstly, the laser power P, which is proportional to the discharge length l (capillary):

$$\frac{P}{l} = \text{const.} \tag{11.150}$$

For this reason, today HeNe lasers with a power above 25 mW are very rare. These lasers are very long (> 1 m) and need sensitive and expensive external resonators. Thus, in this power region the costs for beam shaping of laser diodes (aspheric lens systems with prisms, cylindrical lenses and/or zoom telescopes) are comparable or lower than for a HeNe laser and the mechanical di-
Fig. 11.155 Principle setup of a HeNe resonator with rear and output mirror and a mode-field aperture

mensions of the diode-lasers systems are much smaller (about 15 cm).

The product of the pressure p and capillary diameter d is constant:

$$pd = \text{const.} \tag{11.151}$$

Following this equation, two systems with the same pd product have comparable discharge properties and the excitation of the upper laser levels is comparable in both cases if the same current is applied. This rule is very useful if a well-running laser must be customized in order to get more power or different beam diameter. If the new capillary diameter has been estimated using the formalism of Sect. 11.6.2 then the corresponding gas pressure for this new design can be calculated by means of (11.151).

The current–density scaling relation is less important because there is only a weak dependence on capillary diameter

$$j \sqrt[4]{d} = \text{const.} \tag{11.152}$$

The scaling of the small signal gain g_0 with capillary diameter d

$$g_0 d = \text{const.} \tag{11.153}$$

Equation (11.153) shows that a small capillary diameter d should be achieved in the design process because, with higher gain, losses can be higher too and it is possible to come closer to the theoretical maximum power.

Additionally two electrical relations [11.1470] should be noted: the current density j_K at the cathode

$$\frac{j_K}{p^2} = \text{const.} \tag{11.154}$$

and the ignition voltage U_I

$$U_I = f\left(\frac{pl}{T}\right) \ . \tag{11.155}$$

Equation (11.154) has the consequence that low-pressure laser tubes, like versions for 543 nm, need larger cathodes. Equation (11.155) shows that the voltage necessary to ignite the laser increases with pressure and length and decreases with temperature T.

Laser Line Selection

Today, the HeNe laser has been replaced in the infrared range by laser diodes, but its visible lines, especially those at 632.8 nm, 594.1 nm and 543.3 nm, are widely used in scientific applications such as laser scanning microscopy. Because of this fact, we will only consider

the visible range. Except for some educational lasers, all modern HeNe lasers operate at one wavelength only. The reason is that it is only possible by this approach to obtain the maximum power of each laser line and to reduce the optical noise. The operating wavelength is selected from the possible lasing lines by means of the laser mirrors. In the most common design the rear mirror has as high as possible a reflectivity (> 99.9%) for the desired wavelength, and the output coupler will have approx. 1–2% transmission at this line and > 10% at the other lines. So, the unwanted laser lines have losses greater than their gain and will not be amplified. Because of the low gain of the 543.3 nm line, lasers for this wavelength must have output mirrors with transmissions of about 0.05–0.15%.

3.39 μm Suppression

From Table 11.44 it can be seen that the 3.39 μm line must be suppressed very carefully, because it has a gain that is some orders of magnitude higher than all visible lines. Insufficient suppression of this line causes power loss and power fluctuations at the desired lines. Therefore, both laser mirrors must have a reflectivity for this line below 0.5%. Another approach for the 3.39 μm suppression is to use the Zeeman effect. Applying an inhomogeneous transversal magnetic field to the laser splits the laser levels into the Zeeman sublevels. The gain of the sublevels is the gain of the unsplit level divided by the number of sublevels, so the gain may fall below the losses and this line is suppressed. The frequency difference of the sublevels is the same for all laser lines. However, Doppler broadening of the laser lines depends on their frequencies.

The Doppler broadening of a laser line λ is given by

$$\partial \nu_D = \frac{2}{\lambda} \sqrt{\frac{2kT \ln 2}{m}} \,, \tag{11.156}$$

where k is Boltzmann's constant, T is the gas temperature and m is the mass of the Ne atom.

For visible wavelengths the frequency split caused by the Zeeman effect is lower than the Doppler-broadened line. Thus, the gain is not influenced by the Zeeman effect, whereas for the 3.39 μm line the Zeeman splitting is larger than the Doppler-broadened line and the gain decreases with the number of sublevels. This method is normally used in high-power 633 nm lasers (> 35 mW) or in the 543 nm laser.

Line Width and Coherence Length

The natural line width of a red HeNe laser is about 20 MHz [11.1466] but this line is broadened by two
Fig. 11.156 Typical transmission curve of the output mirror for a 632.8 nm laser

different processes. The first process is collision broadening, leading to a line width of about 500 MHz at typical pressures of 4–6 mbar [11.1466]. This line width is proportional to the gas pressure. The second process is Doppler broadening (11.156)), which results in a width of 1–1.5 GHz for the visible laser lines.

A TEM$_{00}$ laser usually runs at several longitudinal modes, which are spaced by

$$\Delta f = \frac{c}{2L} \,. \tag{11.157}$$

Thus, the longer the resonator (mirror distance L), the more modes can oscillate simultaneously.

As can be seen in Fig. 11.157, the mode spacing is 257 MHz (seven modes) and the gain profile is about 1.5 GHz. A Lamb dip does not occur because the collision broadening is larger than the mode spacing [11.1466]. For interferometric purposes tubes that
Fig. 11.157 Longitudinal modes (*upper curve*) and corresponding gain profile of a 584 mm-long 20 mW laser at 633 nm (LASOS: LGK 7665 P), measured with a scanning interferometer

exhibit only one or two longitudinal modes are often used. The typical length of such a tube is about $140\,\text{mm}$ with a power of $0.5–1.0\,\text{mW}$. Whereas the gain curve is fixed in frequency space, the longitudinal mode pattern shows a movement when the resonator length changes in the dimensions of the wavelength λ, which may result from small ambient-temperature fluctuations. Such a movement causes power fluctuations in the range of about 5% (depending on the laser length). Because in most applications only the sum power of all modes is used, it is possible to stabilize the laser power by increasing the number of modes under the gain profile. This can be done by two methods. The first is to increase the laser length and the second uses a 1 : 1 mixture of the neon isotopes ^{20}Ne and ^{22}Ne instead of natural Ne (90% ^{20}Ne and 10% ^{22}Ne). Because of the heavier nuclear core of the ^{22}Ne isotope the radiated light has a frequency about $800\,\text{MHz}$ higher than the light from ^{20}Ne (isotopic shift, [11.1471] p. 333). This means that the difference between these two lines is smaller than the Doppler broadening. Therefore, using a mixture of these two isotopes gives a broader gain curve. The isotopic mixture has no influence on other laser parameters such as the power or noise.

One of the most exciting applications of the HeNe laser is interferometry. For this purpose, the coherence length of the laser is important. The coherence length can by calculated from the line width $\Delta\nu$ by

$$l_\text{c} = \frac{c}{\Delta\nu} \,.$$

The problem of a multimode laser is that it does not run at a single frequency but at several equidistant modes.
Fig. 11.158 Contrast ratio for the interference of two four-longitudinal-mode laser beams

Figure 11.158 shows the calculation of the measured contrast ratio of a longitudinal multimode laser beam after a Michelson interferometer over the optical path difference. The beam was formed of four laser modes with equal intensity. This picture is overlayed by the decreasing contrast function of the single mode, but the coherence length of the single mode is in the range of kilometers and cannot be seen here. Whereas the interference can be observed over very long distances, the periodic structure makes it necessary to define the coherence length only in the region up to the first minimum. In the case of N longitudinal modes, this first minimum is located at the position

$$l_\text{min} = \frac{2L}{N} \,. \tag{11.158}$$

Thus, for the laser of Fig. 11.157 the coherence length is below $16\,\text{cm}$.

It should be mentioned that in a real laser the different modes have different intensities, but this only changes the amplitudes in Fig. 11.158 and leads to a nonzero intensity at the minima.

11.6.3 Stabilization

In order to obtain a larger coherence length, a common approach is it to use only one of the longitudinal modes. In order to select a single mode, the fact that in an unpolarized laser (without internal Brewster windows) neighboring modes have perpendicular polarization directions can be used. Hence, using a short unpolarized laser with only two modes, it is possible to select one mode by means of an external polarizer.

In some applications the frequency of this mode must be fixed. This can be achieved by controlling the length of the laser tube by means of a heater around the glass tube. One way is to select the two perpendicular modes using a polarizing beam splitter and measure the power
Fig. 11.159 Modes and gain profile of a $140\,\text{mm}$-long laser
Fig. 11.160 Components of a laser tube

difference between these two modes. By means of the heater, this signal should be held at zero. In this case (Fig. 11.159) both modes are located at the sharp flanks of the gain profile. Here, small frequency changes result in large power changes and exact control of the frequency is possible. This principle is much easier than stabilizing a laser diode, at least with an external resonator with a grating, and the frequency depends only on the atomic properties of the neon. This first approach to frequency stabilization is widely used in the field of mechanical engineering for measurement devices with an accuracy of about 1 nm. A detailed description of frequency stabilization is given in Sect. 11.14.

11.6.4 Manufacturing

Because the first HeNe lasers were built in the 1960s, today the manufacturing technology is a fully developed process, where the processes of cleaning, connecting and the vacuum processes are the key know-how of the manufactures.

After an initial cleaning process of the different components, in a first step the metal parts are soldered together in a high-temperature process (about 1000 °C). In the next step, the metal and glass parts are melted together at temperatures of about 800 °C. During this step, care must be taken that the capillary bore is at the position of the subsequent optical axis. In order to avoid mechanical stress, the different materials must be chosen in such a manner that the thermal expansion coefficients of the metal and glass parts are matched. The third step is soldering the mirrors to the mirror holders (at about 500 °C). After this preparation, the tubes are backed out under vacuum for many hours. Than, by means of an oxygen discharge, the inner surfaces of the tube are cleaned of residual organic traces. The

oxygen discharge is also used to form an Al_2O_3 layer on the cathode surface, which is important for the lifetime of the tube. The next steps are filling the tube with the helium–neon gas mixture, carrying out a burn-in process and the final filling. In order to obtain laser emission, after these steps it is only necessary to align the mirrors. A pre-alignment may be done by means of external lasers, using the back reflection of the laser mirrors from the tube, which should be adjusted. The criteria for final alignment is maximization of the output power.

In order to get a robust product and/or because the long high-power tubes are very sensitive to air flow, the glass tube is usually connected to the ballast resistor and both are placed in an outer aluminium tube.

11.6.5 Applications

Most applications make use of the visible wavelengths of the HeNe laser. Typical applications are flow cytometry, confocal microscopy, DNA sequencing, sensing, haematology and photo-finishing. Last but not least the HeNe laser is a very popular teaching apparatus in education, school or studies. A variety of applications use fluorescence imaging and interferometry which are described in more detail below.

Fluorescence Imaging

Fluorescence imaging makes use of the different wavelengths to excite fluorescence of certain fluorophores. Particularly in biomedical applications this is one of the basic methods. Different fluorophores bind to specific cells and allow the detection of abnormal structures. The working principle is that each particular fluorophore is excited by a special wavelength, emitting light at another wavelength, which is detected by highly sensitive sensors. Using various of these markers allows one to distinguish, label or sort cells. This method is applied in basic research as well as in clinical diagnostics, where it helps to detect serious diseases such as leukaemia or acquired immune-deficiency syndrome (AIDS).

Since most of these methods were developed in a period when the only lasers sources available were gas lasers, the fluorescing substances were made especially for these wavelengths. Together with the common wavelengths of the Ar-ion laser they have become a kind of standard for this application, although a variety of other wavelengths and corresponding dyes are also used today. The emission lines of the HeNe lasers are found in nearly all commercial devices. Common applications are flow cytometry and confocal microscopy.

Interferometry

Interferometric methods are used for the precision measurement of various physical values. Examples are the position or speed of particles, distances, stress or vibration. The optical properties and the long coherence length of the HeNe laser make it ideally suited for this kind of application. The narrow line width of the laser allows its wavelength to be used as a measurement standard. For many interferometric applications the frequency of the emission line has to be stabilized to achieve the maximum measurement precision (Sect. 11.6.3).

11.7 Ultraviolet Lasers: Excimers, Fluorine (F_2), Nitrogen (N_2)

In 1984, *Ch. K. Rhodes* stated in the preface to the world's first book on excimer lasers [11.1472]: "The development of excimer laser systems marked a significant turning point in the development of coherent sources. The progress of the last years has been largely predicated upon the combined knowledge of several disciplines including atomic and molecular physics, optical technology, and pulsed-power technology." This early statement was primarily associated with electron-beam excitation of laser transitions of rare gases and rare-gas halogen mixtures. Present excimer lasers are, however, based on precisely controlled electrical discharges, and rely on detailed knowledge of material chemistry to assure long service life of the discharge tubes. Cost-effective operation has therefore become possible, a prerequisite for industrial applications. Together with laser-beam monitoring and control by electronic means, the multidisciplinary approach has made excimer lasers important tools for a large variety of industrial and medical applications.

For semantic reasons, the term *excimer* originally referred to excited dimers. Today it is used for all kind of laser-active media that are characterized by bound excited states and dissociative ground states, more generally named *exciplexes*.

This section is organized as follows. An overview of the unique properties of excimer lasers is followed by a guide to the physics and technology behind these

laser systems, including beam characterization using wavefront diagnostics. The section on applications focuses on the various techniques of material modification using excimer lasers and includes the use of fluorine (F_2) laser radiation at 157 nm. The promising applications of femtosecond excimer laser pulses are also considered. At the leading edge of current research, the chapter on ultrahigh-intensity applications deals with the generation of *hollow atoms* and their application for ultrashort-wavelength X-ray generation.

Lastly, we present the new radiation sources at 13.5 nm for next-generation lithography. Radiation sources in the extreme UV (EUV) can be realized by both laser and discharge pumping and are expected to transform the present microlithography into nanolithography.

Since the field of UV lasers is very large and has recently been covered in a review book [11.1473] this short section just summarizes the various possibilities and requests the reader to browse in [11.1472, 1473], and in primary publications if more details are required.

11.7.1 The Unique Properties of Excimer Laser Radiation

The most impressive property of excimer laser radiation is the large variety of emission wavelengths, which cover the entire ultraviolet spectral region (Fig. 11.161). The shorter the wavelength, the higher the resolution that can be achieved in microprojection and -imaging, thereby opening a wide field of applications. Concurrent with the short wavelength is the high quantum energy. Short-wavelength photons are strongly absorbed by most materials and they can supply sufficient quantum energy to induce photochemical reactions and cause molecules to dissociate. Together with the high peak power available in a laser pulse, the bond-breaking capability of excimer laser radiation allows ablative evaporation that opens the door to microprocessing of many materials, ranging from soft biological tissue to hard diamond.

The pulse duration is an important parameter. Typical excimer lasers emit pulses in the range of a few nanoseconds so that material processing can be frequently performed *on the fly*, i. e., can be applied to a continuous flow of components to be processed. In addition, thanks to the naturally broad line width, excimer lasers can be tailored to supply pulses in the femtosecond range with extremely high peak power. This allows one to generate a plasma that consists of electrons and *hollow* atoms, i. e., inner-shell ionized atoms that recom-
Fig. 11.161 Wavelength (*lower scale*) and corresponding photon energy (*upper scale*) of the various excimer transitions. The *filled symbols* indicate commercially important wavelengths

bine via highly energetic transitions, thereby delivering radiation in the extreme ultraviolet or weak-X-ray region. This is surely one of the most advanced promising applications.

Finally, excimer lasers are scalable to high pulse energies in the joule range, to high repetition rates of a few kHz, to high average powers up to 1 kW, so that they can be conveniently adapted to specific industrial tasks. Compared to these facts, their drawbacks are the fairly broad line widths, the low degree of coherence and the non-continuity of the radiation. However, the latter characteristics are of minor importance considering the strengths discussed above. This leaves some space for other lasers that might conquer the UV range by frequency conversion, until more-powerful semiconductor emitters may partly fill the gap. The low degree of coherence may be utilized for speckle-free imaging, and the broad line width, which enables ultrashort pulses, may be narrowed by some frequency-selecting means in the resonator setup. However, the beam, which somehow resembles the *emission of a lighthouse* (large divergence), requires some harnessing by beam-shaping optics.

Figure 11.161 summarizes the data on wavelength and quantum energy of rare-gas halide lasers, together with those of the fluorine laser and some other diatomic and triatomic species. The F_2 laser is actually not an excimer laser but can be excited in almost the same way. These UV sources are most important for a wide field of applications outlined in the next sections. The exotic types such as KrBr, rare-gas dimers and other dimers as well as trimers are discussed in some detail in [11.1472, 1473].

11.7.2 Technology of Current Excimer Lasers and the N_2 Laser

We start with the fundamentals of excimer lasers and the fluorine laser. Due to its role as a forefather of all gaseous UV lasers, the (molecular) nitrogen laser (N_2 laser) will be briefly dealt with as well. Finally, the technology of discharge-pumped excimer lasers will be briefly outlined.

Excimer Transitions: Unusual Four–Level Laser Systems

Excimer lasers derive their emission from molecules that are generated a priori in an electronically excited state, which decays by emission of (laser) radiation into a repulsive or loosely bound ground state out of which the molecule dissociates. In usual test-tube chemistry the rare gases are noble or inert, i. e., they avoid chemical binding, although special noble-gas compounds do exist also in the electronic ground state. The most important molecules for commercially available excimer lasers are ArF*, KrF*, XeCl*, XeF*, where the asterisk refers to electronic excitation.

The dissociative electronic ground state is responsible for the four-level character of these systems. Generally, four-level laser systems can be operated in continuous manner. However, this is not possible with rare-gas halide excimer lasers because of physical and technical restrictions. A fundamental one is the important role that spontaneous emission plays with respect to the stimulated emission in the ultraviolet spectral region; the ratio of the Einstein coefficient A, which is responsible for spontaneous emission, and that responsible for the stimulated emission in the same transition, B, is proportional to the third power of the transition frequency ν [11.1475]:

$$\frac{A}{B} = \frac{2h\nu^3}{c^2} \ .$$

Hence stimulated emission can only compete with spontaneous emission if the radiation intensity within the transition $I(\nu)$ is so large that the product $BI(\nu)$ exceeds A, that is, if the system is pumped extremely hard. Electrical power densities of some $100\,\mathrm{MW/l}$ must be deposited in the gas volume. In the early days, this excitation density was achieved by using energetic electron beams [11.1472]; nowadays short-pulse transverse electrical discharges are being used. An extension of the pulse duration beyond about $1\,\mu s$ is hampered by discharge instabilities caused by arcing. The detrimental reaction products and heat must be removed before

the next shot so that rapid exchange of the laser gas is required.

After the first experimental demonstration of a bound–free laser system in liquid Xe_2 [11.1476], a large number of other excimer or exciplex molecules were successfully investigated, including homonuclear as well as heteronuclear species [11.1472], but most of these did not gain importance for applications. The door to the systems listed in Fig. 11.161 was opened wide in 1975 [11.1477–1481], with convincing efficiency, wavelengths, and after some technical effort, ease of handling of the laser gases. The gases are primarily the discharge carrier, which is the buffer gas (mostly helium), and, to a much lower extent, the reactants, which are the laser gases.

Molecular Potentials and Reactions Kinetics

The rare-gas halide systems are characterized by two electronic ground states, correlating with the electronic ground states of the rare gas and halogen atoms, which combine to a molecular Σ and a Π state, arising from the p-hole of the halogen atom (Fig. 11.162 [11.1474]). Whereas the Π state is strongly repulsive, the Σ state shows a minimum, mostly with a depth of a few hundred cm^{-1} only, so that thermal energy allows the molecule to dissociate within a few picoseconds. The first electronically excited states correlate with the positive rare gas and negative halogen ions, and hence show a deep minimum. The higher states correlate with the elec-
Fig. 11.162 Typical potential energy diagram of a rare-gas halide molecule. M stands for the rare gas, X for the halogen atom [11.1474]

tronic excitations of the neutrals, and their potential is shallower, as is typical for covalent binding. This general scheme holds for the rare-gas halides, except XeF where the potential of the ground state reaches a depth of 1065 cm^{-1} according to [11.1474].

In the buffer-gas-supported electrical discharge, the excited and ionic species are formed as shown for the KrF* case in Fig. 11.163. The formation of the excited rare-gas halide molecule follows both a *neutral* channel, a chemical exchange reaction, and an *ionic* recombination channel, stabilized by third-body collisions with the buffer-gas atoms. Hence the formation of exciplexes is favored at high pressure, i.e., pressures of a few bars. The buffer gas also provides fast relaxation to the lowest vibrational level within the electronically excited state, followed by a radiative transition to the ground state within a few nanoseconds.

The laser transitions couple with the continuum states above the ground state, showing a homogeneously broadened non-Lorentzian line shape [11.1484]. Hence, excimer lasers can be tuned within a certain bandwidth range if frequency-selective optics are introduced – see the tuning ranges in Fig. 11.161. The homogeneous line broadening turns out to be favorable for the amplification of short pulses.

In more detail, many more excited states that correlate to the excited atomic states exist and are being populated. However, their buffer-gas-induced relaxation feeds the population of the lowest electronically excited state. An overview of the reaction kinetics of both pure rare gases and rare-gas atoms with halogens and the underlying rate constants is given in [11.1474].

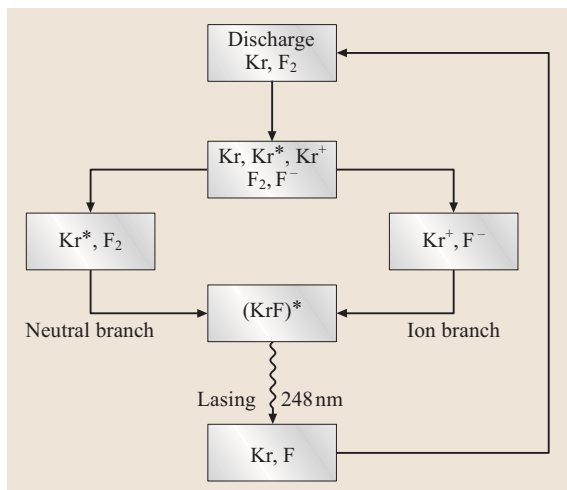
The *fluorine laser* is based on bound–bound transitions. With 157 nm it shows the shortest wavelength of all homonuclear halogen lasers [11.1485]. From the two p-holes of the F atoms, three levels belonging to ground electronic configuration are obtained for the F_2 molecule, two of which are bound, so that the stable molecule can be directly electronically excited in an electrical discharge. In addition, excitation transfer from the electronically excited He* and excited F* atoms, and ionic recombination of F^+ and F^- ions, which have a large electron affinity, during interaction with a He atom lead to the population of the upper $^3\Pi$ laser level that decays to the weakly bound lower $^3\Pi$ level. The F_2 laser transitions can be excited in discharges like those in rare-gas halide lasers. Therefore the F_2 laser is frequently mentioned among the commercial excimer lasers – in particular with respect to its short wavelength [11.1486]. Figure 11.164 shows details of the F_2 laser emission together with a *line-selected* spectrum


Fig. 11.163 Dominant reaction paths for the generation of KrF* [11.1482]

with a half-width of only 1.034 pm (FWHM, [11.1473, Chap. 6, pp. 97]).

Technical Design Principles for Excimer Lasers

From the physical preconditions described in the two preceding sections it follows that the electrical energy of high density, on the order of 10^{-2} J/cm^3 [11.1487], must be discharged homogeneously into the laser gas (Fig. 11.165a) on a time scale of a few nanoseconds so that a high-pressure (up to 0.5 MPa) glow discharge can be maintained for as long as possible.
Fig. 11.164 Emission spectrum of the fluorine laser according [11.1483]. *Inset* shows spectral details of the stronger transition after line selection [11.1473]
Fig. 11.165 (a) Schematic layout of an excimer laser together with gas discharge and laser resonator; **(b,c)** Excitation circuits employing magnetic pulse compression: **(b)** $L–C$ inversion circuit with single-stage pulse compression, **(c)** thyristor-switched circuit using double-stage pulse compression [11.1487]

The electrical charge comes from a storage capacitor or, more effective, a low-impedance pulse-forming line. For a homogeneous ignition, an efficient pre-ionization is required. Pre-ionization by ultraviolet radiation has prevailed over X-rays. Table 11.45 summarizes the different methods of UV pre-ionization. Glow discharges, especially in halogen-containing gases, tend to transform into an arc or sparking discharge due to electron capture by the halogens so that laser emission breaks down. Hence, considerable efforts have been made to stabilize the glow discharge [11.1488, 1489]. In order to supply the charge sufficiently fast, favorable use is made of magnetic pulse compression (Fig. 11.165b,c). The energy switches, formerly thyratrons, are mostly thyristors, gate-turn-off (GTO) thyristors or insulator gate bipolar transistors (IGBT).

To guarantee a long laser-tube lifetime, the choice of electrode material is very important. Considerable

material research has taken place and led to different materials for the fluorine and chlorine rare-gas lasers. Even different materials for either the cathode or the anode, or over the profile of one electrode have been used [11.1487]. Rapid transverse gas circulation provides cooling and supply of fresh laser gas for every shot. In order to achieve stable laser output power, halogen gas consumption is compensated by processor-controlled gas injections so that the laser tube can be operated with a single main fill typically for about 1 billion pulses.

Excimer laser resonators (Fig. 11.165a) mostly consist simply of plane windows made of CaF_2, allowing high out-coupling in the range 50–92%. For special applications, unstable resonators or resonators with frequency-selective optics are employed, as well as oscillator-amplifier systems.

The number of technical papers on the technology and construction of excimer lasers and their applications has become numerous. Excimer laser parameters are scalable to a considerable extent. Special excimer lasers have been developed by putting in the foreground either high single-pulse energy (up to 10 J), or high repetition rate (6 kHz), or medium or high average power (up to 1 kW). The efficiencies, calculated from the ratio of laser output energy to stored electrical energy, are typically a few percent ($< 5\%$). Since digital inter-publisher retrieval has become possible [11.1490], nearly every combination of the above can be electronically traced back, in part, over the last three decades. As an example, Table 11.46 shows data specified for an XeCl excimer laser designed for industrial applications.

Beam Characterization of Excimer Lasers

For various applications such as the production of diffractive structures via direct patterning [11.1491, 1492], semiconductor microlithography or eye surgery, a detailed knowledge of the wavefront of the emitted excimer laser radiation is necessary. In addition, all these applications strongly rely on the stability and the precise control of the laser parameters, such as pulse energy, beam width, divergence, pointing stability, uniformity etc. Thus reliable, standardized methods for the evaluation of beam parameters as well as accurate diagnostic tools for UV laser beam characterization are mandatory. While the output energy and the power can be monitored with the standard tools that are used also for other high-power lasers, the recording of spatial beam profiles and directional distributions (wavefronts) requires specific instrumentation adapted to the characteristics of

Table 11.45 Pre-ionization techniques applied in excimer-laser discharges
	Preionization of the laser gas by UV radiation emitted from spark discharges between pin electrodes mounted in a row parallel to the laser channel. Sparks are being ignited some 10 ns before the main discharge starts so that at least 10^8 electrons/cm^3 are created as a seed for the main discharge.
	A possible modification of a: spark preionization through one of the electrodes designed as a screen or mesh electrode.
	Dielectric(alumina)-surface-guided spark discharge for preionization. Because the discharge spreads, erosion of the pins is reduced considerably, thus the lifetime of the laser gas is increased, and the laser tube can be operated up to 10 billion shots. This design is mostly used in high-average-power excimer lasers.
	Surface corona discharges on a dielectric sheet emit UV with high spatial uniformity. Consuming a lower amount of energy as compared to sparks, they supply an electron density sufficient for a narrow discharge volume as used in high-repetition-rate excimer lasers, and provide increased discharge electrode lifetime.
	Knife-edge-released discharges creeping on a dielectric surface (similar to the well-known Lichtenberg discharges) cover a large area, thus can be conveniently applied for the preionization of large-aperture excimer lasers. The knife edge is connected to the ground electrode of the main discharge.

excimer lasers. Besides sensitivity to the various wavelengths in the deep-UV spectral range, such diagnostic systems must also possess detector apertures adapted to the large near-field beam cross section of excimer lasers, and, most important, must guarantee long-term stability of the employed optics and sensors under pulsed high-power UV irradiation. The evaluation of relevant excimer beam propagation parameters is now possible with camera-based profile and wavefront measurements in accordance with current International Organization
Fig. 11.166 Near-field (*left*) and far-field profile (*right*) of F_2 laser (157 nm, Novaline F1030, Lambda Physik) recorded simultaneously with a camera-based measurement system. The evaluated second-moment beam widths in the horizontal and vertical directions are also indicated

for Standardization (ISO) standards [11.1493, 1494]. Figures 11.166 and 11.167 show results obtained with a Hartmann camera-based measurement system.

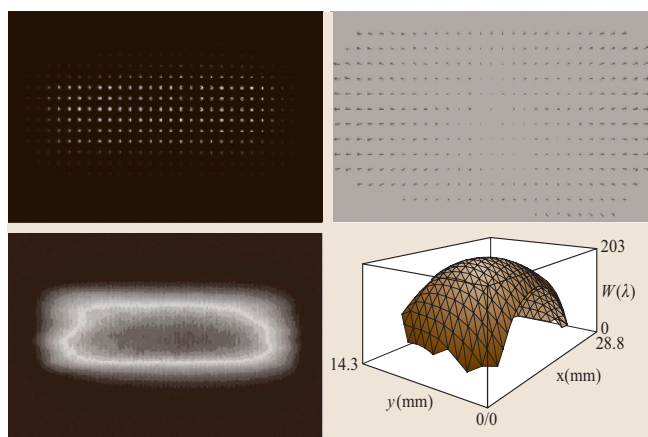
Brief Recollection of the N_2 UV laser

The molecular nitrogen laser, realized as early as 1963 with emission in the near infrared [11.1495]

Fig. 11.167 Wavefront measurement of the emission of an F_2 laser (157 nm) using a Hartmann camera (40×30 pinholes, diameter 100 μm, pitch 1 mm). This technique provides comprehensive beam characterization and propagation analysis of excimer lasers from a single measurement

and shortly later between 300 and 400 nm with the strongest line at 337 nm [11.1496] (described in detail in 1965 [11.1497, 1498]) quickly became the workhorse for laser spectroscopy. Its predominant use was, and still is, optical pumping of pulsed dye lasers throughout the near-UV, the visible and near-infrared spectrum. In addition, it serves as an excitation source in photochemistry and biological research. The lasing is achieved in high-voltage (10–20 kV) high-speed (few-ns) transverse gas discharges in a broad pressure range from some 10 mbar up to atmospheric pressure (TEA laser), in pure nitrogen and also, with lower efficiency, in air. The 337 nm transition is the most intense of the vibronic transitions (0–0) between the $C^3\Pi_u$ and the $B^3\Pi_g$ states. Since the B state is long-lived (about 10 μs) with respect to the C state (about 10 ns), the laser action is quickly self-terminating.

The pumping is achieved from the X state by direct electronic excitation of the C state, which happens to occur with a larger cross section than that for the B state, so that population inversion can be obtained if the discharge current rises much faster than radiative increase of population of the B state. To emit pulse energies in the mJ range, N_2 lasers must be equipped with low-impedance discharge circuits, such as for example can be realized by embedding the laser channel into a Blümlein transmission line, which enables a rise time of a few nanoseconds. Since the gain is very large, the emission may be stimulated predominantly in one direction when the excitation wave is made to reach the discharge channel synchronous to the light propagation; in this way a 10:1 ratio in favor of one direction can be achieved [11.1499], and fairly short lasers with considerable peak output power (1.2 MW) are possible [11.1500]. Transmission line circuits are thoroughly analyzed in [11.1501]. A pulse energy of 20 mJ has been realized using a fast circuit with magnetic pulse compression [11.1502]. On the other hand, just for demonstration purpose, a nitrogen laser can be easily realized by adjusting two electrodes on a glass sheet and supplying the electrodes with a spark-gap-switched high-voltage source. A home-built nitrogen laser, using standard ignition transformers, spark gaps, refrigerator circulating pumps, and some dielectrics and aluminium foil or copper-layered circuit boards, is precisely described on the web [11.1503].

Historically speaking, N_2 lasers as well as the homonuclear excimer lasers and metastable mercury compounds was proposed as early as 1960 by *Houtermans* [11.1504] – much earlier than the first ruby laser had been realized.


11.7.3 Applications

Physically, the applications of excimer lasers can be grouped according to the benefits from

1. short wavelength, and correspondingly,
2. their high quantum energy,
3. the high pulse energy density obtained by focusing, and
4. the extreme peak power when the pulse energy is compressed into ultrashort pulses.

Property 1 allows exposing and patterning of sub-100 nm structures in photoresists for semiconductor lithography, property 2 allows photochemical near-surface modifications such as color change, as used for marking of plastics, and index-of-refraction change used for the generation of fibre Bragg gratings. Property 3 allows the melting of thin silicon films, used to induce large-grain crystallization in the production

line of thin-film transistor (TFT) displays. The properties 1–3 enable microstructuring by material ablation including biological tissue, and property 4 opens the door for the generation of X-rays of extreme brilliance. Besides these technical applications, excimer laser radiation is still widely used for scientific purposes, such as optical pumping of dye lasers. Here, we briefly refer to a few of the technical applications.

Excimer Lasers in the Electronics Industry

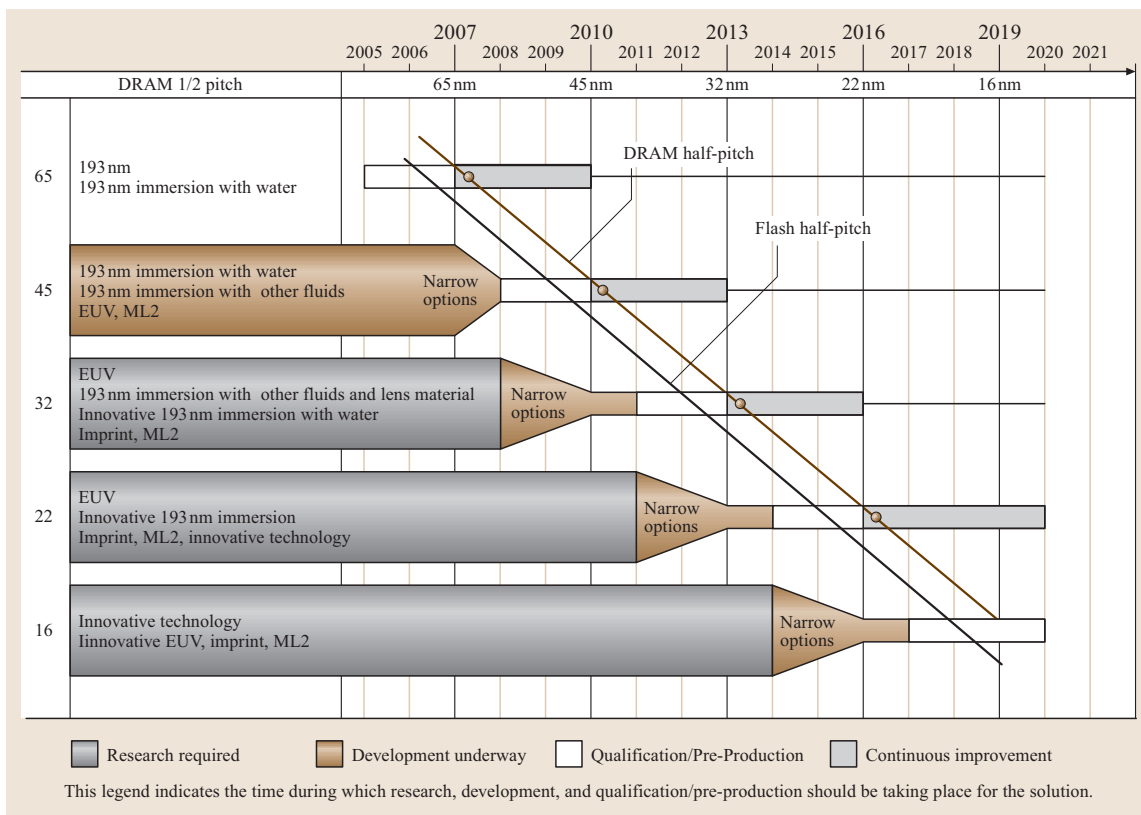
Lithography for the generation of semiconductor circuits has been based on excimer laser light sources for more than a decade now, and will continue to do so for a couple of years. Thus this is the economically most important application of these lasers. Because the diffraction-limited minimum (half pitch) that is resolvable in optical projection is given by $k_1 \lambda / NA$, every effort is made to decrease the wavelength λ for the illumination together with the process factor k_1, and to increase the numerical aperture (NA) of the projection system. After extensive


Fig. 11.168 Potential lithography exposure tool solutions according to the *International Technology Roadmap for Semiconductors 2005* [11.1505]. Courtesy ITRS
Fig. 11.169 30 nm-wide lines and equally sized spaces obtained at IBM Almaden Research Center (*left*) using 193 nm interferometric high-index immersion lithography, compared to current 90 nm features. Courtesy IBM

use of 248 nm lasers, 193 nm illumination is now state of the art, and increasing the NA by using immersion optics turned out to be a highly successful method to arrive considerably below the diffraction limit. In the International Technology Roadmap for Semiconductors 2005 (Fig. 11.168 [11.1505]) the 45 nm half-pitch for dynamic random-access memories (DRAMs) in production is scheduled for 2010, to be achieved with 193 nm immersion technology. Fluorine lasers (157 nm) are not in discussion any more since immersion fluids with an in-

dex of refraction higher than that of pure water are being investigated. These could extend the use of 193 nm down to a 30 nm half-pitch (see Fig. 11.169 from [11.1506]).

For the lasers to be used in lithography, there are considerable requirements with respect to line width, wavelength and pulse-to-pulse stability, lifetime of the laser tube and all the optics [11.1508]. Dual-chamber systems distribute the task of narrow-band generation in the oscillator and power generation in the amplifier tube; the latter can be designed as a regenerative ring amplifier [11.1508]. Recently, a 60 W system operating at 193 nm was introduced (Fig. 11.170 [11.1507]) with the benefit of improved energy stability of the 6 kHz pulses, so that the exposure dose of the resist can be precisely controlled. This system aims for 45 nm half-pitch production.

Transistors in thin films are the key elements to control the individual pixels in displays. To increase the mobility of the electrons, large silicon crystal grains are produced by applying excimer laser radiation to cause melting and controlled recrystallization, the beam being scanned in lines across the surface [11.1509, 1510]. This process, summarized as excimer laser annealing (ELA), is performed by applying 308 nm radiation that is strongly absorbed by silicon so that thin films on glass can be melted without damage to the substrate [11.1511]. In this way, large-area TFT displays can be manufactured. Even doping imperfections due to incomplete annealing near source/drain junctions can be eliminated by oblique-incidence ELA [11.1512].

Further excimer laser applications that are well established in electronics are printed circuit board (PCB) via drilling [11.1513], wire stripping and wire marking [11.1473]. A rather new technology is the lift-off method to de-bond for example an electronic GaN LED from its sapphire substrate, which is used for crystal growth, by shining the laser through the substrate, thereby ejecting the LED onto its heat-sink electrical interconnect [11.1514]. For future optical coupling of PCBs, attempts to integrate optical mirrors manufactured by ablation should be mentioned [11.1515, 1516].

Processing of Optical, Ceramic, Polymeric, and Biological Materials

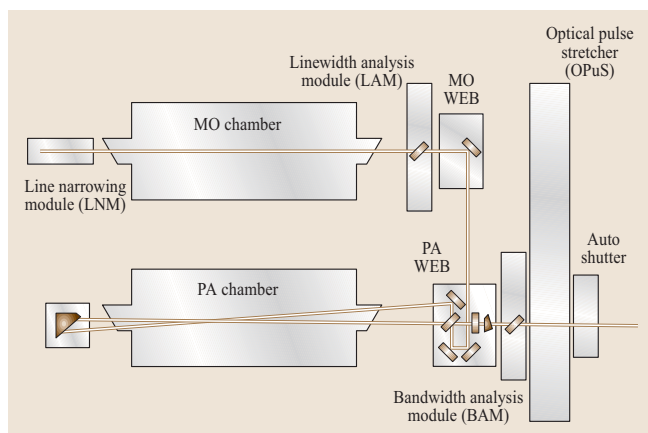
Ablation is surely the best-known application of excimer lasers: drilling and microstructuring of glass, quartz, even diamond, ceramics and polymers [11.1517] allows highly precise contouring with high reproducibility. This subject is covered in chapters 11–14 and 16 of [11.1473], which also includes the ophthalmological application including the laser-assisted in situ keratomileusis (LASIK)


Fig. 11.170 Schematic of a master oscillator power amplifier (MOPA) excimer laser system to be used in semiconductor lithography [11.1507]. Courtesy Cymer Inc.

method ([11.1473, Chap. 19], [11.1518]). Nonablative processing of glass and polymers allows one to generate fiber Bragg gratings in optical waveguides by changing the index of refraction [11.1473, 1519]. Microstructuring is going to play a role also in the upcoming technology of organic light emitting devices (OLEDs) [11.1520].

Femtosecond Excimer Laser Pulses

Another interesting subject of today's excimer technology is their conversion into UV light sources with femtosecond pulse duration. Basically a femtosecond seed pulse at 248 nm is injected into an appropriately modified standard excimer laser resonator to achieve a powerful highly directed short pulse emission. As examples are presented material processing with this radiation and high-intensity studies for the generation of tunable X-rays.

Conversion of a nanosecond excimer-laser system into a fs system is described in [11.1521–1523] and briefly in Fig. 11.171a. The ultrafast UV laser system consists of a Ti:sapphire front laser, a frequency-tripling unit to convert the wavelength of the ultrashort pulses into the UV spectral range, and a specially designed KrF amplifier to boost the energy of the pulses to several mJ. The current laser arrangement, as shown in Fig. 11.171a, uses a commercial Ti:sapphire front-end system (Coherent) delivering pulses of 150 fs duration at a wavelength of 745 nm. After frequency tripling, seed pulses are obtained for the KrF amplifier module, which is the key component of the system. This module is a modified version of a commercial excimer laser. In a three-pass amplification scheme the pulses are amplified up to energies of ≈ 30 mJ at repetition rates exceeding 300 Hz, resulting in an average power of 10 W at 248 nm.

UV femtosecond material processing. Nanoscale fabrication of materials is more and more in demand in scientific and industrial applications. The general trend to reduce the size of optomechanical devices and the growing need for assemblies with feature sizes below one micron generates new challenges for laser fabrication techniques.

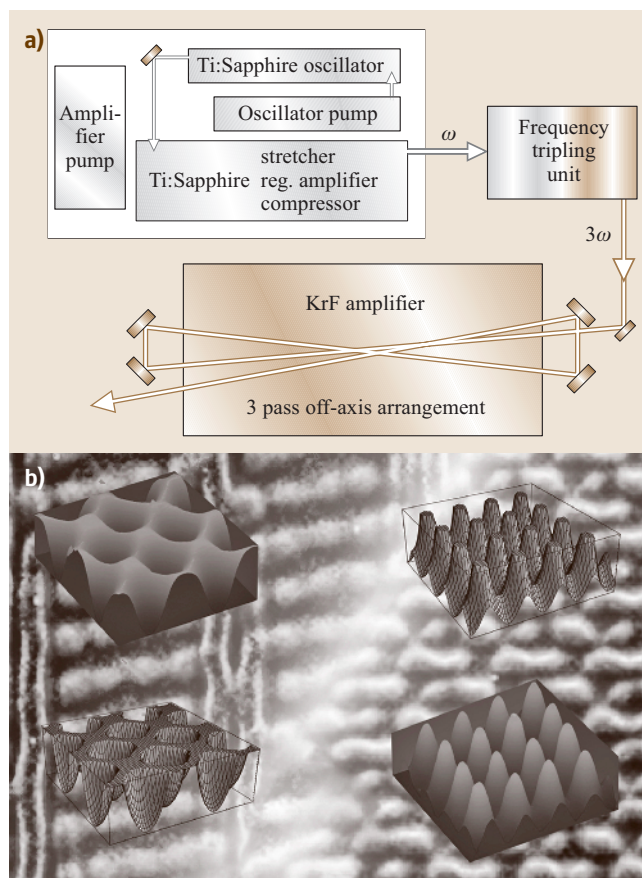
Short-pulse lasers with picosecond and femtosecond pulse duration offer material processing capabilities with highly decreased damaged area around the irradiated spot, and consequently smaller feature sizes. If the short pulse duration is combined with short wavelengths, unprecedented results can be achieved due to the dependence of the spatial resolution on the wavelength. Thus UV femtosecond laser systems provide superior material processing quality.


Fig. 11.171 (a) Layout of the UV femtosecond hybrid laser system showing Ti:sapphire seed system and three-pass off-axis KrF amplifier. **(b)** Comparison between calculated and measured surface textures for four-beam interference at a phase difference of 0π (*left*) and 0.5π (*right*). The surface contours top left and bottom right were measured via atomic force microscopy (AFM)

Such pulses are ideally suited for sub-micron machining of solid surfaces. Applying various diffractive optical masks in combination with reflective imaging/focusing systems allows the generation of complex 2-D and 3-D structures with feature sizes down to ≈ 200 nm or lower on all materials, including metals, semiconductors and dielectrics. Figure 11.171 shows the calculated and experimentally obtained surface relief structures fabricated with the technique of phase-controlled multiple-beam interference [11.1524].

High-intensity UV femtosecond studies. A leading application of KrF* (248 nm) excimer lasers has been the demonstration of saturated amplification in the multi-

kilovolt X-ray regime that arises from the ability to produce and controllably combine two new highly ordered forms of excited matter:

1. hollow atoms and
2. stable electronically hollow plasma channels.

The realization of this new X-ray source provides a peak brightness that is sufficient for the implementation of a new high-resolution technology for biological microimaging.

Hollow atoms and the cluster concept for X-ray amplification. Previous work [11.1526] on the nitrogen molecule N_2 suggested the possibility of *designing* a new class of molecular materials *optimized* for the efficient production and amplification of X-rays [11.1527]. This idea was immediately tested with Xe clusters [11.1528] with the outcome that the copious production of Xe hollow-atom states [11.1529] emitting both Xe(M) and Xe(L) radiation in the kilovolt spectral region [11.1528]
Fig. 11.172 Characteristic spontaneous emission profile of the Xe(L) 3d̃2p hollow-atom spectrum produced from Xe clusters with intense ($\approx 10^{19}$ W/cm^2) femtosecond 248 nm excitation. The splitting between the major and minor lobes arises from the spin–orbit interaction of the 2p vacancy. The full width of the main feature is ≈ 200 eV. The positions of selected charge-state transition arrays (Xe^{31+}, Xe^{32+}, Xe^{34+}, Xe^{35+}, and Xe^{36+}) are indicated. The spectral resolution of these film data is ≈ 4 eV. (After [11.1525])

was observed. These data confirmed that the selective excitation of the inner-shell states initially observed in N_2 could be scaled into the multi-kilovolt spectral region. A good example [11.1528, 1529] is given by the characteristic Xe(L) 3d2p hollow-atom emission profile centered at ≈ 2.8 Å shown in Fig. 11.172. *Hollow atoms* are atoms (ions) that intrinsically possess an *inverted* electronic configuration consisting of deeply bound inner-shell vacancies, perhaps multiple, with the simultaneous retention of several electrons in relatively weakly bound outer orbitals. Accordingly, these states are optimally suited for the prompt emission and amplification of X-rays. The demonstration of saturated amplification [11.1525, 1530–1532] followed, together with the ability to form self-trapped plasma channels [11.1533, 1534]] that are well matched to the conditions necessary for Xe(L) excitation in clusters.

Multi-kilovolt X-ray amplification with clusters in self-trapped plasma channels. The fundamental power compression and its spatial organization were found in the alliance of the two basic phenomena mentioned above. They are

1. the direct multiphoton excitation of hollow atoms from clusters with ultraviolet radiation and
2. a nonlinear mode of *stable* confined propagation in plasmas resulting from a relativistic/charge-displacement mechanism of self-channeling [11.1533, 1534].

The spectrum typical of the X-ray beam amplified axially in the Xe plasma channel and recorded on film with a von-Hámos-spectrograph is illustrated in Fig. 11.173.

In Fig. 11.174 the axially recorded spectrum presented in Fig. 11.173 is compared to a transversely observed single-pulse spectrum that exhibits deep and broad spectral hole burning [11.1535] that corresponds well with the axially amplified transition arrays. This result demonstrates two key attributes of the Xe(L) system, namely,

1. a high efficiency of energy extraction and
2. a very broad bandwidth (60 eV) for amplification.

In this case, the strongly enhanced lines observed correspond to the Xe^{34+}, Xe^{35+}, and Xe^{36+} charge state arrays of the major lobe shown in Fig. 11.172. These observations, along with additional spectra showing comparable results on several other transition arrays in
Fig. 11.173 Axially recorded spectrum showing sharp peaks at the positions of the Xe^{34+}, Xe^{35+}, and Xe^{36+} transition arrays. On the basis of geometric considerations concerning the von-Hámos-spectrograph and the ratio of exposures corresponding to the spontaneous signal and the amplified lines, the recorded enhancement of these features is estimated to be minimally $\approx 1.5 - 3.0 \times 10^3$ over the strength of the spontaneous emission

Fig. 11.174 Comparison of the axially detected film #2 shown in Fig. 11.173 with a single pulse spectrum (#030226B) recorded transversely, illustrating deep spectral hole-burning corresponding to the region of the Xe^{34+}, Xe^{35+}, and Xe^{36+} arrays. Since the hole burning descends to the noise level of the detector, efficient energy extraction is evident. The width of the spectral gap is ≈ 60 eV, a value sufficient for amplification of a pulse with a duration of ≈ 30 as

the $\approx 2.71 - 2.93$ Å region, indicate that the hollow-atom states are strongly inverted and that the amplification can be tuned across a substantial fraction of the spectral profile illustrated in Fig. 11.172. An estimate of the peak spectral brightness achieved in the initial experiments [11.1525] gave a value of $\approx 10^{31} - 10^{32}$ photons $(s\, mm^2\, mr^2)^{-1}$ and (0.1% bandwidth)$^{-1}$, a range approaching that required for single-molecule imaging in living biological material [11.1536–1538].

In summary, the study of high-intensity interactions with ultraviolet excimer lasers on atoms, molecules, and plasmas over the last 20 years has culminated in the ability to produce new forms of matter that are both highly excited and highly ordered [11.1539]. A consequence is the capacity to achieve saturated X-ray amplification in the multi-kilovolt regime at peak brightness figures sufficient for the implementation of biological microimaging. Basically, the amplification proceeds through the creation of a *highly ordered* excited state [11.1525, 1535] that is comprised of four mutually coupled components: atomic (ionic) matter, plasma electrons, and the two coherent radiative fields,

which are the ultraviolet and X-ray waves propagating in the channel. The chief consequence is well-ordered and efficient energy flow conducted through radiation-dominated interactions that are confined to a small phase-space volume. Finally, it is significant to note that *ordered* energy flow was the principal characteristic of excimer systems that made [11.1472] them so abundantly useful over the last three decades. Hence, a key feature of that history appears prominently again in the X-ray range.

11.7.4 Outlook: Radiation in the EUV

The roadmap of the semiconductor industry (Fig. 11.168) shows in which way computer chips with critical dimensions of 32 nm and below are planned to be manufactured: light sources with emission in the extreme ultraviolet (EUV) at a wavelength of 13.5 nm will be used. EUV lithography is considered as the next-generation lithography (NGL) to be established after
Fig. 11.175 EUV microexposure tool from Exitech with an integrated EUV source from XTREME technologies (*left*)

reaching the physical limits of ultraviolet (immersion) lithography based on ArF excimer lasers.

13.5 nm Technology

The first EUV microexposure tools are already under operation for technology development and feasibility studies (Fig. 11.175).

One of the biggest challenges concerning the introduction of EUV lithography is the development of high-power EUV sources at a reasonable cost. Making the operation of the photolithography manufacturing tools economically viable requires a source with power in the kilowatt range at the 13.5 nm exposure wavelength. In addition, the optical design of the collector optics sets limits on the source size, i.e., an emission volume of a few cubic millimeters. Only the combination of both the high power and small emission volume will enable high optical efficiency and therefore high wafer throughput. The goal is the development and manufacturing of these high-power EUV sources as well as their integration into the optical system of the photolithography tool (Fig. 11.176).

Plasmas are known as efficient emitters of 13.5 nm EUV radiation, if their temperature reaches about 200 000 °C, i.e., approximately 35 times higher than at the surface of the sun. Plasmas can be generated either by an electrical discharge or by means of pulsed laser excitation. Both methods are able to generate small plasma volumes fulfilling the technical requirements of photolithography [11.1540, 1541]. The spatially ho-

Fig. 11.176 EUV plasma source integrated into an optical system

mogeneously emitted radiation from such plasmas is pulsed with lengths in the nanosecond range (typically). The distribution of the wavelength spectrum is narrow from elements with low atomic numbers and broad from elements with high atomic numbers. In addition, the radiation is almost fully incoherent, as from a thermal Planck emitter.

Today the highest EUV power is achieved in so-called *pinch plasma* sources. However, the heat load on the static electrode configuration can lead to fast erosion and even melting of the surfaces, thereby limiting the power scaling through increasing repetition rates. Alternative technologies with moving electrodes have been investigated and finally a potential solution with rotating disc electrodes (RDE) has been found. A new excitation scheme has been applied to this technology at XTREME technologies, resulting in a world record (170 mJ/2π sr) of the achieved EUV pulse energy [11.1542]. This effect resulted in a reasonable repetition rate to fulfill the power requirements of high volume manufacturing tools. Further development efforts will be directed to combine the power-scaling capability with the reliability goals for this concept.

11.8 Dye Lasers

11.8.1 Overview

The distinctive feature of dyes as a lasing media is the broad emission band with a typical bandwidth of 50 nm. Laser action from dye molecules was first observed by several research groups in 1966 [11.1543, 1544]. Compared to the gas and solid-state lasers of the 1960s, dye lasers easily excelled both in terms of broad spectral coverage and in versatility of output performance (viz. high per-pulse energy output, long or short pulse operation, flashlamp or laser pumping) Researchers quickly recognized the wavelength tuning capability of dye lasers, which is probably one of the most important operation characteristics in view of applications. In the following years, literally hundreds of organic dyes with emission spectra from the near ultraviolet to the near infrared (300–1200 nm) have been made to lase. Continuous-wave (CW) or ultrashort pulse (femtoseconds) operation of dye laser was also demonstrated. With their broad spectral coverage and narrow linewidth tunability, dye lasers have been the workhorse in scientific laboratories for applications ranging from fundamental physics to clinical medicine for many years. Despite the bad reputation of being prone to various mishaps during operation (e.g., spilling of dye solution being a not infrequent occurrence), there are many loyal fans of liquid dye lasers in the scientific community. This popular support is a tribute to the versatile output performance of these liquid lasers and the simplicity of the technology involved in constructing a liquid dye laser. Almost any research lab can put together a flashlamp with power supply, two mirrors, some common dye (e.g., rhodamine 6 G), and nuts and bolts to build a pulsed liquid dye laser. There are of course numerous user-friendly and powerful liquid dye lasers available. We will first give a short description of the characteristics of liquid dye lasers and then discuss several types that are commonly found in research laboratories for photophysical, photochemical and spectroscopy applications.

11.8.2 General Description

Dyes are organic compounds that contain conjugate double bonds. The presence of the conjugate double bonds renders these compounds optically active. There are over 200 laser dyes that can, in principle, provide spectral coverage from 320 to 1200 nm [11.1545]. The tuning range of each dye is 40–60 nm. When used sequen-

tially, continuous tunable laser action can be obtained from the near ultraviolet to the near infrared. Typically a strongly absorbing and strongly emitting dye is dissolved in a suitable solvent (e.g., a polar solvent such as ethanol or a nonpolar solvent such as chloroform) at concentrations of $10^{-3}-10^{-4}$ molar to serve as the gain medium. A flashlamp or another laser is used as the pump. Powerful coaxial flashlamp-pumped rhodamine 6 G dye lasers can deliver laser energy up to 400 J per pulse [11.1546]. Average output power of up to 1.2 kW in burst mode were obtained in a flashlamp-pumped dye laser by *Morton* and *Dragoo* [11.1547]. Since the advent of high-power short-wavelength lasers in the 1970s, excimer, nitrogen or frequency-multiplied Nd:YAG lasers are frequently used for pumping liquid dye lasers with output pulse around 10 ns and energy output of tens of millijoules. A saturable absorber (another dye) is used to passively mode-lock the dye laser to generate pulses of about 200 fs without dispersive elements and down to tens of fs with dispersive optical elements [11.1548]. For applications that require single-longitudinal-mode laser output, CW operation of dye lasers is achieved by using a modified flow system to remove the long-lived triplet state of the dye molecule. The linewidth of a free-running jet-stream CW dye laser can be as low as to 2 MHz [11.1549]. In the following sections, we discuss several common dye laser arrangements.

11.8.3 Flashlamp–Pumped Dye Lasers

A flashlamp was the pump source for Maiman's epoch-making ruby laser. Today's flashlamps are still used to pump liquid and solid-state lasers. Linear flash-
Fig. 11.177 Schematics of a coaxial flashlamp-pumped dye laser

lamps are often the choice for laser pumping and usually consist of a tubular quartz envelope sealed by tungsten electrodes at both ends. The tube is often filled with a heavy rare gas (e.g., xenon or krypton) for high electrical-to-optical conversion efficiency. Still close to 90% of the electrical power ends up as heat, which requires a cooling system for its removal. Often, an elliptical reflector is used to focus the output from the flashlamp into the dye cell. For optimum coupling of the light from the flashlamp into the dye, the dye cell must be placed close to the lamp. Coaxial lamps have emitting surfaces that completely surround the flowing dye. Figure 11.177 shows a coaxial flashlamp-pumped dye laser, a structure commonly employed in many commercial dye as well as solid-state lasers. The dye cell is set at the center of the coaxial, cylindrically shaped xenon flashlamp for optimal pumping. Two broadband mirrors provide the optical feedback. Such a flashlamp-pumped dye laser typically produces a broadband emission (about 10 nm linewidth) centered at the peak of the gain profile with a pulse duration of $1-2\,\mu s$. The output energy is about 100 mJ for most commercial flashlamp-pump dye lasers.

Fig. 11.179 Schematic of a colliding-pulse dye laser for ultrashort-pulse generation

11.8.4 Tunable Dye Lasers Pumped by High-Power Short-Wavelength Lasers

By incorporating wavelength-selective elements inside the resonator cavity, dye laser output can be tuned. Increasingly excimer or frequency-multiplied Nd:YAG lasers are used to pump dye lasers. Excimer, nitrogen and frequency-multiplied Nd:YAG lasers all provide high pump power (peak power of several MW) at short wavelengths, making them highly suitable for pumping dye lasers. Dye lasers pumped by high-power short-wavelength lasers exhibit such high gain that loss introduced by the additional wavelength-selective elements inside the resonator cavity can be overcome. Either prisms or diffraction gratings can be used for wavelength selection, and gratings are generally superior in terms of large dispersion and wavelength-resolving power. Figure 11.178 shows a variant of the telescopic grating resonator originally used by *Hänsch* [11.1550] for the generation of narrow-linewidth laser output. A nitrogen laser provided the pumping. The use of the telescopic lens increases the number of grooves illuminated by the laser light and reduces the light intensity on the grating, preventing damage to the coating on the grating surface. The linewidth of a telescopic-grating cavity dye laser is in the range of 0.1 nm. To further reduce the linewidth to $0.01-0.05$ nm, an intracavity etalon (e.g., a coated optical flat or air-spaced Fabry–Pérot cavity) may be introduced. Many variants of the grating-cavity (e.g., the hybrid prism–grating cavity) dye lasers have been developed to achieve narrow-linewidth output [11.1551].

11.8.5 Colliding-Pulse Mode-Locked Dye Lasers

The broad emission band of a dye can be used effectively to generate ultrashort laser pulses, since the theoretical limit of the ultrashort-pulse duration supported by the gain medium is proportional to the inverse of the gain bandwidth. As the emission bandwidth of many laser dyes is $40-50$ nm, pulse durations down to tens of fs can be produced. The development of passive mode-locking is essential to the successful demonstration of femtosecond pulse generation in dye lasers. In passive mode-locking, a saturable (nonlinear) absorber (an absorbing dye) with an absorption that matches the emission wavelength of the lasing dye is placed inside the resonator cavity. Ideally, the leading and trailing edges of the optical pulse are removed by the absorber

whilst the peak of the pulse, unaffected by the absorber, experiences amplification. The efficiency of the absorber increases considerably if two oppositely traveling pulses interact or collide in the saturable absorber at the same time (colliding-pulse mode locking). This is a result of the two coherent pulses interfering constructively, leading to the reduction of power required for the saturation of the absorber. The colliding-pulse mode-locking configuration can be realized in either a linear or ring cavity. Because of the ease of alignment, the ring cavity is often preferred. Figure 11.179 shows the type of ring laser used originally by *Fork* et al. to generate pulses shorter than 100 fs [11.1552]. Both the laser dye (e.g., rhodamine 6 G) and the absorbing dye (e.g., DODCI) are in the form of a free-flowing stream jet, and a CW argon-ion laser serves as the pump. The radii of curvature of the mirrors must be carefully chosen so that the spot size in the absorber is smaller than that in the gain medium to assure pulse-forming stability.

11.8.6 Tunable Continuous–Wave Dye Lasers

The linewidth of tunable pulsed dye lasers with intracavity dispersive element for narrow-linewidth operation are of the order of 500 MHz. In contrast, a continuous-wave dye laser is capable of delivering laser output with linewidths as narrow as tens of kHz. The high resolving power is ideal for spectroscopy. Such high performance is connected with high cost, complicated design and a high-power pump source (often a CW argon-ion laser with 10–20 W output power). Continuous-wave dye lasers have much lower gain than their pulsed counter part. The loss reduction becomes critical and the removal of the long-lived triplet state is crucial for the stable operation of the laser. A free-flowing jet is used to effect rapid circulation of the dye. Since the gain profile of most dyes may be regarded as homogeneously broadened, one might expect single longitudinal-mode output from a simple grating or prism-cavity CW dye laser. However, single longitudinal-mode operation may not be possible in such linear-cavity dye lasers without intracavity frequency-selecting elements because spatial hole burning can arise gain saturation by the standing wave. Multimode output then results. Additional frequency-selecting elements such as an etalon must be inserted inside the cavity for single-mode operation increasing losses and lowering output power. Figure 11.180 shows a linear (standing-wave) cavity arrangement for a CW dye laser end-pumped by an argon-ion laser for single-mode operation. The dye jet flows perpendicularly to the page. The etalons assure
Fig. 11.180 Schematic of a linear-cavity CW dye laser for single-mode operation
Fig. 11.181 Schematic of a ring-cavity CW dye laser for single-mode operation. Note the use of an optical diode to assure unidirectional propagation of the traveling wave

narrow-linewidth output. The birefringent filters are for wavelength tuning. A ring-cavity supports the propagation of traveling waves and thus is ideal for single-mode operation. Figure 11.181 shows a tunable single-mode ring laser supporting single-mode operation. The optical diode (a Faraday isolator) ensures unidirectional travelling waves thus avoiding spatial hole burning.

11.8.7 Advanced Solid–State Dye Lasers

The contribution of liquid dye lasers to the advance of laser technology, particularly to ultrafast laser technology and the many applications of tunable lasers, cannot be overstated. Interested readers should consult monographs such as *Dye Lasers* by *Schäfer* [11.1553] or *Dye Laser Principles* by *Duarte* and *Hillman* [11.1554] and references therein for more detailed information on the range of applications of dye lasers. The excellent out-

put performance (as mentioned in the last paragraph) notwithstanding, dye lasers earn skepticism among their users. The main misgivings for dye lasers in liquid form, may be the disposal of the used dye and the maintenance problems associated with the physically large circulation loop for the dye flow. With the emergence of transition-metal solid-state lasers in 1980s, the position of dye lasers as the tunable laser-light source of choice has been facing a rising challenge. These solid-state lasers are based on the vibronic transitions of 3d transition-metal ions such as Cr^{3+}, Ti^{3+}, and Co^{2+} doped into oxide or fluoride crystals that served as the host [11.1555]. These transitional-metal ion-doped crystals show broad emission bands (typically 200–300 nm) in the visible to near-infrared spectral region and thus are good tunable-laser candidates. The most well known among them is the Ti^{3+}:Al_2O_3 (titanium:sapphire) laser. Tunable radiation in the blue–green and in the ultraviolet can in principle be obtained by frequency doubling or tripling the fundamental output of Ti^{3+}:Al_2O_3 lasers. In addition optical parametric oscillators (OPO) based on nonlinear optical crystals such as ADP or BBO (BaB_2O_4) are capable of providing tunable radiation well into the infrared [11.1556]. The leading role of dye lasers as a tunable coherent-light source is indeed somewhat diminished.

Challenges and Opportunities

Solid-state lasers are often preferred because of their ruggedness and easy maintenance. User-friendly dye lasers must do without the flow loop that circulates the dye solvent. Solid-state dye lasers (SSDL) incorporating the dye molecules in solid matrices appear to be able to combine the cost-effectiveness of liquid dye lasers and the ruggedness of inorganic solid-state lasers. In order for SSDL to be a serious competitor to inorganic solid-state lasers in various fields of applications, the problem of photodegradation of dye molecules must first be dealt with.

Good progress has been made in the synthesis of photostable dyes. The recently synthesized perylene family [11.1557] and the pyrromethene family [11.1558] of laser dyes have been shown to outperform rhodamine-6G in efficiency, tunability and photostability. Equally important to the development of SSDL are the solid-state matrices that serve as host materials where there has also been impressive progress. In the 1980s *Avnir* et al. [11.1559] and *Gromov* et al. [11.1560] demonstrated dye-doped sol-gel materials and dye-doped polymeric materials, respectively, as promising laser media. Both sol-gel materials and polymeric materials

were shown to have good chemical stability and wide optical transparency for use as host materials for laser dyes. The pace of research activity has increased considerably since then. In the sections to follow, we will bring the reader up to date with the latest development of solid-state dye lasers. The state of the art of solid-state dye lasers based on pure and hybrid sol-gel materials and on advanced polymers is covered in the next section. The most current development of solid-state dye lasers may be polymeric [11.1561] or sol-gel [11.1562] waveguide lasers using a distributed feedback configuration. These compact lasers produce tunable narrow-linewidth output and appear to be readily integrable into planar optical circuits. This is covered in the penultimate section. Finally the topic of tunable upconverted DFB dye lasers is presented.

Solid-State Dye Lasers Based on a Polymer Host

In 1967, one year after the demonstration of the first liquid dye lasers, *Soffer* and *McFarland* observed lasing in rhodamine-doped poly(methyl methacrylate) (PMMA) [11.1563]. The first polymeric hosts suffered from large thermal coefficients, stress birefringence, optical inhomogeneity and chemical reactivity with laser dyes. The most serious problem of dye-doped polymers is the tendency of aggregation of dye molecules, which effectively quenches fluorescence. As a result, the performance of the initial solid-state dye lasers was less than satisfactory. The properties of PMMA can, however, be improved by purification of the monomer, by introducing alcohol additives [11.1560]
Fig. 11.182 Experimental arrangement of a sol-gel DFB waveguide dye laser

and can be modified through copolymerization with a low molecular-weight polymer [11.1564]. The result is an improved polymer: modified poly(methyl methacrylate) (MPMMA) with the desired optical homogeneity and chemical stability suitable for use as a solid-state dye laser host [11.1565]. Work on the development of new polymeric hosts has been very active. *King* and coworkers showed that the photostability of solid-state dye lasers can be enhanced by deoxygenation of the host [11.1566] and the addition of a triplet-state quencher [11.1567]. Following the idea that photodegradation of dye molecules can be reduced by increasing the rigidity and hence the rate of heat dissipation of the host matrix, *Costela* et al. [11.1568] prepared pyrromethene dye-doped copolymers of methyl methacrylate (MMA) and different methacrylic and acrylic crosslinking polymers. The combined use of a photostable dye and new polymeric hosts results in SSDLs that boost the lifetime exceeding 10^6 shots at a repetition rate of a few Hz when pumped at 532 nm. Narrow-linewidth operation with a linewidth of 1.12 GHz has also been achieved in dye-doped MPMMA using a multiple-prism grating resonator cavity [11.1565]. Further improvement of the polymer host will undoubtedly lead to SSDLs that would gain the acceptance of the common laser users.

Solid–State Dye Lasers Based on a Sol–Gel Host

The sol-gel method is a low-temperature glass-making technique that enables the introduction of organic dyes into inorganic glasses. Porous glass can be obtained via the sol-gel route by hydrolysis and polycondensation of metal alkoxides [11.1568]. Initial studies of sol-gel silica doped with organic dyes indicated that sol-gel materials held good promise as SSDL host materials because of their wide transparency range and the apparently excellent optical and thermal properties of silica [11.1559, 1569]. An added advantage is the high concentration without aggregation and the photostability of a dye when trapped in sol-gel silica, as a result of the isolation of dye molecules in the silica cage. Soon tunable laser action from sulforhodamine-doped sol-gel silica was demonstrated [11.1570]. Lasing and fluorescence properties of a large number of dyes in sol-gel silica that cover the spectral range from the near ultraviolet to the near infrared were fabricated and examined [11.1571]. Several variants of sol-gel materials have been used as solid-state dye-laser host materials with varying degree of success. The first sol-gel material used in dye-laser experiments was in fact a glassy gel obtained by the gelation of a solution and is sometimes called a xerogel [11.1572]. Xerogel derived from inor-

ganic precursors is mechanically fragile and optically lossy due to the presence of numerous pores. The use of organically modified precursors or organic modifiers during the sol-gel process results in organically modified silicates (ORMOSILs) that show improved mechanical strength and much reduced optical loss [11.1565, 1566]. The combined use of the improved sol-gel materials as host and the deoxygenation procedures during sample preparation has lead to sol-gel dye lasers with lifetime exceeding one million shots [11.1573].

One of the attractions of sol-gel materials is the potential that such glassy materials can have properties similar to glasses made via the traditional high-temperature approach. Another attraction is the ability of sol-gel materials to trap both organic and inorganic dopants while showing exceptional chemical stability. Whilst very few polymeric dye lasers work in the blue to near-UV range due to problems related to attenuation and photostability under UV excitation, several UV laser dyes have been doped into sol-gel materials [11.1574, 1575]. Laser action with output wavelengths as short as 340 nm have been observed [11.1575].

From the recent development of polymer or sol-gel dye lasers, one must rely on the role of materials engineering in advancing solid-state dye lasers.

Distributed Feedback Waveguide Dye Lasers

Distributed feedback (DFB) lasers are compact tunable laser sources that produce narrow-linewidth output. The first DFB laser was in fact a solid-state dye laser (dye-doped gelatin film), but it did not operate as a waveguide laser because of the high film thickness [11.1576]. In subsequent developments, the majority of DFB laser work has concentrated on semiconductor lasers that have been of obvious industrial significance. Recently there has been a renewal of interest in organic DFB lasers, particularly those based on waveguide structures. This renewal in interest was caused in part by the application of conjugated polymers as luminescent materials [11.1577, 1578] and the subsequent conjugated polymer laser experiments [11.1579, 1580]. Dye-doped polymeric materials or sol-gel materials can be prepared in a planar waveguide structure by simply using spin-coating or dip-coating. Sol–gel materials have the additional advantage of a larger range of refractive index variation [11.1581, 1582] which allows integrated optics application on a large number of polymer or glass substrates. DFB configuration seems ideally suited for laser output generation in these waveguide structures. Polymeric [11.1583] and sol-gel [11.1562] DFB wave-
Fig. 11.183 Schematics of Nd:YAG-microchip-pumped DFB dye lasers [11.1578]

guide dye lasers with tunable narrow-linewidth output have indeed been demonstrated.

Figure 11.182 shows the typical setup for the generation of a sol-gel DFB waveguide dye laser. The dynamic grating responsible for the lasing effect was produced by the crossing beams, which also served as the pump. Tuning was by varying the incident angle of the beams and hence the grating period. The periodic perturbation necessary for DFB lasing can also be produced by permanent morphological modulation
of the substrate surface. One of the interesting features of DFB waveguide dye lasers is the possibility of the production of tunable multiple-wavelength output. *Oki* et al. [11.1584, 1585] fabricated a multi-striped plastic waveguide laser array that could generate multiple output wavelengths in the range 575–945 nm (Fig. 11.183). Another approach to obtain multiple output wavelengths is to take advantage of waveguide structures that support multiple propagation modes [11.1586]. Figure 11.184 shows the scan traces of a prism coupler for a titania–zirconia organically modified silicate waveguide on a glass substrate [11.1587]. The titania–zirconia organically modified silicate film has a thickness of 6.7 μm and a refractive index of 1.56. Eight TE modes and eight TM modes were observed. The action of the crossing beams produced DFB laser output with wavelengths that obey the Bragg condition, $\lambda_L = \eta \lambda_p / M \sin \theta$, where η is the refractive index of the gain medium at λ_L, λ_p is the pump-laser wavelength, and M is the Bragg reflection order. For DFB laser action in waveguides, η takes on the values of the effective indices for TE_i modes or TM_i modes (i.e., i varies from 0 to 7 for a 6.7 μm film). Figure 11.185 shows a typical DFB laser output spectrum with a polarizer that blocks the TM modes [11.1587]. Without the polarizer all eight pairs of TE/TM modes could be observed. It was found that the crossing s-polarized beam generated purely TE modes, whilst pairs of TE/TM modes were produced when p-polarized beams were used. Furthermore, the separation between the modes and the number of modes can be controlled by varying the waveguide parameters such

Fig. 11.184 Scans of TE TM waveguide modes for a sol-gel titania–zirconia organically modified silicate waveguide of thickness 6.7 μm and a refractive index of 1.56 on a glass substrate using a prism coupler
Fig. 11.185 Output emission spectrum of a multiple wavelength sol-gel DFB waveguide dye laser. The conditions of the waveguide are the same as in Fig. 11.184

as the index difference and guiding-film thickness. Simultaneous tuning of multiple output modes was also achieved (Fig. 11.186). Such compact tunable multiple-wavelength lasers should find wide applications from analytical spectroscopy to optical communications.

Distributed Feedback Laser Action by Polarization Modulation

The original DFB laser theory describes the laser action caused by periodic perturbation of gain or refractive index [11.1576, 1588] both of which could be generated by intensity modulation. A schematic of a typical crossing beam experiment is illustrated in Fig. 11.187. The two beams are shown to have their polarization directions at an angle Φ. The crossing beams must both be s-polarized ($\Phi = 0°$) for the formation of an intensity interference pattern (intensity modulation). The intensity interference pattern in the gain medium produces a concentration grating of excited-state atoms/molecules which will provide the periodic change in gain or refractive index necessary for DFB laser action. The crossing of an s-polarized beam with a p-polarized beam ($\Phi = 90°$), however, does not produce an intensity interference pattern. Instead, a periodic change of the polarization (polarization modulation) of the resultant field that changes from linear polarization to elliptical polarization to circular polarization and then back to elliptical polarization after one period. The grating that results from polarization modulation is a polarization grating.

Figure 11.188 shows the DFB laser emission spectra of rhodamoine 6G-doped zirconia waveguides as Φ changes from 0° to 90° for $\theta \approx 44°$ [11.1587]. The pump energy used was 10 μJ. The situation at $\Phi = 0°$ corresponds to the case of pure intensity modulation. The variation of Φ changes the amplitude of the s-polarized component of the beam. As Φ increases, the effectiveness of intensity modulation weakens as the disparity in amplitude of the s-polarized components of the two crossing beams grows, resulting in a low degree of modulation in the transient intensity grating. At $\Phi = 60°$, the amplitude of the electric field of the s-polarized component is $1/2$ of the companion beam. The effect of intensity modulation is already so weakened that a substantial ASE (attenuated spontaneous emission) background (ratio of the DFB output intensity to the ASE intensity of 10:3) appears in the emission spectrum. At $\Phi = 90°$, DFB lasing is completely extinguished since the s-polarized component of one of the beams has zero amplitude. The pump energy was then gradually raised to about 30 μJ. DFB lasing reappeared at 30 μJ, but this
Fig. 11.186 Wavelength tuning of a multiple wavelength sol-gel DFB waveguide dye laser. The conditions of the waveguide are the same as in Fig. 11.184

time the feedback mechanism was provided by polarization modulation. The distinguishing feature of DFB lasing induced by the polarization modulation is the appearance of a pair of TE_0/TM_0 output modes, whereas only the TE_0 mode is observed in the case of intensity modulation.

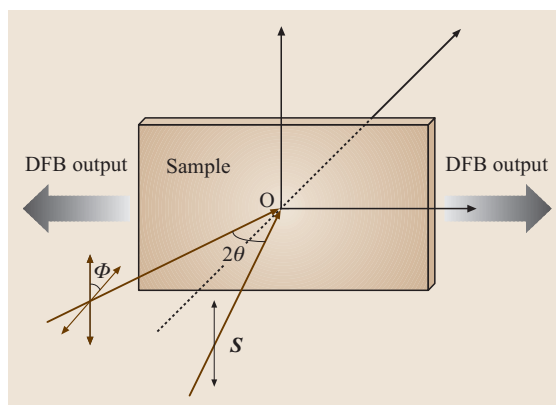
Our latest experiments on polarization modulation have revealed that DFB lasing can also be induced in liquid dye solution. The pump threshold is drastically reduced by increasing θ. For θ larger than 75°, as is the case for DFB lasing of liquid oxazine dye near 800 nm under the first-order Bragg condition, the threshold pump


Fig. 11.187 Schematics for polarization modulation DFB laser experiments
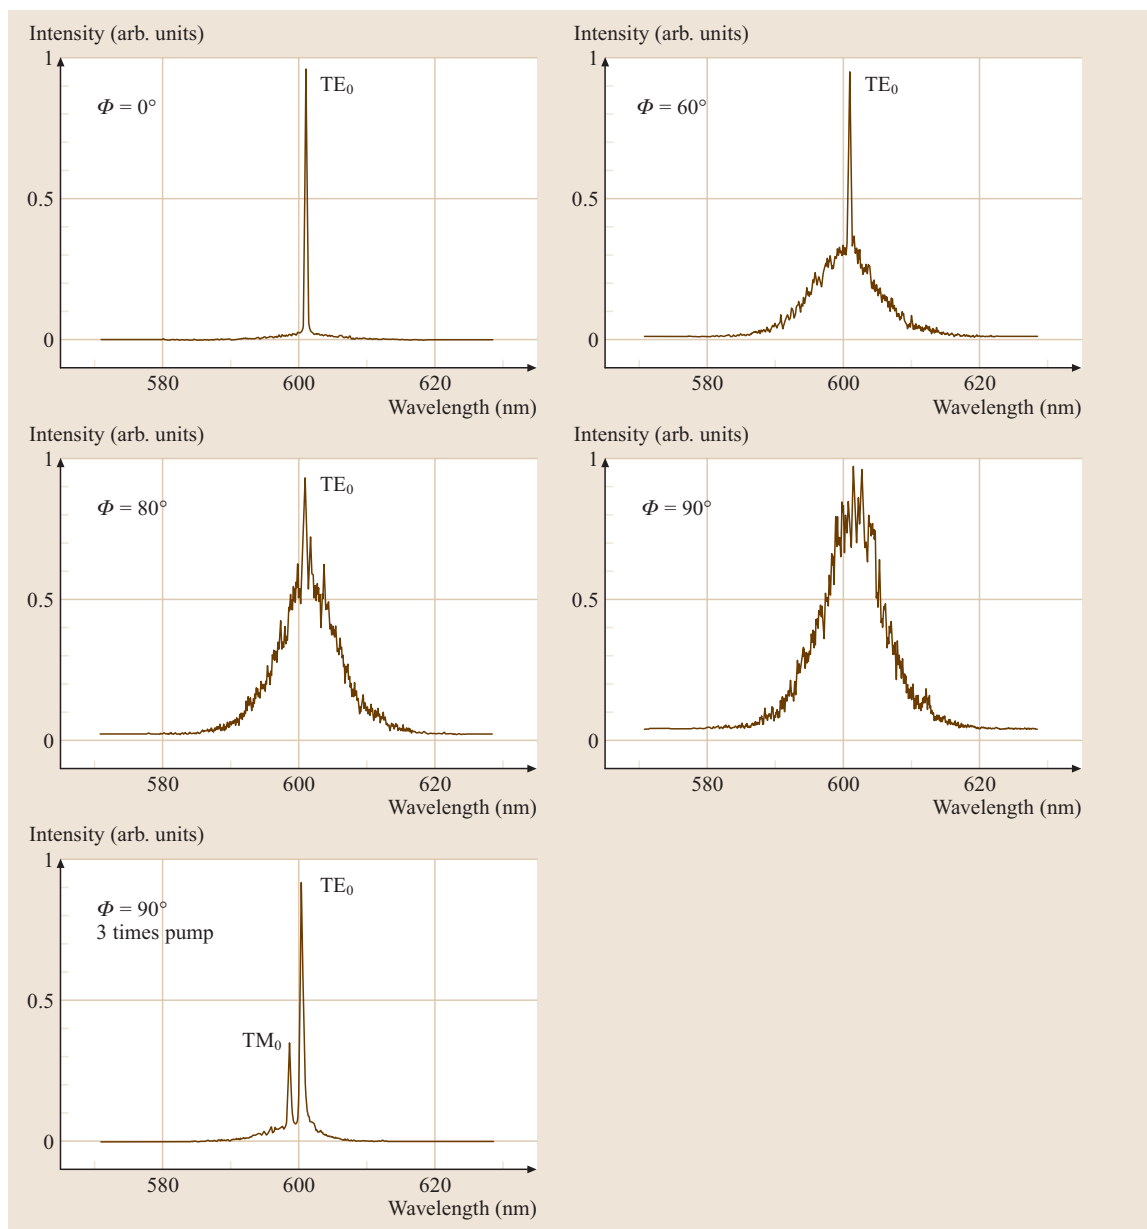

Fig. 11.188 Output emission spectra of sol-gel DFB waveguide dye lasers as Φ varies

energy for DFB lasing by polarization modulation is the same as that by intensity modulation. Further work on DFB lasing by polarization modulation is underway.

Two–Photon–Pumped Solid–State Dye Lasers

Compact visible lasers by direct upconversion of infrared light are versatile light sources that hold promise

for many applications in optoelectronics. Many dyes (e.g., R6G, DCM) have been known to emit weakly in the visible when pumped in the near infrared. Indeed, broadband laser emission in the visible was observed in two-photon pumped polymer waveguide and fiber [11.1589, 1590]. A number of dyes with large two-photon pump upconverted absorption cross
Fig. 11.189 Absorption, two-photon-pumped fluorescence and ASE spectra for an HMASPS-doped zirconia waveguide

Fig. 11.190 Tuning curves for DFB lasing in HMASPS-doped zirconia waveguides

section have been synthesized recently. In particular, a styrylpyridinium dye: trans-4-[p-(N-hydroxyethyl-N-methylamino) styryl]-N-methylpyridinium p-toluene sulfonate (abbreviated as HMASPS) that shows strong emission in the red [11.1591] was doped in sol-gel zirconia thin films on a glass substrate [11.1592]. Figure 11.189 shows the absorption, two-photon-pumped fluorescence and ASE spectra from the HMASPS thin-film waveguides. A strong emission peak centered at 620 nm is seen. Using two crossing 1.06 μm beams as

the pump, DFB lasing was observed in the red with a linewidth as narrow as 45 GHz. Subsequent experiments demonstrated tuning by varying the intersection angle of the two 1.06 μm crossing beams [11.1592]. Figure 11.190 shows the tuning curves for second ($M = 2$) and third ($M = 3$) Bragg orders. A tuning range of 25–30 nm was observed. Extension of the spectral coverage and improved output performance of the two-photon-pumped DFB lasing are expected as more new two-photon dyes are explored for DFB lasing study.

11.9 Optical Parametric Oscillators

Optical parametric oscillators (OPO) are based on non-linear frequency conversion of laser radiation into two coherent light waves with lower frequencies, called the signal and idler waves. The first optical nonlinear conversion experiment was demonstrated soon after the invention of the laser by the observation of second-harmonic generation of ruby laser radiation in a quartz crystal [11.1593]. This first result initiated intense experimental and theoretical investigations to increase the conversion efficiency and the available wavelength range. In the following several years the physics of the nonlinear frequency conversion was theoretically well understood and all important methods of maximizing the conversion efficiency were elaborated, including quasi-phase matching [11.1594, 1595], birefringence phase matching in crystals [11.1596, 1597] and the requirement for optimum focusing [11.1598]. The first optical parametric oscillator was proposed in 1962 by

Kroll [11.1599] and realized in 1965 by *Giordmaine* and *Miller* [11.1600], followed by detailed theoretical and experimental investigations [11.1601–1603]. Several review articles display a survey about the state of the art of optical parametric oscillation until the mid 1980s [11.1604–1607].

However, despite this initial efforts, the success of OPOs as a versatile tunable light source fell short of expectations for almost a decade. At that time the reasons were unsuitable birefringence of the crystals to permit phase matching, low transparency and damage thresholds, difficulties in growing large homogenous crystals and the lack of reliable laser sources with good spatial and spectral properties, which are important for efficient frequency conversion.

This situation changed due to significant advances in crystal growth techniques in the mid 1980s for both laser-active and nonlinear crystals [11.1608, 1609], lead-

ing to a renaissance of solid-state lasers. The availability of reliable pump sources with high spatial and spectral coherence (in continuous and pulsed operation mode), low-loss optical components and the appearance of new or optimized nonlinear materials (BBO, LiB$_3$O$_5$ (LBO), KTiOPO$_4$ (KTP), KNbO$_3$) started a new OPO evolution. Optical parametric oscillators are powerful devices for the efficient generation of widely tunable coherent light. The intense research in OPOs has resulted in reliable OPO systems, which are commercially available. The tunability and the high output power define the optical parametric oscillator as an attractive source in many applications including high-resolution spectroscopy, environmental monitoring, medical research, process control, remote sensing and precision frequency measurements.

Recently a new generation of conversion media have appeared with periodically structured ferroelectric materials for quasi-phase matching. Together with the development of diode-pumped all-solid-state lasers and in particular high-brightness diode-laser systems new perspectives are opened towards modern, compact, efficient, powerful, tunable OPO systems.

11.9.1 Optical Parametric Generation

The theoretical treatment of optical parametric generation has been presented in the early 1960s [11.1610, 1611] and is found in many textbooks and review articles [11.1604–1606,1612–1614]. Therefore, this section will provide only a brief description of the most important equations. The interaction of intense laser fields with a dielectric material induces nonlinear susceptibilities and causes the polarization of the medium to develop new frequency components not present in the incident radiation field.

The lowest-order nonlinear susceptibility $\chi^{(2)}$ is responsible for three-wave mixing processes such as second-harmonic generation (SHG), sum- and difference-frequency mixing (SFG, DFG), optical rectification and the optical parametric generation (OPG). Optical parametric generation with a feedback resonator for at least one of the waves is called optical parametric oscillation (OPO). The relation between the electric field E and the polarization density P in the medium is given for a second-order susceptibility as

$$P = \varepsilon_0(\chi^{(1)}E + \chi^{(2)}EE)$$
$$P = P_l + P_{nl} \tag{11.159}$$

with ε_0 the vacuum permittivity and the susceptibility $\chi^{(k)}$, which are tensors of the rank k for an anisotropic medium. Because $\chi^{(2)}$ is zero in centrosymmetric systems three-wave mixing is only possible in non-isotropic media. Generally, the $\chi^{(2)}$ tensor possesses 27 elements, but many of the components vanish under certain symmetry conditions. The tensor can be reduced even to a scalar if the interacting waves are linearly polarized and monochromatic for a fixed crystal orientation. In this case, the effective nonlinearity is denoted by a coefficient $\chi^{(2)}_{eff}$. In the literature [11.1614] the second-order susceptibility is often expressed by a coefficient d defined by $d := \chi^{(2)}/2$.

The dynamics of optical parametric generation or three wave-mixing processes in general can be described by a set of nonlinear coupled differential equations for the field amplitudes of the optical waves interacting with the nonlinear medium.

Considering the basic wave equation derived from Maxwell's equations for nonmagnetic dielectric media where P_{nl} is regarded as source radiation

$$\nabla^2 E = \mu_0\varepsilon\frac{d^2}{dt^2}E + \mu_0\frac{d^2}{dt^2}P_{nl} \tag{11.160}$$

and assuming

$$\frac{\partial E_1(z)}{\partial z} = i\kappa_1 E_3(z)E_2^*(z)e^{i\Delta kz} , \tag{11.161}$$

$$\frac{\partial E_2(z)}{\partial z} = i\kappa_2 E_3(z)E_1^*(z)e^{i\Delta kz} , \tag{11.162}$$

$$\frac{\partial E_3(z)}{\partial z} = i\kappa_3 E_1(z)E_2(z)e^{-i\Delta kz} , \tag{11.163}$$

with the coefficients $\kappa_i = \omega_i d_{eff}/n_i c_0$ $(i = 1, 2, 3)$, d_{eff} the nonlinear coefficient, z the propagation direction and $\Delta k = k_3 - k_2 - k_1$ the phase mismatch.

This set of equations, the *coupled wave equations* represents the interaction of three plane waves in a $\chi^{(2)}$ nonlinear dielectric. They have been solved exactly by *Armstrong* et al. [11.1594] for various input conditions. Depending on the initial conditions for the three complex amplitudes, these equations describe the various types of three wave-mixing processes generated by the single-pass propagation of the electromagnetic field through the crystal, such as second-harmonic generation, sum- and difference-frequency mixing and parametric generation.

The optical parametric generation process where only one wave with frequency ω_3 enters the dielectric medium and generates two waves with the lower frequencies ω_1 and ω_2 is based on the optical parametric fluorescence starting from the quantum noise. This pure quantum mechanical effect was first proposed and studied in 1961 by *Louisell* et al. [11.1615]. A quantum-mechanical model [11.1616] and semiclas-

sical descriptions of the optical parametric fluorescence can be found in the literature [11.1612, 1613, 1617].

The process of parametric amplification starts with a small field amplitude of the signal ($\omega_1 = \omega_s$) or idler wave ($\omega_2 = \omega_i$). The relation between the frequencies is always $\omega_s + \omega_i = \omega_p$ and per the definition $\omega_s \geq \omega_i$.

Introducing the definition for the intensity $I = 1/2\varepsilon_0 nc|E|^2$ the coupled field equations lead to the Manley–Rowe equation [11.1618] which is equivalent to photon conservation.

$$\frac{dI_s}{\omega_s\,dz} = \frac{dI_i}{\omega_i\,dz} = -\frac{dI_p}{\omega_p\,dz} \tag{11.164}$$

The conversion of every pump photon generates a pair of signal and corresponding idler photons. In this sense the relation $\omega_p = \omega_s + \omega_i$ corresponds to energy conservation and $\Delta k = k_p - k_s - k_i = 0$ to the impulse conservation of the parametric process.

Neglecting pump field depletion ($dE_p/dz = 0$) and assuming the presence of only the signal field ($E_i = 0$) in the beginning of parametric process the coupled wave equations can be solved analytically [11.1605, 1606]. The single-pass fractional gain in signal intensity is obtained as

$$G_s(l) = \frac{I_s(z=l)}{I_s(z=0)} - 1 = \Gamma^2 l^2 \frac{\sinh^2 gl}{(gl)^2}, \tag{11.165}$$

where l is the length of the nonlinear medium and g the total gain factor

$$g = \sqrt{\Gamma^2 - \left(\frac{\Delta k}{2}\right)^2}, \tag{11.166}$$

and Γ the parametric gain factor

$$\Gamma^2 = \frac{2\omega_s\omega_i|d_{\text{eff}}|^2 I_p}{n_p n_s n_i \varepsilon_0 c^3}. \tag{11.167}$$

The material-dependent part of the gain coefficient $|d_{\text{eff}}|^2/(n_p n_s n_i)$ is called the figure of merit (FOM) and classifies the nonlinear quality of the conversion medium.

In the high-gain limit the single-pass gain becomes

$$G_s = \left[1 + \left(\frac{\Delta k}{2g}\right)^2\right] \sinh^2 gl \tag{11.168}$$

which reduces to

$$G_s(l) \cong \frac{1}{4}\,e^{2\Gamma l} \tag{11.169}$$

when $\Delta k < g$.

In the low-gain limit where $\Gamma^2 l^2 < (\Delta k/2)^2$ the gain of a parametric amplifier is

$$G_s(l) = \Gamma^2 l^2 \frac{\sin^2\left\{\left[\left(\frac{\Delta k}{2}\right)^2 - \Gamma^2\right]^{\frac{1}{2}} l\right\}}{\left[\left(\frac{\Delta k}{2}\right)^2 - \Gamma^2\right] l}. \tag{11.170}$$

Considering perfect phase matching $\Delta k = 0$, the single-pass signal gain in the low-gain limit approximates to

$$G_s(l) \cong \Gamma^2 l^2 \propto d_{\text{eff}}^2 l^2 \tag{11.171}$$

It can be seen that the magnitude of the parametric gain depends on the intensity of the incoming field, as well as on the material parameters such as nonlinear coefficient, refractive index and the interaction length. However, the main condition for an efficient parametric amplification is the phase-matching condition. As shown in Fig. 11.191 the parametric gain reaches a maximum for $\Delta k = 0$, and decreases symmetrically to zero for $|\Delta kl| = \pi$.

The gain bandwidth is defined by

$$\left|\left(\frac{1}{2}\Delta k^2\right) - \Gamma^2\right|^{1/2} l = \pi, \tag{11.172}$$

which reduces for low gain to

$$\left(\frac{1}{2}\right)\Delta kl = \pi. \tag{11.173}$$

The gain bandwidth increases with higher gain, but until reaching $\Gamma^2 l^2 \cong \pi$ the bandwidth broadening is small.
Fig. 11.191 Parametric gain of a nonlinear crystal of length l as a function of the phase mismatch Δkl. The gain is maximum by optimum phase matching $\Delta kl = 0$. The full width at half-maximum (FHWM) of the gain function is 0.88π

11.9.2 Phase Matching

As shown before effective three-wave-mixing in a nonlinear medium is only achieved if the phase-matching condition ($\Delta k = k_p - k_s - k_i = 0$) is fulfilled. Together with the frequency-matching condition ($\omega_p = \omega_s + \omega_i$), this condition implies the spatial phase matching of the three waves which is necessary for constructive interference of the interacting waves within the nonlinear medium.

This conservation of energy and momentum is not possible in materials with isotropic dispersion. Due to the different diffraction indices, the optical fields of the three frequencies differ in phase velocity and the relative phase of the interactive waves varies along the medium. A measure of the phase mismatch is the coherence length $L_c = \pi / |\Delta k|$, which defines the distance over which the relative phase of the interacting waves shifts by π. The propagation beyond the coherence length, which is typically several μm, leads to back-conversion from the generated waves into the pump wave. The oscillating behavior of the generated intensity depending on the interaction length is shown in Fig. 11.192.

Today there are two different techniques to realize a phase-matched conversion process: birefringence phase matching and the quasi-phase matching.

Birefringence Phase Matching

This method uses the dependence of the refractive index on the propagation direction and polarization of electromagnetic waves in birefringence crystals. The waves are distinguished into ordinary (o) and extraordinary (e) waves depending on their polarization direction. In uniaxial crystals the refractive index of the ordinary wave is independent from the propagation direction whereas the refractive index of the extraordinary wave depends on the polar angle between the optical axis and the propagation direction. To achieve phase matching the polarization of the high-frequency pump wave should be selected so that the index of refraction is smallest. The phase-matching condition can be realized by choosing an appropriate angle between propagation direction and optical axis. Angular phase-matched wavelength tuning is then possible by changing the phase-matching angle with regard to the phase-matching condition $n_p \omega_p = n_s \omega_s + n_i \omega_i$. The process is called type I phase matching when both generated waves have the same polarization perpendicular to the polarization of the pump wave, for example (e–oo). For type II phase matching the polarization of the generated waves are oriented perpendicular to each other (e–oe). An analyti-
Fig. 11.192 Conversion intensity as function of the propagation length in a nonlinear crystal. NPM: Non-phase-matched process with no significant total conversion intensity. BPM: birefringence phase matching. Intensity increases quadratically with z, with a slope given by $d_{eff,BPM}^2$. QPM: Quasi-phase-matched process. Intensity increases quadratically with z on average, with a slope given by $d_{eff,QPM}^2 \gg d_{eff,BPM}^2$

cal solution of the phase matching angle is only possible for type I phase matching in uniaxial crystals, the other processes have to be solved numerically [11.1609]. The analysis in biaxial crystals is more complicate and has only numerical solutions; only in their principle planes can the formalism be reduced to the uniaxial conditions (Table 11.47 [11.1619, 1620]. A consequence of angular birefringence phase matching is the spatial walk-off generated by the birefringence, which reduces the interaction length of the optical waves. Besides the angular phase matching the indices of refraction can be matched by changing the crystal temperature (temperature phase matching). Combined with a propagation direction perpendicular to the principal axis this method is called noncritical phase matching (NCPM) and results in the absence of spatial walk-off and less angular sensitivity, which is important in applications with tight focusing.

The vector equation of the phase matching condition can be realized in a non-collinear or a collinear way. In contrast to the collinear phase matching is the non-collinear phase matching a vector phase matching. Figure 11.193 shows the non-collinear angle included by the wavevectors. With the choice of a suitable non-collinear angle the angular acceptance is enlarged or the Poynting vector walk-off can be compensated. The conditions for the walk-off compensation are shown in Fig. 11.193a; the Poynting vectors of the ordinary signal and the extraordinary pump wave are paral-

Table 11.47 Refraction indices of ordinary and extraordinary wave for uniaxial and biaxial crystals in the principle planes

Crystal	Extraordinary wave (e)	Ordinary wave (o)
Uniaxial	$n_e(\Theta) = \dfrac{n_o n_e}{\sqrt{n_e^2 \cos^2 \Theta + n_o^2 \sin^2}}$	$n_o(\Theta) = n_o$
Biaxial, xy-plane	$n_e^{xy}(\Phi) = \dfrac{n_x n_y}{\sqrt{n_x^2 \cos^2 \Phi + n_y^2 \sin^2 \Phi}}$	$n_o(\Phi) = n_z$
Biaxial, xz-plane	$n_e^{xz}(\Theta) = \dfrac{n_x n_z}{\sqrt{n_x^2 \cos^2 \Theta + n_z^2 \sin^2 \Theta}}$	$n_o(\Theta) = n_y$
Biaxial, yz-plane	$n_e^{yz}(\Theta) = \dfrac{n_y n_z}{\sqrt{n_y^2 \cos^2 \Theta + n_z^2 \sin^2 \Theta}}$	$n_o(\Theta) = n_x$

lel. Such walk-off compensation is of advantage for nanosecond OPOs reaching higher conversion efficiencies [11.1621] and necessary for critical-phase-matched OPOs pumped by ultrashort pulses because of the small beam radii [11.1622, 1623]. The diagram of tangential phase matching is shown in Fig. 11.193b. This special case of non-collinear phase matching produces a significant enlarged angular acceptance for the extraordinary pump wave. In addition, group-velocity matching for ultrashort pulses is realized via non-collinear phase matching [11.1624].

Quasi–Phase Matching

An alternative method to achieve phase matching via phase correction is quasi-phase matching (QPM). Here the relative phase between the three waves is corrected using a periodic change in the sign of the nonlinear susceptibility (Fig. 11.192) before the back conversion starts. Although the technique of QPM was proposed even before birefringence phase matching [11.1594], difficulties in fabrication of the periodic structure in the range of the coherence length (typically $1-100\,\mu\text{m}$) have prevented its realization

for a long time. Recent advances in the fabrication of structured ferroelectrics meanwhile have established this technique for efficient frequency-conversion applications.

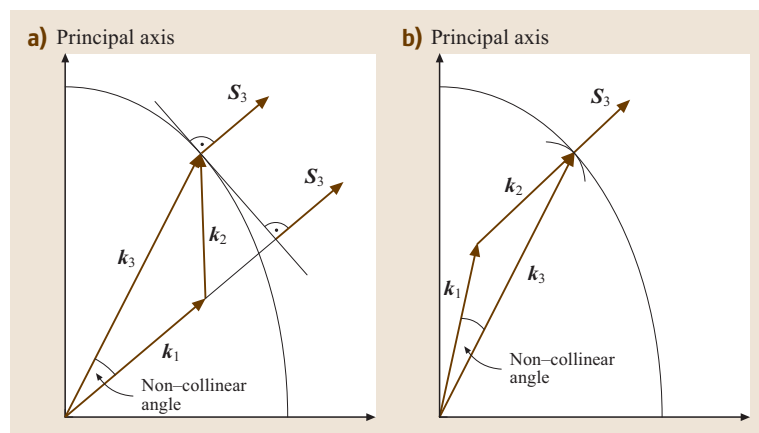
Quasi-phase matching through periodically poling offers two major advantages over birefringence phase matching. First, the polarization of the interacting waves can be equal. This allows the use of the largest $\chi^{(2)}$ coefficient of the crystal, which reduces the pump threshold and increases the conversion efficiency. The second advantage is that the quasi-phase matching of any combination of pump, signal and idler wavelength can be realized in such materials via periodic poling. In addition, QPM provides design flexibility of nonlinear conversion devices by engineered domain structures. Applications with novel configurations such as chirped gratings for pulse compression [11.1625], fan-out gratings for broad tunability [11.1626], quasi-periodic structures for simultaneous operation of two three-wave-mixing processes [11.1627] and two-dimensional gratings for multiple direction phase-matching processes [11.1628] have been demonstrated.


Fig. 11.193a,b Wavevector diagram for different non-collinear phase-matching schemes. (**a**) Walk-off compensation, (**b**) scheme for tangential phase matching

Phase Mismatch and Acceptance Bandwidths

The ideal phase-matched interaction, where the pump wave and idler and signal waves propagate with the same velocity through the nonlinear crystal, $\Delta k = 0$, is affected under real experimental conditions by several parameters such as the divergence and bandwidth of the pump radiation, the bandwidth of the generated radiation and an inhomogeneous temperature distribution. The tolerances of the nonlinear material concerning to these perturbations are expressed by the acceptance bandwidths. They are defined by the FWHM of the parametric gain width (Fig. 11.191) and developed in Taylor series of $\Delta k(0)$:

Angular acceptance

$$\Delta \delta = 2 \times 0.886 \pi l^{-1} (\delta \Delta k / \delta \delta)^{-1} \; ;$$

Gain band width

$$\Delta \omega_s = 2 \times 0.886 \pi l^{-1} (\delta \Delta k / \delta \omega_s)^{-1} \; ;$$

Spectral acceptance

$$\Delta \omega_p = 2 \times 0.886 \pi l^{-1} (\delta \Delta k / \delta \omega_p)^{-1} \; ;$$

Temperature acceptance

$$\Delta T = 2 \times 0.886 \pi l^{-1} (\delta \Delta k / \delta T)^{-1} \; . \qquad (11.174)$$

11.9.3 Optical Parametric Oscillators

An optical parametric oscillator consists of three basic components, namely the pump source, the gain medium, and the feedback resonator. For a qualitative description of the operation principle we consider the most basic OPO setup, as shown schematically in Fig. 11.194.

An intense coherent light field produced by a laser beam propagates through an optically nonlinear crystal with the frequency ω_p. The crystal is placed inside an optical resonator, which resonates for reasons of simplicity with one wave, for example the signal wave. As the nonlinear crystal provides a sufficient nonlinearity, parametric generation takes place and a pump
Fig. 11.194 Schematic setup of an OPO. An optical wave with frequency ν_p from the pump source is converted into two output waves with frequencies ν_s and ν_i via three-wave interaction in a nonlinear crystal. M1 and M2 are mirrors of a feedback resonator

photon is converted into a signal and idler photon fulfilling photon-wise energy conservation $\omega_p = \omega_s + \omega_i$. The resonator feeds the signal wave back into the crystal where it is further amplified through the power transfer from the pump wave, as expressed in (11.164). Optical parametric oscillation starts, when the increased signal intensity surpasses threshold that means the amplified signal wave compensates for the round-trip losses in the resonator (due to mirror transmission, absorption, scattering and diffraction). Reaching this distinct pump intensity, the threshold pump intensity, a significant portion of the pump intensity is converted into signal and idler intensity. This power transfer from the pump to the generated waves reduces the (spatially averaged) pump intensity inside the nonlinear crystal and thus the signal gain. This effect is called gain saturation. It leads to steady-state operation of the OPO, where the signal power generated inside the crystal exactly balances the resonator losses for the signal wave.

As any pair of signal and idler photon can be generated from the initially random vacuum field fluctuations in steady-state operation, the signal and idler frequency pair that has the minimum threshold pump intensity is generated. Thus the generated frequencies, and with them the ratio of the signal and idler frequency, are determined by the frequency dependence of the parametric gain in the crystal and the frequency dependence of the resonator losses.

A detailed description of the behavior of optical parametric oscillators has been published in several reviews [11.1604–1606] and the physics of OPOs is discussed more fundamentally in a number of textbooks about nonlinear optics [11.1612–1614].

In the literature, optical parametric oscillators are mostly classified into three groups: continuous-wave optical parametric oscillators, nanosecond pulsed optical parametric oscillators and synchronously pumped picosecond or femtosecond optical parametric oscillators, depending on the temporal characteristic of their pump laser.

This distinction is not only a practical classification but is important for the theoretical description and the basic performance, such as pump intensity at threshold, conversion efficiency and spectral performance.

11.9.4 Design and Performance of Optical Parametric Oscillators

The performance of an optical parametric system concerning tunability, high output intensity, spectral and spatial coherence is directly related to key elements

of the OPO's architecture, which are pump source, nonlinear material and feedback resonator. In general, the physics of the optical parametric process imposes several requirements of potential OPO components.

A simultaneous optimization of all OPO features cannot be fairly done because of material problems and physical conflicts. Therefore, a general description of an optimized OPO design is not possible and the device configuration is always a compromise depending on the requirements of the specific application.

The choice of the pump laser depends together with the selection of the nonlinear material on the required wavelength range and time resolution for a given application. Obviously, the pump laser has to be powerful enough to drive the OPO well above threshold and guarantee stable OPO operation. Since good spatial and spectral beam quality reduces the threshold, preferred pump sources will be high-power lasers of several watts, which also provide an excellent spatial beam quality, and good power and frequency stability. If the available pump power is restricted, low beam divergence is of particular importance to allow focusing into the nonlinear crystal. The deviations in spectral and spatial coherence tolerated by the parametric frequency conversion are determined by the acceptance bandwidths of the nonlinear material. Wavelength tunability of the pump laser offers an additional attractive feature: tuning of the OPO via the pump wavelength.

The selection of the nonlinear material depends on the nonlinear parametric process, the experimental design and the properties of the pump source. Fundamentally, the nonlinear crystal should be distinguished by a broad transparency range, a high optical-damage threshold and large effective nonlinearity. An important parameter is the birefringence of the crystal that has to be high enough to maintain phase matching. However, this effect should not be too large because another consequence of birefringence is spatial walk-off, which reduces the interacting length of the coupled fields. Large spectral and angular acceptance bandwidths are advantageous because real laser systems show finite bandwidths and divergence and in ultrashort optical parametric oscillation, the temporal walk-off and group-velocity dispersion between pump, signal and idler wave should be low. For stable operation of OPO systems with high energies the thermo-mechanical and thermo-optical stability of the crystal should be sufficient. Finally, the crystals should be available in appropriate dimensions and excellent optical homogeneity.

The design of the feedback resonator is strongly connected to the output characteristic of the pump source. If the available pump power is restricted the OPO design may have to be modified for lower threshold, which might however restrict the tuning capabilities of the OPO. Three types of feedback resonators are distinguished, depending on the number of resonating waves. The singly resonant OPO (SRO) has highly reflecting mirrors at the signal or the idler wave. In principle, this configuration is of particular advantage because it should provide continuous wavelength tunability. The disadvantage of these systems are their high pump power at threshold, which exceeds several watts [11.1629, 1630]. Therefore SRO devices are mainly found for pulsed OPO configurations.

Doubly resonant OPO configurations (DRO) where both signal and idler waves are resonated have received much attention, because the pump power at threshold is reduced by one to three orders of magnitude. However, such DRO OPOs do not provide mode-hop-free tunability and often suffer from frequency and power instabilities [11.1631, 1632]. Continuous wavelength tuning requires active stabilization techniques [11.1633, 1634].

The doubly resonant configuration where pump and signal (or idler) waves are resonated is called pump-enhanced SRO (PESRO). Such devices are very attractive because they provide a compromise between the low pump power at threshold of DROs and the wide tunability of SROs when the length of the OPO is carefully locked to a frequency-stabilized pump laser [11.1635]. In addition, a continuous tunability is possible with a pump-enhanced SRO, by using a resonator internal beam splitter to separate the pump spatially from the resonated OPO wave [11.1636]. These waves are then resonated on two separate cavity end mirrors (dual cavity) for independent control of the resonated OPO wave and the length of the pump cavity.

Triply resonant OPOs (TRO) suffer from the combined problems of both types of DROs, consequently they provide less tunability in comparison to SRO and DRO, but they are remarkable because of their low threshold pump power in the range of several mW or below [11.1637, 1638].

Continuous–Wave Optical Parametric Oscillators

Continuous-wave optical parametric oscillators (CW-OPOs) are efficient and highly coherent light sources in the near- and mid-infrared. Due to their tunability, these sources are of considerable interest for high-resolution spectroscopy of molecules and trace-gas detection [11.1639]. Simplified and improved frequency standards are currently being considered, based on the

strong frequency and phase correlation of the OPO's signal and idler output waves [11.1640, 1641].

After the first demonstration of CW OPOs in 1968 by *Smith* et al. [11.1601] and *Byer* et al. [11.1602] significant progress is this field was made in the beginning of the 1990s, supported by advances in crystal growth techniques [11.1609], low-loss optical components and CW solid-state lasers.

As discussed before pump power at threshold decreases with increasing cavity finesse for each of the wavelengths. Typical values for the pump power at threshold are listed in Table 11.48 for CW OPOs with the different resonators (TRO, DRO, SRO).

The pump power at threshold of singly resonant OPOs is significantly higher than 1 W, even in a high-finesse cavity with no significant output coupling of the resonant wave. Since most commercially available single-frequency lasers provide maximum pump powers of about 1 W, most CW OPOs demonstrated in the past are doubly or triply resonant devices.

The threshold pump intensity can be calculated from the coupled wave equations in analogy to the parametric gain assuming all three waves (pump, signal and idler) are infinite plane waves, with uniform intensity across the beam, neglecting focusing and double refraction. The gain is considered to be unidirectional and the pump depletion is always small at threshold.

At the steady-state threshold, the gain balances the resonator losses for each resonator round-trip. The threshold condition for an SRO is

$$E_s(0) = (1 - \alpha_s)E_s(l_c) . \tag{11.175}$$

Where α_s are the round-trip losses of the resonant signal wave and l_c is the crystal length. In the low-gain limit and assuming small losses, the parametric gain coefficient (11.167) can be written [11.1606]

$$\Gamma^2 l_c^2 = 2\alpha_s . \tag{11.176}$$

Then we obtain the pump intensity at the SRO threshold

$$I_{p,th} = \alpha_s \frac{n_p n_s n_i}{\omega_s \omega_i d_{eff}^2 l_c^2} sinc^{-2}\left(\frac{\Delta k l_c}{2}\right) . \tag{11.177}$$

Table 11.48 Typical pump power at threshold for CW TRO, DRO, SRO

OPO	Pump threshold (mW)	Ref.
TRO	< 1	[11.1633]
DRO	100	[11.1642]
SRO	2600	[11.1643]

With $\Gamma^2 l_c^2 = \alpha_i \alpha_s$ the pump intensity at the DRO threshold is similarly derived as

$$I_{p,th} = \frac{\alpha_i \alpha_s}{4} \frac{n_p n_s n_i}{\omega_s \omega_i d_{eff}^2 l_c^2} sinc^{-2}\left(\frac{\Delta k l_c}{2}\right) . \tag{11.178}$$

A low threshold is achieved when a long nonlinear crystal with a high figure of merit is used inside a signal resonator with highly reflecting mirrors. In general the pump threshold is lower for higher signal and idler frequencies. However, via the sinc function of the phase mismatch the pump threshold is exposed to an additional and much stronger dependence on the signal and idler wavelength. A minimum threshold is achieved for signal and idler wavelengths with $\Delta k = 0$. As a consequence the OPO always seeks to oscillate as close as possible to the phase-matched wavelengths.

Usually CW OPOs are pumped with focused beams to enhance the pump power, therefore pump, idler and signal waves are expressed as Gaussian beams [11.1644]. In this case the intensity shows an inhomogeneous distribution along the propagation axes z and the intensity and phases are not constant within each of the xy-planes. Only for loose focussing can these inhomogeneities be neglected and is equation (11.177) still a good estimation of the pump intensity at threshold. The pump power at threshold for tight focussing has been derived in an detailed mathematical treatment [11.1614, 1645], which is beyond this scope. For optimized confocal focussing [11.1598], the pump power at threshold is given by

$$P_{p,th} = \frac{4\pi c^2 n_s n_i \alpha_s}{\mu_0 \omega_s \omega_i \omega_p d_{eff}^2 l_c} . \tag{11.179}$$

As opposed to the l_c^{-2} dependence of the threshold intensity for plane waves (11.177) for the pump power of Gaussian beams decreases linearly with the crystal length.

Once above threshold a part of the pump power P_p is converted into the appropriate signal and idler waves as long as the effective gain is larger than one. An important parameter is the pump depletion, which occurs until the gain is saturated and the steady state is reached. The analytical description of the internal conversion efficiency η_{int} can be obtained under steady-state conditions assuming small cavity losses and optimum phase matching. The conversion efficiency

$$\eta_{int} = 1 - \frac{P_{out,p}}{P_{in,p}} \tag{11.180}$$

depends on the ratio of the incoming and the transmitted pump power and is a function of the pump ratio

$N_0 (N_0 = P_p/P_{p,th})$ [11.1645]. The maximum conversion efficiency for plane waves comes to 100% for a pump ratio of $N_0 = (\pi/2)^2$. The extension of this model to Gaussian intensity distributions with plane wavefronts yields maximal conversion efficiency of 71% supposing a pump ratio of 6.5. The conversion efficiency is reduced by the inhomogeneous intensity distribution of the pump wave as well as distortions of the wavefronts.

Due to parasitical losses in the cavity (Fresnel losses at the surfaces, diffraction and absorption), the measured output power is lower than predicted by the internal efficiency. Therefore, it is useful to determine an external (utilizable) conversion efficiency, which in steady-state conditions is

$$\eta_{ext,s} = \frac{T}{T+L} \frac{\omega_s}{\omega_p} \eta \,, \tag{11.181}$$

assuming small transmission T of the output mirror and small losses L for the resonant signal wave.

In order to operate the CW OPO continuously with low fluctuations in output power and frequency, the cavity length needs to be stabilized. The main sources of cavity length fluctuations are thermally induced fluctuations of the refractive index, mostly in the crystal, and acoustically and thermally induced perturbations of the position of the cavity mirrors. Fluctuations caused by these sources are usually significant just for low-frequency ranges, i. e., $\nu < 10\,\text{kHz}$, which can be compensated, for example, by an electronic stabilization device. (For higher-frequency components, i. e., $\nu > 10\,\text{kHz}$, the noise of the pump laser is significant instead of the cavity length fluctuations). For an OPO with pump enhancement resonance, a change of the cavity length induces a mismatch between the cavity resonance frequency and the pump laser frequency, resulting in an increased OPO threshold and decreased output power. If the OPO is resonant for the signal or the idler wave or for both simultaneously, the change of the cavity length leads to fluctuations of the signal and idler frequencies and to mode hops and cluster hops. One possible method to stabilize the cavity length is to increase the passive stability in a monolithic setup [11.1646]. However, pump-enhanced OPOs and doubly resonant OPOs usually require active control of the cavity length [11.1647]. To stabilize a cavity resonance to a laser frequency several methods have been successfully demonstrated [11.1648–1650]. Long-term stabilization of a doubly resonant parametric oscillator where the frequency instability is below 1 kHz has been demonstrated [11.1651]

One of the most crucial components of CW OPOs is the nonlinear material. For successful CW OPO operation it is of particular importance that the crystals nonlinearity is high and noncritical phase matching is possible. Crystals used so far are noncritical phase-matched $LiNbO_3$, KTP, LBO, $Ba_2NaNb_5O_{15}$ and $KNbO_3$ whereas especially KTP and its arsenate isomorphs $KTiOAsO_4$ (KTA) and $RbTiOAsO_4$ (RTA) turned out to be attractive materials for CW OPOs. Wavelength tuning of NCPM OPOs requires either temperature tuning of the crystal or wavelength tuning of the pump laser. Because of the low-temperature tuning capability of the KTP crystal family wavelength tuning in such OPOs depends on tunable pump sources. Many investigations have been performed with DROs and pump-enhanced OPOs to achieve continuous tunability. A significant increase of the continuous tuning range was realized with the dual-cavity design [11.1634, 1636, 1652]. Low-threshold operation has been demonstrated with a TRO and pump-enhanced SRO KTP OPO pumped with a single-stripe GaAlAs diode laser [11.1652, 1653]. High idler powers of $840\,\text{mW}$ in the wavelength range of $2.4\text{–}2.9\,\mu\text{m}$ have been achieved with KTP and KTA OPOs designed as an intracavity SRO configuration and pumped by Ti:sapphire lasers [11.1654]. An important step was the realization of a singly resonant CW OPO [11.1629].

In recent years the availability of novel quasi-phase-matched nonlinear material and high-power solid-state lasers enabled significant advances in the development of CW OPOs. The high optical nonlinearity of periodically poled $LiNbO_3$ (PPLN) and long interaction lengths up to 50 mm enables the operation of CW SROs pumped by CW solid-state lasers. Pumping such a 50 mm-long PPLN crystal with the 13.5 W output of a high-power diode-pumped Nd:YAG laser, infrared radiation tunable in the range of $3.25\text{–}3.95\,\mu\text{m}$ with an output power of 3.6 W has been reported [11.1655]. The measured pump depletion was as high as 93%. Wavelength tuning was achieved through temperature tuning or by using different poling periods implemented on the crystal. A step toward compact efficient and powerful CW OPOs was performed with the realization of a diode-laser-pumped singly resonant PPLN OPO [11.1656]. The SRO consists of a 38 mm-long PPLN in a four-mirror cavity (Fig. 11.195). Pumping with 25 W of 925 nm laser radiation from an AlGaAs master-oscillator power-amplifier (MOPA) system, 480 mW of single-frequency idler radiation was generated. The tuning range of the idler covers $2.03\text{–}2.29\,\mu\text{m}$. In addition several investigations have been performed with pump-enhanced SROs in
Fig. 11.195 Experimental setup of the diode laser pumped singly resonant OPO (SRO). The pump beam from the MOPA system propagates through a 60 dB isolator (iso) and focuses into the PPLN crystal. All mirrors of the ring cavity are highly reflecting for the signal wave and highly transmitting for the pump and idler wave. The idler output behind M2 is filtered from the residual pump and signal radiation by dielectric filters [11.1656]

Fig. 11.196 Temperature tuning curve of a near-degenerate PPLT OPO calculated for a pump wave of 925 nm and a grating period of 27.3 μm [11.1660]. *Shaded areas*: parametric gain bandwidth of the 35 mm long PPLT crystal at degeneracy is as large as 460 nm. The Sellmeier coefficients can be found in [11.1661]

PPLN. Tunable radiation was generated in the range of 2.29–2.96 μm with an output power of 140 mW pumped by 800 mW delivered from a miniature diode-pumped single-frequency Nd:YAG laser [11.1657]. An extension of the wavelength into the mid-IR between 4.07–5.26 μm was demonstrated by pumping a PPLN PESRO by CW single-frequency Ti:sapphire radiation [11.1658]. Another pumping design was performed using a high-power fiber laser. The Yb-doped fiber laser generated in a 40 mm-long PPLN crystal mid-IR idler powers in the range 2.98–3.7 μm. Pumping with 8.3 W laser power the OPO generated 1.9 W [11.1659].

Besides the successful demonstration of powerful PPLN OPOs one severe disadvantage of PPLN is the appearance of photorefractive effects, which may damage the crystal. Some effort is made to optimize the growing technique in such a way that these defects can be avoided.

Other QPM materials have also been developed, such as periodically poled KTP (PPKTP) [11.1662–1664], RTA (PPRTA) [11.1665] and Lithium tantalate (PPLT) [11.1660]. Due to the high purity of these materials photorefractive defects do not occur even at high pump levels.

Wide wavelength tunability has been reported in the range 1.5–4 μm in PPLN [11.1666] and 1.55–2.3 μm in PPLT[11.1660] pumping the OPOs near degeneracy, which provides large parametric gain bandwidths for a given poling period, crystal temperature and pump wavelength (Fig. 11.196). In PPLT the wavelength tuning is achieved by changing the crystal temperature within an interval of only 10 K. Operating a CW OPO with subsequent frequency-doubling wavelength tunability from the visible to the mid-IR range between 550–2830 nm has recently been demonstrated. A com-

parison between the performance of PPKTP and PPLN was performed within these investigations [11.1664].

These cited examples clearly indicate the dynamic in this field. Further research in new ferroelectrics generating radiation beyond 5 μm and the improvement of the existing materials concerning dimensions, homogeneity and structure design will lead to high-efficiency compact integrated optical systems.

Nanosecond Optical Parametric Oscillators

Optical parametric oscillators pumped with nanosecond pulses are the most well-established OPO systems generating powerful tunable radiation in the spectral range from the visible to the near infrared. Since the first demonstrated optical parametric oscillator [11.1600], which was a nanosecond pulsed OPO, reliable nanosecond OPOs were not established before the late 1980s. The appearance of new nonlinear materials with large nonlinearity and high damage thresholds (larger than 1 J/cm^2) such as BBO, LBO, and the improvement of the optical quality of KTP or KNbO$_3$ was the start of an intense OPO evolution. These materials together with the optimized spatial beam quality and high peak powers of modern nanosecond Q-switched lasers made it possible to reach the threshold of the single-resonant OPO configuration.

The basic principle of optical parametric oscillation for nanosecond OPOs is the same as for CW oscilla-

tors; however, due to the finite length of the pump pulse (typical pulse lengths are 2–30 ns) the OPO does not reach the steady-state regime. In nanosecond OPOs, the cavity length is about a few centimeters, which corresponds to less than 100 round-trips for the pump pulse. The steady-state threshold is no longer valid because of the transient character of pulsed OPOs. The dynamic behavior was considered in a model developed by *Brosnan* and *Byer* [11.1667] using a time-dependent gain analysis. They calculated the buildup to threshold for a signal resonant optical parametric oscillator by assuming a Gaussian temporal profile for the incident pump pulse intensity and a Gaussian spatial distribution for the pump and the signal beams. Additionally their model assumes single pass of the pump wave and considers the effects of mode overlap and spatial walk-off.

They introduced the time-dependent parametric gain coefficient Γ_t

$$\Gamma_t = \sqrt{g_s}\,\Gamma\,e^{-\left(\frac{t}{\tau}\right)^2} \quad \text{with} \quad g_s = \frac{\omega_p^2}{\omega_p^2 + \omega_s^2}\,,$$

(11.182)

where τ is the $1/e^2$ intensity half-width of the Gaussian pump pulse. The spatial coupling efficient g_s describe the mode overlap between the resonant signal wave and the pump wave. The influence of the Poynting vector walk-off defines the effective parametric gain length Λ

$$\Lambda = l_\omega \mathrm{erf}\left(\frac{\sqrt{\pi}}{2}\frac{l_c}{l_\omega}\right)$$

(11.183)

with the walk-off length, which depends on the birefringence angle ρ,

$$l_\omega = \frac{\sqrt{\pi}}{2}\frac{\omega}{\rho}\sqrt{\frac{\omega_p^2 + \omega_s^2}{\omega_p^2 + \omega_s^2/2}}\,.$$

(11.184)

The threshold energy fluence for the single-resonant OPO is derived from the coupled wave equations, assuming low pump depletion, as

$$J_{th} = \frac{2.25}{\kappa g_s \Lambda^2}\tau$$
$$\times \left(\frac{l_r}{2\tau c}\ln\frac{P_{s,th}}{P_{s,0}} + 2\alpha_2 l_c + \ln\frac{1}{\sqrt{R}} + \ln 2\right)^2$$

(11.185)

with $\kappa = \frac{2\omega_s\omega_i d_{eff}^2}{n_p n_s n_i \varepsilon_0 c^3}$, where R is the reflectivity of the mirrors, α_2 are the internal losses of the resonant wave inside the crystal, l_r is the optical cavity length and l_c is

the length of the crystal. The threshold identifies the detectable level of the signal energy, which corresponds to an energy of typical 100 µJ, giving a threshold power to noise ratio of $\ln(P_{th}/P_s) = 33$. The time required from the parametric gain of the signal field starting from the noise level P_0 to reach the oscillation threshold P_{th} is called the rise time of the parametric oscillator. The rise time is an important parameter in the design and operation of a parametric oscillator and can be calculated from the time-dependent coupled amplitudes equations. For efficient conversion, the rise time has to be as short as possible. *Pearson* et al. [11.1668] carried out a detailed investigation of the rise time as a function of various experimental parameters, such as pump pulse length, cavity length, cavity losses and the pump ratio N_0, which is the factor between the pump pulse energy and the pump pulse energy at threshold, $N_0 = P_p/P_{p,th}$. Important experimental parameters to minimize the rise time are high pump energy densities and a short cavity length. Beyond the influence of the rise time the threshold energy density can be reduced by using long pump pulse durations τ, optimizing the reflectivity R and avoiding intracavity losses α. Additionally the nonlinearity of the crystal should be large and the length of the crystal should be as long as possible with regard to the limitation through the Poynting vector walk-off.

The spectral bandwidth of a singly resonant optical parametric oscillator depends primarily on the gain bandwidth, which is determined by the dispersion, the birefringence and the length of the nonlinear crystal. In addition, the bandwidth is determined by the spectral properties of the resonator, the correlation between the resonator modes and the characteristics of the pump laser, the wavelength, spectral bandwidth, intensity and divergence. Because of the short pump pulse duration for nanosecond pumped OPOs there is only a weak spectral-mode condensation and the nanosecond OPO does not reach the stationary state, unlike the CW OPO. Usually the nanosecond OPO bandwidth is estimated with the gain bandwidth, as there is no exact analytical description of the spectral bandwidth of pulsed OPOs. Neglecting any saturation *Brosnan* and *Byer* [11.1667] deduced an expression for the spectral condensation depending on the number p of cavity round-trips

$$\Delta\nu(p) = \frac{1}{\sqrt{p}}\Delta\nu\,.$$

(11.186)

A more exact prediction concerning the theoretical bandwidth can be calculated using numerically simulations [11.1669, 1670].

Nanosecond pulsed optical parametric oscillators are powerful devices of widely tunable coherent light. With the nonlinear crystals BBO and LBO such OPOs provide coherent radiation in the entire spectral range from the UV (300 nm) to the near IR (2.5 μm). The advantageous properties of these crystals are high optical damage threshold, high nonlinearities, a wide transparency range and a large birefringence. Since the first successful operation of a BBO OPO reported by *Fan* et al. in 1989 [11.1671] significant progress in OPO technology has been achieved. In the investigations reported so far, BBO OPOs have been pumped with the second, third, and fourth harmonics of a *Q*-switched Nd:YAG laser at 532 nm [11.1671, 1672], 355 nm [11.1672–1677] and 266 nm [11.1672, 1678], and with the fundamental of an XeCl excimer laser at 308 nm [11.1679, 1680]. The highest output energies and efficiencies have been obtained with the third harmonic of *Q*-switched Nd:YAG laser. The generated output energies are in the range 100–200 mJ/pulse and external conversion efficiencies of up to 61% have been reported [11.1672, 1681].

Similar advances have been demonstrated for the LBO OPO that covers almost the same spectral range [11.1669, 1682–1688]. The power densities at threshold for the 355 nm-pumped LBO OPO are typically higher by a factor of two compared to those of equivalent BBO OPOs due to the lower effective nonlinear coefficient. However, LBO possesses a smaller spatial walk-off angle than BBO [ρ(LBO) ≈ 0.25ρ(BBO)] allowing the use of longer LBO crystals to compensate the lower nonlinearity. The experimental comparisons of LBO and BBO [11.1669, 1686] demonstrate the advantageous properties of LBO as there are large angular acceptance, low spatial walk-off (which can even be zero for temperature-tuned noncritical phase matching). These properties are valuable if the OPO is to be operated with low-pump-energy laser sources (< 3 mJ) [11.1689], whereas BBO with restricted angular acceptance and larger nonlinearity is more suitable for high-pump-energy laser sources (> 100 mJ).

In the past many investigations were performed primarily for the type I critically phase matched BBO OPO pumped by the third harmonic of a Nd:YAG laser. This well-established standard OPO consists typically of a 12–15 mm-long BBO crystal placed in a linear signal resonant Fabry–Pérot resonator. Changing the phase-matching angle in the range of 10° the OPO covers a tuning range of 400–710 nm for the signal wave and 710–3100 nm for the idler wave. Experimentally the idler tuning is restricted by an increase of absorption in

the crystal for wavelengths longer than 2600 nm. The pump energy density at threshold is about 200 mJ/cm². Pumped with 2–10 ns-long pulses such OPO devices operate routinely with conversion efficiencies in the range of 20–50% whereby the optical damage threshold of the OPO components limits the pump ratio. The spectral bandwidth of the type I phase-matched 355 nm-pumped BBO OPO varies from 0.2 nm in the blue spectral range ($\lambda = 400$ nm) to more than 10 nm at degeneracy ($\lambda = 710$ nm). The spectral bandwidth of the idler wave equals (expressed in wavenumbers or GHz) that of the corresponding signal frequency.

In the past, many efforts have been made to reduce the spectral bandwidth of OPOs. Significant line narrowing, even to single-mode operation, can be achieved with the insertion of frequency selective elements (such as gratings or etalons) into the OPO resonator or with external injection seeding of the OPO. Although these methods can provide single-mode operation, the disadvantages are obvious. First, the addition of frequency-selective elements increases the resonator length, the cavity losses and thus the oscillation threshold. Therefore, higher pump densities are required and a compromise is needed between the necessary pump power and the damage threshold of the optical components. Second, continuous wavelength tuning may be affected by the complexity of such devices. The spectral line narrowing via injection seeding avoids these disadvantages; the threshold is even reduced, because of a shorter rise time [11.1690]. Nevertheless, successful injection seeding in pulsed OPOs depends on many fundamental parameters of the OPO operation. Besides proper collinear alignment and divergence adaptation between the seed radiation and the seeded OPO wave, the frequency matching between the cavity mode and the seed frequency is essential. Despite these difficulties successful line narrowing was demonstrated with both methods [11.1675, 1681, 1691–1693]. A theoretical description of the spectral characteristic of free-running or injection-seeded OPO systems are given in several numerical models [11.1669, 1670, 1694, 1695].

The investigation and the control of the spatial beam quality of nanosecond OPOs is still a challenge. As a result of large pump-beam diameters, high nonlinear gain in the crystal and a large Fresnel number of the optical resonator the beam quality factor M^2 of the generated radiation are often high > 2–10 and thus far from the diffraction limit ($M^2 = 1$). Most of the numerical models simulating the spatial behavior of nanoseconds OPO are time integrated [11.1696–1699]. Recently time-resolved experimental and numerical investigation of the spec-

tral and spatial dynamics of nanosecond OPO has been reported [11.1700, 1701]. The result of the different investigations is, that the OPO starts on the optical axis with an almost Gaussian beam profile. However, during the buildup of the pulse the fields undergo an inhomogeneous gain caused by the birefringence walk-off in the OPO crystal, pump depletion and back-conversion and as consequence the M^2 value increases with the size of the pump energy, pump depletion and back-conversion.

Some investigations of the spectral and temporal dynamics of the OPO has been performed using a BBO OPO, which consists of a 2–3 mm-long crystal in a 3.5 mm-long cavity [11.1670, 1701]. Due to the wide mode spacing of about 1 cm^{-1} each single mode can be considered. Figure 11.197 shows the statistical mode fluctuation of 10 successive pulses. Thus, the short-cavity OPO proofs the macroscopic manifestation of the zero-point fluctuation of the vacuum.

Based on the numerical and experimental results some improvement on the spectral and spatial performance of nanosecond OPOs were developed based on novel pumping and resonator configurations [11.1621, 1702–1708].

For the generation of wavelengths up to 5 μm the appropriate crystals are KTP, KTA and KNbO$_3$ [11.1709–1712]. Further extension to wavelengths beyond 5 μm can be achieved in ZnGeP$_2$, CdSe and AgGaSe$_2$ [11.1713–1717]. Avoiding two-photon absorption in the materials these crystals have to be operated with pump wavelengths longer than 1.5 μm. Meanwhile nanosecond OPOs are demonstrated with a tuning range up to 14 μm. They provide conversion ef-

Fig. 11.197 Mode spectra of the signal wave (550 nm) recorded for 10 successive OPO pulses. The OPO is operated at 1.44 times above threshold. The mode spacing is 28.8 GHz (0.96 cm^{-1}) [11.1670]

ficiencies up to 40%, generating output powers of about 5 W or pulse energies of 5 mJ [11.1716, 1717]. The difficulty of finding the appropriate pump lasers for these materials has been overcome with cascaded OPO systems published for AgGaSe$_2$ and CdSe [11.1717–1720].

A new generation of nanosecond OPOs appeared with the availability of periodically poled QPM materials as there are PPLN, PPKTP, PPKTA and PPRTA. These crystals have large effective nonlinearities (8–16 pm/V), up to eight times higher than in a corresponding BBO crystal, and possess long interaction lengths. Typically the aperture of the QPM crystals are 1 mm high. Therefore, these materials are well suited for the generation of mid-IR radiation pumped with high-repetition low-power-pump pulses [11.1721–1723]. With the development of wide large-aperture PPRTA crystals, QPM becomes suitable also for high-power applications [11.1724, 1725]. The large nonlinearity of PPLN enables the operation of efficient single-pass optical parametric oscillators [11.1721, 1726–1728]. More recently tunable single-frequency generation has been demonstrated with injection-seeded PPLN OPOs and PPLN OPGs [11.1729–1731].

Synchronously Pumped Optical Parametric Oscillators

Optical parametric oscillators synchronously pumped by mode-locked solid-state lasers are powerful devices for the generation of tunable ultrashort laser pulses. The first CW synchronously pumped picosecond OPO was demonstrated by *Piskarskas* et al. in 1988 [11.1732] and the first synchronously pumped femtosecond OPO by *Edelstein* et al. in 1989 [11.1733].

Many reports of such OPOs generating pulses in the picosecond or femtosecond regime have been published in recent years [11.1734–1736]. Ultrafast laser systems are attractive pump sources for optical parametric oscillators. They combine high peak pulse intensities providing sufficient nonlinear gain with a moderate energy fluence preventing optical damage of the material. However, remembering the instantaneous character of nonlinear polarization the optical gain is obtained exclusively during the time interval of the pump pulses length. In contrast to nanosecond OPOs, the time interval of ultrashort pulses ($\tau < 100$ ps) is too short to allow a finite number of cavity round-trips. Therefore, the basic operation principle of ultrafast optical parametric oscillators is synchronous pumping to achieve macroscopic amplification of the parametric waves from quantum noise. In this pumping scheme the length of the optical parametric oscillator is matched to that of the pump laser
resonator, so that the round-trip transit time in the OPO resonator corresponds to the repetition time of the pump pulses. The consecutive coincidence of parametric and pump wave in the nonlinear crystal amplifies the gain until it overcomes the threshold.

In general, two types of synchronously pumped OPOs are to be distinguished: the pulsed (or quasi-CW) synchronously and the continuous synchronously pumped OPOs. CW synchronously pumped OPOs are pumped with a continuous train of ultrashort pulses as they are emitted by CW mode-locked neodymium lasers or Kerr lens mode-locked Ti:sapphire lasers, while the pump sources of pulsed synchronously pumped OPOs are mode locked Q-switched Nd lasers generating a train of ultrashort pulses contained within a nanosecond or microsecond envelope.

The physical description of CW synchronously pumped OPOs is equivalent to the steady-state formalism for CW OPOs considering the peak pump pulse intensity determining the nonlinear gain. Pulsed synchronously pumped OPOs show the transient behavior of nanosecond OPOs so their analysis has to take into account the rise-time effects caused by the finite time duration of the nanosecond pulsed envelope [11.1667]. An analysis of synchronously pumped OPOs can be found for plane-wave conditions [11.1737] and for Gaussian beams in CW synchronously pumped OPOs [11.1738, 1739].

Most of the early synchronously pumped OPOs were pulsed OPOs [11.1734] because of the significant higher peak pump pulse powers compared to CW mode-locked pump lasers at that time. Picosecond optical parametric oscillation even in the SRO configuration was generated using the nonlinear materials KTP [11.1740], BBO [11.1622] and LBO [11.1741]. However due to the pulsed pump characteristic the output of such OPOs does not consist of a really repetitive pulse train, and the amplitude, intensity and the pulse duration of the output pulse can vary under the pulse envelope. In applications where no high peak powers are needed CW synchronously pumped OPO are advantageous because of their continuous train of output pulses. Meanwhile with the availability of efficient CW mode-locked lasers and more-reliable nonlinear materials the research in this field is focused on CW synchronously pumped OPOs.

In practice, synchronously pumping is a reasonable pumping mechanism only for high repetition rates (> 50 MHz) otherwise the resonator length becomes too long and unpractical. For example, typical repetition rates of Kerr lens mode-locked Ti:sapphire lasers are about 80 MHz, which corresponds to an OPO resonator
Fig. 11.198 Experimental setup for a linear standing wave resonator consisting of two plane mirrors M1 and M4 and two spherical mirrors M2 and M3. The pump laser beam is focused into the crystal C between the spherical mirrors M2 and M3. The total resonator length depends on the distance between two successively pump pulses

length of 1.85 m. The tolerance of the resonator length detuning can be calculated from $\Delta l_{\mathrm{res}} = \Delta \tau (c/2)$, which is half the geometrical pump pulse length. The theoretical detuning calculated for 1 ps is about 150 μm, however experimentally even shorter detuning tolerances of 30 μm are affordable.

Commonly used resonator designs for synchronously pumped OPOs are ring or standing-wave resonators, where the latter is favorable for compactness reasons (its length is half that of the ring). A typical standing-wave resonator for synchronously pumped OPOs is shown in Fig. 11.198 consisting of two plane and two spherical mirrors.

Picosecond optical parametric oscillators. Picosecond optical parametric oscillators synchronously pumped by CW mode-locked solid-state lasers are powerful devices for the generation of tunable ultrashort laser pulses especially in the IR spectral region. For many applications in high-resolution spectroscopy a high spectral intensity and a narrow bandwidth is required. As the light of such OPOs is almost Fourier limited (15 ps = 1 cm^{-1}) picosecond pulses (with $t > 10$ ps) have a sufficient selectivity for spectroscopy, in contrast to pulses in the femtosecond regime. Similar to the nanosecond pulsed OPOs the high peak powers of modern CW mode-locked lasers easily overcome the threshold of SRO resonators. As a consequence, most synchronously pumped CW OPOs operate in the SRO configuration.

In the past, there have been various ways to generate tunable picosecond IR radiation by CW synchronously pumped OPOs. In most synchronously pumped picosecond OPOs, the use of noncritical phase matching prevents a reduction of interaction length due to walk-off

between the focused beams inside the nonlinear crystal. Wavelength tuning of noncritical OPOs requires a variation of the pump wavelength or the crystal temperature.

A temperature-tuned picosecond LBO OPO has been reported [11.1742] generating continuously tunable radiation between 650 nm and 2.5 μm with a single crystal. The average output power achieved by this system was below 100 mW. By using tunable pump laser systems like the Kerr-lens mode-locked Ti:sapphire laser pump wavelength tuning offers a convenient tuning mechanism.

A noncritical-phase-matched picosecond KTP OPO [11.1743] generates tunable picosecond pulses in the spectral ranges of 1−1.2 μm for the signal and 2.3−2.9 μm for the idler wave via wavelength tuning of the pump between 720−853 nm. Average output powers of up to 700 mW in 1.2 ps pulses has been achieved with a pump power of 1.6 W at a 82 MHz repetition rate.

The combination of wavelength tuning of the Ti:sapphire laser and temperature tuning in LBO has been performed under the type I noncritical-phase-matching condition, providing continuously tunable picosecond pulses in the spectral range of 1−2.4 μm [11.1744]. The pump power was 1.2 W in 1−2 ps pulses at a 81 MHz repetition rate and generated an average OPO output power of about 325 mW. Using the arsenate isomorphs of KTP, such as KTA and RTA, the wavelength range of the OPO can be extended up to 3.6 μm [11.1745]. Due to their wider transparency range and the lack of grey tracking inside the crystal these materials are advantageous for IR picosecond OPOs.

Further extension of the tuning range of picosecond OPOs into the mid-IR was demonstrated with a critical-phase-matched AgGaS$_2$ OPO pumped by a Q-switched mode-locked Nd:YAG laser [11.1746]. This OPO had an idler tuning range of 3.5−4.5 μm and a maximum output power of 2 W.

Picosecond pulse generation in the visible spectral range has been demonstrated in an LBO OPO pumped with the third harmonic of a CW mode-locked Nd:YLF laser [11.1747]. The generated output power was about 275 mW in the spectral range of 453−472 nm in 15 ps-long pulses at a repetition rate of 75 MHz.

In general, it should be pointed out that the device Ti:sapphire-laser-pumped KTP or KTA OPO is a versatile tool for the generation of tunable picosecond pulses in the entire spectral region from the UV to the near-IR. The frequency-conversion schemes involved, such as second, third, and fourth harmonics of the Ti:sapphire laser, optical parametric oscillation in KTP and frequency doubling of the OPO's signal

wave, are summarized in experimental investigations for picosecond and femtosecond radiation [11.1748, 1749].

High-power operation of a singly resonant picosecond OPO has been reported pumping a critical-phase-matched KTP OPO with the fundamental of an mode-locked Nd:YLF laser at 1.053 μm [11.1750]. This device generates 12 ps-long signal pulses at 1.55 μm for 40 ps-long pump pulses at a repetition rate of 76 MHz. A total average output power of 2.8 W was achieved with 800 mW in the idler wave at 3.28 μm.

The new generation of mode-locked lasers are diode-pumped CW mode-locked Nd:YVO$_4$ oscillator–amplifier laser systems. Such an all-solid-state laser system operating at 1.064 μm with 7 ps pulse lengths at repetition rates of about 83 MHz delivers average output powers of 29 W. Pumping a noncritical-phase-matched KTA OPO the OPO output power reaches the multiwatt region providing a signal wavelength of 1.53 μm with an output power of 14.6 W and an idler output power as high as 6.4 W at 3.47 μm in the mid-IR [11.1751]. The total average output power of 21 W corresponds to an external efficiency of 70%. However, both systems operate at a specific signal and idler wavelength without any tunability.

With the availability of QPM nonlinear materials like PPLN, PPKTP, PPRTA new perspectives have arisen in the research of efficient tunable picosecond OPOs. With the advantageous properties of these materials as their large nonlinearities, transparency in the mid IR and the capability to choose an optimized phase-matching condition for the interacting waves, for example non-critical phase matching, they become ideal candidates to realize singly resonant synchronously pumped OPOs with low thresholds, large tunability and efficient output powers. Compact all-solid-state devices have been reported based on PPLN and PPRTA with a pump power threshold as low as 10 mW [11.1752, 1753]. The generated radiation covers the wavelength range from 3.35−5 μm with total output powers of up to 400 mW in 1−5 ps pulses. The power of the idler wave was up to 100 mW. The spectral range of the PPLN OPO has been extended even beyond 5 μm [11.1754] and idler output powers of 0.5 mW are achieved. The operation of a PPLN OPO at GHz repetition rates was demonstrated by pumping the PPLN OPO with an all-solid-state neodymium laser at 10 GHz [11.1755]. Rapid wavelength access was achieved with the use of a mode-locked diode laser master-oscillator power-amplifier (MOPA) system providing 7.8 ps pulses at 2.5 GHz repetition rate. The InGaAs oscillator–amplifier system delivered an output power of 900 mW, which was

converted to 78 mW idler power tunable in the spectral range of 2.2–2.8 μm [11.1756].

A high-power picosecond PPLN-OPO was performed by synchronously pumping a PPLN crystal with the fundamental wave of a CW mode-locked Nd:YLF laser. The tuning range of the PPLN OPO is for the signal radiation 1.765–2.06 μm and 2.155–2.61 μm for the idler radiation, respectively. High average output powers for the signal and idler radiation of 2.55 W and 2.4 W have been achieved in 45 ps-long pulses at a 76 MHz repetition rate for an input pump power of 7.4 W, which corresponds to a total external conversion of about 67%. The measured pump depletion was 71% [11.1757].

Much emphasis is placed on further extension of the tuning range of picosecond systems into the IR. For this purpose OPO/OPA and OPG/OPA devices are of great interest [11.1758, 1759] as their output powers and tuning ranges are sufficient to be used for difference-frequency mixing into the mid-IR. The difference frequency mixing in GaSe or CdSe [11.1760–1762] of signal and idler frequencies generated from an PPLN OPO seeded KTP-OPA provides picosecond pulses tunable at 3–24 μm.

Femtosecond optical parametric oscillators. Tunable femtosecond OPOs are attractive light sources for time-resolved spectroscopy of chemical and biological reactions. Femtosecond pulses are characterized by their high peak powers, which easily overcome the threshold of a singly resonant OPO configuration. The short pulse length of about 100 fs is combined with a huge spectral bandwidth of several nanometers (≈ 10 nm) and dispersion effects, such as group velocity dispersion, group velocity mismatch (i. e., temporal walk-off) and spectral acceptance bandwidths can no longer be neglected. The group-velocity dispersion causes a pulse broadening whereas the temporal walk-off lowers the nonlinear gain and/or changes the time characteristic of output pulse. For efficient frequency conversion, the temporal walk-off has to be minimized by an appropriate choice of the crystal length. Typical crystal lengths of femtosecond OPOs are only 1–2 mm, and therefore high nonlinearities are desirable for low operation thresholds. The group velocity dispersion can be minimized via dispersion compensation in the OPO cavity. Additionally to these dispersion effects, other higher-order nonlinear effects come with the high peak pump powers, such as self-phase modulation and cross-phase modulation which result in a chirped OPO output pulse [11.1613].

The start of an extensive development of femtosecond OPOs was initiated with the commercial availability of the Kerr-lens mode-locked Ti:sapphire laser. The first material used in synchronously pumped femtosecond OPOs was KTP [11.1763–1765] in non-collinear critical-phase-matching conditions and collinear noncritical-phase-matching condition. Due to the higher transmission in the mid-IRA OPOs with KTA [11.1766, 1767], RTA [11.1768], CsTiOAsO$_4$ (CTA) [11.1769, 1770], and KNbO$_3$ [11.1771] generate a wider wavelength range of 1–5 μm with pulse durations of less than 100 fs. Typical maximum output powers of such devices are 100–200 mW for the signal and 50–100 mW for the idler wave.

The periodically poled nonlinear materials PPLN, PPRTA, and PPKTP are of particular importance for femtosecond OPOs because noncritical phase matching becomes possible even for the extended wavelength tuning. This feature results in compact, low-threshold, efficient OPO devices. The wavelength tuning of such femtosecond QPM OPOs is performed via grating, pump wavelength or cavity tuning and covers the spectral range from 1.7–5.4 μm in PPLN [11.1772], 1.06–1.22 μm (λ_s) and 2.67–4.5 μm (λ_i) in PPRTA [11.1773], and 1–1.2 μm in PPKTP [11.1774]. Comparing these QPM materials, PPLN and PPRTA have an advantage because of their large transmission range, where PPLN possesses the higher nonlinearity. However PPLN suffers from process-induced photorefractive defects, which may be suppressed by heating the crystal to temperatures higher than 100 °C. Recently MgO-doped PPLN-OPO was investigated [11.1775] allowing reliable OPO operation at room temperature.

Tunable radiation in the range of 4–8 μm have been achieved using a cascaded AgGaSe$_2$ OPO, which has been pumped with the idler of a CTA OPO. This system generates average powers of 35 mW in 300–600 fs-long pulses at a repetition rate of 82 MHz.

Moreover, optical parametric generators and amplifiers are powerful tools for the generation of ultrashort pulses into further infrared regions [11.1776]. The generation of femtosecond pulses in the spectral range 3–12 μm with almost bandwidth limited pulses of 100–200 fs have been reviewed for different parametric processes and a number of relevant materials [11.1777].

Many new perspectives for the generation of intense ultrashort pulses are given by parametric amplification of chirped laser pulses. The basic principle of optical parametric chirped pulse amplification (OPCPA) is that stretched linearly chirped pump pulses are amplified in a non-collinear phase-matched OPA. After the single-pass amplification, the pulses are compressed, providing high energy in short pulse lengths of 10 fs

or less. The non-collinear phase-matching scheme is important because of the huge spectral bandwidths of femtosecond pulses. For ideal OPCPA the pump pulse duration corresponds to the length of the chirped pulse. The spatial beam profile should be rectangular (flat-top), and the gain should be constant temporally and spatially. *Dubietis* et al. [11.1776] published the first proposal and demonstration of OPCPA. The first experimental demonstrations of OPCPA were performed in degenerate LBO, KDP and BBO [11.1778–1782]. Amplification of 10^{10} have been achieved in single-pass amplification at degeneracy.

The use of non-collinear phase matching enables the efficient parametrical amplification of nondegenerate wavelengths despite large spectral bandwidth. Recently different sources of supercontinuum have been amplified in BBO and other crystals via frequency-doubled Ti:sapphire lasers with 1 kHz repetition rate [11.1783, 1784]. Ultrashort pulses below 6 fs have been generated, however the achieved pulse energies was lower than 5 μJ.

The generation of higher energies is possible by employing visible picosecond pump pulses and temporally stretched seed pulses. At a center wavelength of 800 nm and a pump wavelength of about 530 nm in BBO and LBO gain bandwidths broader than $2000\,\mathrm{cm}^{-1}$ are obtained, which is sufficient to amplify Fourier-limited pulses with 5 fs duration [11.1778]. Due to the large damage thresholds of both materials, high pump intensities can be applied. Recently OPCPA was performed at 800 nm and with a Nd:YAG laser at 532 nm, generating a gain of 4×10^6 in two BBO crystals [11.1785]. The pulse energy was 2 mJ at a 10 Hz repetition rate.

QPM materials also turn out to be advantageous in OPCPA. Broad-bandwidth amplification is not restricted any longer to collinear phase matching at degeneracy or to non-collinear phase matching but can be obtained at practically any center wavelength in the crystals transparency window. Additionally QPM OPA can be increased by using engineered grating profiles, such as chirped gratings [11.1625], fanned gratings [11.1626], and aperiodic gratings [11.1786].

Nondegenerate OPCPA has been demonstrated in PPKTP at a wavelength of 1573 nm pumped by a Nd:YAG laser [11.1787] and close to degeneracy at a wavelength of 1053 nm pumped by a Nd:glass laser [11.1788].

This chapter describes the basic properties and current performance of CW, nanosecond and ultrashort optical parametric oscillators. Today these parametric systems are powerful tunable light sources providing a spectral range from the visible to the mid-IR in all time regimes. The main progress in this field is based on the development of more-sophisticated optical materials and efficient, reliable laser systems. With the realization of QPM materials there was an important breakthrough towards compact widely tunable OPOs. Especially for CW OPOs, QPM materials are the key element for the realization of widely tunable singly resonant OPOs. The high nonlinear gain of QPM materials enables the reduction of the optical parametric oscillation to optical parametric generation, which leads to more-simple devices. The combination of diode-pumped solid-state laser systems and QPM crystals, which already leads to direct diode-pumped OPOs, is the way to future, compact tunable laser systems that may be realized in integrated designs.

Finally it should be mentioned that, besides the importance of the generated OPO radiation for many spectroscopic and technical applications, the OPO itself is still an interesting physical system to be explored in the field of quantum mechanics.

11.10 Generation of Coherent Mid–Infrared Radiation by Difference–Frequency Mixing

The fundamental infrared (IR) or mid-IR region of the electromagnetic spectrum between, say 3–20 μm, is of special interest for many applications, notably molecular spectroscopy [11.1789]. The reason is that most organic and inorganic molecules exhibit strong vibrational–rotational transitions in this wavelength region. This is illustrated in Fig. 11.199, where the absorption ranges of some important functional groups of molecules are plotted for wavelengths of 2–20 μm (top), whereas absorption features of a few selected molecules are depicted in the center. In view of applications in air monitoring the (relative) transmission through the terrestrial atmosphere is plotted at the bottom of Fig. 11.199.

This atmospheric absorption is obviously dominated by the presence of water vapor and CO_2. The atmospheric windows at 3–5 μm and 8–14 μm are clearly visible.

In addition to the ultraviolet–visible and the near-IR range, the mid-IR region has attracted a lot of interest in recent times owing to the numerous applications of

Fig. 11.199 Absorption ranges of important molecular functional groups (*top*) and of selected molecules (*center*). The size of the symbols is related to the absorption strength. Atmospheric transmission is depicted at the *bottom*

tunable laser source is a prerequisite for successful trace-gas sensing and analysis. In addition to tunability, a narrow line width guarantees sufficient specificity of detection in multicomponent real-world gas mixtures. In the preferred mid-IR range, the choice of coherent sources is, however, rather limited. Table 11.49 lists tunable lasers with wavelengths longer than 3 μm. It essentially includes the conventional well-established line-tunable CO and CO_2 gas lasers, continuously tunable semiconductor lasers (lead-salt diode and quantum cascade lasers), color center lasers, novel crystalline solid-state lasers and nonlinear optical devices [optical parametric oscillators (OPOs) and difference-frequency generation (DFG) sources].

Recent progress both in solid-state lasers and in quantum cascade lasers (QCLs) appears promising. Solid-state laser materials such as Ce^{2+}:ZnSe or Fe^{2+}:ZnSe offer tuning ranges of 2.2−3.1 μm [11.1790] or 4−4.5 μm, respectively (though the latter only when pulsed and with cryogenic cooling) [11.1791]. New developments in QCLs equipped with external cavities yield a continuous tuning range of around 10% of the central wavelength and – at least partly – room-temperature continuous-wave operation [11.1792, 1793]. Despite these attractive prospects the broadest tuning range, best wavelength coverage, room-temperature operation and highest flexibility in terms of wavelength selection is currently still achieved with nonlinear optical devices (DFG and OPOs) [11.1794]. Here we focus on DFG as the scheme that has been widely used in recent times to access mid-IR wavelengths for trace-gas sensing. In fact, these important applications have fostered further developments of DFG systems.

11.10.1 Difference−Frequency Generation (DFG)

Difference-frequency generation (DFG) represents a nonlinear optical effect that is related to the nonlinear susceptibility of second order ($\chi^{(2)}$) of a material. Other related effects are second-harmonic generation (SHG) and sum-frequency generation (SFG). Hence, DFG represents a three-beam interaction process that is mostly used to generate tunable coherent mid-infrared radiation, although it has also been employed for THz generation.

Birefringent, Quasi−Phase Matching and Conversion Efficiency

In difference-frequency generation the light of two laser beams is mixed in a nonlinear crystal and light with a frequency of the difference of the two incident fre-

trace-gas sensing in rather diverse fields including environmental monitoring and climate research, industrial and process surveillance, workplace safety, agriculture (e.g., ethylene or ammonia detection, surveillance of fermentation), homeland security (e.g., chemical warfare or explosives detection) and medical diagnosis (e.g., human breath monitoring). It has been demonstrated in numerous cases that laser spectroscopy offers the potential for high sensitivity and selectivity, multicomponent capability, and large dynamic range. These are all crucial properties for trace-gas sensing. An important aspect of laser-based sensors is that usually no sample preparation, i. e., neither pretreatment nor pre-concentration, are required, in contrast to many competing techniques. Apart from an appropriate detection scheme, which enables sensitive absorption measurements, a mid-infrared

Table 11.49 Tunable continuous-wave mid-IR laser sources with wavelengths $\geq 3\,\mu m$. RT: room temperature, LN_2: liquid nitrogen (77 K), TE: thermoelectric cooling, SHG: second-harmonic generation, QCL: quantum cascade laser, OPO: optical parametric oscillator, DFG: difference-frequency generation

Laser	Wavelength (μm)	Tuning characteristics	Power	Operation
CO	5–6 (2.7–4, overtone)	only line tunable	50 mW to W	LN_2 cooling, also $\leq 0\,°C$
CO_2	9–11 (4.5–5.5, SHG)	only line tunable	W	RT operation
Lead salt diode	4–30	$\approx cm^{-1}$ mode hop-free	< 0.1 mW	Cryogenic cooling
QCL	4–> 24, THz	cm^{-1} to $> 100\,cm^{-1}$ per device	mW	LN_2/TE cooling, also RT
Color center	1–3.3	$\approx 0.5\,\mu m$ for single crystal	100 mW	LN_2 cooling
Solid-state	2.2–3.1	$\approx 0.5–1\,\mu m$	$\leq 1\,W$	RT operation
OPO	3–16	$\sim \mu m$ for specific setup	$\leq 1\,W$	RT operation
DFG	3–16	$\sim \mu m$ for specific setup	μW to mW	RT operation

quencies is generated. The generated frequency is given by energy conservation:

$$\hbar\omega_p - \hbar\omega_s = \hbar\omega_i \rightarrow \omega_i = \omega_p - \omega_s \ . \qquad (11.187)$$

The laser with the highest frequency ω_p is called the pump laser, while the second laser is called the signal laser with a frequency ω_s. The generated idler beam has the lowest frequency ω_i. The phase-matching condition is given by the conservation of momentum:

$$\Delta k = k_p - k_s - k_i = 0 \ , \qquad (11.188)$$

where Δk is the phase mismatch, and k_p, k_s, and k_i are the wavevectors of the pump, signal, and idler beam, respectively. In the case of collinear wave propagation the wavevectors can be replaced by $|k| = nc/\lambda$ and (11.188) changes to:

$$\frac{n_p}{\lambda_p} - \frac{n_s}{\lambda_s} - \frac{n_i}{\lambda_i} = 0 \ , \qquad (11.189)$$

where n is the refractive index at the corresponding wavelength, λ is the wavelength with the subscripts p,

s, and i corresponding to pump, signal and idler, respectively, and c is the speed of light in vacuum. Phase matching in a birefringent crystal can be achieved by

1. angle tuning
2. temperature tuning
3. wavelength tuning (changing the wavelength of the pump and/or signal laser).

The most common way to achieve phase matching with a birefringent crystal is realized by angle tuning, i. e., by rotating the crystal until the phase-matching condition is fulfilled.

For infinite plane waves the idler intensity is given by [11.1795]:

$$I_i = 2 \frac{\omega_i^2 d_{eff}^2 L^2 I_s I_p}{c^3 \varepsilon_0 n_p n_s n_i} sinc^2 \left(\frac{\Delta k L}{2} \right) \qquad (11.190)$$

where d_{eff} is the effective nonlinear coefficient, L is the crystal length, I is the intensity of the laser beam for pump, signal and idler beams, respectively, ε_0 is the dielectric constant, and Δk is the phase mismatch. Hence the idler intensity scales with the product of the incident intensities $I_s I_p$ and the square of the crystal length L^2. This is valid as long as there is no pump depletion and negligible walk-off between the beams. These effects limit the useful crystal length and they are discussed in more detail in the section on nonlinear crystals. The effective nonlinear coefficient d_{eff} describes the nonlinearity of the crystal seen by the incident light and depends on the crystal structure, the direction of propagation, the polarization of the light, and the nonlinear coefficients d_{ij} (Table 11.51) given by the tensor of the nonlinear susceptibility $\chi^{(2)} = 2\mathbf{d}$.

To achieve phase matching it is taken advantage of the different refractive index for ordinarily and extraordinarily polarized light. Depending on the combination

Table 11.50 Different phase matching types for DFG processes for positive and negative birefringent crystals. PM: phase matching, e: extraordinarily polarized, o: ordinarily polarized, QPM: quasi-phase matching

of polarization of the pump and signal beam and depending on positive or negative birefringence of the crystal, the phase matching is called type I, type II or type III, as defined in Table 11.50. For quasi-phase matching (see below) all three beams have the same polarization.

Equation (11.190) implies a possibility to generate light at the idler frequency without phase matching. I_i has a maximum at $\Delta kL/2 = m\pi/2$, where m is a natural number. This yields the coherence length $l_c = \pi/\Delta k$ after which the newly generated idler light will interfere destructively with the light generated within the previous coherence length. Thus, after twice the coherence length all generated light is destroyed. This can be avoided by changing the polarization of the material by 180° after one or an odd multiple of the coherence length l_c because this will change the sign of the nonlinear coefficient, so the light will interfere constructively and a buildup of the generated light occurs, as illustrated in Fig. 11.200. This means that idler power can be generated without fulfilling the phase-matching condition by using a periodically poled crystal. A quasi-phase matching (QPM) condition can be written by using the grating period $\Lambda = 2l_c$ of the crystal:

$$\frac{n_p}{\lambda_p} - \frac{n_s}{\lambda_s} - \frac{n_i}{\lambda_i} - \frac{1}{\Lambda} = 0 .$$ (11.191)

For the same parameters as for the bulk material less idler power will be generated for quasi-phase matching than for birefringent phase matching by a factor of $(2/\pi)^2$. This factor is often included in d_{eff} by reducing its value by a factor $2/\pi$. Although the efficiency is lower than in the case of birefringent phase matching, more power can often be generated this way because the highest nonlinear coefficient can be used [e.g., for LiNbO$_3$ $d_{33} = -27$ pm/V (Table 11.51) instead of $d_{22} = 3.07$ pm/V, which is relevant for birefringent type II phase matching]. Since all involved polarizations are the same (extraordinarily polarized, Table 11.50), the walk-off angle is zero, therefore longer crystals can be used, resulting in higher idler power. Furthermore, the selection of pump and signal wavelengths is rather flexible. However, the production of periodically poled crystals is difficult and not possible for all crystals. Until now only LiNbO$_3$ (PPLN), RbTiOAsO$_4$ (PPRTA), KTiOPO$_4$ (PPKTP), and KTiOAsO$_4$ (PPKTA) are commercially available periodically poled. These are ferroelectric crystals that are poled by applying a strong electrical field. Another, non-ferroelectric material is GaAs. In the beginning thin plates of GaAs with alternate polarization were stacked manually [11.1805]. Today orientation patterned GaAs, where the periodic poling is implemented during crystal growth [11.1806–1808], is becoming available.

Equation (11.190)) is obtained under the assumption of infinite plane waves and no absorption. For Gaussian beams the relationship between idler power P_i, crystal length L, pump power P_p, signal power P_s, and absorption coefficient α is given by [11.1809–1811]:

$$P_i = P_p P_s \frac{32\pi^2 d_{\text{eff}}^2 L}{\varepsilon_0 c n_i \lambda_i^2 (n_s\lambda_p + n_p\lambda_s)} h(\xi, \sigma, \mu, \alpha, L) .$$ (11.192)

The focusing function $h(\xi, \sigma, \mu, \alpha, L)$ for diffraction-limited Gaussian beams is given by:

$$h(\xi, \sigma, \alpha, L)$$
$$= \text{Re} \left(\frac{e^{-\frac{\alpha L}{2}}}{4\xi} \right.$$
$$\left. \times \int_{-\xi}^{\xi} d\tau \int_{-\xi}^{\xi} d\tau' \frac{e^{-i\sigma(\tau-\tau')+\frac{\alpha L}{4\xi}(\tau+\tau')}}{1 + \tau\tau' - i\frac{1+\mu^2}{1-\mu^2}(\tau-\tau')} \right) ,$$ (11.193)

where

$$\xi = \frac{L}{b} ,$$ (11.194)

$$\mu = \frac{k_s}{k_p} = \frac{n_s\lambda_p}{n_p\lambda_s} ,$$ (11.195)

$$\sigma = -\pi b \left(\frac{n_p}{\lambda_p} - \frac{n_s}{\lambda_s} - \frac{n_i}{\lambda_i} - \frac{1}{\Lambda} \right) .$$ (11.196)

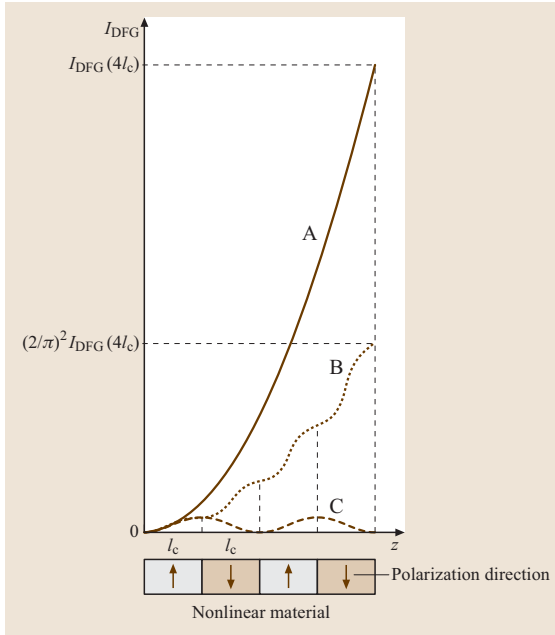
Here Λ is the grating period, and b is the confocal parameter of both the pump and signal beam and is given by the minimal beam waist $w : b = k_p w_p^2 = k_s w_s^2$, σ describes the phase mismatch. The focusing function h is discussed further below (see also Figs. 11.204, 205, 206 and 11.208). These equations are valid for both bulk and periodically poled crystals, only d_{eff} changes by a factor $2/\pi$ compared to the case of a bulk crystal. The focusing function describes two competing effects: the efficiency is increased by focusing the beams because of higher intensities, but at the same time reduced because of less collinear wavevectors. A possibility to overcome this problem is to use waveguide periodically poled nonlinear crystals [11.1812]. Here the beams are confined in a waveguide in the crystal leading to collinear wavevectors and high intensities at the same time. With this


Fig. 11.200 Idler power generation for phase-matching condition $\Delta k = 0$ (A), non-phase-matching condition $\Delta k \neq 0$ (C) and quasi-phase-matching condition in the case of a periodically poled crystal (B). l_c denotes the coherence length [11.1813]

technique continuous-wave (CW) idler powers in the milliwatt range can be achieved whereas with bulk or periodically poled crystals the CW idler power is normally in the microwatt range.

The limit $\xi \to 0$ gives the result for the infinite plane wave because $b \to \infty$ for plane waves. In this case the focusing function reduces to $h \sim \xi$, resulting in an idler power proportional to L^2, as in the case for the plane waves (11.190).

An often used nonlinear crystal for difference-frequency generation in the mid-infrared is LiNbO$_3$ because it can be made periodically poled (known as PPLN) and has a large nonlinear coefficient. Its effective nonlinear coefficient is given by $d_{eff} = 2/\pi d_{33} M_{ij} = -14.4 \, \text{pm/V}$ with $d_{33} = -27 \, \text{pm/V}$ and $M_{ij} = 0.85$ for LiNbO$_3$ at $3.3 \, \mu\text{m}$ [11.1814]. M_{ij} is the Miller factor, which describes the dispersion of the nonlinear coefficient [11.1800, 1815, 1816]. The factor $2/\pi$ is needed when using quasi-phase matching.

To calculate the phase-matching condition the refractive index needs to be known for all wavelengths. It is given by the temperature-dependent Sellmeier equation, e.g., for extraordinary polarized light in

LiNbO$_3$ [11.1817]:

$$n_e^2 = 5.35583 + 4.629 \times 10^{-7} F$$
$$+ \frac{0.100473 + 3.862 \times 10^{-2} F}{\lambda^2 - (0.20692 - 0.89 \times 10^{-8} F)^2}$$
$$+ \frac{100 + 2.657 \times 10^{-5} F}{\lambda^2 - 11.34927^2} - 1.5334 \times 10^{-2} \lambda^2 .$$

$$(11.197)$$

Here $F = (T - 24.5)(T + 570.82)$ describes the temperature dependence when T is the temperature in °C and λ is the wavelength in nm. This equation takes also the multiphonon absorption into account, which yields more-accurate data for wavelengths between $4 \, \mu\text{m}$ and $5 \, \mu\text{m}$.

When choosing the grating period and the temperature of the crystal, the thermal expansion of the crystal also needs to be taken into account because it also influences the grating period, although much less than the change of the refractive index with temperature. The thermal expansion is (at 25 °C) $a_a = 15 \times 10^{-6} \, /°\text{C}$ and $a_c = 7.5 \times 10^{-6} \, /°\text{C}$ [11.1818] where the indices a and c correspond to the crystal axis. The refractive index of LiNbO$_3$ strongly depends on its composition, the Sellmeier equation is for congruent composition, it will be different for stoichiometric composition. Also the refractive index of MgO doped LiNbO$_3$, as often used in experiments, differs from that of ordinary LiNbO$_3$.

Nonlinear Crystals

Numerous crystals show nonlinear optical effects, but only a few are useful for difference-frequency generation. The crystal material needs to be transparent at all wavelengths of pump, signal and idler beams, it should have a high nonlinear coefficient and a high damage threshold. In some cases, e.g., strong dispersion and weak birefringence, phase matching is not possible. These requirements limit the choice of nonlinear crystals. The optical properties of some nonlinear crystals used in DFG systems are listed in Table 11.51. Figure 11.201 shows the absolute nonlinear coefficient and the transparency range of selected crystals for comparison.

For an easier comparison and characterization of crystals and DFG setups reported in the literature the following figure of merit (FoM) is useful:

$$\text{FoM} = \frac{P_i}{P_p P_s L} ,$$

$$(11.198)$$

where P_i, P_p and P_s denote the power of the idler, pump and signal beams, respectively, and L is the crystal
Fig. 11.201 Transparency range of some selected nonlinear crystals used for mid-IR DFG generation as a function of the absolute value of the nonlinear coefficient. For the periodically poled materials (PPLN, PPRTA, PPKTA, PPKTP), the nonlinear coefficient d_{33} is given [11.1813]

length. This way the comparison is independent of the laser powers and crystal lengths chosen. In Table 11.52 this FoM is listed for some representative setups involving various crystals and combinations of pump and signal lasers. Some of the setups generate a CW idler beam by using two CW lasers for pump and signal; other setups have a pulsed idler beam by using two pulsed lasers or one pulsed and one CW laser.

When choosing the pump and signal lasers several issues have to be considered. The laser wavelengths need to be within the transparency range of the crystal, and the wavelengths and the polarizations should be chosen so that phase matching is possible. Another important aspect is the laser power. As the conversion efficiency is rather low, high laser powers are preferred, but too-high powers will damage the crystal, the surface of the crystal or the antireflection (AR) coating on the crystal. The

AR coating often has a lower damage threshold than the crystal itself. At high power of the pump laser other effects such as optical parametric generation (OPG) or amplification (OPA) could become even stronger than the difference-frequency generation, resulting in an enlarged line width. If the signal laser has much more power than the pump laser, pump depletion might be a problem. Therefore pump and signal laser and nonlinear crystal have to be carefully matched. To estimate how low the signal power needs to be to avoid pump depletion, the following formula can be used:

$$\eta = \frac{I_i}{I_p} = \frac{8\pi^2 d_{eff}^2 L^2 I_s}{\varepsilon_0 n_p n_s n_i c \lambda_i^2} \ll 1 \,, \tag{11.199}$$

where I_i, I_p, and I_s denote the idler, pump, and signal intensity, respectively, d_{eff} is the effective nonlinear coefficient, L is the crystal length, λ_i is the idler wavelength, ε_0 is the dielectric constant and n is the refractive index with the subscripts p, s, and i referring to pump, signal and idler, respectively. η is the conversion efficiency from pump beam to idler beam, where $\eta = 1$ implies that 100% of the pump beam is converted to the idler beam. This case gives the nonlinear interaction length L_{nl}, one of several characteristic lengths of a DFG system

$$L_{nl} = \sqrt{\frac{\varepsilon_0 n_p n_s n_i c \lambda_i^2}{8\pi^2 d_{eff}^2 I_s}} \,. \tag{11.200}$$

Crystal lengths longer than L_{nl} will not increase the idler power because of pump depletion. The aperture length L_{an} is the distance after which the beam is displaced by $2w_0$ because of walk-off effects and is given by:

$$L_{an} = \sqrt{\pi} \frac{w_0}{\rho_n} \,, \tag{11.201}$$

where w_0 is the minimal beam waist and ρ_n is the walk-off angle. The diffraction length L_{diff} is the length after which the beam diameter has increased by a factor of $\sqrt{2}$. Longer crystals will not increase the idler power. This effect can be calculated more precisely by using the focusing function in (11.192).

$$L_{diff} = 4kw_0^2 \,. \tag{11.202}$$

For pulsed lasers the interaction length L_{qs} represents a further important issue

$$L_{qs} = \sqrt{\pi} \tau \left(\frac{1}{v_{g1}} - \frac{1}{v_{g2}} \right)^{-1} \,, \tag{11.203}$$

where τ is the pulse duration, v_{g1} and v_{g2} are the group velocities of the pump and the signal beams, respec-

tively. L_{qs} describes the length after which the pulses from the two beams are separated by τ. Another characteristic length for pulsed laser is the dispersion length L_{ds}, given by

$$L_{ds} = \frac{\tau^2}{g_n} , \tag{11.204}$$

where g_n is the group-velocity dispersion. This length describes the length after which the pulse duration has doubled. With these characteristic lengths first estimations for crystal lengths and pulse durations can be made.

11.10.2 DFG Laser Sources

The literature on DFG laser sources, new nonlinear crystal materials and applications has become extensive in recent years. By far the largest part of these systems have been, and still are, developed for spectroscopic gas sensing and analysis application. A recent overview of systems is given in reference [11.1813]. In the following we describe a typical DFG setup that has been implemented in our laboratory for measurements on isotopomers of trace gases. Precise isotope ratio measurements of trace gases represent an important contribution to the solution of key questions in various areas, e.g., differentiation between natural and anthropogenic origin of specific compounds. Isotopic compositions are of interest in such diverse fields as ecological CO_2 exchange, volcanic emission, medical diagnostics, extraterrestrial atmospheres, etc.

Detailed Discussion of a DFG Laser Source
Isotopic composition of trace gases such as CO_2, CO or N_2O are of special interest. These molecules with their isotopomers exhibit strong absorption lines between 4.3 to 4.7 μm (Fig. 11.202). Therefore a continuous-wave DFG source, which enables continuous tuning and narrow line width (to differentiate between isotopomers), was implemented. In the following sections the theoretical calculations, the setup and the characterization of this system is described.

Calculations of optimal crystal length and beam parameter. For the wavelengths of interest we chose $LiNbO_3$ as nonlinear optical medium because it has a transmission range from 0.4 μm to 5.0 μm, a large nonlinear coefficient, and it can be produced periodically poled.

However, $LiNbO_3$ has an absorption band at 5 μm so the absorption between 4 μm and 5 μm cannot
Fig. 11.202 Absorption lines of CO, N_2O and CO_2 as a function of wavenumber in the mid-IR region [11.1830]

be neglected. The absorption coefficient at 4.3 μm is $0.25\,\text{cm}^{-1}$, at 4.6 μm it is $0.55\,\text{cm}^{-1}$ and at 4.7 μm $0.75\,\text{cm}^{-1}$ [11.1831]. There are other crystals that can be used at this wavelength, e.g., $AgGaS_2$ or $AgGaSe_2$ (Table 11.51), but they are not available periodically poled, so birefringent phase matching has to be used. This means the crystal length needs to be shorter because of walk-off effects and it is not possible to use the maximum nonlinear coefficient. Furthermore alignment is more critical than with a periodically poled crystal. Finally, wavelength tuning is also an important issue. When working with such crystals angle tuning has to be used, which makes wavelength tuning over larger ranges more complicated. Often noncritical phase matching is used, because of its larger acceptance bandwidth, but for a certain idler wavelength the pair of signal and pump wavelength is fixed in this case. This limits the choice of lasers and normally two diode lasers with lower power than other lasers have to be used.

In contrast, when using quasi-phase matching, the phase matching is realized by choosing a grating period, so nearly every combination of lasers can be used (e.g., an external cavity diode laser (ECDL) that can be conveniently wavelength tuned, and a Nd:YAG laser that delivers high laser power). Phase matching is achieved by choosing the correct grating period Λ, which can be adjusted to other wavelengths by changing the temperature of the crystal because of the temperature dependence of the refractive index (11.197). When scanning the wavelength for spectroscopy, the crystal temperature can be changed simultaneously to achieve
Fig. 11.203 A periodically poled crystal with several gratings for different wavelengths. $\lambda_{p,s,i}$: pump, signal, idler wavelength, respectively; Λ: grating period

mid-IR wavelength ranges of several hundred nm with only one grating period. Depending on wavelength the temperature acceptance bandwidth can be quite large (Fig. 11.209b). Even larger wavelength ranges can be achieved by using a crystal with several gratings, as shown in Fig. 11.203. Typical grating periods for our wavelength range are approximately $23\,\mu m$. As a result it appears advantageous to use PPLN for the envisaged $4.3–4.7\,\mu m$ wavelength range rather than a bulk $AgGaS_2$ or other crystal despite the non-negligible absorption of PPLN.

According to (11.192) the idler power increases with the crystal length but also the absorption increases, therefore there is an optimum crystal length for this wavelength region. The maximum of the focusing function h (11.193) is not at $\sigma = 0$ but, e.g., at $\sigma = 1.3$ for a pump wavelength of 863 nm, a signal wavelength of

1064 nm and a crystal length of 5 cm (Fig. 11.208), so the maximum idler power is not obtained at perfect phase matching, but for a slightly different grating period. However, to simplify the calculations, σ was set to 0. The focusing function and hence the idler power has a clear maximum at about $\xi = 1.3$ (Fig. 11.204). It depends only slightly on wavelength and absorption. Therefore for a chosen crystal length L there is an optimal confocal parameter b.

When the idler power is plotted as a function of crystal length L and of the confocal parameter b, it can be seen that a long crystal combined with a large confocal parameter yields higher idler power (Fig. 11.205). However, in a real experiment the confocal parameter is limited by the thickness of the crystal and crystals longer than 6 cm are not easily commercially available. The problem with longer crystals is that crystal defects have too much influence. The thickness of the crystal is limited by the production process of the periodically poled grating. This is done by applying an electric field to change the orientation in the crystal, which requires very strong field strengths. This limits the thickness to 1 mm. Most crystals have a thickness of 0.5 mm, resulting in a better grating quality than for a thickness of 1 mm.

In Fig. 11.206 it can be seen how the idler power changes for different crystal lengths. The calculations were made with $\sigma = 0$ and keeping $\xi = L/b = 1.3$ at the maximum. The result is that at $\lambda_p = 853$ nm ($\lambda_s = 1064$ nm, $\lambda_i = 4.3\,\mu m$) the optimal length is longer

Fig. 11.204 Focusing function $h(\xi)$ versus ξ calculated for $\lambda_p = 868$ nm, $\lambda_s = 1064$ nm, $\alpha = 0.75\,cm^{-1}$, $\sigma = 0$, and $L = 5$ cm. The maximum is at $\xi = 1.3$ and for small ξ the focusing function h is proportional to ξ. The symbols are explained in (11.192, 193, 194, 195, 196)
Fig. 11.205 Idler power P_i versus crystal length L and confocal parameter b calculated at a pump wavelength of 853 nm. The idler power increases with increasing crystal length and confocal parameter
Fig. 11.206 Idler power as a function of crystal length for pump wavelengths λ_p of 853 nm, 863 nm, 868 nm. The signal laser is a Nd:YAG laser fixed at $\lambda_s = 1064$ nm. The calculations were made with $\sigma = 0$ and keeping $\xi = L/b = 1.3$ at the maximum. At 853 nm the ideal crystal length is longer than 10 cm, at 863 nm it is 5.9 cm, at 868 cm it is 4.0 cm

than 10 cm, at $\lambda_p = 863$ nm ($\lambda_i = 4.6\,\mu$m) it is 5.9 cm, and at $\lambda_p = 868$ nm ($\lambda_i = 4.7\,\mu$m) it is 4.0 cm. We chose a crystal length of 5 cm, implying $b = 4$ cm, which gives a minimal beam waist of 0.13 mm. Such a Gaussian beam propagates within the crystal over the whole length.

Based on (11.192), an idler power of $55-170\,\mu$W is expected for a pump power of 150 mW, a signal power of 2 W and a crystal length of 5 cm.

Setup and characterization. Our DFG system consists of an external cavity diode laser (EDCL) as pump laser, a continuous-wave Nd:YAG laser as signal laser and a MgO-doped periodically poled LiNbO$_3$ crystal (MgO:PPLN). The ECDL (Sacher TEC-120-850-150) has a power of 150 mW and a wavelength range of 820–875 nm. To cover the idler wavelength range of 4.3–4.7 µm, pump wavelengths of 852–868 nm are needed. The Nd:YAG laser (Innolight Mephisto) has a CW power of 2 W and a wavelength of 1064.5 nm. The MgO:PPLN crystal (HC-Photonics) is 5 cm long and 0.5 mm thick. It has several gratings with periods of 21.45, 22.00, 22.50, 23.10, and 23.65 µm, each with a width of 1.2 mm. For the wavelength of interest in this experiment, only the grating period of 23.1 µm is needed, it is quasi-phase matched for the different wavelengths by changing the temperature from 30 °C to 130 °C. The crystal is antireflection coated for the pump, signal and idler wavelengths.

The laser beams are focused by several lenses (including cylindrical lenses, not shown in Fig. 11.207) so that the minimal beam radius is 0.13 mm within the crystal. The $\lambda/4$ and $\lambda/2$ plates are used to match the beam polarization for quasi-phase matching in the PPLN crystal. A small part of the pump beam is directed to a wavemeter. The recorded pump wavelength then yields the idler wavelength. After the crystal a germanium filter is used to block the near-infrared light. The setup is depicted in Fig. 11.207.

This DFG system was tested and characterized by focusing the mid-IR beam onto a detector (VIGO PDI-2TE-5, TE-cooled) and recording the signal with a lock-in amplifier with a time constant of 100 ms. For modulating the laser power with a frequency of 1.8 kHz, a chopper was placed after the Nd:YAG laser. To find the crystal temperature for phase matching, the temperature was increased in steps of 0.2 °C or 0.5 °C while keeping the pump wavelength constant (Fig. 11.208).

The temperature for phase matching is 6.6–11.2% higher than theoretically calculated (Fig. 11.209a) and

It can be seen that the measured and the calculated curve have a similar shape

the temperature acceptance bandwidth increase for longer wavelengths and is 2.5–3.7 °C (Fig. 11.209b). The power of the CW mid-infrared beam amounts to 23 μW at 4.3 μm and 5 μW at 4.76 μm (Fig. 11.209c). It decreases for increasing wavelengths because of the crystal absorption near 5 μm. The generated idler power is about four to ten times lower than calculated, most probably because of imperfections in the crystal, its grating quality and non-Gaussian beam shape of the ECDL pump laser.

For measurements of the isotopic composition of trace gases, the laser line width should be sufficiently narrow to resolve adjacent molecular lines clearly, also when recorded at reduced gas pressure. The line width of our CW mid-IR source has been determined as approximately 1 MHz and thus fulfills the requirements by far.

Measurement of isotopic composition of trace gases. We measured the isotopic ratios of ^{13}C/^{12}C and ^{18}O/^{16}O in CO_2 and CO, and of ^{15}N/^{14}N in N_2O. N_2O is of special interest because ^{14}N^{15}N^{16}O and ^{15}N^{14}N^{16}O have the same mass, so they cannot be distinguished by conventional mass spectrometry but laser spectroscopy enables an easy identification. Our measurements were done with the DFG system described above and direct absorption spectroscopy with an astigmatic Herriot cell (New Focus 5611) with an optical path length of 10 m. The setup is shown in Fig. 11.210.

One problem in measuring isotopomers is that the concentration of the main isotopomer is typically a hundred times higher than that of the less-abundant isotopomer. There are two possibilities to overcome this problem, either to measure two lines of similar strength resulting in a strong temperature sensitivity of the measurement, or by choosing lines with similar lower energy levels but with very different line strength. The astigmatic multipass Herriot cell offers the possibility to enter the cell at a different angle than usual, so that the beam leaves the cell after only two passes (Fig. 11.210). This makes it possible to measure two lines of very different line strength by using two different path lengths (the balanced-path-length detection scheme) [11.1832].

As an example, Fig. 11.211 shows the result of a measurement on CO_2 isotopomers in ambient air at a concentration of 350 ppm. The measurements were

performed at a total pressure of 50 mbar and at room temperature. The experimental data are fitted with Voigt curves to calculate the concentrations of the isotopomers.

The derived isotope ratios of $^{13}C/^{12}C$ for CO_2 are $1.3\% \pm 0.2\%$ (only long path) and $1.4\% \pm 0.3\%$ (balanced-path-length detection scheme), which is in good agreement with the natural abundance of 1.1%. The isotope ratio $^{18}O/^{16}O$ of CO_2 is deduced as $0.44\% \pm 0.06\%$ (only long path) and $0.47\% \pm 0.11\%$ (balanced-path-length detection scheme), which again is in good agreement with the natural abundance of 0.39%. A more-detailed discussion of these studies, which also includes measurements of CO and N_2O isotopomers, can be found in [11.1833]. A further study on N_2O isotopomers, testing different detection schemes for low concentrations (100 ppm) has been published in [11.1834].

11.10.3 Outlook

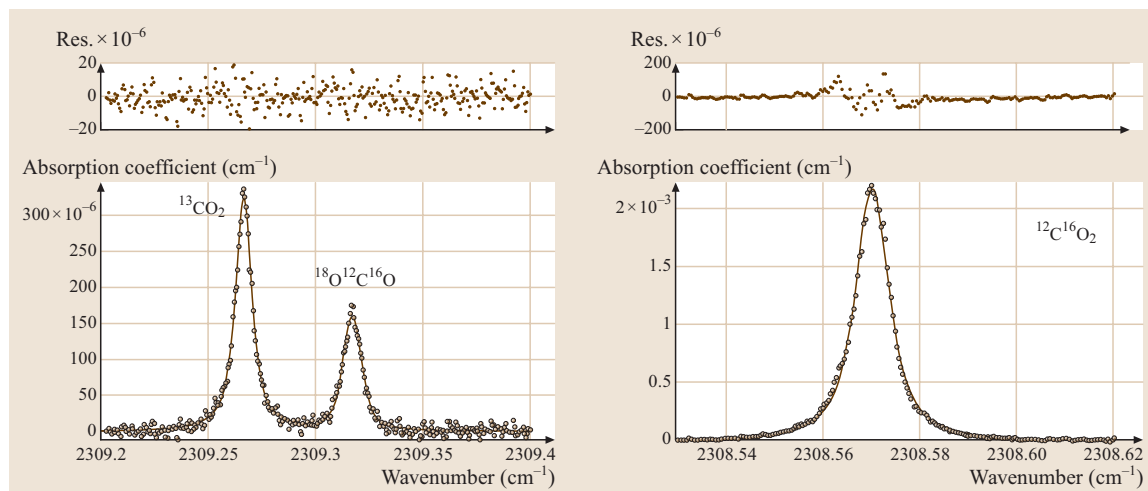
Tunable coherent sources in the mid-infrared range play an important role. This is manifested by the ever-growing number of publications. The development is fostered by numerous applications, primarily in gas sensing. The requirements with respect to sensitive and selective monitoring devices with multicomponent capability are manifold: access to a broad wavelength range, broad – preferentially continuous – wavelength tunability, narrow line width (i. e., much narrower than typical molecular absorption line widths), preferentially room-temperature (RT) or near-RT operation, and compact and robust setups for field applications. In this respect, DFG systems represent a very valuable choice. Since their first realization in 1974 [11.1835], DFG-based devices have reached a mature level. Today, their wavelength range can be chosen between, e.g., 2 μm and 19 μm only depending on the available pump and signal sources and nonlinear crystals. The tuning of a DFG source is straightforward and continuous, and the wavelength generated can be accurately determined via the near-infrared input wavelengths. The line width is basically given by the line width of the pump and signal laser. This enables narrow mid-IR line widths as required for high-resolution spectroscopy. In contrast to alternative mid-IR sources, DFG systems are generally room-temperature devices except for the crystal, which may require heating in a small temperature-controlled oven. Line widths of continuous-wave DFG sources are in the MHz range, which makes them attractive


Fig. 11.211 Absorption lines of different isotopomers of 350 ppm CO_2 in ambient air. Experimental data (*dots*) and Voigt fit (*solid line*) for 10 m path length, residuals on top

for studies requiring high spectral resolution such as the briefly discussed isotopomer measurements. DFG sources are rather low-power lasers with CW powers in the μW to mW range. With fiber amplifiers for the near-IR pump and signal sources, higher powers can be achieved if necessary [11.1820]. Recent developments in waveguide technology in PPLN [11.1812] or KTP appear particularly attractive in view of higher conversion efficiencies. Last but not least, a DFG system can be made compact in view of today's diode lasers and diode-pumped solid-state lasers used as pump and signal sources.

In view of the variety of applications a further impetus for DFG systems can be expected. Current developments in several areas appear promising: the availability of compact and powerful signal and pump lasers, fiber amplifiers, new nonlinear crystal materials including organic media to access further wavelength ranges, new materials with higher nonlinear optical coefficients, birefringent bulk crystals with better quality, larger crystal sizes and higher damage thresholds, quasi-phase matching becoming available for more crystals than today, waveguide technology, etc. These developments will contribute to improve the performance of DFG devices, enhance their distribution, lower their costs and hence further increase their role as attractive spectroscopic tools.

11.11 Free-Electron Lasers

The free-electron laser (FEL) is a system consisting of a relativistic electron beam and a radiation field interacting with each other while they propagate through an undulator [11.1836, 1837]. The main components of the free-electron laser are electron accelerator, undulator, and optical resonator (optionally for an FEL oscillator). The undulator is a periodic magnetic structure with a planar, or helical magnetic field that causes periodical transverse deflections of the electron-beam trajectory [11.1838]. Optical resonators are fairly similar to those used in conventional lasers. FEL devices have been realized with nearly all types of accelerators: electrostatic accelerators, RF linear accelerators, induction accelerators, microtrons, storage rings, etc. The wavelength range covered by FELs spans from centimeters down to nanometers [11.1839] (Table 11.53).

Table 11.53 Parameter space of free-electron lasers as of 2006

Radiation	
Wavelength	13 nm–10 mm
Peak power	up to 5 GW
Average power	up to 10 kW
Pulse duration	10 fs to CW
Driving electron beam	
Energy	200 keV–1 GeV
Peak current	1–3000 A
Undulator	
Period	0.5–20 cm
Peak magnetic field	0.1–1 T
Undulator length	0.5–27 m

The scale of the FEL setup is mainly defined by the scale of the driving accelerator. For FELs operating in the millimeter wavelength range this could be a room scale, while unique devices such as VUV and X-ray FELs user facilities have a scale comparable with conventional third-generation synchrotron radiation facilities (Fig. 11.212).

11.11.1 Principle of Operation

The FEL is not actually a laser; it is most closely related to vacuum-tube devices. As with vacuum-tube devices, FEL devices can be divided in two classes: amplifiers and oscillators (Fig. 11.213). An FEL amplifier is a single-pass device, and there is no feedback between the output and input. The FEL oscillator can be considered as an FEL amplifier with feedback. For an FEL oscillator in the optical wavelength range the feedback is carried out by means of an optical resonator. FELs based on the oscillator principle are limited on the short-wavelength side to ultraviolet wavelengths primarily because of mirror limitations. Free-electron lasing at wavelengths shorter than the ultraviolet can be achieved with a single-pass high-gain FEL amplifier.

The field of the electromagnetic wave only has transverse components, so the energy exchange between the electron and the electromagnetic wave is due to the transverse component of the electron velocity. The latter occurs due to periodical wiggling of the electron in the undulator. The driving mechanism of free-electron lasers is the radiative instability of the electron beam, which develops due to the collective interaction of elec-

trons with the electromagnetic field in the undulator. The basic principle of radiation-induced instability can be described within the standard picture for the generation of the synchrotron radiation. Electrons propagate along a sinusoidal path and emit synchrotron radiation in a narrow cone in the forward direction. When an electron beam traverses an undulator, it emits radiation at the resonance wavelength $\lambda = (\lambda_w/2\gamma^2)(1 + K^2/2)$. Here, λ_w is the undulator period, $mc^2\gamma$ is the electron beam energy, $K = eH_w\lambda_w/2\pi mc$ is the dimensionless undulator strength parameter, and H_w is the maximum on-axis magnetic field strength of the undulator. Although the electromagnetic wave is always faster than the electrons, a resonant condition occurs such that the radiation slips a distance λ relative to the electrons after one undulator period. The fields produced by the moving charges in one part of the undulator react on moving charges in another part of the undulator. Thus, we deal with some tail–head instability, which leads to a growing concentration of particles wherever a small perturbation started to occur (Fig. 11.214). In the beginning – without microbunching – all N electrons can be treated as individually radiating charges producing the power of the spontaneous emission $\propto N$. With complete microbunching, all electrons radiate almost in phase. This leads to a radiation power $\propto N^2$ and thus to an amplification of many orders of magnitude with respect to the spontaneous emission of the undulator.

The figure of merit for FEL performance is the radiation power gain during one pass of the undulator. The gain primarily depends on the value of the peak beam current. Another quantity of importance for the development of the radiative instability is the electron beam density in the six-dimensional phase space. Low beam quality (large energy spread and emittance) leads to degradation of the FEL gain. Errors in the periodical magnetic structure also degrade FEL performance. Presently accelerator techniques and undulator technology have reached such a level that it is possible to have power gains of the order of 10^7 for the amplification of the radiation of a nanometer wavelength range.

11.11.2 Current Status and Perspective Applications of Free-Electron Lasers

Free-electron lasers hold several potential advantages: continuous tunability of the radiation wavelength, the possibility to obtain high levels of average output power, and the possibility to obtain high conversion efficiencies of the net electrical power to radiation power. An important feature of the FEL radiation is that it has a high
Fig. 11.212 Aerial view of the experimental hall for the FLASH user facility in Hamburg (*center*) and the tunnel for the superconducting accelerator and undulator (*covered with grass*). The hall in the upper right corner houses the injector part of the linac. The total length of the FLASH facility is 300 m. The maximum energy of electrons is 1 GeV, and the minimum radiation wavelength is 6 nm. The undulator of the FLASH (photo in the *upper left corner*) is a permanent magnet device (period 2.73 cm, gap 12 mm, peak field 0.47 T). The undulator system is subdivided into six segments, each 4.5 m long

degree of transverse coherence. In other words, the FEL radiation can always be focused on to a spot whose size is defined totally by diffraction effects. This feature reveals a wide range of possibilities for FEL applications in the transportation of the radiation over long distances and in obtaining high focused intensities.

However, FELs are relatively expensive devices, thus their applications are in the fields not covered by conventional radiation sources, in the far-infrared wavelength range and the THz gap (the sub-millimeter wavelength range). Another field for FEL applications is the generation of short-wavelength radiation, from the vacuum ultraviolet down to X-ray range. Technological developments are on the way, aiming at industrial applications of powerful FELs, and the use of FELs for energy transfer in space is also under consideration. Organiza-
Fig. 11.213 Free-electron laser configurations: oscillator (*top*), seeded amplifier (*middle*), and self-amplified spontaneous emission (SASE) FEL (*bottom*)

tion of user operation at the FEL facilities is similar to that used at synchrotron radiation facilities: the host organization constructs and serves free-electron laser and user beam lines, and users perform their experiments according to the schedule of the facility.

Linac–Based FEL User Facilities

There are several operating linear accelerator (linac)-based FEL user facilities (in China, France, Germany, Japan, Korea, The Netherlands, Russia, and USA) working for scientific applications [11.1840–1853]. The wavelength range covered with these facilities spans from 200 nm to a few hundred micrometers. Typical parameters of the FELs driven by RF linear accelerators are: pulse duration of a few picoseconds, peak

power in the MW range, and micropulse repetition rate in the range 10 MHz to 3 GHz. FELs driven by normal conducting RF accelerators operate in pulsed mode with a macropulse repetition rate of 10–100 Hz. The macropulse duration is defined by the length of the RF pulse, typically 1–20 μs. Thus, the average radiation power is in the watt range. FELs driven by superconducting accelerators operate in continuous mode and produce a high level of average output power, up to a few kW. Linac-based FEL facilities are recognized nowadays as a unique tool for scientific applications that require tunable coherent radiation in the infrared wavelength range. The general tendency is that the wavelength region of interest for users at these facilities is moving into the far-infrared and THz gap.

FEL User Facilities at Storage Rings

Several storage rings are equipped with free-electron lasers [11.1854–1857]. Typical parameters of the radiation are: wavelength range of 190–700 nm, pulse duration of some tens of picoseconds, average power of 10–300 mW, and peak power in the kW range. Operation in a locked-mode regime allows the peak power to be increased by an order of magnitude. The general tendency is that users' interest in these facilities is gradually reducing due to the limited features compared with conventional lasers.

High–Average–Power FELs

Recent progress in accelerator technology has paved the way for construction of high-average-power linear accelerators. The quality of electron beams produced by such machines are sufficient to drive free-electron lasers. Application of the energy-recovery technique allows a high level of overall efficiency to be achieved. Pilot facility are already in operation in Japan, Russia, and USA [11.1851–1853]. The demonstrated level of the average radiation power is about 10 kW in the 3–20 μm wavelength range [11.1852], and about 0.4 kW
Fig. 11.214 Distribution of the electrons in the electron beam (longitudinal cut). The *left*, *middle*, and *right* snapshots are taken at the beginning, middle, and the end of the undulator. Electron beam density is modulated periodically with the period of the resonance wavelength due to the radiative instability

in the THz gap [11.1851]. Projects of next-generation FELs based on energy-recovery linacs aim at increasing the average power into the tens of kilowatt range, and also to build high-power FELs operating in the UV range [11.1858–1863].

Potential industrial applications of high-average-power FELs involve material processing (for instance, the treatment of polymer surfaces), lithography, isotope separation, and chemical applications. Production of pure isotopes on an industrial scale may have a big impact on future developments. For instance, isotope $_{28}$Si is a radiation-resistant material of great interest for space research and the nuclear energy industry. The thermal conductivity of the pure isotope $_{28}$Si is 50% higher than that in the natural mixture, which seems very attractive for the semiconductor industry. The are also many other isotopes of great practical interest such as $_{13}$C (medical applications) and $_{15}$N (for the study and current control of use of nitrogen fertilizers in agriculture and agrochemistry). The basic process of isotope separation is a selective multiphoton dissociation of molecules. The required resonance wavelength range is in the range $2-50 \mu$m. The required energy in a pulse is no less than 0.1 mJ and monochromaticity of $10^{-2}-10^{-4}$, depending on the type of reaction. Industrial production of isotopes requires FELs with average power exceeding 10 kW. Construction of such facilities is on the way, and the first results are expected in the near future.

X-ray Free–Electron Lasers

At the start of this century, we have seen a revolution in synchrotron source intensities. This revolution stemmed from the technique of free-0electron lasers combined with recent progress in accelerator technologies, developed in connection with high-energy linear colliders [11.1866]. X-ray FELS (XFELs) have made a new regime of intensities accessible, thus opening up a fundamentally new physical domain.

A new era of synchrotron radiation research has begun withthe first user experiments on a vacuum UV FEL based on self-amplified spontaneous emission (SASE) [11.1865, 1867]. It is worth mentioning that such an essentially quantum terminology [introduced after amplified spontaneous emission (ASE)] does not reflect the actual physics of the process. The amplification process in the SASE FEL has its origin in density fluctuations in the electron beam. The latter effect is completely classical. The results have been obtained at the TESLA test facility (TTF) at the Deutsches Elektronen-Synchrotron DESY (Hamburg, Germany), using radiation pulses at a wavelength of 98 nm with a 40 fs pulse duration and a peak power of 1.5 GW [11.1864, 1868] (Fig. 11.215). Compared to present-day synchrotron radiation sources its peak brilliance is more than 100 million times higher (Fig. 11.216), the radiation has a high degree of transverse coherence and the pulse duration is reduced from hundreds of picoseconds down to ten-femtosecond time domain. While modern third-generation synchrotron light sources are reaching their fundamental performance limit, recent success in the development of the VUV FEL at DESY has paved the way for the construction of a novel type of light source that will combine most of the positive aspects of both a laser and a synchrotron.

In an X-ray FEL the radiation is produced by the electron beam during a single pass of the undulator [11.1869–1871]. The amplification process starts from shot noise in the electron beam. Any random fluctuations in the beam current correspond to an intensity modulation of the beam current at all frequencies simultaneously – including of course, the frequency to which the undulator is tuned. When the electron beam enters the undulator, the presence of the beam modulation at frequencies close to the resonance frequency initiates the process of radiation. The FEL collective instability in the electron beam produces an exponential growth (along the undulator) of the modulation of the electron
Fig. 11.215 *Left*: Average energy in the radiation pulse versus undulator length for TTF FEL at DESY [11.1864]. *Right*: interaction of powerful VUV radiation with solids [11.1865]. Ablation of a gold target after one pulse of the TTF FEL at DESY. The radiation wavelength is 98 nm, the pulse duration is 40 fs, and the peak power density is about $100 \, \text{TW/cm}^2$

Peak brilliance (Photons/s mrad^2 mm^2 0.1% BW)
Fig. 11.216 Peak brilliance of X-ray FELs versus third-generation storage rings light sources. Circles show the experimental performance of the FLASH free-electron laser at DESY

density on the scale of undulator radiation wavelength (Figs. 11.214, 215). The fluctuations of current density in the electron beam are uncorrelated, not only in time but also in space. Thus, a large number of transverse radiation modes are excited when the electron beam enters the undulator. These radiation modes have different gains. Obviously, as undulator length progresses, the high-gain modes will predominate increasingly and we can regard the XFEL as a filter, in the sense that it filters from arbitrary radiation field those components corresponding to the high-gain modes. Hence, for a long enough undulator, the emission will emerge in nearly complete transverse coherence. An intensity gain in excess of 10^7 is obtained in the saturation regime. At this level, the shot noise of the electron beam is amplified up to complete microbunching, and all electrons radiate almost in phase, producing powerful, coherent radiation.

The amplification bandwidth of a high-gain FEL amplifier is restricted by the resonance properties of the undulator, that is, by the number of undulator periods N_w within one gain length (the distance over

which the power increases by the factor of e = 2.718). The spectrum of transversely coherent fraction of the radiation is concentrated within the narrow band, $\Delta\lambda/\lambda \simeq (2\pi N_w)^{-1}$. The typical amplification bandwidth of the XFEL is of the order of 0.1%. The electron beam in an XFEL transfers enormous peak power. For instance, for typical XFEL parameters (electron energy of 17.5 GeV and peak current 5 kA) it is about 100 TW. The conversion efficiency of kinetic energy of electrons to the light is of the order of the amplification bandwidth, thus the peak power of X-ray radiation is in the multi-GW range (Table 11.54).

Experimental realization of XFELs has developed very rapidly during the last decade. The first demonstration of the SASE FEL mechanism took place in 1997 in the infrared wavelength range [11.1874]. In September 2000, a group at Argonne National Laboratory (ANL) became the first to demonstrate saturation in a visible (390 nm) SASE FEL [11.1875]. In September 2001, a group at DESY (Hamburg, Germany) demonstrated lasing to saturation at 98 nm [11.1864, 1868]. In June 2006 saturation was achieved at 13 nm, the shortest wavelength ever generated by FELs. The experimental results have been achieved at FLASH (*F*ree-Electron-*LAS*er in *H*amburg, Fig. 11.212). Regular user operation of FLASH started in 2005 [11.1872]. Currently FLASH produces GW-level, laser-like VUV radiation pulses with 10–50 fs duration in the wavelength range 13–45 nm. After the energy upgrade of the FLASH linac to 1 GeV planned in 2007, it will be possible to generate wavelengths down to 6 nm.

Recently the German government, encouraged by these results, approved funding of a hard-X-ray SASE

Table 11.54 Main parameters of present and future X-ray FELs [11.1872, 1873]

	2006: FLASH	2013: European XFEL
Radiation		
Wavelength	13–180 nm	down to 0.1 nm
Peak power	up to 5 GW	up to 150 GW
Average power	10 mW	up to 500 W
Pulse duration	10–50 fs	0.2–100 fs
Driving electron beam		
Energy	0.3–0.7 GeV	up to 20 GeV
Peak current	1–3 kA	up to 5 kA
Undulator		
Period	2.73 cm	3.6–8 cm
Peak magnetic field	0.5 T	0.5–1.4 T
Undulator length	27 m	up to 200 m

FEL user facility – the European X-ray free-electron laser [11.1873]. The US department of energy (DOE) has given SLAC the go ahead for the engineering design of the linac coherent light source (LCLS) device to be constructed at SLAC [11.1876]. These devices should produce 100 fs X-ray pulses with over 10 GW of peak power. New X-ray sources will be able to produce intensities of the order of 10^{18} W/cm^2. The main difference between these projects is the linear accelerator: an existing room-temperature linac for LCLS at SLAC, and a future superconducting linac for the European XFEL. The XFEL based on superconducting accelerator technology will enable not only a jump in peak brilliance of ten orders of magnitude, but also an increase by five orders of magnitude in the average brilliance. The LCLS and European XFEL projects are scheduled to start operation in 2009 and 2013, respectively.

In the period from 1985 to 2002 the FEL Conference Proceedings have been published in *Nuclear Instruments and Methods*, Section A. Starting from 2004 they are collected in electronic form on a WEB page dedicated to accelerator physics http://www.JACoW.org.

11.12 X–ray and EUV Sources

The extension of lasing into the X-ray region has been investigated by a wide variety of methods since the first demonstration of the visible laser in 1960. Although laser operation in the hard-X-ray region, which can be categorized as wavelengths shorter than 0.2 nm, has not been realized, much progress on the development of coherent light sources has been made in the soft-X-ray (0.2–30 nm) and extreme-ultraviolet (EUV, 30–100 nm) regions during these 20 years. There are two major methods to produce coherent short-wavelength radiation in these spectral regions. One is the use of transitions in highly charged ions in high-density plasmas created by laser irradiation of various targets or electric discharge. The other is the generation of very high harmonics of intense laser pulses. Each method has its advantages. X-ray lasers based on high-density plasmas can produce much higher energy per pulse and narrower spectra. High harmonics can be generated with compact, high-repetition rated lasers and produce a wide range of the spectrum from 100 nm to 3 nm. The use of these sources depends on the application and will be complementary.

11.12.1 X–Ray Lasers

The development of an X-ray laser has been one of the elusive dreams of laser physicists. Proposals for excitation schemes for X-ray lasers date back to 1965, when the possibility of achieving soft-X-ray amplification by collisional recombination was first suggested by *Gudzenko* and *Shelepin* [11.1877]. This was followed by proposals for photoionization pumping of X-ray lasers in 1967 [11.1878] and of electron-impact excitation schemes [11.1879]. The latter were inspired in part by the earlier success in the development of visible and ultraviolet ion lasers excited by electron collisions. However, the drastic scaling of the pump power requirements with decreasing wavelength and the low reflectivity of optics at soft-X-ray wavelengths, combined with the short lifetime of the excited levels involved in the lasing process, made the realization of soft-X-ray lasers a very challenging task [11.1880, 1881]. Several experiments carried out during the 1970s and early 1980s yielded the observation of population inversion and gain [11.1882].
Fig. 11.217 Schematic drawing of an exploding-foil-target X-ray laser

Nevertheless, the experimental demonstration of large amplification at soft-X-ray wavelengths was not realized until 1984. *Matthews* et al. [11.1883] at the Lawrence Livermore National Laboratory reported soft-X-ray amplification at wavelengths of 20.6 and 21.0 nm in Ne-like Se by electron collisional excitation. An exploding-foil-target X-ray laser demonstrated by Matthews et al. and the observed spectra are shown in Figs. 11.217 and 11.218, respectively. In parallel with this, *Suckewer* et al. [11.1884] at Princeton University reported amplification at 18.2 nm in H-like C by recombination excitation. These pioneering works were soon followed by numerous successful soft-X-ray amplification experiments conducted using of the world's most powerful lasers as pump sources [11.1885–1887]. Subsequent experiments achieved soft-X-ray laser operation in the saturated-gain regime [11.1888], and brought several potential applications to fruition [11.1889, 1890]. These applications include microscopy, holography, diagnostics of dense plasmas, and the excitation of nonlinear photoluminescence in crystals. In spite of their pioneering works, these soft-X-ray lasers have not been used as a laboratory tool because both schemes required huge laser energies of several hundred joules

Fig. 11.218a,b Grazing-incidence spectrograph data from **(a)** off axis and **(b)** on axis

and were operated at a low repetition rate. Since saturated amplification at a *water window* wavelength has not been accomplished even with the world largest laser driver [11.1891], a new excitation scheme has been sought for obtaining soft-X-ray lasers operating at shorter wavelengths. Many efforts have been directed in order to reduce the driver laser energy. The reduction of the pump laser energy is essential for the realization of tabletop X-ray lasers for potential applications [11.1892].

Electron Collision Excitation

Ions with specific numbers of electrons have a fully occupied outer-shell structure and survive over a wide range of plasma parameters. This is a significant advantage for plasma X-ray lasers because it results in a high relative abundance of the lasing ions over a wide range of temperature and density. To date, amplification has been observed in those ions. For example, the electronic structure of highly ionized selenium with 24 electrons removed (Se^{24+}) is similar to that of neutral neon (Ne-like), and the transitions are also similar to those of neutral neon [11.1893]. Such a comparison is referred to as isoelectronic scaling of energy levels and transitions.

Figure 11.219 shows a simplified energy-level diagram of a Ne-like ion scheme. The 3p laser upper states are populated mainly by electron collision excitation from the $2p^6$ Ne-like ion ground state. The population inversions are maintained by the rapid radiative decay of the 3s lower states to the ground state. The Ne-like scheme is well studied and is the most robust for electron collisional soft-X-ray lasers. However, it has the disadvantages that a large pump power is required to produce population inversion at a given wavelength. The nickel-like scheme was first proposed by *Maxon* et al. [11.1894] and proved to be useful for shorter-wavelength amplification, below 10 nm [11.1895]. Although the lasing scheme of the Ni-like ions is directly analogous to that of Ne-like ions, its higher quantum efficiency for a given ionization state allows the required pumping energy to be significantly reduced. Recently, gain-saturated amplification in the Ni-like scheme has been obtained at wavelengths as short as 7.3 nm [11.1896].

Transient Collision Excitation

The transient collisional excitation (TCE) scheme first proposed by *Afanasiev* and *Shlyaptsev* [11.1897] is a variation of the electron collisional excitation. TCE has attractive properties such as:
1. the gain coefficients are $1-2$ orders of magnitude larger than those obtained for the same transition in the quasi-steady-state regime,
2. the required laser energy for amplification can be reduced greatly, resulting in the realization of tabletop X-ray lasers.

In the TCE scheme, an intense picosecond laser pulse overheats the preformed plasma at a rate faster than other collisional processes. The preformed plasma, containing the lasing ions such as Ne-like and Ni-like ions, is produced by a preceding low-intensity nanosecond laser pulse. Transient gains in excess of $100\,\mathrm{cm}^{-1}$ have been predicted theoretically. Similar to the quasi-steady-state scheme, the TEC was firstly demonstrated in an Ne-like ion [11.1898] and has been successfully applied to Ni-like ions [11.1899]. Saturated amplification with a gain coefficient as high as $63\,\mathrm{cm}^{-1}$ has been reported from Ni-like Pd at 14.7 nm with a total pump energy as low as 7 J [11.1900]. Figure 11.220 shows the evolution of the 14.7 nm laser line along the plasma column. Recently, this scheme has been extended to lasing at 8.8 nm in Ni-like La [11.1901].

Optical–Field Ionization X–Ray Lasers

There are two kinds of plasma production scheme for X-ray laser media by use of high-power lasers. The optical-field ionization (OFI) scheme is completely different from the conventional plasma production scheme. The OFI is direct ionization by a strong optical field, which modifies the Coulomb potential of the atoms or ions to create electrons by tunneling ionization [11.1902]. In contrast to conventional X-ray laser schemes using electron collisional ionization, the OFI scheme requires an intense laser power rather than the large laser energy. Recent advances in the technology of ultrashort-pulse generation and amplification have achieved laser powers high enough to realize OFI X-ray lasers with a tabletop device. The requirement for low pump energy will also allow soft-X-ray lasers to operate at high repetition rates, which is critical for most of the promising applications.

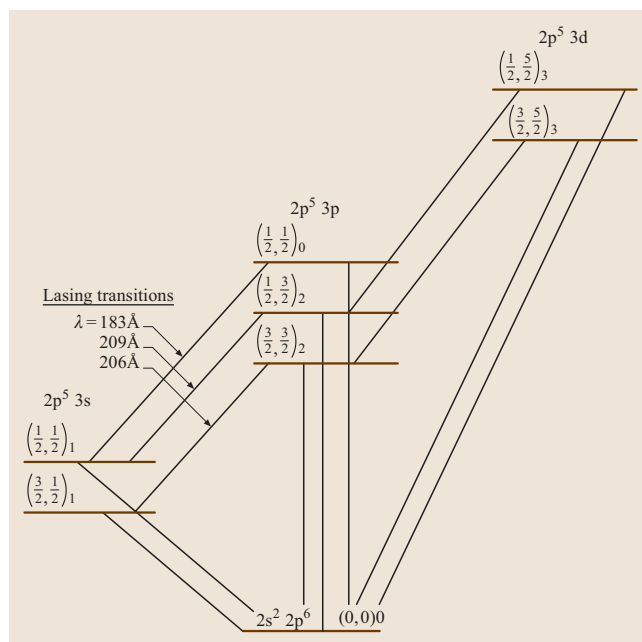
By applying this scheme to low-atomic-number media, a plasma consisting of fully stripped ions and free electrons is produced on a time scale much shorter than their collisional and radiative time. In other words, the temperature of electrons produced by the OFI is not determined by the charge state of ions, but can be controlled separately by ionizing-laser parameters such as the polarization and wavelength [11.1903]. By means


Fig. 11.219 Simplified energy-level diagram for Ne-like Se

of a quasistatic model, *Burnett* and *Corkum* [11.1904] showed that cold dense multiply ionized plasmas could be produced by OFI, which are suitable for recombination X-ray lasers. *Nagata* et al. [11.1905] demonstrated amplification of the Lyman $\alpha\,(n=2-1)$ transition at 13.5 nm in H-like Li by the recombination pumping scheme following the OFI. Using a sub-picosecond KrF
Fig. 11.220 Intensity of 14.7 nm X-ray laser line for $1-8$ mm Pd target lengths
Fig. 11.221 Schematic diagram of the experimental setup of 13.5 nm optical-field ionization X-ray laser

excimer laser focused at 10^{17} W/cm^{-2} (Fig. 11.221), singly ionized lithium ions were further ionized to fully stripped states, resulting in population inversion with respect to the ground state of hydrogen ions. A small signal gain of 20 cm^{-1} and a gain-length product of 4 have been observed. Subsequently, *Korobokin* et al. [11.1906] used a plasma waveguide in a LiF microcapillary to improve the propagation of the pump pulse and successfully increase the gain-length product to 5.5.

On the other hand, *Corkum* et al. also suggested the use of circularly polarized laser pulses for collisional excitation following OFI [11.1907]. Lemoff et al. proposed the specific systems [11.1908] and demonstrated lasing at 41.8 nm in eightfold-ionized Xe [11.1909]. In this experiments, circularly polarized Ti:sapphire laser pulse with an energy of 70 mJ and a duration of 40 fs was focused into a Xe static gas cell to create Pd-like Xe. The intense pump pulse produce the hot electrons which collisionally excite the Pd-like ions to the laser upper level. Recently, *Sebbon* et al. reported the sat-

Fig. 11.222 Schematic diagram of the experimental setup of optical-field ionization X-ray laser based on electron collision excitation

urated amplification of the 41.8 nm line in Pd-like Xe with 0.6 J, 30 fs Ti:sapphire laser pulses. 5×10^9 photons per pulse were obtained at gain saturation [11.1910]. They also reported the lasing at 32 nm in nickel-like krypton [11.1911]. The experimental setup is shown in Fig. 11.222.

Discharge Excitation
Direct excitation of plasma X-ray lasers by an electrical discharge has the potential advantage of high efficiency and compactness over a laser-produced-plasma device. The uniform high-density plasmas required for X-ray amplification can barely by produced by a conventional electric discharge. *Rocca* et al. proposed [11.1912] and demonstrated [11.1913] a capillary discharged soft-X-ray laser operating on the 46.9 nm transition in Ne-like Ar in 1994. A fast electrical discharge in a capillary was used to excite plasma columns up to 20 cm in length with a peak current of 40 kA. Figure 11.223 shows the fast capillary discharge soft-X-ray laser setup. The variation of the spectra as a function of capillary length is shown in Fig. 11.224. A recently developed compact discharge occupies a space of only 0.4×1 m^2 in an optical table and produces an average output energy of 0.88 mJ at a repetition rate of 4 Hz. In two-pinhole interference experiments, a high degree of spatial coherence was observed by single-pass amplification in a 36 cm-long capillary. This compact soft-X-ray laser has been used in a variety areas including plasma physics, material characterization, and the characterization of soft-X-ray optics [11.1914].

11.12.2 High–Order Harmonics

Survey
High-order-harmonic generation (HHG) by the interaction of femtosecond high-intensity laser pulses with a gaseous medium has been extensively studied since it has promising potential for use as a coherent extreme ultraviolet and a soft-X-ray (XUV) source as an alternative to soft-X-ray lasers or synchrotron radiation sources. The harmonic spectrum has a very characteristic shape, that is, it falls off for the first few harmonics, then shows a plateau where all the harmonics have the same intensity strength, and finally ends with a sharp cut-off. A typical harmonic spectrum observed by the interaction of ultrashort high-intensity pulses with rare gases is shown in Fig. 11.225. The temporal duration of the harmonics is considered to be shorter than that of the driving laser pulse whose width is typically 100 fs or
less. These spectral and short temporal properties make the high-order harmonics an unique coherent source in the XUV region and are opening new application fields.

Approach to Shorter–Wavelength Generation

Since the demonstration of HHG in rare gases using a KrF excimer laser by *McPherson* et al. [11.1915] and a mode-locked Nd:YAG laser by *Ferray* et al. [11.1916] in 1987, much effort has been made to extend the harmonic wavelength to a shorter one with various pumping sources. *Macklin* et al. [11.1917] generated the 109th harmonic (7.4 nm) in neon gas excited with a 806 nm Ti:sapphire laser. *L'Huillier* and *Balcou* [11.1918] observed the 135th harmonic (7.8 nm) using a 1 ps Nd:glass laser. In these experiments, ionization of the neutral rare-gas medium limits the achievable wavelength because of the low effective interaction intensity due to the occurrence of ionization during the interaction. Although ions having larger ionization energy potentially produce higher harmonics, simultaneously existing free electrons cause a large phase mismatch between the pump and high-harmonic waves, resulting in the lowering of cut-off orders. This drawback, which arises from the use of ions as a nonlinear medium, was compensated for to some extent with an ultraviolet pump source [11.1919]. *Nagata* et al. [11.1920] and *Preston* et al. [11.1921] reported the generation of the 37th harmonic (6.7 nm) of a 248 nm KrF excimer laser. In those studies with pumping pulses longer than 100 fs, the shortest wavelength achieved was limited to around 7 nm. More recently, however, progress of ultrashort-pulse laser technology has enabled the use of extremely short pulses with high intensity, which allows the circumvention of the limitation due to ionization [11.1922, 1923]. That is, the effective interaction intensity before the occurrence of ionization can be increase with the extremely short pulses. Consequently, harmonic wavelengths well within the *water window* region was attained, using an ultrashort Ti:sapphire laser operating with a 26 fs pulse duration [11.1924]. With a sub-10 fs Ti:sapphire laser, *Spielmann* et al. [11.1925] obtained coherent continuum emission shorter than 2.5 nm, which corresponds to a photon energy greater than 0.5 KeV. On the other hand, a few approaches from the medium side were reported. Although ions [11.1926, 1927], molecules [11.1928, 1929] and clusters [11.1930, 1931] have been investigated as nonlinear medium in place of rare gases, the output property of the harmonics was hardly improved for practical use.

Theoretical Progress

Theoretical understanding of HHG must be based on two processes:

1. a single-atom response in the driving laser field, and
2. a macroscopic response including propagation effects.

Both responses must be taken into account to make a comparison between the experimental and theoretical results.

The emission property of harmonic radiation from a single atom is determined by the induced atomic polarization, or dipole acceleration, which is calculated from the solution of the time-dependent Schrödinger equation (TDSE). *Krause* et al. [11.1932] showed that the photon energy E_{max} of the highest harmonic in the plateau is give by $E_{max} = I_p + 3.17U_p$, where I_p is the ionization energy of the nonlinear medium and $U_p = 9.33 \times 10^{-14} I \lambda^2$ (eV) is the ponderomotive energy of the electron subjected in the pump laser field I (W/cm^2) at a wavelength of λ (μm). In a semi-classical picture [11.1933], the physical origin of this expression is explained in terms of tunneling ionization of the atom, followed by acceleration of the ionized electron in the pump field and recombination with its parent ion. During the acceleration by the optical field, the electron obtains the maximum energy of $3.17U_p$. When this electron recombines with the parent ion, the electron release this energy plus the ionization energy as a harmonic photon. Figure 11.226 shows a semiclassical model of high-order-harmonic generation.

Since calculation based on the TDSE is quite time consuming, it is very difficult to combine the numerical results of TDSE with the propagation equations. The calculation load is considerably relieved by using the model of *Lewenstein* et al. [11.1934, 1935]. This model is based on the strong-field approximation and is valid in the region $U_p > I_p$. *L'Huillier* et al. developed a propagation code coupled to the Lewenstein model and successfully described the harmonics characteristics observed in various experiments [11.1936, 1937].

Phase Matching

In order to increase conversion efficiency and improve the spatial quality of high harmonics, phase matching is essential. It is, however, not easy to satisfy the phase-matching condition along the interaction length because, in contrast with low-order-harmonic generation in the perturbative regime, the dipole phase is dependent on
Fig. 11.223 Variation of the intensity of the spectral lines in the neighborhood of 48 nm as a function of capillary length
Fig. 11.224 Schematic illustration of the fast capillary discharge setup

Fig. 11.225 Schematic drawing of typical harmonic spectrum
Fig. 11.226 Schematic drawing of a semiclassical model of high-order-harmonic generation

pump pulse also make the experimental achievement of phase matching quite troublesome.

Several techniques to control the phase-matching conditions have been investigated. Phase matching can be achieved by controlling the balance of

1. the Gouy phase shift and atomic dispersion [11.1939, 1940]
2. nonlinear phase shift and plasma dispersion [11.1941] or
3. waveguide dispersion of hollow fiber and atomic dispersion [11.1942, 1943]

A geometrical phase and a dipole phase that have opposite dispersions are compensated by adjusting the focal

the driving laser intensity [11.1938]. Furthermore, in addition to the medium's dispersion, nonlinear phenomena such as self-focusing and plasma defocusing of the

position around a gas jet. This method is extended to a loosely focused geometry and successfully improved conversion efficiency and beam quality [11.1944]. The use of a hollow fiber provides a few advantages for high-harmonic generation. Due to the flat phase front of the driving (pumping) laser in the hollow fiber, one can avoid undesirable phase modulation of the harmonics, which originates from the intensity-dependent phase change around the focus [11.1938]. This facilitates the clear and easy identification of the phase-matching conditions by adjusting the medium density. The increase of the intensity–interaction length product would also lead to an improvement in conversion efficiency. Furthermore, the use of a hollow fiber results in lower beam divergence and better spatial coherence. Such improvements are very important for practical applications. With this new technique, several groups have reported harmonic generation. *Tamaki* et al. first demonstrated HHG of a Ti:sapphire laser pulse in an Ar-gas-filled hollow fiber and showed hundredfold enhancement around the 25th harmonic [11.1945], [11.1946]. Figure 11.227 shows the observed harmonic spectra with and without the hollow fiber filled with 5 torr Ar gas. *Rundquist* et al. [11.1942, 1947] also reported phase-matched generation of the 29th harmonic and improvement of both the generation efficiency and the beam quality in the hollow fiber. However, the output energy from the hollow fiber was restricted to a few nanojoules because only a few millijoules of laser pulse could be introduced due to the limited aperture of the hollow fiber [11.1948].

Energy Scaling

For the development of a variety of applications of high harmonics (HH), one of the most important issues is energy scaling. High-energy HH is expected to boost new physics in the soft-X-ray region. *Takahashi* et al. report energy scaling of HH in Ar under the optimized phase-matched condition [11.1944, 1949]. Their scaling method demonstrated a linear increase of harmonic energy with respect to the geometrical focusing area of the pump pulse, while keeping an almost perfect spatial profile of the harmonic output. The maximum energy of the 27th harmonic attained was 0.33 nJ with a conversion efficiency of 1.5×10^{-5}. The evolution of HH intensities in the spectral region from the 23rd- to 27th-order harmonics was also measured as a function of medium length. The result is shown in Fig. 11.228. The solid line shows theoretically fitted intensities for the 23rd, 25th and 27th harmonics. The coherence length was estimated to be ≈ 15 cm by fitting the theoretical curves. As was pointed out by *Constant* et al. [11.1943], the optimizing conditions for the medium, coherence and absorption lengths are given by $L_{med} > 3L_{abs}$ and $L_c > 5L_{abs}$, where L_{med}, L_c, and L_{abs} are the medium
Fig. 11.227a,b Observed harmonic spectral distribution emerging **(a)** from a 3 cm hollow fiber and **(b)** in 0.5 cm free space. Ar gas pressure is 5 torr

length, the coherence length, and the absorption length, respectively. The 23rd- and 25th-order harmonics satisfied the optimized condition for this relation. Therefore, those orders were saturated under the experimental conditions. On the other hand, the 27th-order harmonic did not yet satisfy the above conditions, because of low absorption.

Spatial Coherence

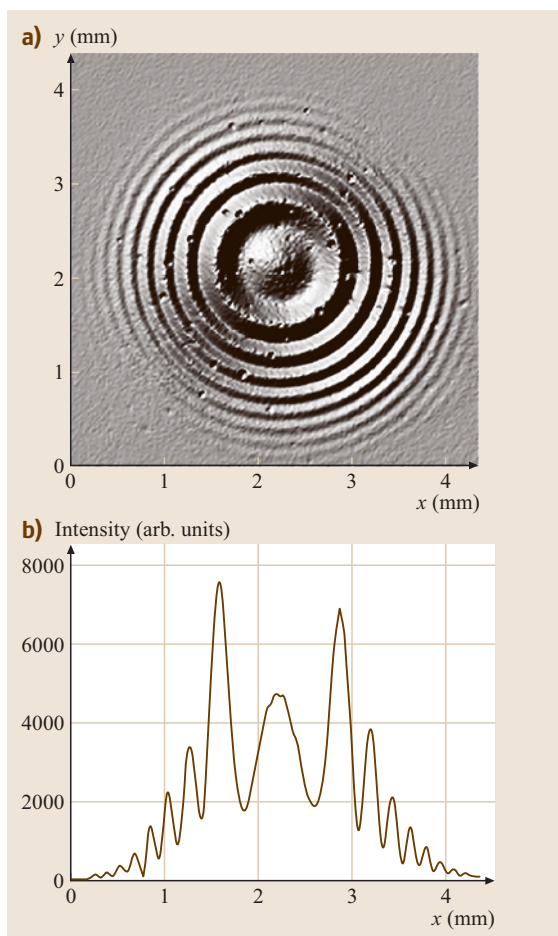
Since HHG is based on nonlinear frequency conversion, the spatial and temporal coherences of high-order harmonics are expected inherently to succeed to those of the fundamental laser pulse. However, HHG conducted by use of a tight-focusing geometry in thin gas media did not allow full phase matching to enhance the coherence. Typically multimode components are observed as broadened peaks in the spectrum or the pedestal of the spatial profiles. Recent studies have revealed that macroscopic


Fig. 11.230 (a) Interferogram recorded with a PDI plate with a 10 μm pinhole. **(b)** Intensity profile of interferogram along a horizontal line passing through the center

phase matching can realize highly efficient and spatially well-characterized (nearly Gaussian profile) high-order harmonic light [11.1949, 1950]. Several groups have reported the interferometric measurement of the spatial coherence of high harmonics [11.1951–1954]. When the macroscopic phase matching is achieved in the hollow fiber or loosely focused geometry, the measurements show that the harmonic beams have almost perfect spatial coherence. Figure 11.229 shows the interferogram of the 27th-harmonic beam generated with an Ar-filled hollow fiber pumped with 20 fs, 0.35 mJ Ti:sapphire laser pulses [11.1954]. This interferogram was obtained with two pinholes separated by 100 μm, while the harmonic-beam diameter was measured to be 130 μm. Figure 11.230 also shows the

interferogram recorded by point-diffraction interferometry, which indicates that the harmonic beam can be considered as a spherical wave within a phase error of $\lambda/15$ [11.1954].

Applications

In addition to applications in atomic physics [11.1955], high harmonics have been used for solid-state spectroscopy [11.1956] and plasma diagnostics [11.1957]. High intensity of high harmonics is also expected to give rise to nonlinear phenomena in the XUV region. As described above, *Takahashi* et al. [11.1944, 1950] generated a peak power of 130 MW at 62.3 nm in 0.6 torr Xe and 10 MW at 30 nm in 2 torr Ar. When these harmonic pulses are focused with multilayer mirrors, the focused intensity will reach 10^{14} W/cm^2, which is high enough to cause nonlinear interactions. Theoretical predictions of nonlinear interaction between soft

X-rays and matter have been reported by a few groups, such as two-photon ionization of He$^+$ [11.1958], He double ionization for the autocorrelation of an extreme-ultraviolet (XUV) pulses [11.1959], the advantages of high-intensity short-wavelength radiation for Coulomb explosion imaging [11.1960], and the ionization of cluster targets. These research field can be expected to open a new area in high-intensity physics.

Furthermore, coherent XUV and X-ray pulses are not only useful owing to their short wavelengths, but are also important due to their potential to produce electromagnetic radiation in the range of attoseconds. High-order harmonics have been expected to be the source of attosecond pulses [11.1961, 1962]. Recently, *Hentschel* et al. [11.1963] demonstrated the generation of isolated soft-X-ray attosecond pulses and their temporal characterization by a novel cross-correlation technique using intense few-cycle visible laser pulses.

11.13 Generation of Ultrahigh Light Intensities and Relativistic Laser–Matter Interaction

Modern laser technologies allow the amplification of short laser pulses to energies of some tens of kJ. Additionally, ultrashort pulses containing only a few optical cycles can be generated. By merging these techniques nowadays focused laser beams can reach unprecedented intensities in the range of 10^{21} W/cm^2 and will reach even higher values in the near future. At these intensities the electric and magnetic field strength is many orders of magnitude higher than those that will ever be possible in a static generation scheme. By applying these fields to a target it becomes possible to gain access to a new interaction regime of light and matter: relativistic optics. This opens a new wide area in experimental science where classical optics meets plasma dynamics, relativistic quantum mechanics, and high-energy physics.

11.13.1 Laser Systems for the Generation of Ultrahigh Intensities

Amplification of Ultrashort Pulses to High Energies

For ultrashort pulses the energy density of light at the surface and in the volume of all the optical elements is limited by the onset of nonlinear effects and laser damage due to the high peak power. Moreover, in a laser amplifier the energy extraction efficiency is a function of the ratio of the energy density and the saturation fluence

of the laser material. Hence, a short pulse cannot be amplified efficiently. The chirped pulse amplification (CPA)
Fig. 11.231 The CPA principle. An ultrashort pulse generated in a mode-locked laser is stretched by adding a spectral phase that group delay different wavelengths of the pulse. After amplification retaining the pulse spectrum and chirp the pulse is recompressed to its original length, resulting in ultrahigh peak power

technique [11.1964] circumvents this difficulty. The principle of CPA is depicted in Fig. 11.231. Ultrashort pulses contain a broad spectral bandwidth according to their Fourier transformation (see Chap. 12). This fact enable the possibility to add a phase shift to different frequencies or wavelengths of the laser pulse just after its generation in a mode-locked laser cavity. The result is a stretched pulse containing a chirp, i. e., the pulse duration is no longer bandwidth limited. The lengthened pulse has accordingly a lower peak power. It can be amplified much more efficiently and compressed to a very short pulse afterwards by adding a spectral phase with an opposite sign to that introduced by the stretcher.

After the invention of the CPA technique tremendous progress in the development of ultrashort pulse lasers towards higher peak power has been witnessed. Nowadays, terawatt (TW) laser pulses can be produced using tabletop laboratory-scale laser systems that operate at repetition rates of 10 Hz or higher. Whereas, even higher power up to the petawatt (PW) can be generated by flashlamp-pumped lasers that have factory-building sizes, like the first PW laser, that was realized in 1999 [11.1965]. The CPA technique is common to all of these devices.

Because pulse stretching and compression are related to each other and are normally based on the same principle, the stretcher and compressor are treated here as a stretcher–compressor pair (SCP). Pulse stretching naturally occurs in the vicinity of dispersion. Hence, the propagation of pulses in dispersive media always leads to pulse stretching. In order to keep the required space and size of optical elements as small as possible highly dispersive optics, i. e., gratings will be used. Nevertheless other elements such as prisms, grating prisms (so called grisms), fibers and chirped fiber Bragg gratings as well as chirped mirrors can be applied. Here we limit ourselves to the simplest case of flat reflective phase gratings, because these offer the largest group delay.

The principle of pulse compression with identical parallel gratings was first described by *Treacy* [11.1966]. A pulse is diffracted by a grating, angularly split into its different wavelengths and propagated to the second parallel-aligned grating. The second grating removes the angular modulation, i. e., redirects all wavevectors of the different wavelets into the same direction. If all the waves are treated as plane waves, the introduced lateral shift can be neglected. For a real, limited beam size the same device of parallel gratings has to be used once more in order to combine the wavelets again spatially. As a side effect this doubles the stretching factor

of the arrangement. Section 12.1.3 contains a detailed description of these devices.

For ultrahigh-peak-power lasers a maximum stretching/compression factor, i. e., the ratio of stretched pulse length to bandwidth limited pulse length is required in order to maximize the fluence in the amplifier chain. The stretching factor depends on the line density of the gratings, the center wavelength, and the bandwidth of the pulse. Very long stretching factors of 10 000 or more are required for most broadband rare-earth-doped laser materials in order to allow fluences in the amplifier close to or above the gain-saturation fluence.

If the grating distance is chosen in this way, such that the unclipped spectral bandwidth is twice the spectral full width at half maximum (FWHM) of the pulse, the maximum stretched pulse length $\tau_{\max}$ is only a function of the grating size L:

$$\tau_{\max} = 2\frac{L}{c}\cos(\alpha) , \qquad (11.205)$$

where $\cos\alpha$ is a factor according to the diffraction angle α of the grating and has a maximum of unity in the unrealistic case of a diffracted beam parallel to the grating surface. The factor of 2 refers to the Littrow case, i. e., the input and diffraction angle being equal. The latter normally maximizes the grating diffraction efficiency. For holographic metal-coated diffraction gratings with near-rectangular groove shapes it has been shown that an optimum diffraction efficiency of a metal grating at wavelength λ can be achieved for a grating constant of about $\sqrt{2\lambda}$ [11.1967], which results in a Littrow angle of 45°. This leads to a minimum grating size for an SCP of about 24 cm if a femtosecond pulse has to be stretched to 1 ns. Passing a stretcher or compressor setup again can, in principle, increase the stretching factor, but introduces losses that are most often acceptable for the stretcher but not for the pulse compressor.

Very large grating distances and hence long stretched pulses require a similar accuracy for the compensation of dispersion by a well-matched stretcher and compressor as in the case of ultra-broadband fs pulses, because higher-order dispersion terms increase together with the second-order term. Because most often aberrations of the telescope optics cannot be tolerated, aberration-free all-reflective designs like the Öffner triplet are applied [11.1968]. In special cases aberrations introduced by the stretcher may help to compensate for laser-material dispersion in the amplifier chain [11.1969].

The required grating sizes for the compressor of a high-energy laser system is ruled by the generated group delay in order recompress the pulse and the size

Fig. 11.232 (a) Capability of laser materials for energy storage and generation of high energy pulses. The inverse saturation fluence is plotted against the fluorescence lifetime. For a higher gain amplified spontaneous emission (ASE) become an issue whereas for lower gain damage limits efficient energy extraction. Effective pumping will be useful if the fluorescence lifetime exceeds a certain limit. The limits are marked with *dashed* lines. **(b)** Capability of laser materials for energy storage and generation of high peak power. The inverse saturation fluence multiplied by minimum possible pulse width plotted against fluorescence lifetime τ. Differently doped materials are marked with different colors

required to fit the compressor to the beam diameter. Before compression the laser beam has to be expanded to reduce the fluence in the beam to an amount well below the damage threshold of the compressor optics, particularly the gratings. For a metal-coated grating damage thresholds may reach the $0.5\,\text{J/cm}^2$ level [11.1967] for half-ps pulses, but will normally be less than $0.25\,\text{J/cm}^2$. In the compressor setup these fluences result in intensities that are well above the onset of nonlinear effects in air at normal pressures. In order to prevent the pulse from self-focusing and self-splitting into white-light filaments, pulse compression has to be performed in a vacuum vessel.

In the region of fs to ps pulses the damage threshold for metal coatings is nearly independent of pulse duration, in contrast to dielectrics where the main damage mechanism is linked to nonlinear absorption effects. For pulses longer than 100 fs dielectric gratings may substantially improve overall performance [11.1970]. Damage thresholds two to four times that of gold-coated gratings are reported. These dielectric phase gratings on top of a multilayer mirror can, in principle, show a 100% diffraction efficiency to the minus-first order [11.1971]. Therefore they are favored in high-energy high-peak-power laser systems.

The peak power of a laser system is limited mainly by the possible sizes of the diffraction gratings. A workaround is to add identical smaller gratings to a mosaic grating or tiled grating. The smaller grating tiles have to be coherently phased together in order to make them work like a single one. Using this technique to build a compressor opens the way to further power scaling of high-peak-intensity lasers. Compression of pulses to 650 fs with a tiled grating replacing a meter-sized grating in a high-energy laser system has already been demonstrated [11.1972], as well as pulse compression of a chirped 2 ns pulse down to 150 fs [11.1973] by phasing
two 350 mm-wide gold-coated gratings with the help of a six-axis piezo-driven mount.

Laser Materials for High Peak Power

A crucial issue conceiving a high-peak-power laser system is the choice of the gain material. Broad band width and a high cross section for stimulated emission are required. Due to the limited peak power of the pump source a long fluorescence lifetime for energy storage is desired. At higher fluorescence lifetimes either the emission cross section, or the gain bandwidth, or both decrease. For efficient amplification the extracted laser

pulse energy density has to be close to the saturation fluence of the gain medium.

Figure 11.232 illustrates the possibility of generating high peak power out of some established laser materials. The inverse of the product of the saturation fluence and the shortest pulse duration indicates the capability of a laser material for high amplification at maximum bandwidth. Assuming Gaussian-shaped gain spectra the correlation between the emission cross section, bandwidth and fluorescence lifetime of a laser material is given by

$$\sigma_{em} = \frac{c_0^2}{4\pi n^2 \nu^2} \frac{1}{\tau_f} \frac{\sqrt{\ln 2}}{\Delta\nu\sqrt{\pi}} \qquad (11.206)$$

with c_0 the velocity of light in vacuum, n the refractive index, h Planck's constant, ν the center frequency, τ_f the fluorescence lifetime, and $\Delta\nu$ the bandwidth (FWHM). Applying the time–bandwidth product for Gaussian lineshape a criteria for the generation of high peak power at a corresponding fluorescence lifetime depending on the laser wavelength lambda and the refractive index n is obtained

$$\frac{\tau_f}{t_p F_{sat}} \leq 4.26 \times 10^9 \frac{(\lambda[\mu m])^3}{n^2} \frac{[cm^2]}{[J]} . \qquad (11.207)$$

Here the saturation fluence F_{sat} is given by $F_{sat} = h\nu/\sigma_{em}$.

In Fig. 11.232 suitable materials for amplification to a high energy level are mapped. Furthermore, there is an optimum region between high gain and low gain, where amplified stimulated emission and damage issues, respectively, are likely to occur.

Recently, it was observed that cryogenic laser materials may show enhanced performance. Either spectroscopic parameters and thermal behavior can be improved by cooling to liquid-nitrogen temperatures [11.1974]. Ti:Sapphire for instance gain, higher efficiency and thermal conductivity. Quasi-three-level systems represented by the Yb-level system show higher emission cross sections and additionally reduced absorption at the laser wavelength, because population of the low laser level is suppressed.

Laser Amplifier Schemes for High Peak Power

Except some examples of high-energy excimer lasers and upcoming free-electron lasers for the generation of high peak power at very short wavelengths typical scientific lasers are based on solid-state lasing materials as presented above, all of which are pumped optically. Because a high flux of pump photons is needed to invert the energy-level population significantly only

three options for pumping exist: flashlamps, lasers, and diode lasers. Diode lasers are treated separately because no enhanced additional pumping is required for them, providing a stabilized current is sufficient.

So far the flashlamp is the cheapest generator for a high pump photon flux. In the past flashlamp-pumped solid-state lasers have been scaled to 20 kJ pulse energy in a single beam. Such systems are based on schemes where bundles of meter-size flashlamps pumping several Nd-doped glass discs arranged at Brewster's angle in the laser beam path as sketched in Fig. 11.233. For fusion lasers like the National Ignition Facility in the US (NIF) [11.1975], Laser Megajoule in France (LMJ) [11.1976] or Gekko in Japan [11.1977] several such beam lines are bundled together to form megajoule laser facilities. Such beam lines were the first with the capability to generate petawatt laser pulses [11.1965]. Typical for this kind of lasers are a double-pass main amplifier and a single-pass booster amplifier section.

The drawback of flashlamp pumping is the low efficiency of this scheme. Pump photons are not only generated at the absorption wavelength of the laser material but also at wavelengths not involved in the lasing process. This low efficiency results in substantial heat left inside the laser materials, which are themselves poor heat conductors. The maximum repetition rate of this disc configuration scales with the inverse square of the beam diameter. Amplifiers with beam diameters of some 10 cm can be operated at repetition rates of some shots per day only. With these systems scientific investigations of plasma effects are extremely difficult and expensive. For Nd-doped glasses the gain bandwidth limits the shortest pulses to about 400 fs. To generate 100 TW to PW peak power pulses, energies in the 100 J range are needed, which require large amplifiers. Nevertheless, using these lasers for pumping an OPCPA (see below) opens the door for ultra-broadband amplification of few-
Fig. 11.233 Typical flashlamp pumped slab amplifier configuration. The seed pulse is injected at the spatial filter between a double-pass section and a single-pass booster amplifier

cycle pulses to the 10 J level with reasonable repetition rates [11.1978].

Using laser diodes as the pump source helps to relieve some of these difficulties because their emission spectrum is much narrower and can be fitted to the absorption line of the laser-active medium. Consequently less energy is wasted and less heat is left inside the laser active medium. However, high-power diodes with energy-conversion efficiencies up to 75% and continuous-wave output in the 100 W range are only available in the red and near-infrared spectrum. These diodes are based on double heterostructures of ternary and quaternary semiconductors incorporating GaAs. This spectral range is preferred for pumping rare-earth-doped laser materials, where Nd and Yb are most favored. Broadband gain materials including transition metals such as Cr:LiSAF will attract more interest if suitable diodes providing high brightness are developed. Today diode-pumped infrared frequency-doubled lasers are used to pump Ti:sapphire, the laser material able to amplify the widest spectrum and hence the shortest pulses.

The direct diode-pumped amplification of 150 fs pulses to the joule and 10 J level has already been shown by pumping an Yb-doped fluoride-phosphate glass at 940 nm [11.1979, 1980] with the edge-cooled disc arrangement shown in Fig. 11.234a.

To accomplish experimentalists' demands for higher repetition rates advanced cooling technologies have to be developed even for diode-pumped solid-state lasers (DPSSL). Figure 11.234 shows a variety of DPSSL pumping schemes with different cooling architectures.

In slab lasers, where the various pump schemes depicted in Fig. 11.234b–d are employed, one dimension is used to provide a small distance for heat removal. They differ in the way in which pump light is provided. Expanding this idea to two dimensions results in the cladding pumped fiber amplifier (Fig. 11.234g), which is not or only radiatively cooled like the heat capacity lasers (Fig. 11.234f), which are able to run as long as the temperature does not reach a certain level. These lasers provide bursts of pulses. Thin disc lasers (Fig. 11.234e) allow a very high average power and can produce very good beam profiles but are difficult to scale to larger beam diameters and higher pulse energies. A compromise is the use of a thicker disc at a moderate repetition rate in the same configuration. The thicker disc does not require multiple pump-beam passes for full absorption and provides a larger single-pass amplification than the thin-disc amplifier.
Fig. 11.234a–h Amplifier schemes for diode pumping. Edge cooling: (**a**) discs – conductive cooling (**b**) transverse diode-pumped structured slab and (**c**) transverse diode-pumped slab. Water cooling: (**d**) zigzag slabs and (**e**) thin discs. No cooling: (**f**) heat-capacity lasers and (**g**) fiber amplifiers. Gas cooling: (**h**) thin-disc assemblies

By putting several thin discs together and using the amplifier slab interspace for gas cooling, as in the architecture sketched in Fig. 11.234h, the gain and absorption equals that of the thick disc but efficient cooling is enabled. A diode-pumped laser of this type was developed at the Lawrence Livermore National Laboratory in the US. It is called Mercury [11.1981] and allows an output of 65 J, the highest ns pulse energy from a single DPSSL at a repetition rate of 10 Hz so far reported.

The long propagation length in a fiber that confines the laser light field to the doped and amplifying core allows high amplification factors in a single pass and optical-to-optical efficiencies close to the theoretical limit given by the quantum efficiency. For TEM_{00}-mode radiation the maximum pulse energy is limited to some mJ for CPA. Nevertheless, average powers from several 100 W to the kW region are possible. To reach a high extraction efficiency for the low-energy seed pulses provided by fs oscillators multipass amplifiers or regenerative amplifiers are adopted. Multipass amplifiers can be found with a variety of geometries. All pulse parameters, such as the polarization or propagation direction, can be used to separate pulses from successive passes and finally for out-coupling.

The regenerative amplifier is a seeded oscillator with an active element, in most cases a fast switching Pockels cell, that allows the extraction of the amplified pulse when the gain of the active medium is saturated. It benefits from a stability that stems from gain saturation and beam quality that is ensured by successive spatial filtering in the laser cavity. The drawbacks of regenerative amplifiers are pre-pulses produced by leakage from the cavity in round-trips before extraction and long path lengths in dispersive material that has to be compensated by the SCP of a CPA system.

The last section of a high-power laser amplifier system is a booster amplifier with a low number of passes or one pass only. In order to extract the energy with high-efficiency, saturation fluence has to be reached across the full beam diameter. The result is a so-called top-hat beam profile with a uniform fluence in the center and a steep fluence rise at the edge. In gain media with a long propagation distance this may be achieved automatically after some distance and the length were uniform aperture filling is not guaranteed hardly affects the overall efficiency of the amplifier. For amplifiers with short propagation
distances of the pulse in the active medium the seed pulse itself has to be converted into a top-hat profile starting from a Gaussian. A simple method to implement this is by diffraction at a serrated aperture [11.1982].

Because a top-hat beam unlike the Gaussian changes its profile while propagating it has to be relay imaged to successive optical elements of the laser system to avoid hot spots and laser damage. In high-power laser systems relay imaging is often combined with beam expanders and spatial filters [11.1983].

Broadband Optical Parametric Chirped Pulse Amplification

Alternatively instead of conventional laser amplifiers a parametric amplification process (OPA) can be used for the generation of high-energy broadband pulses. In this second-order nonlinear interaction a pump photon is split into a signal and an idler photon. This process is the reverse of sum-frequency generation. Energy-conservation demands that the sum of the signal and idler frequencies equals the pump frequency. Additionally, fulfilling momentum conservation ensures coherence of the involved waves while propagating through the nonlinear medium. The latter is known as phase matching. The nonlinear medium has to be a crystal in order to show second-order nonlinearity and achieve phase matching. The phase-matching condition also determines the wavelengths of the signal and idler waves.

For a certain direction of pump, signal, and idler waves only one combination of wavelengths can be generated. In order to allow broadband amplification of a signal input wave using a narrow-band pump the different idler wavelengths should have different directions in the crystal. This principle is illustrated in Fig. 11.235 and is called optical chirped pulse amplification (OPCPA) if the signal beam is a chirped stretched pulse [11.1984–1987].

With the OPCPA scheme, energy can be transferred from a narrow-band nanosecond pulse to a stretched broadband signal pulse. The problem of amplification of ultrashort pulses is thereby split into the task of amplification of high-energy laser pulses and the task of implementation of broadband OPA. Comparing the OPCPA with a conventional laser-pumped CPA several advantages can be realized. Firstly no energy is stored in the nonlinear crystal and, except parasitic absorption, no energy is lost in the crystal, which results in no heat being produced in the process. This fact allow easy high-repetition-rate scaling of the amplifiers without phase distortions by thermal effects. Because no resonance to energy levels of a dielectric medium is required, very

Fig. 11.235 Scheme to achieve broadband optical parametric amplification. In order to achieve broadband signal amplification in a parametric nonlinear optical process using a narrow-band pump different idler wavelengths have different propagating directions in a crystal to fulfill the phase-matching condition while all signal waves propagate collinearly

large band widths at any center wave length can be generated. It was shown that pulses shorter than 10 fs can be amplified. Using crystals with high nonlinear optical coefficients like the most prominent crystal BBO and at sufficient intensities a single pass can provide an amplification of the signal by many orders of magnitude. Regenerative amplifiers are not needed and the problem of pulse leakage from them disappears. Amplification lasts only as long as the pump passes the crystal and therefore pre-pulses and post-pulses as well as back-reflected pulses are not amplified any more and higher pulse contrasts are possible with the OPCPA technique. Lastly the amplified signal beam is an analog of the input signal and unwanted phase distortions of the high-energy pump are carried away with the idler beam like the different $\boldsymbol{k}$ vectors in Fig. 11.236.

In order to use all of these advantages a careful design of OPCPA is required. For instance if an OPCPA stage is driven to its maximum amplification and the process starts to saturate, the impact of intensity variations of the signal to the output is reduced but intensity variations of the pump are transferred to the amplified beam. Additionally, signal and idler waves are generated starting from noise, a problem similar to the amplified spontaneous emission (ASE) in a conventional laser amplifier. To minimize this effect a pump pulse length no longer than the seeding signal pulse and their perfect synchronization is required, which is challenging for ps pulses. Contrariwise ps pulses offer higher intensities at a fixed fluence, which reduces the required crystal length, with the advantage of increasing the amplification bandwidth without changing the crystal orientation. More requirements may arise at different wavelengths involved, like absorption, or second-harmonic generation from the signal or idler beams, amongst others.

Nevertheless, OPCPA is the technique that allows the implementation of an ultrashort pulse option to all coherent high-energy light sources that emit pulses in the nanosecond and picosecond range and transfers them to an ultrahigh-peak-power laser system. A 200 TW 45 fs laser system was recently demonstrated [11.1988] based on OPCPA in a large-aperture KDP crystal. These crystals are used for Pockels cells and frequency converters in fusion laser systems and can be grown with meter-size apertures. This in principle allows multi-petawatt power scaling.

High Demands on Pulse Preparation for Advanced Experiments

The acceleration of electrons and protons by a laser requires light intensities on the order of $10^{20}\,\text{W/cm}^2$, which is many orders of magnitude above the onset of nonlinear effects and atom ionization, which results in Coulomb explosion even in low-density targets such as gases, triggered by lower intensity background radiation of the laser. Experiments are strongly affected by this pre-pulse laser-target interaction [11.1989]. To prevent the target from being destroyed before the main part of the laser pulse arrives, laser output has to be cleaned from its leading pedestal. A typical laser pulse characteristic is shown in Figure 11.236. The long-term pre-pulse pedestal results from ASE of the laser active material, whose duration is closely linked to its fluorescence lifetime. Additionally, regenerative amplifiers that are often used as the first devices in the amplifier chain, always have a certain leakage of pulses from preceding round-trips. The pulses are again amplified in successive multipass and booster amplifiers, generating high-energy pre-pulses on target. Finally, non-bandwidth-limited pulse recompression based on material dispersion, wavelength clipping, aberrations in stretcher and compressor setups and uncompensated higher-order dispersion terms result in pre-pulses and pedestals as shown in Sect. 12.1.2 for frequency-domain-filtered short pulses.

Numerous methods are used to remove this unwanted pre-pulse laser light. Primarily, the total amplification is split into stepwise amplification with additional possibilities for time-domain and spatial pulse filtering. For this purpose fast Pockels cells [11.1990] and spatial filters, which are often combined with
Fig. 11.236 Typical pulse contrast characteristics. The main femtosecond laser pulse is typically preceded by amplified stimulated emission (ASE), amplified pre-pulses and uncompressed chirp

beam expanders, are applied. Spatial filters and apertures prevent spontaneously emitted fluorescence light from propagation to the subsequent amplifiers. These measures can often improve pulse contrast ratios considerably [11.1991].

Nonlinear optical effects that favor high intensities can be used as well. Examples of the latter case are saturable absorbers and laser pulse switched gates. The OPCPA inherently embodies such a gate if a rectangular-shaped pump pulse is used. Therefore prepulse suppression in the OPCPA [11.1992] can be as high as its gain.

Saturable absorbers and self-phase-conjugating mirrors are used for nanosecond laser systems. In the case of a chirped pulse amplification system these techniques require pulse compression before and stretching after filtering. This limits their application to low-energy pulses or prohibits their use if very long stretching factors are needed.

Nonlinear effects can also be used after final pulse recompression. One possibility is frequency conversion by second-harmonic generation. Another pre-pulse suppression method with high efficiency and low loss is the usage of a plasma mirror [11.1993]. Because the laser has to be focused anyway a perfectly transmitting dielectric medium is placed near the focus of the beam. The leading edge of the pulse is transmitted until the intensity reaches the ionization threshold. At this step a plasma is generated with increasing electron density. The plasma occurs on a time scale that does not allow it to expand. If the plasma frequency matches the laser frequency this plasma acts as a perfect mirror and the main pulse is reflected to the target. With a single plasma mirror the contrast ratio for petawatt-class lasers can be improved by factors of about 100 [11.1965].

Experiments with lasers at ultrahigh intensities require the focusing of a high-peak-power laser onto a very small spot. Phase distortions in the beam line can increase the minimum spot size in the focal plane considerably. Adaptive mirrors are used to correct phase fronts [11.1994]. Closed-loop systems allow near-diffraction-limited focusing of ultrashort pulses [11.1995, 1996]. These techniques today allow intensities in the range of 10^{20}–10^{21} W/cm^2 with terawatt and petawatt laser systems.

11.13.2 Relativistic Optics and Laser Particle Acceleration

The interaction of light and matter at intensities of 10^{20}–10^{21} W/cm^2 changes considerably when compared to classical, even classical nonlinear optics. At intensities of 10^{13}–10^{15} W/cm^2 matter becomes ionized and the high intensity laser pulse interacts with a dynamically evolving plasma where the dominant mechanism for the interaction of light and matter is the interaction with free electrons.

In classical optics the interaction of light and matter is described in the following way: the electric field of an electromagnetic wave exerts a force on the bound or free electrons, which then oscillate with the frequency of the wave. The dependence of the oscillating polarization induced in the material by the motion of the electrons on the driving electric field then yields the linear and nonlinear optical constants of the material. Although this picture is inherently classical it also provides the general idea of a quantum-mechanical description of light–matter interaction.

This classical description of light–matter interaction is based on two assumptions, which are valid for sufficiently low light intensities:

1. the force exerted on the electrons by the magnetic field of the electromagnetic wave may be neglected.
2. The speed of the oscillating motion of the electron is small compared to the speed of light.

The breakdown of these two approximations marks the onset of relativistic optics, which is based on a fully relativistic description of the interaction of an electromagnetic wave with matter.

Relativistic Motion of an Electron in an Electromagnetic Wave

We first consider the equation of motion of a free electron in the field of an electromagnetic wave

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\gamma m \dot{\boldsymbol{r}}\right) = -e\left(\boldsymbol{E} + \dot{\boldsymbol{r}} \times \boldsymbol{B}\right) , \qquad (11.208)$$

where t is the time, m the electron rest mass, $\dot{\boldsymbol{r}}$ the velocity of the electron, e the elementary charge, $\boldsymbol{E}$ the electric, $\boldsymbol{B}$ the magnetic field of the electromagnetic wave, and

$$\gamma = \left(1 - |\dot{\boldsymbol{r}}|^2/c^2\right)^{-\frac{1}{2}} ,$$

where c is the speed of light in vacuum. For a plane electromagnetic wave of frequency ω and wavenumber $k = \frac{\omega}{c}$ propagating in the z-direction we insert $\boldsymbol{E} = \boldsymbol{E}_0 \cos{(\omega t - kz)}$. Since $\nabla \times \boldsymbol{E} = -\partial \boldsymbol{B}/\partial t$ we obtain: $|\boldsymbol{B}| = |\boldsymbol{E}|/c$. Before solving (11.208) we introduce the normalized quantities: $\hat{t} = \omega t$, $\hat{z} = z\omega/c$, $\boldsymbol{\beta} = \dot{\boldsymbol{r}}/c$ and

$a_0 = \frac{eE_0}{m\omega c}$. Then we rewrite (11.208) in components assuming linear polarization of the electric field in the x-direction:

$$\frac{\mathrm{d}}{\mathrm{d}\hat{t}}(\gamma\beta_x) = a_0(1-\beta_z)\cos(\hat{t}-\hat{z}) ,$$

$$\frac{\mathrm{d}}{\mathrm{d}\hat{t}}(\gamma\beta_y) = 0 ,$$

$$\frac{\mathrm{d}}{\mathrm{d}\hat{t}}(\gamma\beta_z) = a_0\beta_x\cos(\hat{t}-\hat{z}) . \qquad (11.209)$$

Although (11.209) may be solved for more-general initial conditions we give here the solution for an electron initially at rest in the origin of our coordinate system, i.e., $\mathbf{r}(0)=0$ and $\dot{\mathbf{r}}(0)=0$, with the phase parameter

a) $x\,(c/w_L)$

b) $x\,(c/w_L)$

Fig. 11.237 (a) Trajectories of a free electron in a traveling electromagnetic wave for different laser field strengths $a_0 = 1$ and $a_0 = 2$ calculated for the initial conditions $\theta_{\mathrm{in}} = 0$ and $\beta_{z0} = 0$ in the laboratory frame. **(b)** The trajectories in the moving frame of the electron (indicated by the *primed coordinate*) exhibit the characteristic figure-of-eight movement. Laser field strength and initial conditions corresponding to **(a)** were used

$\Theta = \hat{t} - \hat{z}$:

$$\hat{x} = a_0(1-\cos\Theta) ,$$

$$\hat{y} = 0 ,$$

$$\hat{z} = \frac{a_0^2}{4}\left(\Theta - \frac{1}{2}\sin 2\Theta\right) , \quad\text{and}$$

$$\gamma^2 = 1 + \frac{a_0^2}{2}\sin^2\Theta . \qquad (11.210)$$

The motion of the electron is displayed in Fig. 11.237 in two different coordinate systems:

1. the laboratory frame and
2. the *average rest frame* of the electron, which is a coordinate system co-moving with the electron in the $\hat{z}'$-direction, where the coordinate $\hat{z}'$ is given by $\hat{z}' = \hat{z} - a_0^2/4\Theta$.

It is immediately apparent that the motion of the electron in the fully relativistic case is quite different from the classical picture, where a solution of (11.208) is obtained for $\gamma = 1$ and $\mathbf{B} = 0$.

The electron oscillates, as in the classical case, periodically in the $\tilde{x}$-direction, the direction of polarization of the oscillating electric field. However, unlike in the classical case the electron is also accelerated in the $\hat{z}$-direction, the propagation direction of the electromagnetic wave. The magnitude of the electron motion is governed by the parameter a_0, the dimensionless electric field strength [11.1997]. In the classical picture $\gamma = 1$, $\mathbf{B} = 0$ which of course becomes incorrect at high velocities; the condition $a_0 = 1$ would correspond to an electron that acquires a maximum oscillation velocity of $\dot{\mathbf{r}} = c$. The condition $a_0 \ll 1$, therefore corresponds to the classical case of $|\dot{\mathbf{r}}| \ll c$ while $a_0 \gg 1$ describes the extreme relativistic motion of the electron. In practical units a_0 is given by:

$$a_0^2 = \frac{I\lambda^2}{1.37\times 10^{18}\,\mathrm{W\,cm^{-2}\,\mu m^2}} \qquad (11.211)$$

where I is the light intensity and λ its wavelength. For optical wavelength where $\lambda \approx 1\,\mu\mathrm{m}$ intensities above $I \approx 10^{18}\,\mathrm{W/cm^2}$ are therefore called relativistic intensities. In the extreme relativistic case $a_0 \gg 1$ the distance the electron travels in $\hat{z}$-direction during one electric field oscillation is much larger than its excursion in the $\hat{x}$-direction, and a complete reversal of the conditions found in the weakly relativistic case $a_0 < 1$ occurs. The acceleration of electrons in the propagation direction of the electromagnetic wave appears to be in contradiction to the well-known fact derived from energy and

momentum conversation that free photons cannot accelerate free electrons. In fact if a light pulse is considered the electron acquires kinetic energy in the rising part of the pulse and looses it again to the electromagnetic wave in the falling part of the pulse. After the pulse has left, the electron experiences a shift in the propagation direction of the pulse but has not acquired a net energy in agreement with the conservation laws for energy and momentum. If, however, the field of the electromagnetic wave is suddenly switched off while the electron moves in the propagation direction the electron cannot give its energy back to the field and maintains its energy acquired from the field. The switching of the field may be achieved, i. e., by shielding the field in a steep plasma gradient or by a guiding channel.

The second interesting feature of the solution of the equation of motion (11.209) is the anharmonic oscillating motion of the electron in the $\hat{x}$- and $\hat{z}$-direction best seen in the co-moving frame (Fig. 11.237b). This means that the electron radiates not only at the frequency of the diving electromagnetic wave but also emits other frequencies. While for $a_0 < 1$ the spectrum contains essentially the even (polarized in the $\hat{z}$-direction) and odd (polarized in the $\hat{x}$-direction) harmonics, the spatial and spectral emission pattern becomes very complex for higher intensities ($a_0 > 1$). This phenomenon is called nonlinear Thomson scattering and has been observed experimentally.

The Ponderomotive Force

The total energy of the electrons driven by the electromagnetic field of a laser is given by

$$E(\boldsymbol{r}, t) = \gamma(\boldsymbol{r}, t) mc^2 . \tag{11.212}$$

Due to the dependence of γ on the electron velocity $|\dot{\boldsymbol{r}}|$ the energy will vary widely on the length scale of the laser wavelength and the time scale given by the laser frequency. If one is not interested in the fast, mostly oscillatory motion of the electrons one may average over time, yielding:

$$\langle \gamma(\boldsymbol{r}) \rangle = \sqrt{1 + \frac{a_0^2(\boldsymbol{r})}{2}} . \tag{11.213}$$

The slow spatial dependence indicated in $a_0^2(\boldsymbol{r})$ may, for example, be due to the intensity variation over the focus of the laser beam, which usually occurs over much larger length scales than a wavelength.

The spatial dependence of the time-averaged energy gives rise to a force called the ponderomotive force

$$\boldsymbol{F}_{\mathrm{p}} = -\nabla \langle E(\boldsymbol{r}) \rangle = -mc^2 \nabla \langle \gamma(\boldsymbol{r}) \rangle . \tag{11.214}$$

This force will act on particles that oscillate in spatial regions where the laser intensity is high and push them into regions of lower laser intensity. It is instructive to consider the weakly relativistic limit of the ponderomotive force. With the definition of a_0 we find for $\langle \gamma \rangle - 1 \ll 1$:

$$\boldsymbol{F}_{\mathrm{p}} = -\frac{e^2}{4m\omega^2} \nabla E_0^2(\boldsymbol{r}) . \tag{11.215}$$

In the classical limit this constitutes the gradient of the time-averaged kinetic energy of the electron oscillating in the laser field [11.1998].

Another way to look at the ponderomotive force is to view regions of high laser intensity as regions of high electromagnetic energy density $W = \varepsilon_0 \boldsymbol{E}^2(\boldsymbol{r}, t)/2$, which represents a pressure pushing the electrons from regions of high pressure to those of low pressure.

The Optical Properties of a Relativistic Laser Plasma and Relativistic Channeling

When an intense laser pulse at relativistic intensities propagates through a gas consisting of atoms with low atomic number, such as hydrogen or helium, the rising part of the laser pulse fully ionizes the gas and the laser pulse interacts with a fully ionized plasma. For example helium is fully ionized already at an intensity of a few times $10^{16}\,\mathrm{W/cm^2}$ while relativistic intensities usually exceed $10^{18}\,\mathrm{W/cm^2}$. The dielectric constant of a fully ionized plasma is given by

$$\varepsilon_{\mathrm{r}} = 1 - \frac{\omega_{\mathrm{p}}^2}{\omega^2} , \tag{11.216}$$

where $\omega_{\mathrm{p}}^2 = \frac{e^2 n_{\mathrm{e}}}{\varepsilon_0 \gamma m}$ and n_{e} is the electron density.

Collisions have been neglected here which is a reasonable assumption for laser pulses of durations of less than 1 ps and electron densities of $n_{\mathrm{e}} \le 10^{22}\,\mathrm{cm^{-3}}$. It should be noted that in a relativistic plasma the plasma frequency ω_{p} depends on γ and therefore on the laser intensity. The dielectric constant becomes negative for electron densities where the plasma frequency ω_{p} exceeds the laser frequency ω. In the nonrelativistic case ($\gamma = 1$) an critical electron density n_{crit} is defined through the condition $\omega_{\mathrm{p}}^2 = \omega^2$ yielding [11.1998]

$$n_{\mathrm{crit}} = \frac{\varepsilon_0 m \omega^2}{e^2} . \tag{11.217}$$

For electron densities $n_{\mathrm{e}} > n_{\mathrm{crit}}$ the plasma is called dense while it is underdense for $n_{\mathrm{e}} < n_{\mathrm{crit}}$. In practical units the critical electron density is given by $n_{\mathrm{crit}} = 1.1 \times 10^{21}\,(1\,\mathrm{\mu m}/\lambda)^2\,\mathrm{cm^{-3}}$. With this definition the dielectric constant may be rewritten

$$\varepsilon_{\mathrm{r}} = 1 - \frac{n_{\mathrm{e}}}{\gamma n_{\mathrm{crit}}} \tag{11.218}$$
Fig. 11.238 Experimental setup. The main pulse is focused to an intensity of a few $19\,\mathrm{W/cm^2}$ into a pulsed He-gas jet, where a relativistic channel due to relativistic self-focusing is forming. By splitting and frequency doubling part of the main pulse a probe pulse is generated. This probe pulse is used for imaging and observing the laser–plasma interaction on a time scale determined by the probe pulse duration of $\approx 100\,\mathrm{fs}$. The electrons that are accelerated in the relativistic channel are characterized by magnetic spectroscopy and nuclear reactions

Electromagnetic radiation propagates in a medium where $\varepsilon_\mathrm{r} > 0$ and is reflected from a medium with $\varepsilon_\mathrm{r} < 0$. The condition for light propagation is therefore $n_\mathrm{e}/\gamma < n_\mathrm{crit}$.

The index of refraction of the plasma is given by $n = \sqrt{\varepsilon_\mathrm{r}}$. In an underdense plasma n is real and the laser pulse propagates. But n is a complicated function of intensity for two reasons:

1. At the center of the propagating laser pulse the intensity is high. Therefore the ponderomotive force pushes the electrons away from the center and the electron density in the center decreases, increasing the index of refraction.
2. The remaining electrons in the center gain higher energies in the laser field than those sitting at the edges of the laser beam. This increases γ further and thus increases the index of refraction at the center of the laser beam.

This means that a relativistic laser pulse self-modulates the index of refraction in such a way that self-focusing of the laser occurs. As in other self-focusing phenomena known from nonlinear optics self-focusing is countered by diffraction and therefore self-focusing depends on a critical power rather than on intensity. A laser pulse interacting with a fully ionized plasma will therefore undergo self-focusing if its total power P exceeds the critical power

P_crit [11.1999].

$$P > P_\mathrm{crit} = \frac{8\pi\varepsilon_0 m^2 c^5}{e^2}\frac{n_\mathrm{crit}}{n_\mathrm{e}} = 17.4\,\mathrm{GW}\frac{n_\mathrm{crit}}{n_\mathrm{e}}\ .$$
(11.219)

The dynamic equilibrium of defocusing because of diffraction and self-focusing due to nonlinear effects leads to a guiding effect for the high-intensity laser pulse in a plasma called relativistic channeling. This phenomenon has been observed experimentally. A typical experimental arrangement is shown in Fig. 11.238.

A Ti:sapphire laser ($\lambda = 800\,\mathrm{nm}$) with a total power of 8 TW is focused to an intensity of about $2\times10^{19}\,\mathrm{W/cm^2}$ into a helium gas jet from a nozzle with a very well-characterized gas density profile (Fig. 11.239).

Figure 11.239 shows the relativistic channel which extends over a length of about $300\,\mu\mathrm{m}$, corresponding to about 15 Rayleigh lengths of the laser focusing optics. At the onset of the channel the electron density amounts to $5\times10^{19}\,\mathrm{cm^{-3}}$. The critical density is $1.7\times10^{21}\,\mathrm{cm^{-3}}$ at $\lambda = 800\,\mathrm{nm}$. Therefore the total laser power of 8 TW exceeds the critical power of $P_\mathrm{crit} \approx 0.6\,\mathrm{TW}$ obtained from (11.219) substantially and relativistic channeling is expected and observed. In addition a probe pulse at $\lambda = 400\,\mathrm{nm}$ was used to measure the electron density in the channel interferometrically (Fig. 11.238). The result shown in Fig. 11.240 gives the electron density profile across the channel at the onset of the channel. It is ap-
Fig. 11.239 The lateral plasma density profile above the nozzle has a Gaussian shape (*dotted line*). The density along the channel and its position is indicated by the bold line. The inset shows the corresponding observed channel of the same spatial region. The extension of the emission indicates a channel length of 274 μm, about 12 times the Rayleigh length of the laser. The relativistic channel starts near the steepest density gradient and ends close to the maximum density (grad $n_e = 0$)

parent that the electron density at the channel center is depressed, due to the expulsion of electrons because of the ponderomotive force. This result also provides direct evidence for the guiding structure of a relativistic channel.
Fig. 11.240 Plasma density at the start of the channel determined by interferometry. The electron density in the walls of the channel rose up to values of $n_e(\text{wall}) = 6 \times 10^{19}\,cm^{-3}$. The image in the upper right corner shows the interferogram from which the plasma density was obtained

Finally it should be noted that optics in the relativistic regime is always nonlinear. The index of refraction is always intensity dependent due to the ponderomotive force and the intensity dependence of the electron mass.

Electron Acceleration

Since in the relativistic regime of laser–plasma interaction charged particles may be accelerated to high energies, it has been recognized for some time that laser plasmas are an ideal medium for high-field compact accelerators. The plasma as an ionized medium may sustain much higher fields than it is possible to generate with conventional accelerator technology, where material breakdown imposes a limit at less than 100 MV/m. Electric fields in the TV/m range may however be generated in laser plasmas.

In many experiments over the past two decades a variety of acceleration mechanisms have been identified. A selection of these mechanisms will briefly be described in the following with focus on schemes where only a single laser pulse is needed to accelerate initially resting electrons to relativistic energies. All these schemes have in common that a laser pulse is focused into a gas jet, generating an underdense plasma (Fig. 11.238).

Laser wakefield acceleration. When a relativistic laser pulse impinges on a plasma the ponderomotive force expels electrons in both the transverse and longitudinal directions. The electrons expelled from the laser pulse in the backward direction lead to a plasma wave called the laser wakefield (Fig. 11.241) [11.2000].

The plasma wave follows the driving laser pulse with a phase velocity determined by the laser pulse group velocity. The electric fields associated with the plasma wave are now longitudinal. An electron can *ride* on the plasma wave and be accelerated to relativistic energies in the direction of laser propagation. This process is called laser wakefield acceleration (LWFA).

This process is most efficient when the laser pulse length $c\tau$, where τ is the pulse duration, is shorter than the plasma wavelength $\lambda_p = 2\pi c/\omega_p$.

This condition is depicted in Fig. 11.241a. When a large number of electrons acquire a velocity close to the phase velocity of the plasma wave, wave-breaking occurs. The fast electrons are *surfing* on the wake of the plasma wave.

Self–modulated laser wakefield acceleration. If the laser pulse length is longer than the plasma wavelength

$c\tau > \lambda_p$ the laser pulse undergoes a self-modulation instability. The leading edge of the laser pulse drives a plasma wave. The electron density modulation of the plasma wave in turn represents a periodic modulation of the refractive index. It acts on the long laser pulse such that the pulse is self-modulated and breaks up into a train of short pulses (Fig. 11.241b). These shorter pulses now match the conditions for LWFA and can resonantly drive a plasma wave. This self-modulated laser wakefield acceleration (SM-LWFA) is not as efficient as pure LWFA, but still high-energy even quasi-monoenergetic electron beams may be generated.

Direct laser acceleration. Another acceleration process which is quite different in nature to wakefield acceleration is direct laser acceleration (DLA) which is closely related to the formation of a relativistic channel. The ponderomotive force expels electrons from the laser beam axis and generates a radial quasistatic electric field. Electrons that are accelerated along the laser propagation generate an azimuthal magnetic field. The combination of these two fields results in an effective potential well for relativistic electrons. Electrons trapped in this well will oscillate at the frequency $\omega_\beta = \omega_p/(2\sqrt{\gamma})$, the betatron frequency. If the trapped electron is moving fast enough along the laser propagation, the laser oscillations may be in phase with the betatron oscillations in the frame of the electron.

In this case, an efficient energy coupling is possible. The energy gained by the electron in this process directly results from the laser field and therefore the name direct laser acceleration is appropriate.

Bubble acceleration. A novel regime of laser wakefield acceleration, called *bubble acceleration*, was proposed in 2002 on the basis of particle-in-cell (PIC) simulations [11.2002]. Short ($\tau < 7\,\text{fs}$) and intense ($a_0 > 1$) laser pulses were predicted to produce quasi-monoenergetic electrons with energies exceeding 100 MeV.

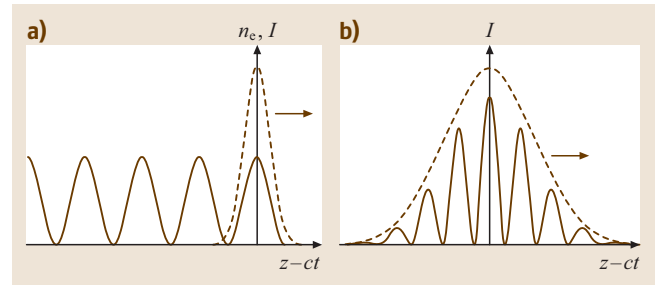
The ponderomotive force also plays an important role for this acceleration mechanism. In a frame moving with an intensive laser pulse propagating through a plasma the electrons are expelled from the center of the pulse in both the longitudinal and transverse directions. It turns out that behind the laser pulse an electron density depression, called a bubble, is generated and electrons the stream around this bubble and enter it again from the back side. In this way a strong electric field in longitudi-


Fig. 11.241 (a) LWFA: a short laser pulse ($c\tau \leq p$) shown as a *dashed line* drives a plasma wave. **(b)** SM-LWFA: an initially long laser pulse (*dashed line*) breaks up into a train of shorter pulses that match the condition of LWFA and resonantly drive a plasma wave (after [11.1999])

nal direction reaching TV/m is generated, which leads to efficient electron acceleration.

Experiments. Numerous laser acceleration experiments have been carried out, mostly using experimental setups like the one shown in Fig. 11.238. Initially always quasi-exponential electron spectra were obtained with electron temperatures that follow the scaling law

$$kT_e \approx mc^2 \left(\sqrt{1 + \frac{a_0^2}{2}} - 1 \right) , \qquad (11.220)$$

which corresponds to the kinetic energy of the electron in the laser field. These exponential spectra
Fig. 11.242 Monoenergetic electron spectrum generated in an experimental setup similar to the one shown in Fig. 11.232 [11.2001]

are not only observed in underdense plasmas but also in the overdense plasmas encountered in laser–solid interactions [11.2003]. For a typical intensity of $I = 10^{20}\,\mathrm{W/cm^2}$ and $\lambda = 1\,\mu\mathrm{m}$, $a_0 = 8.5$ we obtain $kT_e \approx 2.6\,\mathrm{MeV}$ from (11.220).

Only recently, however, has it became possible to generate monoenergetic electron spectra. As predicted by numerical simulations the bubble regime may be reached for high-power, gently focused laser pulses of short pulse duration. Although the requirements of the pure bubble regime have not yet quite been reached experimentally the experiments show that in the transition regime between LWFA and bubble acceleration monoenergetic electron spectra may be generated [11.2001, 2004, 2005]. A typical result is shown in Fig. 11.242.

Ion Acceleration

Relativistic laser–matter interaction also leads to the generation of monoenergetic beam of ions of MeV ener-

Fig. 11.243 Laser acceleration of protons from the back side of a microstructured target. A terawatt (TW) laser pulse is focused onto the front side of the target foil, where it generates a blow-off plasma and subsequently accelerates electrons. The electrons penetrate the foil, ionize hydrogen and other atoms at the back surface and set up a Debye sheath. The inhomogeneous distribution of the hot electron cloud causes a transversely inhomogeneous accelerating field [target normal sheath acceleration (TNSA)]. Applying a small hydrogen-rich dot on the back surface enhances the proton yield in the central part of the accelerating field, where it is nearly homogenous. These protons constitute the quasi-monoenergetic bunch

gies by a mechanism quite different from the mechanism involved in electron acceleration.

As discussed earlier the interaction of an intense light field with matter yields the generation of a hot plasma and the subsequent acceleration of electrons up to relativistic energies. Protons and ions are accelerated by a well-controlled mechanism known as *target normal sheath acceleration* (TNSA) following the initial electron acceleration (Fig. 11.243). Fast electrons are accelerated by an intense laser pulse (intensity $I \geq 10^{19}\,\mathrm{W/cm^2}$) from the surface of a thin metal foil in the forward direction. They penetrate the foil and ionize atoms along their paths. Within about a picosecond, those electrons leaving the target at the rear surface (that is, the back surface with respect to the laser irradiation) build up a quasistatic electric field. The field acts normally to the target surface, has cylindrical symmetry and decreases in the transverse direction. Owing to the ultra-short duration of the electron bunch and its high charge, this field may reach values of several TV/m close to the axis and thus the potential can attain several tens of MeV. Protons and positively charged ions present on the back surface of the foil may be accelerated by this field until they compensate the electron charge. In most cases, the origin of these parasitic protons has been identified to be a hydrocarbon contamination layer on the target surface.

As the duration of the acceleration is ultrashort and the protons (as well as the ions) are at rest before acceleration, comprising a very small phase-space volume, the transverse emittance of the proton beam reaches values as low as a few 10^{-3} mm mrad for 10 MeV protons. However, laser-accelerated ion beams still show an energy spectrum exhibiting a quasi-exponential shape with a distinct cut-off energy. This can be explained by the inhomogeneous distribution of electrons in the sheath, which causes an accelerating field that is inhomogeneous in the transverse direction. For a plane and unstructured target, the transverse dimension of the electric field and hence the source size of the accelerated protons is much larger than the laser's focal spot. Therefore, different parasitic protons experience a range of potentials, resulting in a broad distribution of energies.

Following this understanding of the mechanism of laser acceleration of protons, it was pointed out that the resulting proton energy spectrum has a strong correlation to the spatial distribution of the protons on the target surface. In order to generate high-quality proton beams with monoenergetic features, a bilayered, microstructured target, consisting of a thin high-Z metal foil and a small proton-rich dot on the back surface

was proposed. The transverse dimension of such dots is smaller than that of the acceleration sheath, and hence the protons will only be subject to the central – that is, homogeneous – part of the acceleration field. In this configuration, the protons all experience the same electric field and are accelerated in the same potential (Fig. 11.243). The resulting proton beam has a spectrum with a strong monoenergetic peak [11.2006].

Recent experiments with a 10 TW, 600 mJ laser showed that in this way quasi-monoenergetic proton beams containing 10^8 protons with energies of a few MeV and a relative width of $\Delta E/E \approx 10\%$ and a total charge of about 100 pC were generated.

In a different experiment quasi-monoenergetic carbon ions of 4 MeV energy were generated from a very thin carbon layer on a metal target [11.2007].

Applications and Future Developments

Relativistic optics leads to laser particle accelerators that are considerably more compact than classical accelerators. Presently laser accelerators reach maximum energies for monoenergetic electron beams approaching 1 GeV and several MeV for monoenergetic ion beams with a total charge of up to 1 nC per bunch. The scaling for both electron and ion acceleration with laser and target parameters appears to be sufficiently well understood that electron energies exceeding 1 GeV and ion energies of a few hundred MeV in a single acceleration stage appear to be possible in the near future. There are

however at least two challenges laser accelerators that have to overcome before widespread applications will become attractive.

In order to reach energies in the TeV range multistaging of both electron and ion accelerators appears necessary. Although energy, beam quality and charge per bunch are already attractive for low-energy applications of laser accelerators their average power presently remains orders of magnitude below the average power of conventional accelerators. This is solely due to limitations in laser technology and may be overcome in the future when high-average-power high-intensity lasers become available.

Laser accelerators have already been used for a number of demonstration experiments. Low-energy nuclear reactions have been induced using high-intensity lasers [11.1999] and nuclear transmutation scenarios employing lasers have been discussed [11.2008]. Laser-generated ion beams carry enough dose for radiation therapy using ion beams, a very promising application because the average power of a laser accelerator is already sufficient for this innovative method of cancer treatment.

With ever-increasing laser intensities other areas of physics such as gravitational physics, elementary particle physics or nonlinear quantum electrodynamics (QED) effects [11.1999] also come into the focus of high-intensity lasers.

11.14 Frequency Stabilization of Lasers

Soon after the development of the first HeNe laser, it was realized that the radiation of a continuous-wave laser would be ideally suited as a measurement tool, provided its frequency was stable and reproducible. Applications of frequency-stabilized lasers include high-resolution laser spectroscopy, quantum optics, optical frequency standards, the determination of fundamental constants, and the detection of gravitational waves. In these various cases, the requirements on frequency-stabilized lasers are quite different. For example, optical frequency standards and optical clocks need the smallest possible uncertainty in the knowledge of the absolute laser frequency whereas gravity-wave detectors need lasers of extremely low frequency noise while the absolute laser frequency is less important. Hence, different stabilization methods have been developed to address the various tasks. The purpose of this chapter is to review

the general methods of laser frequency stabilization and to describe some representative examples of frequency-stabilized lasers. The radiations of a variety of stabilized lasers are recommended as optical reference frequencies [11.2009].

Basically, the frequency of any laser is determined within the bandwidth of its amplifying medium by the optical length of the resonator. This optical length in turn is a function not only of its actual geometrical length but also of the refractive index of the gain medium itself, which may depend on several different parameters. The width of the gain profile may vary between a few 10^{-6} ν for gas lasers up to approximately 10% for, e.g., dye lasers or laser diodes. Different types of lasers have different noise characteristics. In most cases, the dominant frequency noise is of technical nature and is far above the Schawlow–Townes limit [11.2010]. Since

such technical frequency fluctuations are relatively slow they can be controlled by a suitable electronic servo system even if the frequency excursions of the free-running laser are large. Different laser types and the specific requirements on these lasers have led to a variety of stabilization methods. Within the limited space of this article, it is impossible to present a comprehensive and detailed description of all these stabilization schemes. Hence, we concentrate on the description of the basic principles of laser frequency stabilization. For a deeper understanding, the reader is encouraged to study the references given in this article as well as textbooks on laser spectroscopy and optical clocks [11.2011–2014].

We start with a brief discussion of the terms characterizing the frequency behavior of a laser. These are noise, stability, line width, reproducibility, and the uncertainty of the laser frequency. Section 11.14.2 describes the basics of laser frequency stabilization. Examples of stabilized lasers are presented in Sect. 11.14.3. Section 11.14.4 explains a universal method of optical frequency measurements by means of mode-locked femtosecond lasers.

11.14.1 Characterization of Noise, Stability, Line Width, Reproducibility, and Uncertainty of the Laser Frequency

Noise, stability, line width, reproducibility, and the uncertainty of the frequency are important parameters of any frequency-stabilized laser. In general, the laser frequency fluctuates about a mean value which itself may drift and walk randomly. Such variations may be caused, e.g., by changes in the temperature, air pressure, vibrations, acoustics or by fluctuations within the active laser medium itself.

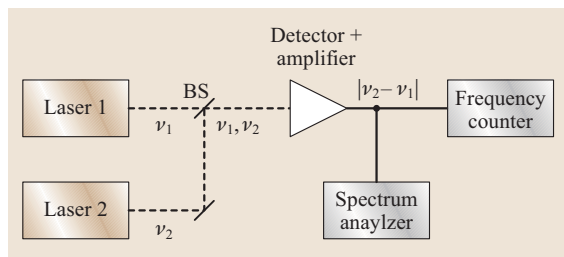
The variations in the laser frequency can be investigated, e.g., by measuring the beat frequency $v_B = |v_1 - v_2|$ between two identical but independently stabilized lasers 1 and 2 (Fig. 11.244). For this purpose, the beams


Fig. 11.244 Schematics of a beat-frequency measurement

of two lasers are coaxially combined by a beam splitter and focused onto a fast photodetector. The *beat frequency* v_B shows up as an oscillation in the power of the combined laser beams. The photodetector transforms it to an oscillation of the photocurrent, provided v_B is small enough that it can be processed by state-of-the-art electronics.

Frequency fluctuations of a laser can be measured in both the frequency and time domain. Measurements in the frequency domain are often used at higher fluctuation (Fourier) frequencies whereas slower-frequency fluctuations and drifts can be measured conveniently in the time domain (see below).

Spectral Density of Frequency Noise

In the frequency domain, fluctuations δv at the frequency f can be detected by a frequency discriminator, which converts frequency fluctuations to proportional voltage fluctuations. Since the noise components are not correlated, it is convenient to describe the fluctuations $\delta v(f)$ by the mean square $\langle \delta v(f)^2 \rangle$ which occurs within a bandwidth B at the Fourier frequency f. This value is equivalent to the spectral noise power. The power spectral density is then defined as $S_f = \langle \delta v^2 \rangle / B$ and the integration of S_f over B results in the total power of the frequency noise within the bandwidth B. For the *relative* power spectral density S_y we get $S_y = \langle (\delta v/v)^2 \rangle / B$.

To a good approximation, the frequency noise of any oscillator can be modeled by a power series of the Fourier frequency

$$S_y = \sum_{\alpha=-2}^{2} c_\alpha f^\alpha . \tag{11.221}$$

Depending on the exponent a the five terms of (11.221) describe

- a random frequency walk for $\alpha = -2$
- flicker ($1/f$) frequency noise for $\alpha = -1$
- white frequency noise for $\alpha = 0$
- flicker ($1/f$) phase noise for $\alpha = 1$
- white phase noise for $\alpha = 2$

Superimposed on the noise given in (11.221), we may also find peculiarities in the noise spectrum that are generated by noise sources specific to the individual laser. Such noise may be generated, e.g., by environmental sources such as the excitation of mechanical resonances in the laser resonator, by instabilities of the mechanical setup, or by fluctuations in the refractive index of the laser medium. Furthermore, the laser frequency is sensitive to optical feedback and careful isolation of the

laser system from back-scattered light is important for successful operation of stabilized lasers. Usually, the different noise components show up at different Fourier frequencies. Hence, the detection of these noise components helps us to identify the various noise sources and to reduce their influence. In addition, the knowledge of the frequency noise spectrum of a free-running laser is also important for the design and optimization of the frequency control system.

The noise spectra of various types of lasers may be quite different. For example, most of the frequency noise in gas lasers such as HeNe or CO_2 lasers occurs at low Fourier frequencies. It is generated in part by mechanical instabilities of the laser setup. The corresponding frequency excursions $\delta\nu$ may amount to a few MHz at Fourier frequencies up to about $10\,\text{kHz}$. In addition, random-walk and flicker $(1/f)$ frequency noise shows up at these low frequencies. Neglecting further possible noise sources originating from plasma resonances of the discharge, the noise spectrum at higher Fourier frequencies may be approximated by white frequency noise. In tunable CW dye lasers, on the other hand, the frequency noise is much larger than in gas lasers. It is generated mostly by variations in the thickness and the refractive index of the dye jet, which is flowing at high speed through the small active volume of the laser. Hence, rather strong frequency fluctuations are observed at Fourier frequencies around $50\,\text{kHz}$. At higher Fourier frequencies the influence of the dye jet decreases and hence the noise also decreases, eventually reaching the photon shot-noise level.

Allan Standard Deviation

Slow variations, in particular drifts and random walk of the laser frequency can be measured conveniently in the time domain by counting the mean frequency ν within a time interval τ. Such measurements are advantageous if changes in the frequency within time intervals between seconds and several hours are of interest. The relative frequency instability in the time domain is characterized by the Allan deviation [11.2015, 2016]

$$\sigma_y(\tau) = \frac{1}{\nu}\left[\frac{1}{2(N-1)}\sum_{n=1}^{N-1}(\nu_{n+1}-\nu_n)^2\right]^{1/2},$$

(11.222)

where the root mean square of the difference between two consecutive frequency measurements $(\nu_{n+1}-\nu_n)$ is used as a measure of the stability. The frequency values

ν_{n+1} in (11.222)

$$\nu_{n+1} = \frac{1}{\tau}\int_{i=n\tau}^{(n+1)\tau}\nu_i(t)\,dt$$

(11.223)

represent the mean frequency averaged during the n-th interval of duration τ. Since it is difficult to measure the optical frequency directly, it can be down-converted by beating the laser radiation against the radiation of a second laser such that the beat frequency arrives in the radio-frequency range, where it can be counted directly. In this case, the measurement contains the instabilities of both lasers. If the two lasers are identical but independent, we can assume that both lasers contribute equally to the standard deviation and consequently, the measured value corresponds to $\sqrt{2}$ times the Allan deviation $\sigma_y(\tau)$ of a single laser.

The dependence of $\sigma_y(\tau)$ on the averaging time τ contains information about the frequency noise spectrum of the laser. If the relative power spectral density of the noise S_y is known, $\sigma_y(\tau)$ can be calculated by the relation [11.2016]

$$\sigma_y^2(\tau) = \int_0^\infty S_y(f)\frac{(\sin\pi f\tau)^4}{(\pi f\tau)^2}\,df.$$

(11.224)

For the different models of the noise process given in (11.221), we can describe the Allan variance $\sigma_y^2(\tau)$ by the relation

$$\sigma_y^2(\tau) = d_\alpha\tau^\beta$$

(11.225)

where β is determined by the relation [11.2016]

$$\beta = \begin{cases} -\alpha - 1 & \text{for} \quad \alpha \le 1 \\ -2 & \text{for} \quad \alpha > 1 \end{cases}$$

(11.226)

and d_α is a constant. The dependence of $\sigma_y^2(\tau)$ on τ is listed for the noise processes of (11.226) in Table 11.55.

Of course, any frequency modulation will also show up in the Allan standard deviation. In the case that the

Table 11.55 Dependence of the Allan deviation on τ for the different noise processes discussed in (11.226)

Noise category	α	β	$\sigma_y^2(2,\tau)$
White frequency noise	0	-1	$\propto 1/\tau$
White phase noise	2	-2	$\propto 1/\tau^2$
$1/f$ (frequency noise)	-1	0	constant
$1/f$ (phase noise)	1	-2	$\propto 1/\tau^2$
Random frequency noise	-2	1	$\propto \tau$

gate time τ is an integer multiple of the modulation period $\tau_m = 1/f_m$, where f_m is the modulation frequency, the influence of the modulation is eliminated. It will be maximum for $\tau_m = (2n+1)/(2f_m)$. With increasing integration times τ, the influence of the modulation washes out and can be neglected, eventually.

As a result of (11.227), we find that the noise process can be estimated from the slope of a log–log $\sigma_y(\tau)$ plot. For example, in a HeNe laser that is frequency stabilized to an absorption line of molecular iodine, $\sigma_y(\tau)$ decreases in a wide range of τ with the square root of τ corresponding to a slope of $-1/2$, (Fig. 11.245) indicating white frequency noise within the corresponding time interval τ. At longer integration times, $\sigma_y(\tau)$ flattens out due to flicker frequency noise and in some cases eventually increases again due to drifts and random frequency walks. For practical applications, the $\sigma_y(\tau)$ plot indicates the minimum integration time τ necessary to achieve a given statistical frequency uncertainty.

Line Width of Laser Radiation

In incoherent light sources such as spectral lamps, where the radiation consists of uncorrelated photons emitted within a certain narrow frequency band, the line width is determined by a superposition of the natural width of the transition and Doppler broadening. It can be measured, for example, by a high-resolution scanning Fabry–Pérot interferometer. In the case of laser radiation, the line broadening is caused by frequency fluctuations of the continuously emitted coherent laser radiation. The frequency fluctuations generate noise sidebands that cause broadening of the laser spectrum. The line width is then
Fig. 11.245 Allan deviation $\sigma_y(\tau)$ versus integration time τ of an iodine-stabilized HeNe laser

determined by the size and spectral extension of these sidebands. In the case of pure harmonic phase modulation, the field E of the laser radiation is given by the relation

$$
\begin{aligned}
E(t) &= E \sin\left[\Omega_0 t + \delta\phi \sin(\omega t)\right] \\
&= E\Bigg\{ J_0(\delta\phi)\sin(\Omega_0 t) \\
&\quad + \sum_{n=1}^{\infty} J_n(\delta\phi)\exp[i(\Omega_0 + n\omega)t] \\
&\quad + \sum_{n=1}^{\infty} J_n(-\delta\phi)\exp[i(\Omega_0 - n\omega)t] \Bigg\},
\end{aligned}
$$

(11.227)

where $\Omega_0 = 2\pi\nu_0$ and $\omega = 2\pi f$ represent the carrier and modulation frequency, respectively; $\delta\phi = \delta\nu/f$ is the modulation index with $\delta\nu$ the amplitude of the frequency deviation. The amplitude of the n-th sideband given by the n-th order of the Bessel function $J_n(\delta\phi)$ decreases strongly with n for $n > \delta\phi$. Basically, we can distinguish between the two limiting cases of

1. large frequency fluctuations $\delta\nu$ at low Fourier frequencies f and
2. small, fast frequency fluctuations δf in a broad band.

Case 1 is frequently observed with laser resonators, which pick up environmental acoustic or mechanical noise. The mean amplitudes $\langle\delta\nu^2\rangle^{1/2}$ of such fluctuations may be in the range between a few $10\,\text{kHz}$ up to several megahertz, whereas they usually occur at Fourier frequencies in a range below $1\,\text{kHz}$. Hence the modulation index $\delta\varphi \gg 1$. In this case, the line width is given by [11.2017]

$$
\begin{aligned}
\Delta\nu_{\text{FWHM}} &= \left[8\ln(2)\langle\delta\nu^2\rangle\right]^{1/2} \\
&\cong 2.355\langle\delta\nu^2\rangle^{1/2}
\end{aligned}
$$

(11.228)

close to the frequency excursions between the peaks.

If the servo gain of the frequency stabilization is high enough to reduce the frequency fluctuations at low Fourier frequencies, we may observe case 2. Under the assumption that we can neglect frequency drifts and frequency changes at very low Fourier frequencies, we arrive at frequency fluctuations $(\langle\delta\nu\rangle^2)^{1/2} \ll B$ and correspondingly to a small modulation index. In this case, only the amplitudes of the first-order sidebands $J_n(\delta\phi)$ and $J_{-n}(\delta\phi)$ contribute significantly to the line width. If the spectral density S_f is constant, the line profile is Lorentzian and the line width is given by the

relation [11.2017]

$$\Delta \nu_{FWHM} = \pi S_f \ . \tag{11.229}$$

Frequency Reproducibility and Uncertainty of Laser Radiation

Whenever the laser frequency is needed as a precise reference, knowledge of the *reproducibility* and *uncertainty* is essential. Since the frequency of the stabilized laser depends on various operational and environmental parameters it is necessary to analyze this dependence and to control these parameters carefully. The *frequency reproducibility* is a measure of the scatter in the frequency values either of an ensemble of differently designed laser systems of the same kind, developed for example in different laboratories. The reproducibility can then be investigated by frequency inter-comparisons between such differently designed lasers. Alternatively, the term *frequency reproducibility* is also used to describe the scatter in the frequency of a single laser caused by the uncertainty in the precise control and optimization of the operation parameters.

The *frequency uncertainty* is a measure of how accurately we can realize the reference frequency and determine its value. Basically, the total uncertainty contains two contributions. The first represents the uncertainty to which the transition frequency of an unperturbed atomic or molecular absorber at rest can be realized. This part contains all values in the uncertainty of frequency shifts caused by environmental and/or operational conditions. Such shifts may be generated, e.g., by a residual Doppler effect, by collisions, and by external fields. The second term in the total uncertainty is linked to the determination of the frequency value. Such frequency measurements have to be referenced to the primary standard of time and frequency, the Cs atomic clock. If the frequency measurement is phase-coherent, the measurement itself does not contribute to the total uncertainty. Under this condition, the uncertainty of the optical frequency is determined only by the uncertainty of the standard itself and that of the Cs reference.

11.14.2 Basics of Laser Frequency Stabilization

In any active frequency control system, the laser frequency is servo-controlled to a reference frequency. This may be provided by an eigenfrequency of a stable optical (Fabry–Pérot) resonator, by the gain profile of the laser itself, or by a suitable atomic or molecular transition. The first case has the advantage that it provides a good

signal-to-noise ratio, allowing a fast servo lock. However, since the laser frequency is coupled to the length of an artifact, it may change in time. Stabilization to such artifacts is often applied as an intermediate step to reduce the line width of the laser emission and to allow for high spectral resolution. In a second step, the frequency can then be stabilized to an absolute frequency reference provided by a suitable atomic or molecular absorption line.

The following sections give an introduction to basic methods of laser frequency stabilization. We start with the generation of the error signal and review four prominent examples. The first two methods – the *side-of-the-fringe stabilization* and the *phase-modulation (Pound–Drever–Hall) technique* are used to stabilize the laser frequency to a resonance of a stable optical cavity. Absolute frequency stabilization to an atomic reference is then reviewed and the fundamentals of the electronic servo-control system are described.

Generation of the Error Signal

Basically, the frequency stabilization of a laser converts the frequency deviation $\delta \nu = \nu_l - \nu_0$ between the laser frequency ν_l and the reference frequency ν_0 to an error signal that is proportional to $\delta \nu$. This signal is amplified by a servo amplifier and used to control the laser frequency such that the error signal vanishes. Figure 11.246 shows the basic scheme of a stabilization to an atomic reference frequency.

Side-of-the-fringe stabilization. In commercial stabilized lasers such as tunable dye lasers, it is a well-established practice to stabilize the frequency to a resonance of a stable optical cavity. The frequency
Fig. 11.246 Schematic of a laser frequency stabilization to the center of an absorption line

discriminator is provided by the side of a transmission fringe [11.2018]. The basic idea is that the sloping side of the fringe converts the laser frequency fluctuations to amplitude fluctuations with high conversion efficiency and a good signal-to-noise ratio. To prevent laser amplitude noise from entering the discriminator channel, two balanced photodetectors are used (Fig. 11.247a). One looks at the frequency-selective transmission of the resonator and the other views an attenuated portion of the input beam.

The attenuation is adjusted such that the resulting difference of the two photodetector signals crosses zero at the half-point of the maximum transmission. In a frequency interval close to the zero crossing, the signal depends almost linearly on the frequency deviation $\delta\nu$ and can be used as an error signal for stabilization. This side-of-the-fringe method is quite simple and very useful for many applications. However, if high spectral resolution and low drift rates are required, it turns out that the reference frequency is not defined precisely enough. For example, if the direction of the laser beam incident to the resonator changes, the transmission will also change whereas the power in the other reference beam stays constant. Hence, the zero crossing of the error signal changes, leading to a shift of the stabilized laser frequency. A further difficulty arises from the fact that

the speed of the servo control is ultimately limited by the response time of the cavity [11.2019]. Furthermore, the locking range of the servo control is asymmetric. For example, if the laser frequency is locked to point A (Fig. 11.247b), the locking range towards lower frequencies corresponds almost to the total free spectral range of the cavity, whereas for higher frequencies it corresponds only to approximately one full width at half-maximum. Hence, spontaneous and fast excursions towards higher frequencies exceeding the half-width may force the laser to fall out of lock and relock at the next-higher interference order. To increase the locking range and to avoid such unwanted frequency jumps, commercial lasers usually apply reference resonators of rather low finesse at the cost of a strongly reduced sensitivity. Nevertheless, side-of-the-fringe stabilization has been used very successfully in many stabilized lasers.

Phase–modulation technique. Many of the shortcomings of the side-of-the-fringe method are avoided if the laser frequency is locked to the *center* of a symmetric resonance. This can be achieved in transmission or reflection. In the latter case, the amplitude of the return beam is a superposition of the beam reflected directly at the entrance mirror and a small part of the light stored inside, which is leaking out of the cavity. At resonance, the two beams interfere destructively and the intensity of the return beam has a minimum at the line center. It follows that an abrupt change of the laser frequency shows up instantaneously in the interference signal between these two beams and the transient behavior of the resonator does not limit the bandwidth of the servo control [11.2020, 2021]. Hence, a servo bandwidth up to a few megahertz can be achieved even with ultrahigh-finesse cavities with line widths in the low kilohertz range.

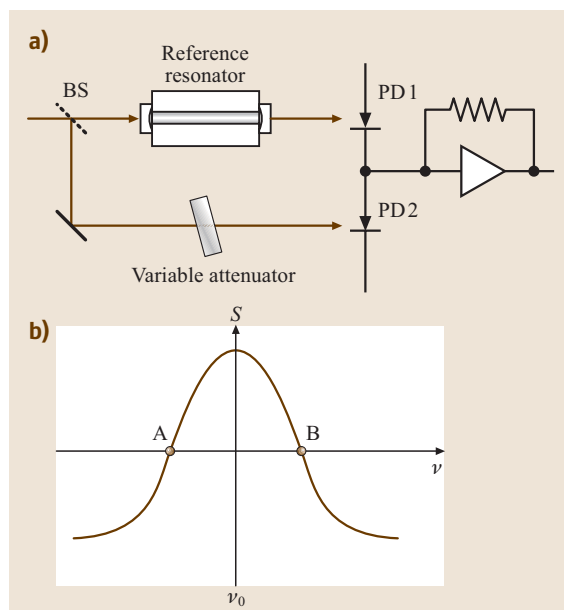
Fast stabilization techniques to line center have been developed [11.2022–2024] utilizing either DC or radio-frequency (RF) methods. In the following, we describe an RF method where the signal is detected in reflection. This method was introduced by *Pound* [11.2025] to stabilize the frequency of a microwave oscillator and later applied in the optical range by *Drever* (the PDH technique) [11.2023]. To generate the error signal, the phase of the laser radiation is modulated at a radio frequency. For an optimum signal size, the modulation frequency should be larger than the width of the cavity resonance. A high modulation frequency is also advantageous, since the influence of $1/f$ noise decreases and can eventually be neglected, leading to a signal-to-noise level close to the shot-noise limit.


Fig. 11.247a,b Frequency stabilization to the side of a fringe. **(a)** Experimental setup, **(b)** either point A or point B can be selected as the reference

The basic experimental setup of the PDH stabilization scheme is shown in Fig. 11.248. A small fraction of the laser power ($< 10\%$) is split off the main laser beam and used for the stabilization. It is phase modulated by an electrooptic modulator (EOM). The modulation frequency (typically $\approx 15\,\text{MHz}$) is several times larger than the width of the resonance. The modulation index $\delta\nu/f_\text{m}$ is in the range 10–30%. After passing a polarizing beam splitter (PBS) and a 45° Faraday polarization rotator (FR), the incident beam is mode-matched into the reference resonator. The polarization of the returning beam is rotated by another 45°. Hence, the incident and the returning beam are polarized perpendicular to each other and separated by the PBS. The return beam is sent to a photodetector (PD).

If the laser frequency is tuned far from resonance, the carrier and the sidebands of the modulated beam are promptly reflected and no intensity modulation is observed by the photodetector. If the carrier or either sideband approaches the cavity resonance, its amplitude and phase changes depending on the detuning of the corresponding frequency component from the cavity resonance. The other frequency components which are off-resonance are promptly reflected. Hence, in the returning beam, the balance between the carrier and the sidebands is broken and power modulation is generated. The corresponding amplitude modulation of the photocurrent is phase-sensitively detected by the PD followed by a double-balanced mixer, which is driven at the modulation frequency. The corresponding demodulated signals – after passing a low-pass filter – are shown for different modulation frequencies G versus the laser

Fig. 11.249a,b Demodulated signals versus detuning observed with the PDH technique, (**a**) in phase ($\varphi = 0$) and (**b**) in quadrature ($\varphi = \pi/2$) with the modulation. $G = (\nu_\text{m}/\nu_\text{h})$ corresponds to the ratio between the modulation frequency ν_m and the half-width ν_h of the resonance

Fig. 11.248 Schematic of the PDH frequency stabilization technique (see text) (BS: beam splitter, PBS: polarizing beam splitter, EOM: electrooptic modulator, RF: modulation-frequency generator, PD: photodetector, DBM: double balanced mixer)

frequency in Fig. 11.249a in phase and Fig. 11.249b in quadrature with the modulation voltage at the EOM.

In the first case (Fig. 11.249a), we observe a dispersive signal $D(\Delta)$ with zero crossings at the resonance of the carrier and close to the resonances of the sidebands. It is given by the relation [11.2013].

$$D(\Delta)$$
$$\propto \frac{\Omega^2 \Gamma \Delta (\Gamma^2 + \Omega^2 - \Delta^2)}{(\Delta^2 + \Gamma^2)[(\Delta + \Omega)^2 + \Gamma^2][(\Delta - \Omega)^2 + \Gamma^2]}.$$
$$(11.230a)$$

The absorptive signal $A(\Delta)$ (Fig. 11.249b) is given by

$$A(\Delta)$$
$$\propto \frac{\Omega \Gamma \Delta (\Gamma^2 + \Omega^2 + \Delta^2)}{(\Delta^2 + \Gamma^2)[(\Delta + \Omega)^2 + \Gamma^2][(\Delta - \Omega)^2 + \Gamma^2]}.$$
$$(11.230b)$$

In (11.230), $\Gamma/2\pi = \nu_h$ is the half-width at half-maximum of the cavity resonance, $\Omega/2\pi$ is the

modulation frequency, and $\Delta/2\pi = (\nu - \nu_0)$ is the frequency detuning.

The central zero crossing of the dispersion signal $D(\Delta)$ (Fig. 11.249a) is used as the error signal for the frequency control. The signal detected in quadrature (Fig. 11.249b) shows a resonance feature when either of the sidebands coincides with the cavity resonance. The different polarities of the two features are caused by the phase difference π between the carrier and the upper sideband and that between the carrier and the lower sideband. Independent of the detection phase, the demodulated signal is always antisymmetric with respect to the central zero crossing. Consequently, a small phase deviation from zero does not change the frequency of the central zero crossing. However, it will slightly change the slope of the frequency discriminator and thereby the gain of the servo loop.

Since the returning beam results from an interference between the frequency components promptly reflected at the entrance mirror and part of the stored radiation leaking out of the cavity, any fast frequency change shows up as a change in the interference signal instantaneously even if the response time of the cavity is much longer. At low Fourier frequencies f, smaller than the half-width $\Gamma/2\pi(2\pi f \ll \Gamma)$, the transient response of the cavity can be neglected and the demodulated signal acts as a *frequency* discriminator. With increasing Fourier frequency, the signal turns to a *phase* discriminator for $2\pi f \gg \Gamma$. Hence, the amplitude $A(f)$ and the phase $\phi(f)$ of the error signal, have a low-pass characteristic which rolls off with $1/f$ for frequencies f above the cut-off frequency $\Gamma/2\pi$ [11.2020]

$$A(f) = A(0)\frac{1}{\sqrt{1 + (2\pi f/\Gamma)^2}},$$
$$\varphi(f) = -\arctan(2\pi f/\Gamma). \qquad (11.231)$$

If this integrating behavior for $\Gamma > 2\pi f$ is taken into account in the design of the servo amplifier, a servo bandwidth much larger than $\Gamma/2\pi$ can be envisaged. Basically, the servo bandwidth is limited to a few megahertz by delays in the servo system.

If the frequency of the laser is stabilized, the size of the residual error signal provides us with information about the quality of the servo electronics. However, this error signal is by no means a measure of the actually achieved frequency stability or laser line width. There are still frequency fluctuations that are not detected by the electronic servo. In particular, at very high spectral resolution, small variations of the optical length in the cavity can no longer be neglected. The true line width of

the laser can be estimated only by methods independent of the actual servo loop, e.g., by beat-frequency comparisons with a second laser or by the use of a second independent frequency discriminator.

To achieve a narrow line width, it is important to isolate the cavity from any distortions, e.g., from vibrations, acoustics, and temperature changes, caused by the environment. For this reason, the resonator is frequently vibration isolated and supported in a temperature-controlled vacuum chamber [11.2020, 2026]. A further cause of possible frequency offsets is a spurious residual amplitude modulation (RAM) of the intrinsic laser beam. Such RAM may be generated, e.g., by an imperfect phase modulator itself. Very often, RAM is also introduced by spurious interferences in the optical setup caused, for example, by light backscattered at the surfaces of optical elements. The servo cannot distinguish between the true error signal and the RAM. Hence, the total of the superimposed signals are servo controlled to zero, leading to a nonzero error signal and consequently to a frequency shift. Usually, this spurious RAM varies with time and we experience frequency fluctuations that are not identified by the error signal of the servo loop. At high spectral resolution, these fluctuations may be orders of magnitude larger than those estimated from the noise in the error signal. Hence, it is important to isolate the cavity from environmental disturbances and to minimize the RAM very carefully.

The narrowest line width achieved with the PDH method in a dye laser was as low as 0.5 Hz [11.2027] and even with diode lasers a line width in the range of approximately 1 Hz could be achieved [11.2021]. The PDH stabilization technique is now used almost exclusively, if a precision stabilization to a cavity resonance is required combined with extremely high spectral resolution.

Stabilization to a Doppler–free atomic reference. The stabilization methods discussed above describe methods to stabilize the laser frequency to a reference provided by the length of an artifact. An *absolute* stabilization requires that the frequency is traced back to a natural constant, e.g., to the center of a suitable atomic or molecular absorption line. Ideally, the frequency of such transition should not depend on environmental or operational parameters such as external fields, atomic collisions, laser power, etc. The atomic reference line should be narrow and provide us with a sufficient signal-to-noise ratio. The atoms may be contained in an absorption cell, in an atomic beam or stored in a trap. At room temperature, the thermal velocity distribution of the atomic absorbers cause a Doppler broadening of

the line which is in the range of $\delta\nu/\nu \cong 10^{-6}$ and which is usually much larger than the natural line width of the reference transition. An atom moving with a velocity component ν_z in the direction of the laser beam sees a Doppler-shifted frequency

$$\nu_D = \nu_l \left[1 \pm \nu_z/c + \nu^2/(2c^2) \right] , \qquad (11.232)$$

where ν_l is the laser frequency and ν_z is the velocity component in the direction of the laser beam. In (11.232), the term $\nu_l \nu_z/c$ represents the first-order Doppler effect. The positive sign is valid for atoms counter-propagating to the laser beam whereas the minus sign belongs to the co-propagating ones. The third term $\nu_l \nu^2/(2c^2)$ corresponds to the (relativistic) second-order Doppler effect. Whereas the first-order Doppler effect can be strongly suppressed by the application of nonlinear Doppler-free spectroscopic methods such as, e.g., *saturated absorption* [11.2028, 2029] or Doppler-free *two-photon excitation* [11.2030, 2031] the second-order effect can be reduced only by cooling the absorbers.

As a typical example of Doppler-free spectroscopy, we concentrate on the saturated absorption and give a brief description of this method. For simplicity, we neglect the influence of the second order Doppler effect. Let us consider an atomic ensemble which is excited by two counter-propagating laser beams of the same frequency ν_l. If ν_l does not coincide with the line center ν_0 of the transition, the two beams will excite and saturate *two* groups of atoms with velocity components ν_z and $-\nu_z$, of which the Doppler-shifted frequencies ν_D coincide with the laser frequency ν_l. Consequently, two saturation holes are burned into the velocity distribution of the ground state. If we tune the laser frequency closer to the center of the line, $|\nu_z|$ decreases and the holes approach each other until they overlap for $\nu_z = 0$ when the laser frequency is tuned to line center. In this singular case, the number of atoms contributing to the absorption decreases and hence less laser power is absorbed, resulting in a narrow Doppler-free absorption dip which is used as a reference for the stabilization. Hence, (first-order) Doppler broadening is suppressed and the width of this dip is determined by the natural width of the transition, by power and collision broadening of the line, and ultimately by the limited interaction time of the atoms moving across the laser beam. To first order, the profile of this dip can be approximated by a Lorentzian line shape.

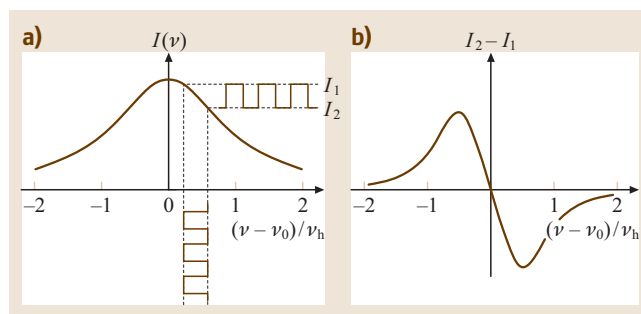
As a practical example, let us consider an absorbing gas contained in a cell at low pressure. It can be placed inside or outside the laser cavity. If the cell is placed


Fig. 11.250 Generation of the error signal by a square-wave frequency modulation

inside, a Doppler-free feature caused by saturated absorption will show up as a small symmetric dip in the tuning curve of the laser at the center of the reference transition. This feature has to be converted to an error signal which is antisymmetric with respect to the detuning $\Delta\nu = \nu_l - \nu_0$. A simple concept to generate the error signal is to switch the laser frequency between two discrete values (Fig. 11.250a). The difference in the corresponding two absorption signals $I_2 - I_1$ leads to an antisymmetric error signal with a zero crossing at the line center (Fig. 11.250b). For small modulation amplitudes, the error signal is proportional to the first derivative of the absorption signal.

Instead of a square-wave modulation, most lasers use a harmonic frequency modulation. Consequently, the laser power will contain harmonics of the modulation frequency. The amplitudes of these harmonics depend on the modulation width and on the detuning. The amplitude of a particular harmonic signal in the laser power can be detected by a photodetector followed by a phase-sensitive detector which is gated by the corresponding harmonic of the modulation frequency. For a symmetric absorption line, the amplitudes of the odd harmonics are antisymmetric and have a zero crossing at $\Delta\nu = 0$. Hence, these odd harmonics are suitable as error signals for frequency stabilization. In many cases, third-harmonic detection is applied in order to suppress a residual slope [11.2032, 2033]. If the modulation width is small compared to the line width, the derived signal represents the corresponding derivative of the saturation signal, e.g., the first derivative for the first harmonic and the third derivative for the third harmonic.

If we approximate the Doppler-free saturation feature by a Lorentzian line profile $I(\nu)$.

$$I(\nu) = \frac{A}{1 + \left[(\nu - \nu_0)/\nu_{1/2} \right]^2} \qquad (11.233)$$

we can estimate the amplitudes of the harmonics versus the detuning for various modulation widths [11.2034]. In (11.233), A and $v_{1/2}$ are the height and the half-width (HWHM) of the saturated absorption feature, respectively. The modulated laser frequency $v(t)$ can be written as

$$v(t) = v_0 + \Delta v + \delta v A \cos(\omega t), \qquad (11.234)$$

where Δv is the detuning of the mean laser frequency from the line center v_0 and δv_A is the modulation amplitude. If the modulation frequency $\omega/2\pi$ is small compared to the line width, the detected signal follows the laser frequency $v(t)$ closely and we can replace v in (11.233) by $v(t)$ of (11.234), leading to a time-dependent absorption signal

$$I(t) = \frac{A}{1 + \left\{ [\Delta v + \delta v_A \cos(\omega t)]/v_{1/2} \right\}^2}.$$

If we relate Δv and δv_A to the half-width (HWHM) $v_{1/2}$ we get with the reduced detuning $d_D = \Delta v/v_{1/2}$ and the reduced modulation amplitude $d_A = \delta v_A/v_{1/2}$

$$I(t) = \frac{A}{1 + [d_D + d_A \cos(\omega t)]^2}. \qquad (11.235)$$

The signal $I(t)$ is periodic in time and can be expressed by a Fourier series

$$I(t) = \frac{A_0}{2} + \sum_{m=1}^{\infty} A_m \cos(m\omega t), \qquad (11.236)$$

where the Fourier coefficient A_m represents the signal amplitude of the m-th harmonic of the modulation frequency $\omega/(2\pi)$. It can be calculated by the relation

$$A_m = \frac{2}{\pi} \int_0^{\pi} I(\tau) \cos(m\tau) d\tau.$$

For the coefficients A_1 and A_3 we get [11.2034]

$$A_1 = \frac{1}{d_A} \left[(\text{sign } d_D) \, P_- - d_D P_+ \right] \qquad (11.237a)$$

and

$$A_3 = \frac{1}{d_A^3} \left\{ (\text{sign } d_D) \left[4\left(1 - 3d_D^2\right) + 3d_A^2 \right] P_- \right.$$
$$\left. + \left[4\left(3 - d_D^2\right) + 3d_A^2 \right] d_D P_+ - 16 d_D \right\}$$

$$\qquad (11.237b)$$

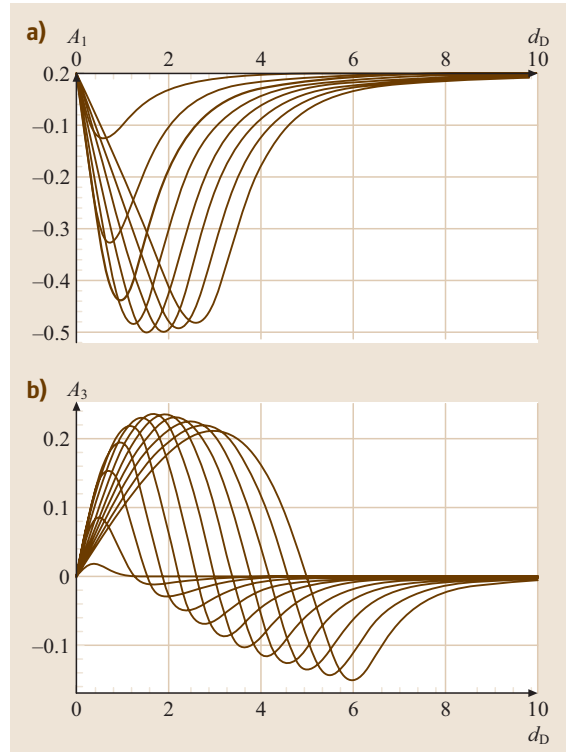
with $P_\pm = \frac{1}{\rho}\sqrt{2(\rho \pm \alpha)}$ and $\rho = \sqrt{\alpha^2 + 4d_D^2}$ and $\alpha = 1 + d_A^2 - d_D^2$.


Fig. 11.251 Amplitudes of the first harmonic (A_1) and the third harmonic (A_3) versus the detuning $d_D = \Delta v/v_{1/2}$. The modulation amplitude was chosen as $d_A = 0.2, 0.6, 1.0, \ldots, 3.0$ for A_1, and $d_A = 0.5, 1.0, 1.5, \ldots, 6.0$ for A_3

A_1 and A_3 are shown versus the detuning d_D for various modulation amplitudes d_A in Fig. 11.251a and Fig. 11.251b, respectively. Both curves have zero crossings at $d_D = 0$. In the central part, their amplitudes depend linearly on the detuning d_D. Hence, both signals A_1 and A_3 can be used as discriminator signals for frequency control. Their slope depends on the modulation width d_A. For small amplitudes $d_A \ll 1$, the slope of the first-harmonic signal depends linearly on d_A and that of the third harmonic increases with the third power of d_A. The largest slope and consequently the highest sensitivity can be obtained with the first harmonic $A_1(d_D)$. In many cases, however, the saturation signal $I(d_D)$ is superimposed on a frequency-dependent (sloping) background. Consequently, a signal is added to the first-harmonic signal $A_1(d_D)$ and the zero crossing is shifted, leading to a frequency offset of the stabilized laser frequency. This shift can be strongly reduced if the third or a higher odd harmonic is applied for the stabilization.

A typical example of a laser utilizing the third-harmonic detection technique is the iodine-stabilized HeNe laser (see Sect. 11.14.3).

Servo Amplifier and Filter

This subsection describes how the error signal is used to control the laser frequency. If the servo control is operating, the initial frequency ν_i of the free-running laser is corrected by the servo loop to ν_S, which is close to the reference frequency ν_0 (Fig. 11.252). The difference $\delta\nu = \nu_S - \nu_0$ represents the residual frequency deviation from the line center ν_0 of the stabilized laser. The deviation $\delta\nu$ is converted to an amplitude $U = C\delta\nu$ by the error signal, where the constant C is proportional to the sensitivity of the frequency discriminator. The signal $C\delta\nu$ is amplified in the following servo amplifier by a factor $g(f)$ and is then transferred to a frequency transducer, which corrects the laser frequency ν_i by $-CDg(f)\delta\nu$. Here D is the sensitivity of the transducer, which transforms the control voltage to a corresponding frequency shift of the laser. The term $g(f)$ characterizes the frequency-dependent gain of the electronic servo amplifier. The servo loop provides a negative feedback to the laser frequency and the corrected value ν_S can be written as

$$\nu_S = \nu_i - CDg(f)\delta\nu \qquad (11.238)$$

which can be transformed to

$$\frac{\delta\nu}{\Delta\nu} = \frac{1}{1 + CDg(f)}, \qquad (11.239)$$

where $\Delta\nu = \nu_i - \nu_0$ is the initial frequency offset of the free-running laser.

We see that the servo-control circuit reduces the frequency deviation $\Delta\nu$ of the free-running laser by a factor of $1/[1 + CDg(f)]$, where $CDg(f)$ represents the gain of the open servo loop. To achieve a negligibly small value of the residual frequency deviation $\delta\nu$,

the servo gain should be as high as possible. In particular, the deviation of the mean frequency averaged over long times should be close to zero. This requires that $g(f \to 0) \to \infty$. In any servo-control system, phase shifts and time delays of the servo loop put limitations on the maximum gain and the bandwidth of the servo-control. A simple technique to provide high servo gain at low frequencies and to reduce the influence of phase shifts and time delays at high frequencies is to reduce the servo gain with increasing Fourier frequency f. Such a characteristic can be obtained by an integrating behavior of the servo gain, i. e., if $CDg(f)$ decreases with $1/f$ for increasing frequencies. In this case, the total transfer function of the control system can be characterized by a unity-gain frequency f_C, the frequency at which the gain of the open servo loop $CDg(f_C) = 1$. At low fluctuation frequencies $f \ll f_C$, the frequency deviations $\Delta\nu(f)$ will be reduced by a factor of f/f_C and an increase of the servo gain corresponds to a proportional increase of the unity-gain frequency f_C. Consequently, in an integrating servo loop a high servo gain requires a large servo bandwidth f_C. In cases where the servo bandwidth f_C is limited and where large frequency fluctuations at low frequencies have to be suppressed, an additional integration can be introduced, leading to a double integrating behavior and consequently to a higher servo gain at low frequencies. The stability of the servo loop requires that this double integration is

Fig. 11.252 Equivalent circuit of a laser frequency stabilization
Fig. 11.253 Typical servo gain versus Fourier frequency of a PDH frequency stabilization to a cavity resonance (see text)

effective only at frequencies well below the unity-gain frequency f_C. In practice, the maximum crossover frequency f_{di} between single and double integration should be smaller than $f_C/4$. Figure 11.253 shows a typical dependence of servo gain on the fluctuation frequency of a frequency stabilization to a narrow cavity resonance using the PHD technique.

11.14.3 Examples of Frequency–Stabilized Lasers

This section describes a few examples of stabilized lasers. The radiations of some of them are recommended as reference frequencies for the realization of the length unit *meter* and as references for scientific applications [11.2009]. Frequency-stabilized lasers have been developed covering a wide range of wavelengths from the near UV to the far IR. Of these examples, HeNe lasers are of great practical importance since they are often employed in many applications, e.g., as wavelength standards in interferometers for dimensional metrology. Most of these lasers utilize the frequency of their gain profile itself as the reference for the stabilization. In these cases, the stabilized frequency depends on the discharge parameters, the gas pressure, and gas mixture inside the laser tube and the relative reproducibility is limited to some 10^{-7}. Hence, if the absolute value of the laser frequency is important, it should be compared from time to time with a superior standard, e.g., a HeNe Laser of which the frequency is stabilized to an absorption line of molecular iodine.

With increasing requirements on reproducibility and accuracy, the laser frequency needs to be stabilized to suitable references such as the narrow absorption lines of atoms, molecules, or ions and line broadening caused by the movement of the absorbers needs to be reduced by Doppler-free techniques such as saturated absorption or two-photon excitation. Ultimately any frequency shifts caused by a residual Doppler effect can be strongly reduced if the laser radiation interacts with cold atomic absorbers only.

This section is organized as follows. In the first part, we explain as a typical example the stabilization of a tunable diode laser to the resonance of a stable optical cavity. We then continue with HeNe lasers stabilized to their gain profile. The next section represents laser radiations that are stabilized to suitable absorption lines of atoms, molecules, or ions. In view of its practical importance, we focus on HeNe lasers, which can be stabilized to the absorption lines of molecular iodine. The absorbing particles of these lasers are contained in an absorption cell. In the next step, laser stabilization systems based on atomic or molecular beams are discussed. The last part of this section presents a brief description of lasers stabilized to cold ions and atoms.

Frequency Stabilization of Diode Lasers

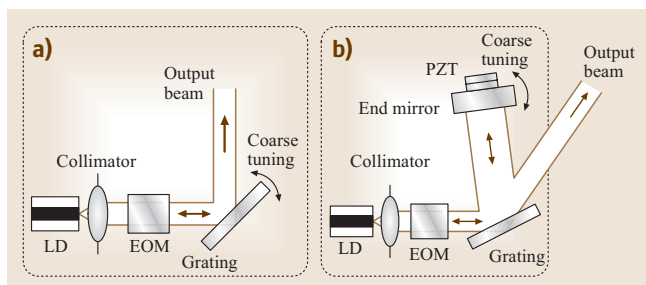
Tunable lasers are important tools in the field of precision laser spectroscopy. Whereas in the past the visible spectrum was covered mostly by dye lasers, diode lasers are increasingly taking over due to their small size, high efficiency, high power, and reliability. They are available in a wide range of the visible and infrared spectrum. However, if high spectral resolution is required, the line width of most solitary laser diodes, which ranges from 10 MHz to 300 MHz, is orders of magnitude too large. Several methods have been developed to improve the spectral purity of these lasers. Most of them apply optical feedback [11.2035, 2036]. This section discusses a typical example, where the length of the laser resonator is increased by an external reflector [11.2037, 2038]. Compared to solitary laser diodes, the line width of such extended-cavity diode lasers (ECDL) can be reduced to some 100 kHz. Figure 11.254 shows two typical setups of ECDLs in the Littrow and Littman configurations. In both configurations, the beam leaving the antireflection-coated facet of the laser diode (LD) is collimated and directed onto a reflection grating. In the Littrow configuration (Fig. 11.254a), the laser grating acts as the end mirror of the extended laser resonator where the beam is back-reflected into the laser diode in the first diffraction order. The zeroth-order beam is coupled out. Coarse frequency tuning can be performed by rotating the grating whereas a piezoelectric transducer (PZT) and/or an electrooptic modulator (EOM) can be used to fine-tune and control the laser frequency by changing the optical length of the cavity. Frequency tuning can also be achieved by changing the injection current of the


Fig. 11.254a,b Typical setups of extended-cavity diode lasers (ECDLs). (**a**) Littrow configuration, (**b**) Littman configuration (see text)

laser diode; this method, however, will also change the laser power. The Littrow configuration can be designed to be very compact. Unfortunately, the direction of its output beam changes with any rotation of the grating. This shortcoming is avoided in the Littman configuration [11.2039] where the ECDL contains an additional mirror (Fig. 11.254b). In this configuration the beam deflected in the first diffraction order is directed onto this extra mirror and back-reflected from there into the laser diode. In the Littman configuration, the laser beam passes the grating twice and hence the wavelength selectivity is increased compared to the Littrow configuration. The output beam leaves the grating in the zeroth order. In this configuration, coarse frequency setting is achieved by rotating the end mirror, with the consequence that the direction of the output beam does not change. Fine-tuning of the frequency can be performed in the same way as with the Littrow configuration by means of a PZT or an EOM.

The frequency noise of ECDLs occurs at Fourier frequencies low enough that a further line width reduction below 100 kHz can be achieved by active frequency stabilization to the resonance of an optical cavity [11.2040], as described in Sect. 11.14.2. Precise frequency tuning can be performed, e.g., by changing the length of the optical reference cavity. This method, however, strongly perturbs the stability of the cavity. To achieve the highest possible resolution, it is better to introduce a variable frequency difference between the laser output beam and the cavity resonance. Since the frequency-shifted beam is locked to the cavity resonance, which is not affected, the stabilization circuit will shift the laser frequency, with the consequence that it can be tuned very precisely relative to the stable cavity resonance. Such a shift can be achieved, e.g., by an acoustooptic modulator or an electrooptic modulator. Using the PDH technique and a carefully designed and isolated reference cavity of ultrahigh finesse, a line width as narrow as 1 Hz was recently observed, demonstrating the great potential of diode lasers for applications in precision spectroscopy and optical frequency standards [11.2021].

Frequency Stabilization of HeNe Lasers

HeNe lasers can operate at several different wavelengths within the spectral range between the green ($\lambda = 543$ nm) and the infrared ($\lambda = 3.39$ μm). Regarding the various wavelengths, the emission at $\lambda = 633$ nm is probably most important. HeNe lasers are advantageous since their operation is simple, the intrinsic frequency noise is small, and the output power in the range between 100 μW and some 3 mW is sufficient

for many applications in metrology. Provided the neon gas inside the laser tube consists of a single isotope, the width of the Doppler-broadened gain profile is in the range of approximately 1.5 GHz and single- or two-frequency operation can easily be achieved by choosing a sufficiently short length of the laser resonator. Owing to these favored properties and their simplicity, frequency-stabilized HeNe lasers were developed very early [11.2041]. The first stabilization systems – which are still used in many laboratories – apply the gain profile itself as the frequency reference.

Lamb–dip stabilization. The Lamb-dip-stabilized laser was one of the first frequency-stabilized lasers [11.2042]. It makes use of the fact that the output power passes through a local minimum – the *Lamb dip* – when the laser frequency is tuned across the center of the gain curve (Fig. 11.255a). Similar to the Doppler-free minimum of saturated absorption, the Lamb dip is caused by an increased saturation of the gain at the line center when both the forward- and backward-running waves inside the resonator interact with the same velocity group ($v_z = 0$) of atoms. Hence the number of atoms contributing to the laser action is decreased, leading to a reduced laser power at line center. To generate the error signal (Fig. 11.255b), the laser frequency is modulated and the first harmonic in the output power is detected.

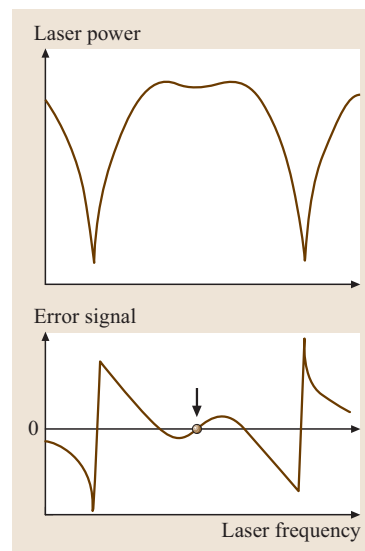
Two–mode stabilization. A simple stabilization system can easily be set up, if the HeNe laser is operating at two adjacent longitudinal modes (Fig. 11.256a) and if


Fig. 11.255a,b Tuning curve (**a**) and error signal (**b**) of a Lamb-dip-stabilized HeNe laser
Fig. 11.256a,b Tuning curve (**a**) and error signal (**b**) of a two-mode stabilized HeNe laser

these modes are polarized perpendicular to each other. These conditions are provided, e.g., in commercial HeNe laser tubes of 30 cm length with internal mirrors. Perpendicular polarization is observed since it minimizes the gain competition of two modes. Furthermore, the two planes of polarization are fixed within the tube. These properties allow us to separate the two modes by a polarization divider, e.g., a Wollaston prism, and to monitor the power in each mode by a separate photodetector. The difference between the photocurrents of the two detectors $I_1 - I_2$ depends on the frequencies of the two modes (Fig. 11.256b). It crosses zero when they are distributed symmetrically with respect to the center of the gain curve and the powers in the two modes are identical. Hence, the difference in the photocurrents is used as the error signal for frequency stabilization and no frequency modulation is necessary [11.2043]. Several means can be applied to transfer the control signal to the length of laser tube, such as heating the tube via the discharge current or a separate external heater. With this simple laser stabilization technique, a relative reproducibility of better than 10^{-7} has been demonstrated. During a time interval of five days relative frequency variations as low as 10^{-9} have been demonstrated under favored laboratory conditions [11.2044].

Zeeman stabilization. Another method of frequency stabilization widely applied in commercial HeNe lasers and laser interferometers utilizes the Zeeman effect in a short (≈ 10 cm) single-mode laser. If we apply a longitudinal magnetic field, the Zeeman effect causes a splitting of the laser mode into two submodes ν_+ and ν_- of opposite circular polarization and slightly different frequencies. Depending on the size of the magnetic field, the frequency difference $\nu_+ - \nu_-$ is in the range between 300 kHz and 2 MHz. The two submodes can be separated by a quarter-wave plate followed by a polar-

izing beam splitter. Similar to two-mode stabilization, the difference of the output powers at ν_+ and ν_- can be utilized as the error signal [11.2045].

Alternatively, the error signal can also be generated by utilizing the frequency difference $\delta\nu = \nu_+ - \nu_-$. It has been shown that $\delta\nu$ changes with the mean laser frequency and that it has a minimum at the line center. This dependence is caused by nonlinear mode-pulling effects in the gain medium. The error signal to find this minimum is generated by modulating the laser frequency and monitoring the beat frequency between the two Zeeman modes by means of a reversible counter [11.2046]. To derive the error signal, the direction of counting is reversed at every half period of the modulation. The accumulated counter content, which corresponds to the integrated error signal, is then fed into a digital-to-analog converter after each period. Its output is used to control the frequency of the laser so that the mean laser frequency coincides with the minimum of the beat frequency. With such lasers a relative frequency reproducibility of 10^{-8} can be achieved over a period of five months under laboratory conditions [11.2046].

Absolute Frequency Stabilization Utilizing Separate Absorption Cells

As indicated above, the frequency of HeNe lasers stabilized to their gain profile may change with time. Such frequency shifts can be reduced by several orders of magnitude if the frequency reference is provided by a suitable narrow absorption line of which the transition frequency is largely independent on the parameters of operation. There are now several different laser systems available in a wide range of the optical spectrum which are stabilized to such frequency references. Some of these have been recommended by the Comité International des Poids et Mesures (CIPM) [11.2009]. Their radiations are listed together with the values of their frequencies, wavelengths, and their relative uncertainties in Table 11.56. Six of the recommended reference frequencies are stabilized to hyperfine-structure components of molecular iodine, which has a rich spectrum of narrow absorption lines in the visible range. They belong to the transition between the electronic B level and the ground state (X level). Since the iodine molecule is heavy, its velocity – and hence the Doppler broadening – is rather low at room temperature. Furthermore, the vapor pressure – causing a pressure-induced shift and broadening – can be controlled conveniently via the temperature of a cooling finger attached to the iodine absorption cell. Four of the iodine references are used to stabilize HeNe lasers at $\lambda \approx 543$ nm, 612 nm, 633 nm, and 640 nm. From this

Table 11.56 Recommended reference wavelengths/frequencies generated by stabilized lasers [11.2009]

	Atom / Molecule	Transition	Wavelength (fm)	Frequency	Rel. std. uncertainty (1 σ)
1	$^{115}In^+$	$5s^2\ ^1S_0$–$5s5p\ ^3P_0$	236 540 853.54976	1 267 402 452 899.92 kHz	3.6×10^{-13}
2	^1H	1S–2S (Two-photon transition)	243 134 624.62603	1 233 030 706 593.61 kHz	2.0×10^{-13}
3	$^{199}Hg^+$	$5d^{10}6s\ ^2S_{1/2}\ (F = 0)$–$5d^96s^2\ ^2D_{5/2}\ (F = 2)$ $\Delta m_F = 0$	281 568 867.591969	1 064 721 609 899.143 Hz	1.9×10^{-14}

group, the one operating at 633 nm is of particular importance since it is used in many standard laboratories as a reference for interferometric length measurements, laser wavelength calibrations, and applications in precision laser spectroscopy. It can also act as a reference to calibrate HeNe lasers that are stabilized to their gain profile by beat-frequency comparisons. Hence, the I_2-stabilized HeNe laser at $\lambda = 633$ nm can be regarded as the workhorse in many laboratories.

The iodine molecules are contained at low vapor pressure in a cell. Depending on the laser system, the length of the cell may range from a few centimeters up to several meters. In either case, the content of impurities has to be low in order to prevent any frequency shifts caused by collisions with impurities. For example, in the case of iodine-stabilized lasers, the quality of the iodine filling limits the uncertainty ultimately achievable. Nevertheless, as a result of its rich spectrum, I_2 is often used as the frequency reference for different types of lasers operating within the visible spectrum. Two types of I_2-stabilized lasers, the HeNe laser ($\lambda = 633$ nm) and the frequency-doubled Nd:YAG laser ($\lambda = 532$ nm) will be discussed in the following.

Iodine-stabilized HeNe laser ($\lambda = 633$ nm). Figure 11.257 schematically shows a typical setup of an iodine-stabilized HeNe laser. The laser head consists of a HeNe discharge tube and an iodine absorption cell mounted inside the laser resonator. The lengths of the discharge tube and the absorption cell are typically

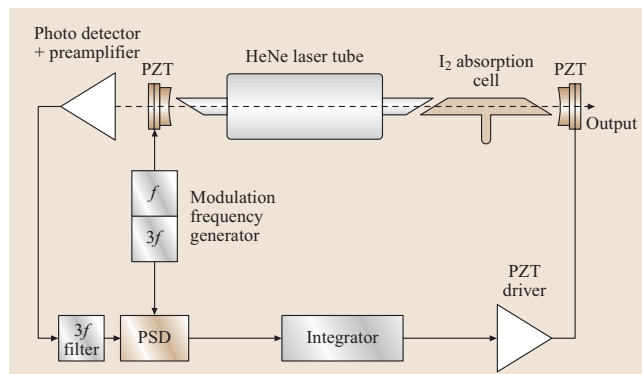
20 cm and 10 cm, respectively, corresponding to a minimum length of the resonator of approximately 35 cm and a free spectral range of ≈ 430 MHz. Despite of the rather long resonator the laser emits only one single frequency, owing to the loss in the absorption cell. In order to reduce the influence of acoustics and vibrations, the resonator should be made as rugged as possible. The spacers should consist of a material of low thermal expansion. The radii of curvature of the laser mirrors are usually in the range $r = 0.6$–4 m with a radius of $r = 1$ m most commonly used. Both mirrors have a reflectivity of approximately 98%, allowing single-frequency operation over most of the free spectral range. Output powers of up to 300 μW have been achieved, sufficient for most applications in laser spectroscopy and interferometry.


Fig. 11.257 Experimental scheme of an iodine-stabilized HeNe laser

The two mirrors are mounted on PZT actuators, allowing one to change the resonator length and thereby the laser frequency by applying a voltage to the PZTs.

Figure 11.258a shows four absorption features in the tuning curve of the laser. They belong to the hyperfine-structure (HFS) components d, e, f, and g of the transition R(127), $v' = 5$, $v'' = 11$ of $^{127}I_2$. The separation between the components d, e, f, g is approximately 13 MHz and the full width at half-maximum of each line is in the range of 5 MHz, corresponding to a quality factor of $Q = v/\delta v \approx 10^8$. The height is approximately 0.1% of the laser power. To generate the error signal for the stabilization, the length and thereby the frequency of the laser is modulated harmonically by applying a sine-wave voltage to the left PZT (Fig. 11.257). For the stabilization, third-harmonic detection is used. The third-harmonic signal in the output power is filtered out, demodulated by a phase-sensitive detector (PSD) and passed through a low-pass filter. It then serves as error signal for the stabilization. A typical third-harmonic spectrum of molecular iodine containing seven HFS components within the tuning range of the laser is shown in Fig. 11.258b. Each absorption feature is suitable as a reference for the stabilization.

With the servo loop operating, the length of the laser is stabilized such that the third-harmonic signal of the corresponding HFS component vanishes at its central zero crossing.

The stability and the reproducibility of the I_2-stabilized HeNe laser can be investigated by beat-frequency measurements of two independent laser systems. Figure 11.245 shows the measured Allan standard deviation $\sigma(\tau)$ of an iodine-stabilized HeNe laser versus the integrating time τ. In the range between $\tau = 10$ ms and $\tau = 100$ s, $\sigma(\tau)$ decreases approximately with the square root of τ, corresponding to white frequency noise. The minimum instability of about 2×10^{-13} is observed at an integrating time $\tau \approx 1000$ s.

The reproducibility of the iodine-stabilized HeNe laser was investigated by measuring the dependence of the laser frequency on the various operation parameters and by frequency inter-comparisons between lasers of different institutes. The laser frequency depends on the modulation width, the iodine vapor pressure, and slightly on the laser power. The coefficients are approximately -6 kHz/Pa and -10 kHz/MHz for the pressure and modulation dependence, respectively. International frequency comparisons between iodine-stabilized lasers have shown that the stabilized frequencies of the majority of iodine-stabilized HeNe lasers coincide within a range of approximately 12 kHz, corresponding to $2.5 \times 10^{-11}v$. For specified operation parameters (temperature of the cell: (25 ± 5) °C, temperature of the cold point: (15 ± 0.2) °C, width of frequency modulation between the peaks: (6 ± 0.3) MHz, one-way intracavity beam power: (10 ± 5) mW) a relative standard uncertainty of the recommended frequency value of 2.5×10^{-11} can be achieved [11.2009].

Iodine–stabilized frequency–doubled Nd:YAG lasers ($\lambda = 532$ nm). Frequency-doubled YAG lasers pumped by diode lasers are of particular interest in applications as optical frequency standards for the following reasons. Small lasers providing us with high output powers of 100 mW at 532 nm are commercially available. The intrinsic frequency noise of YAG lasers can be very low. Part of the emission range coincides with strong absorption lines of molecular iodine (Fig. 11.259a) that are suitable as reference frequencies for the stabilization. Figure 11.259b shows the Doppler-free absorption spectrum observed within the continuous tuning range of 5 GHz of a commercial laser. The observed absorption lines represent two sets of hyperfine components belonging to the 32-0, R(57) and the 32-0, P(54) ro-vibrational lines labeled #1104 and #1105, respectively [11.2047]. Any of these transitions is suitable as a frequency reference. Since the frequency difference to the recommended a_{10} component of the 32-0, R(56) transition is known to about 2 kHz an accurate optical frequency can be attributed to each HFS component.

Various methods have been used in different laboratories to generate the error signal. The methods of modulation transfer spectroscopy [11.2048, 2049] and phase-modulation spectroscopy [11.2050, 2051] are very powerful to achieve discriminant signal with a high signal-to-noise ratio.

International frequency comparisons show that the frequency reproducibility of these lasers is in the range of 5 kHz [11.2052, 2053], mostly limited by potential im-

purities in the absorption cell. Regarding its high power, its compactness, and its high frequency reproducibility, the iodine-stabilized frequency-doubled Nd:YAG laser represents an optical frequency standard with important applications in precision length metrology, interferometry, and spectroscopy.

Laser stabilized to a two-photon transition in rubidium. The radiation of a laser stabilized to the two-photon transition $5S_{1/2}$–$5D_{5/2}$ in rubidium (Fig. 11.260) [11.2054] represents a reference in the near infrared at a wavelength of 778 nm. In this spectral range, easy-to-handle laser diodes of low frequency noise are available, allowing the development of a transportable optical frequency standard of high precision. Furthermore, the laser may provide a precise frequency reference for optical communication systems since twice its wavelength coincides with the transmis-

sion band at 1.55 μm. Its optical frequency has been determined [11.2055].

In a simple setup [11.2054], the collimated beam of an extended-cavity diode laser passes through an absorption cell filled with rubidium vapor. The cell is sealed with Brewster windows at its ends and filled with natural rubidium (73% ^{85}Rb and 27% ^{87}Rb). The beam is retro-reflected by a mirror or a cat's eye in order to allow Doppler-free two-photon excitation. Optical feedback into the diode laser is avoided by Faraday isolators. When the laser frequency is scanned through the two-photon resonance, the excitation of the upper level ($5^2D_{5/2}$) is observed via the blue fluorescence (420 nm) of the 6P–5S transition in the cascade of the spontaneous decay 5D → 6P → 5S. With this setup, a frequency stability of $\sigma(\tau) = 3 \times 10^{-13}\tau^{-1/2}$ has been achieved for integrating times τ up to 2000 s.

It is known that the stabilized frequencies of standards based on two-photon transitions suffer from light shifts. Its magnitude depends linearly on the intensity. Therefore, it is important to control the laser power and to prepare a well-defined laser beam geometry for the excitation. This requirement can be fulfilled if the absorption cell is mounted inside a nondegenerate optical resonator. The use of a resonator also allows a power buildup of the radiation and therefore an increase of the two-photon excitation. Furthermore, it provides exact retro-reflection of the laser beam, which is necessary to suppress residual first-order Doppler shifts. In the experiments [11.2054], the laser frequency was pre-stabilized in a first step to a resonance of this cavity. It could then be tuned through the two-photon resonance by changing the length of the resonator via a PZT actuator to which one of the mirrors is mounted. Compared to the results of the simple setup described before, the observed frequency stability was approximately the same. However the light shift could be better controlled and consequently the frequency of the tran-

sition can be extrapolated more precisely to zero laser power.

Laser-cooled ensembles of Rb atoms have also been used for frequency stabilization to reduce the influence of the second-order Doppler effect [11.2056]. Further evaluations will show if a standard based on cold Rb atoms leads to a significant reduction of the relative frequency uncertainty. Nevertheless, in its present state, the Rb-stabilized laser represents an interesting precision frequency reference.

Stabilized Lasers Based on Atomic or Molecular Beams

Atomic and molecular absorbers are often prepared in beams rather than in absorption cells for various reasons. First, some gases such as hydrogen are not stable as atomic species and need to be prepared just shortly before excitation. Vapors of metals would soon coat the cell windows and strongly decrease their transparency. Second, the use of a collimated beam allows us to utilize an excitation geometry in which the laser beam crosses the atomic beam at a right angle. In the case of single-photon transitions, this may reduce the first-order Doppler effect by several orders of magnitude. Furthermore, for long-lived atomic states, the excitation and detection zones can be separated, leading to an increased signal-to-noise ratio since scattered light from the excitation beam can be better suppressed.

The mean velocity of molecules or atoms at room temperature ranges from approximately 100 m/s to more than 2000 m/s. At this velocity, the interaction time of the particles crossing the laser beam at a right angle, is typically less than 10^{-5} s for beam diameters of a few millimeters. Hence, the corresponding line broadening is more than 0.1 MHz. This broadening can be reduced by applying Ramsey's method of separated field excitation first introduced in the microwave range [11.2057]. For single-photon transitions in the optical regime, where the wavelength of the radiation is typically much smaller than the diameter of the atomic beam, additional steps need to be taken to use separated field excitation. This can be achieved either by blocking well-defined trajectories of the atomic beam [11.2058] or by using three [11.2059] or more [11.2060] spatially separated excitation zones.

An alternative method is a longitudinal excitation where the atoms fly parallel or anti-parallel to the laser beam. This method is suitable in the case of two-photon transitions. For example, one of the recommended radiations (Table 11.56) corresponds to the 1S–2S two-photon transition of atomic hydrogen. In the experiment, a beam of cold atomic hydrogen is formed by guiding hydrogen molecules through a gas discharge and reflecting the atomic particles at a plate which is cooled by liquid helium. The reflector directs the hydrogen atoms on the optical axis of an optical resonator which is tuned close to the 1S–2S two-photon transition. The *longitudinal* excitation inside a resonator allows the strong power buildup necessary for a two-photon excitation, precise mode-matching of the forward- and backward-running waves inside the resonator, and an increased interaction time of the atoms with the laser beam, leading to increased spectral resolution. The relative uncertainty of the transition frequency recommended by the CIPM is as low as 2.0×10^{-13} [11.2009].

In the case of single photon transitions, the transvers excitation by separated laser fields (Fig. 11.262) is frequently applied to achieve high spectral resolution and a good signal-to-noise ratio. It was shown by Bordé that this method leads to an atom interferometer (Ramsey–Bordé interferometer) where the laser beams act as coherent beam splitters for the atomic beam [11.2061–2063]. The prominent advantage of optical Ramsey excitation with separated fields results from the fact that the transit-time broadening and the resolution can be adjusted independently. The former can be increased by choosing short interaction times in each zone, thereby allowing a large fraction of the atoms to contribute to the signal. The resolution, however, is mainly determined by the time of flight between the interaction zones. In the following, we give a brief description of the Ramsey–Bordé interferometer. Utilizing the internal energy structure of the atoms, absorption and induced emission, processes can be used to split or deflect atomic beams. If an atom absorbs a photon from a traveling wave, it also absorbs the photon momentum $\hbar\boldsymbol{k}$ (Fig. 11.261a). Hence, the excited atom suffers a photon recoil. If the atomic wave was in the excited state
Fig. 11.261 Laser beams as beam splitters for an atomic wave
Fig. 11.262 Ramsey–Bordé matter–wave interferometer (the figure shows only those partial beams that lead to an interference structure)

Fig. 11.263 Partial energy-level diagram of ^{40}Ca

before interaction with the laser radiation, the inverse process (induced emission) will occur (Fig. 11.261b). The probability ρ of observing such excitation or emission process depends on the intensity, the frequency of the light field, and the duration of the interaction. In general, the atom will be left in a coherent superposition of the ground and the excited state (Fig. 11.261). Since the atoms have different momenta in both states, it is more appropriate to use the picture of atomic wave packets. The interaction can act, e.g., as a 50% beam splitter ($\rho = 0.5$, $\pi/2$ pulse) or as a mirror ($\rho = 1$, π pulse). In any case, the phase of the light beam is transferred to the deflected partial atomic wave. If the light field is slightly detuned from the atomic resonance, the corresponding energy difference $\hbar\delta\omega$ is also transferred to the deflected partial wave as kinetic energy and consequently the de Broglie wavelength is changed.

The combination of such beam splitters may lead to atom interferometers that are similar to an optical Mach–Zehnder interferometer (Fig. 11.262). During the first and each subsequent interaction, the matter wave is coherently split into partial waves with the internal states $|g\rangle$ and $|e\rangle$, which are represented by the solid and the dashed lines in Figs. 11.261 and 11.262. If an absorption or emission is induced, the momentum of the corresponding wave packet is changed by the photon momentum $\hbar\boldsymbol{k}$. At the final interaction, the loop of the trajectories closes and the laser field superimposes the partial waves, resulting in an atom interference. Since the atomic wave packets leave the two outputs of each interferometer in different internal states, the interference structure can be observed by monitoring the population either in the excited or the ground state.

The inter-combination transitions $^1S_0$–$^3P_1$ of the alkaline-earth atoms are well known to represent excellent references for optical frequency standards (see, for example, [11.2065] and references therein). They exhibit narrow natural line widths of about 0.04 kHz (Mg), 0.3 kHz (Ca), and 6 kHz (Sr). In all three cases
the frequencies of the $\Delta m_J = 0$ transitions are almost insensitive to electric and magnetic fields.

The inter-combination lines have been investigated in effusive beams of magnesium [11.2066], strontium [11.2067, 2068], and barium atoms [11.2069]. Most work for optical frequency standard applications has probably been performed with Ca atomic beams [11.2070, 2071]. This transition was investigated by various groups [11.2064, 2072–2074]. The radiation of a Ca-stabilized laser is also recommended as a reference frequency by the CIPM [11.2009]. As a typical example let us discuss the layout of a transportable Ca-atomic-beam standard (Fig. 11.264) [11.2064].

A few milliwatts of the available output power of an ECDL – pre-stabilized to a reference frequency of an optical cavity – is sent through a polarization-preserving single-mode fiber to a beam splitter/mirror configuration and is split into two beams 1 and 2 of equal power. From each one of the beams (1 or 2) crossing
Fig. 11.264 Scheme of a transportable diode-laser frequency stabilized to the $^1S_0$–$^3P_1$ inter-combination transition by means of separated field excitation of a ^{40}Ca beam [11.2064]

the atomic beam perpendicularly an excitation geometry with two pairs of counter-propagating laser beams is obtained by the help of two cat's-eye retro-reflectors. The co-propagating beams are separated by the distance $D = 10\,\text{mm}$ and the distance between the two innermost counter-propagating beams is $d = 13\,\text{mm}$. The optical layout with the fused silica block is designed in such a way that the part 2 leads to the same excitation geometry as part 1, but its direction with respect to the atomic beam is reversed (Fig. 11.264). During the experiment, the laser beams are propagating either in direction 1 or 2 and the beams propagating in the opposite direction are blocked.

The excited atoms are detected by measuring the fluorescence intensity from the decay of the excited atoms by a photomultiplier. The detected fluorescence intensity of the $\Delta m_{\text{j}} = 0$ transition versus laser frequency detuning $\Delta\omega/2\pi = (\omega - \omega_g)/2\pi$, representing the frequency difference between the laser frequency $\omega/2\pi$ and the frequency $\omega_0/2\pi$ of the Ca inter-combination line, can be described by the expression [11.2060].

$$
\begin{aligned}
I(\Delta_0) \\
= \int_0^\infty A(P, v, \Delta_0) f(v) \\
\times \Bigg\{ \cos\left[2T\left(\Delta_0 + \delta_{\text{rec}} + \frac{\omega_0 v^2}{2c^2}\right) + \Phi_{\text{L}} \right] \\
+ \cos\left[2T\left(\Delta_0 - \delta_{\text{rec}} + \frac{\omega_0 v^2}{2c^2}\right) + \Phi_{\text{L}} \right] \Bigg\} \, dv \\
+ B(P, \Delta_0) \, .
\end{aligned}
\tag{11.240}
$$

In (11.240), $A(P, v, \Delta_0)$ describes the contribution of a particular atom with velocity v to the signal, and $B(P, v, \Delta_0)$ describes the amplitude of the background of the Doppler-broadened line including the saturation dip, both depending on the laser power P and weakly on the detuning $\delta v = \Delta_0/2\pi$ of the laser frequency. The factor $f(v)$ represents the velocity distribution, where we have neglected the influence of the velocity components perpendicular to the atomic beam.

$$
\Phi_{\text{L}} = \Phi_2 - \Phi_1 + \Phi_4 - \Phi_3
\tag{11.241}
$$

is a residual phase between the four exciting laser beams having the phases Φ_i in the interaction zone, and $T = D/v$ is the flight time of the atoms between two co-propagating beams. The phase Φ_{L} – which shifts the frequency of the interference structure – can be detected by reversing the directions of the laser beams (from 1 to 2

or vice versa, Fig. 11.264) and compensated by rotating the phase plate [11.2064].

The phase of each cosine function in (11.240) contains three contributions. Besides Φ_{L} there are the terms Δ_0 resulting from the detuning, $\delta_{\text{rec}} = \hbar k^2/(2m_{\text{Ca}}c^2)$ from the photon recoil where $\mathbf{k}$ is the wavevector of the laser field and m_{Ca} the mass of a Ca atom, and $\omega_0 v^2/(2c^2)$ from the second-order Doppler effect.

The signal for each velocity group v consists of two cosine functions with a period $1/(2T)$ that is determined by the distance D and the atomic velocity. The two components are separated by the recoil splitting $2\delta_{\text{rec}} = 2\pi 23.1\,\text{kHz}$. For an optimum superposition of the two cosines, the period should be an integer fraction of the recoil splitting. The FWHM line width of the signal is approximately given by $1/(4T)$.

From the measured fluorescence signal versus detuning $\delta v = v - v_o$ (Fig. 11.265) one clearly recognizes in the central part of the saturation dip the two central minima of the two cosine terms separated by the recoil splitting. With increasing detuning the cosine structure is washed out, since all velocity groups v of the atomic beam contribute with a slightly different period. The inset of Fig. 11.265 shows the total detected signal where the Doppler broadening is determined by the degree of collimation and the velocity distribution of the atomic beam, leading to a FWHM of the structure of 7.5 MHz. With an evaluated relative uncertainty of 1.3×10^{-12} combined with a relative stability of $\sigma(\tau) = 9 \times 10^{-13}$ at $\tau = 1\,\text{s}$, the transportable Ca frequency standard is one order of magnitude superior to
Fig. 11.265 Atom interference structures observed in a thermal beam of Ca atoms [11.2064]

the widely used transportable iodine-stabilized HeNe laser at $\lambda = 633$ nm.

Optical Frequency Standards Based on Laser–Cooled Absorbers

In the case of frequency-stabilized lasers utilizing *thermal* absorbers, the uncertainty in the center of the reference line is ultimately limited by frequency shifts caused by residual phase errors in the optical excitation and by the second-order Doppler shift $\delta\nu/\nu = -\nu^2/(2c^2)$. Both frequency shifts scale with the velocity of the absorbers and can be reduced by orders of magnitude if the control signal is only generated by slow absorbers. In addition, the increased interaction time of the atoms with the laser beam leads to reduced broadening of the reference line. Hence, the most accurate optical frequency standards are based on cold absorbers. Two typical examples are described in the following subsections. The first describes a standard utilizing a single trapped Yb$^+$ ion whereas the second part presents a frequency standard based on an ensemble of cold Ca atoms.

Optical frequency standards based on cold, stored ions. The ideal reference for an optical frequency standard would consist of an ensemble of identical but independent atoms at rest in free space. This condition can be approximated in part by a single ion confined in a small volume inside an axially symmetric configuration of electrodes shown schematically in Fig. 11.266 (Paul trap) [11.2075]. Trapping is performed by applying a suitable RF voltage to the electrodes. Such traps allow us to store and cool *single* ions in the field-free region of the trap center.

Ions suitable for precision frequency standards provide a closed transition for cooling and a reference (clock) transition. Cooling of the ion is performed by irradiating it with laser radiation which is tuned slightly

Fig. 11.267 Simplified energy-level diagram of ^{171}Yb

below resonance and the cooling occurs by repeated absorption and emission [11.2077, 2078]. When the *clock* transition is probed, the cooling radiation has to be turned off in order to suppress light shifts and strong line broadening. The RF trapping field, however, may stay unchanged, allowing ideally unlimited interrogation times. If several ions are confined in a trap, their repelling forces will lead to an *ion cloud*, extending into the nonvanishing RF field and kinetic energy from the oscillating trapping field will be picked up. Such heating can be avoided if only a single ion is trapped in the center of the trap, where the trapping field vanishes. Since only *one* ion can contribute to the stabilization, it is important to detect the excitation of the reference transition with high efficiency. An efficiency close to 100%

Fig. 11.266 Electrode configuration of an RF ion trap (Paul trap) [11.2075]
Fig. 11.268 Absorption signal of a single trapped and cooled ^{171}Yb$^+$ ion [11.2076]
Fig. 11.269 Time sequence of atom cooling and trapping and probing of the reference transition

can be accomplished by the method of *electron shelving* [11.2079], which utilizes the fact that the strong fluorescence on the cooling transition is interrupted if the ion is excited to the upper state of the reference transition.

Several different ions are being investigated for applications in frequency-stabilized lasers. Very promising results have been observed with standards based on the ions of mercury [11.2080], strontium [11.2081, 2082], indium [11.2083], and ytterbium [11.2076, 2084]. As a typical example, we consider an optical standard based on a single ^{171}Yb ion (Fig. 11.267). There are three different clock transitions that can be accessed by the frequency-doubled radiation of diode lasers. The 435 nm clock transition has recently been observed with a line width as narrow as 30 Hz (Fig. 11.268). In the meantime, this linewidth could be further reduced to 10 Hz [11.2085]. Utilizing this reference line a relative uncertainty of 9×10^{-15} has recently been estimated [11.2086], demonstrating the great potential

Fig. 11.270 Interference structure of cold, free Ca atoms generated by time-separated excitation

of optical frequency standards based on cold stored ions.

Frequency standards based on cold neutral atoms. Neutral atoms can be cooled and trapped in a magnetooptical trap (MOT) [11.2087] if they have a suitable cooling transition. In contrast to ions, a large number of atoms in the range of 10^7 can be utilized to contribute to the stabilization, leading to an increased signal-to-noise ratio. However, to avoid unwanted frequency shifts, all trapping fields have to switched off when the reference transition is probed. Hence, the interaction time of the free atoms released from the trap is limited by their acceleration in the gravitational field.

Candidates for cold-atom optical frequency standards are silver [11.2088] and the alkali-earth atoms magnesium [11.2089, 2090], strontium [11.2091, 2092], and calcium [11.2065, 2070, 2088]. As a typical example, we describe a frequency-stabilized laser based on cold neutral calcium atoms.

Besides of the narrow reference transition $^1S_0$–$^3P_1$ at $\lambda = 657$ nm (Fig. 11.263), ^{40}Ca has a strong cooling transition $^1S_0$–$^1P_1$ ($\lambda = 423$ nm) that can be used to cool and trap Ca atoms in a MOT [11.2093]. On this transition, the Ca atoms can be cooled to approximately 3 mK. Further cooling to several mikrokelvin can then be achieved in a second step by means of the narrow intercombination transition $^1S_0$–$^3P_1$ utilizing the method of *quench cooling* [11.2094].

In order to achieve high spectral resolution combined with a good signal-to-noise ratio (SNR), the method of separated field excitation in the time domain can be applied, similar to the spatially separated field excitation of an atomic beam. Short pulses of 1 μs duration are used to excite a significant part of the cold ensemble of atoms. The necessary high spectral resolution is then achieved by a sufficiently large time separation T between two consecutive pulses. If the lengths of the pulses are small compared to their separation, the width of the interference fringes $\delta \nu = 1/(4T)$ is inversely proportional to T.

Cooling and trapping of the atoms and probing of the clock transition are performed sequentially (Fig. 11.269). After the atoms have been trapped and cooled for about 15 ms in the first step, the trapping fields (laser beams and magnetic quadrupole field) are switched off, a small homogeneous magnetic quantization field (Helmholtz field) is turned on and the clock transition is probed by two pulsed pairs of counterpropagating laser beams (Fig. 11.269). During this time, the cloud of cold, free Ca atoms expands according to
the temperature of about 3 mK at a root-mean-square velocity of $v_{rms} \approx 80 \, cm/s$. In the third step, the excitation to the $^3P_1$ state is detected by observing the fluorescence of its spontaneous decay to the $^1S_0$ ground state.

If the laser frequency is tuned across the atomic resonance, the fluorescence intensity contains a contribution that oscillates with the cosine of the laser detuning (Fig. 11.270). Similar to spatially separated field excitation, this oscillating behavior can be explained by an atom interference generated by the excitation with time-separated fields [11.2093].

The error signal for the stabilization is generated from the interference signal by modulating the laser frequency and simultaneously measuring the fluorescence intensity. In the most straightforward approach, the frequency is square-wave modulated between two discrete values with the mean frequency tuned close to the center of the central fringe. The difference in the corresponding fluorescence intensities is used as the error signal. This method corresponds to a first-harmonic detection (1f method) of a servo-control system using analog electronics and harmonic modulation. The maximum slope is obtained for a total modulation width of $\delta\nu_{mod} = 1/4T$, i. e., if the frequency alternates between the points of maximum slope of the interference signal. After detection, the error signal is used to step the frequency of the laser spectrometer which corresponds to a digital integrating servo control. The linear drift of the eigenfrequency of the reference resonator can be determined by the servo control and compensated for by adding a corresponding feedforward signal to the signal controlling the laser frequency. Using Ca atoms, cooled on the $^1S_0$–$^1P_1$ transition to approximately 3 mK, a relative uncertainty of $\delta\nu/\nu \cong 2 \times 10^{-14}$ has been determined [11.2095].

11.14.4 Measurement of Optical Frequencies

In many cases, the use of frequency-stabilized lasers requires precise knowledge of their frequencies. They have to be determined in relation to the primary standard of time and frequency, the Cs atomic clock. Earlier concepts of optical frequency measurements used a harmonic frequency chain of several lasers [11.2096]. For example, measurements of the Ca inter-combination line with such harmonic chain led to a fractional uncertainty of 2.5×10^{-13} [11.2097]. In the meantime alternative powerful methods have been developed to determine optical frequencies. An elegant and successful method is based on a mode-locked femtosecond
Fig. 11.271a,b Signal of a mode-locked fs laser, shown (**a**) in the time domain and (**b**) in the frequency domain

laser [11.2098–2101]. Such lasers emit a continuous train of very short pulses covering a wide range of the optical spectrum of some 100 THz. This range can be further increased to more than one octave utilizing the phase modulation induced by the pulsed laser beam in an optical fiber of low dispersion [11.2102].

In the frequency domain, the continuous train of femtosecond pulses (Fig. 11.271a) corresponds to a comb of frequencies of which the inverse of the pulse separation is equal to the pulse repetition frequency f_{rep} (Fig. 11.271b). The value of an arbitrary comb frequency $\nu(m)$ is determined by

$$\nu(m) = \nu(0) + m f_{rep} \,, \tag{11.242}$$

where m is an integer representing the respective order number of the comb frequency $\nu(m)$ and f_{rep} is the repetition frequency (Fig. 11.271b). Since the group velocity and the phase velocity of the short light pulses circulating in the laser cavity are slightly different an extrapolation to $m = 0$ leads to the frequency $\nu(0)$ which – in general – does not coincide with the zero frequency (Fig. 11.271b). According to (11.242), the determination of an arbitrary frequency $\nu(m)$ requires the knowledge of f_{rep}, the integer m, and $\nu(0)$. The pulse repetition frequency f_{rep} can be measured phase-coherently against the primary standard of time and frequency. If f_{rep} is larger than approximately 100 MHz it can easily be identified by an interferometric wavelength measurement of moderate relative uncertainty ($\leq 10^{-7}$). In order to measure $\nu(0)$, we take advantage of the fact that the comb spans over a frequency range of more than one octave. This allows us to frequency double the low frequency

part of the comb spectrum $2\nu(0) + 2m f_{rep}$ and beat it against the corresponding high-frequency part of the comb spectrum $\nu(0) + n f_{rep}$. This *self-referencing* of the frequency comb leads to a beat

$$
\begin{aligned}
\delta\nu &= 2\nu(0) + 2n f_{rep} - \left[\nu(0) + m\nu_{rep}\right] \\
&= \nu(0) + (2n - m) f_{rep}
\end{aligned}
\tag{11.243}
$$

that contains $\nu(0)$ plus integer multiples of the pulse repetition frequency f_{rep}. Since m, n and f_{rep} are known [11.2099, 2100]. Hence, any comb frequency $\nu(m)$ can now be measured with very low uncertainty [11.2099, 2100]. Hence, any comb frequency $\nu(m)$ can now be connected phase-coherently to the frequency of the primary standard of time and frequency, the Cs atomic clock. Therefore, we can conclude that the frequency of any other laser emitting within the spectral range of the frequency comb can also be determined phase-coherently by measuring the beat between the laser frequency and a corresponding comb frequency $\nu(m)$. Femtosecond lasers have been applied for the first time to measure the frequency measurements of 1S–2S two-photon transition in hydrogen, leading to the recommended value of the frequency given in Table 11.56 [11.2098].

In the meantime femtosecond lasers are widely used for optical frequency measurements in many laboratories worldwide. The first experiments applied titanium-sapphire femtosecond lasers as frequency comb generators. They are now going to be replaced by femtosecond fibre lasers in view of their high reliability, ease of operation, and accuracy [11.2103]. It has been shown that frequency comb generators based upon fs lasers are well suited for optical frequency measurements of the lowest possible uncertainty. Furthermore, it was demonstrated that frequency ratios could be determined with fs lasers with relative uncertainties as low as 10^{-18} [11.2104]. Basically, in their present state, frequency comb generators based on fs lasers allow the measurement of optical frequencies with uncertainties determined only by the uncertainty of the primary standard of time and frequency and the reproducibility of the stabilized laser whereas the

uncertainty of the comb generator itself can still be neglected.

11.14.5 Conclusion and Outlook

The aim of this chapter was to review the foundations and methods of laser frequency stabilization including modern methods of optical frequency measurements. Regarding the wide field of lasers, laser spectroscopy and frequency stabilization and the fast development in these fields, this chapter could not be comprehensive within the limited space available. However, we hope that it presents a reasonable overview and gives some introduction to those scientists who are entering the fascinating field of laser frequency stabilization and laser spectroscopy.

The examples of stabilized lasers in Sect. 11.14.3 are discussed to illustrate the variety of methods applied in this field. The development of stabilized lasers is still progressing in various directions. One is the development of efficient, reliable and small lasers, e.g., diode lasers, diode-pumped solid-state lasers, or optical parametric oscillators (OPOs), which may be important to achieve efficient, reliable long-term operation. Another branch is the design of stable optical reference resonators to further decrease the laser line width close to the quantum limit. An important task is to isolate them from seismic influences and environmental disturbances. Here, alternative novel methods are being developed to compensate and reduce the seismic influence. A further reduction of the frequency uncertainty can be envisaged from the refinement of laser cooling. The introduction of optical frequency combs created by mode-locked fs lasers has provided us with a universal tool to determine optical frequencies and optical frequency ratios. This field will certainly be further explored by the development of frequency combs operating continuously over long periods and by increasing the total width of their emission ranges. It is expected that the combination of all these efforts will lead to optical frequency standards and clocks of unprecedented low uncertainty.

Femtosecond

12. Femtosecond Laser Pulses: Linear Properties, Manipulation, Generation and Measurement

In this contribution some basic properties of femtosecond laser pulses are summarized. In Sect. 12.1 we start with the linear properties of ultrashort light pulses. Nonlinear optical effects that would alter the frequency spectrum of an ultrashort pulse are not considered. However, due to the large bandwidth, the linear dispersion is responsible for dramatic effects. For example, a 10 fs laser pulse at a center wavelength of 800 nm propagating through 4 mm of BK7 glass will be temporally broadened to 50 fs. In order to describe and manage such dispersion effects a mathematical description of an ultrashort laser pulse is given first before we continue with methods how to change the temporal shape via the frequency domain. The chapter ends with a paragraph on the powerful technique of pulse shaping, which can be used to create complex-shaped ultrashort laser pulses with respect to phase, amplitude and polarization state.

In Sect. 12.2 the generation of femtosecond laser pulses via mode locking is described in simple physical terms. As femtosecond laser pulses can be generated directly from a wide variety of lasers with wavelengths ranging from the ultraviolet to the infrared no attempt is made to cover the different technical approaches.

Part C | 12

In Sect. 12.3 we deal with the measurement of ultrashort pulses. Traditionally a short event has been characterized with the aid of an even shorter event. This is not an option for ultrashort light pulses. The characterization of ultrashort pulses with respect to amplitude and phase is therefore based on optical correlation techniques that make use of the short pulse itself. Methods operating in the time-frequency domain are especially useful.

A central building block for generating femtosecond light pulses are lasers. Within only two decades of the invention of the laser the duration of the shortest pulse shrunk by six orders of magnitude from the nanosecond regime to the femtosecond regime. Nowadays femtosecond pulses in the range of 10 fs and below can be generated directly from compact and reliable laser oscillators and the temporal resolution of measurements has outpaced the resolution even of modern sampling oscilloscopes by orders of magnitude. With the help of some simple comparisons the incredibly fast femtosecond time scale can be put into perspective: on a logarithmic time scale one minute is approximately half-way between 10 fs and the age of the universe. Taking the speed of light in vacuum into account, a 10 fs light pulse can be considered as a 3 μm thick slice of light whereas a light pulse of one second spans approximately the distance between earth and moon. It is also useful to realize that the fastest molecular vibrations in nature have an oscillation time of about 10 fs.

It is the unique attributes of these light pulses that open up new frontiers both in basic research and for applications. The *ultrashort pulse duration* for example allows the motion of electrons and molecules to be frozen by making use of so-called pump probe techniques that work similar to strobe light techniques. In chemistry complex reaction dynamics have been meas-

ured directly in the time domain and this work was rewarded with the Nobel price in chemistry for A. H. Zewail in 1999. The *broad spectral width* can be used for example in medical diagnostics or – by taking the longitudinal frequency comb mode structure into account – for high-precision optical frequency metrology. The latter is expected to outperform today's state-of-the-art caesium clocks and was rewarded with the 2005 Nobel price in physics for J. L. Hall and T. W. Hänsch. The extreme concentration of a modest energy content in focused femtosecond pulses delivers *high peak intensities* that are used for example in a reversible light matter interaction regime for the development of nonlinear microscopy techniques. The irreversible light matter regime can be for example applied to nonthermal ma-

terial processing leading to precise microstructures in a whole variety of solid state materials. Finally the *high pulse repetition rate* is exploited, for example, in telecommunication applications.

These topics have been reviewed recently in [12.1]. The biannual international conference series *Ultrafast Phenomena* and *Ultrafast Optics*, including the corresponding conference proceedings, cover a broad range of applications and latest developments.

Besides the specific literature given in the individual chapters some textbooks devoted to ultrafast laser pulses are recommended for a more in-depth discussion of the topics presented here and beyond (see, for example, [12.2–5] and especially for the measurement of ultrashort pulses see [12.6]).

12.1 Linear Properties of Ultrashort Light Pulses

12.1.1 Descriptive Introduction

It is quite easy to construct the electric field of a *Gedanken* optical pulse at a fixed position in space, corresponding to the physical situation of a fixed detector in space. Assuming the light field to be linearly polar-

Fig. 12.1a–d Electric field $E(t)$ and temporal amplitude function $A(t)$ for a cosine pulse (**a**), a sine pulse (**b**), an up-chirped pulse (**c**) and a down-chirped pulse (**d**). The pulse duration in all cases is $\Delta t = 5$ fs. For (**c**) and (**d**) the parameter a was chosen to be $\pm 0.15/\text{fs}^2$

ized, we may write the real electric field strength $E(t)$ as a scalar quantity whereas a harmonic wave is multiplied with a temporal amplitude or envelope function $A(t)$

$$E(t) = A(t)\cos(\Phi_0 + \omega_0 t) \tag{12.1}$$

with ω_0 being the carrier circular (or angular) frequency. The light frequency is given by $\nu_0 = \frac{\omega_0}{2\pi}$. In the following, angular frequencies and frequencies are only distinguished from each other via their notation. For illustration we will use optical pulses centered at 800 nm, corresponding to a carrier frequency of $\omega_0 = 2.35$ rad/fs (oscillation period $T = 2.67$ fs) with a Gaussian envelope function (the numbers refer to pulses that are generated by the widely spread femtosecond laser systems based on Ti:sapphire as the active medium). For simple envelope functions the pulse duration Δt is usually defined by the FWHM (full width at half-maximum) of the temporal intensity function $I(t)$

$$I(t) = \frac{1}{2}\varepsilon_0 c n A(t)^2 , \tag{12.2}$$

with ε_0 being the vacuum permittivity, c the speed of light and n the refractive index. The factor $1/2$ arises from averaging the oscillations. If the temporal intensity is given in W/cm^2 the temporal amplitude $A(t)$ (in V/cm for $n = 1$) is given by

$$A(t) = \sqrt{\frac{2}{\varepsilon_0 c}}\sqrt{I(t)} = 27.4\sqrt{I(t)} . \tag{12.3}$$

Figure 12.1a displays $E(t)$ for a Gaussian pulse with $\Delta t = 5$ fs and $\Phi_0 = 0$. At $t = 0$ the electric field strength

reaches its maximum value. This situation is called a cosine pulse: for $\Phi_0 = -\pi/2$ we get a sine pulse $E(t) = A(t)\sin(\omega_0 t)$ (Fig. 12.1b) where the maxima of the carrier oscillations do not coincide with the maximum of the envelope $A(t)$ at $t = 0$ and the maximum value of $E(t)$ is therefore smaller than in a cosine pulse. In general Φ_0 is termed the absolute phase or carrier-envelope phase and determines the temporal relation of the pulse envelope with respect to the underlying carrier oscillation. The absolute phase is not important if the pulse envelope $A(t)$ does not significantly vary within one oscillation period T. The longer the temporal duration of the pulses, the more closely this condition is met and the decomposition of the electric field into an envelope function and a harmonic oscillation with carrier frequency ω_0 (12.1) is meaningful. Conventional pulse characterization methods as described in Sect. 12.3 are not able to measure the absolute value of Φ_0. Furthermore the absolute phase does not remain stable in a conventional femtosecond laser system. Progress in controlling and measuring the absolute phase has been made only recently [12.7–10] and experiments depending on the absolute phase are starting to appear [12.11–13]. In the following we will not emphasize the role of Φ_0 any more.

In general, we may add an additional time dependent phase function $\Phi_a(t)$ to the temporal phase term in (12.1)

$$\Phi(t) = \Phi_0 + \omega_0 t + \Phi_a(t) \tag{12.4}$$

and define the momentary or instantaneous light frequency $\omega(t)$ as

$$\omega(t) = \frac{d\Phi(t)}{dt} = \omega_0 + \frac{d\Phi_a(t)}{dt} . \tag{12.5}$$

This additional phase function describes variations of the frequency in time, called a chirp. In Fig. 12.1c,d $\Phi_a(t)$ is set to be at^2. For $a = 0.15/\text{fs}^2$ we see a linear increase of the frequency in time, called a linear up-chirp. For $a = -0.15/\text{fs}^2$ a linear down-chirped pulse is obtained with a linear decrease of the frequency in time. However, a direct manipulation of the temporal phase cannot be achieved by any electronic device. Note that nonlinear optical processes such as, for example, self-phase modulation (SPM) are able to influence the temporal phase and lead to a change in the frequency spectrum of the pulse. In this chapter we will mainly focus on linear optical effects where the spectrum of the pulse is unchanged and changes in the temporal pulse shape are due to manipulations in the frequency domain (Sect. 12.1.3). Before we start, a more mathematical description of an ultrashort light pulse is presented.

12.1.2 Mathematical Description

For the mathematical description we followed the approaches of [12.4,14–19]. In linear optics the superposition principle holds and the real-valued electric field $E(t)$ of an ultrashort optical pulse at a fixed point in space has the Fourier decomposition into monochromatic waves

$$E(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{E}(\omega)\, e^{i\omega t}\, d\omega . \tag{12.6}$$

The, in general complex-valued, spectrum $\tilde{E}(\omega)$ is obtained by the Fourier inversion theorem

$$\tilde{E}(\omega) = \int_{-\infty}^{\infty} E(t)\, e^{-i\omega t}\, dt . \tag{12.7}$$

Since $E(t)$ is real-valued $\tilde{E}(\omega)$ is Hermitian, i. e., obeys the condition

$$\tilde{E}(\omega) = \tilde{E}^*(-\omega) , \tag{12.8}$$

where $*$ denotes complex conjugation. Hence knowledge of the spectrum for positive frequencies is sufficient for a full characterization of a light field without dc component we can define the positive part of the spectrum as

$$\tilde{E}^+(\omega) = \tilde{E}(\omega) \quad \text{for } \omega \geq 0 \quad \text{and} $$
$$\qquad\qquad 0 \quad \text{for } \omega < 0 . \tag{12.9}$$

The negative part of the spectrum $\tilde{E}^-(\omega)$ is defined as

$$\tilde{E}^-(\omega) = \tilde{E}(\omega) \quad \text{for} \quad \omega < 0 \quad \text{and} $$
$$\qquad\qquad 0 \quad \text{for} \quad \omega \geq 0 . \tag{12.10}$$

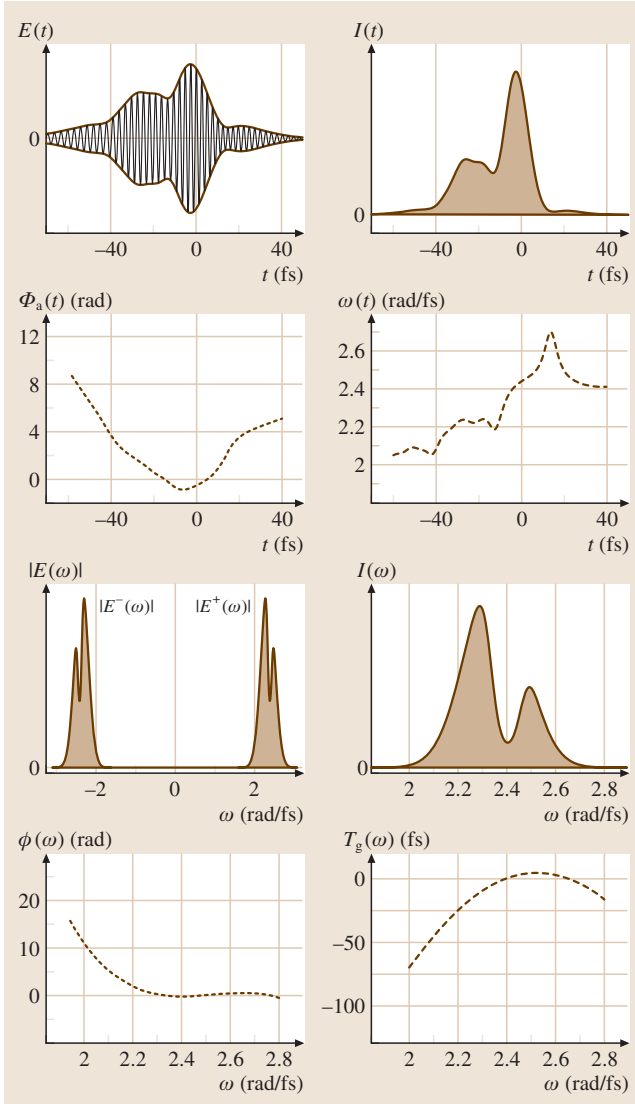
Just as the replacement of real-valued sines and cosines by complex exponentials often simplifies Fourier analysis, so too does the use of complex-valued functions in place of the real electric field $E(t)$. For this purpose we separate the Fourier transform integral of $E(t)$ into two parts. The complex-valued temporal function $E^+(t)$ contains only the positive frequency segment of the spectrum. In communication theory and optics $E^+(t)$ is termed the analytic signal (its complex conjugate is $E^-(t)$ and contains the negative frequency part). By definition $E^+(t)$ and $\tilde{E}^+(\omega)$ as well as $E^-(t)$ and $\tilde{E}^-(\omega)$ are Fourier pairs where only the relations for the


Fig. 12.2 Electric field $E(t)$, temporal intensity $I(t)$, additional temporal phase $\Phi_a(t)$, instantaneous frequency $\omega(t)$, spectrum $|\tilde{E}(\omega)|$, spectral intensity $I(\omega)$, spectral phase $\phi(\omega)$ and group delay $T_g(\omega)$ of a pulse that looks complicated on first glance [having a relatively simple spectral phase $\phi(\omega)$]. When measured with a spectrometer the spectral intensity as a function of wavelength is usually obtained, and the corresponding transformation on the basis of $I(\lambda)\,d\lambda = I(\omega)\,d\omega$ yields $I(\lambda) = -I(\omega)\frac{2\pi c}{\lambda^2}$ where the minus sign indicates the change in the direction of the axis. To avoid phase jumps when the phase exceeds 2π, *phase unwrapping* is employed. That means adding or subtracting 2π to the phase at each discontinuity. When the intensity is close to zero, the phase is meaningless and usually the phase is not plotted in such regions (phase blanking)

positive-frequency part are given as

$$E^+(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{E}^+(\omega)\,e^{i\omega t}\,d\omega \tag{12.11}$$

$$\tilde{E}^+(\omega) = \int_{-\infty}^{\infty} E^+(t)\,e^{-i\omega t}\,dt \;. \tag{12.12}$$

These quantities relate to the real electric field

$$\begin{aligned} E(t) &= E^+(t) + E^-(t) \\ &= 2\,\mathrm{Re}\{E^+(t)\} \\ &= 2\,\mathrm{Re}\{E^-(t)\} \end{aligned} \tag{12.13}$$

and its complex Fourier transform

$$\tilde{E}(\omega) = \tilde{E}^+(\omega) + \tilde{E}^-(\omega) \;. \tag{12.14}$$

$E^+(t)$ is complex-valued and can therefore be expressed uniquely in terms of its amplitude and phase

$$\begin{aligned} E^+(t) &= |E^+(t)|\,e^{i\Phi(t)} \\ &= |E^+(t)|\,e^{i\Phi_0}\,e^{i\omega_0 t}\,e^{i\Phi_a(t)} \\ &= \sqrt{\frac{I(t)}{2\varepsilon_0 c n}}\,e^{i\Phi_0}\,e^{i\omega_0 t}\,e^{i\Phi_a(t)} \\ &= \frac{1}{2}A(t)\,e^{i\Phi_0}\,e^{i\omega_0 t}\,e^{i\Phi_a(t)} \\ &= E_c(t)\,e^{i\Phi_0}\,e^{i\omega_0 t} \end{aligned} \tag{12.15}$$

where the meaning of $A(t)$, Φ_0, ω_0 and $\Phi_a(t)$ is the same as in Sect. 12.1.1 and $E_c(t)$ is the complex-valued envelope function without the absolute phase and without the rapidly oscillating carrier-frequency phase factor, a quantity often used in ultrafast optics. The envelope function $A(t)$ is given by

$$A(t) = 2|E^+(t)| = 2|E^-(t)| = 2\sqrt{E^+(t)E^-(t)} \tag{12.16}$$

and coincides with the less general expression in (12.1). The complex positive-frequency part $\tilde{E}^+(\omega)$ can be analogously decomposed into amplitude and phase

$$\begin{aligned} \tilde{E}^+(\omega) &= |\tilde{E}^+(\omega)|\,e^{-i\phi(\omega)} \\ &= \sqrt{\frac{\pi}{\varepsilon_0 c n}\,I(\omega)}\,e^{-i\phi(\omega)} \;, \end{aligned} \tag{12.17}$$

where $|\tilde{E}^+(\omega)|$ is the spectral amplitude, $\phi(\omega)$ is the spectral phase and $I(\omega)$ is the spectral intensity proportional to the power spectrum density (PSD) – the familiar quantity measured with a spectrometer. From

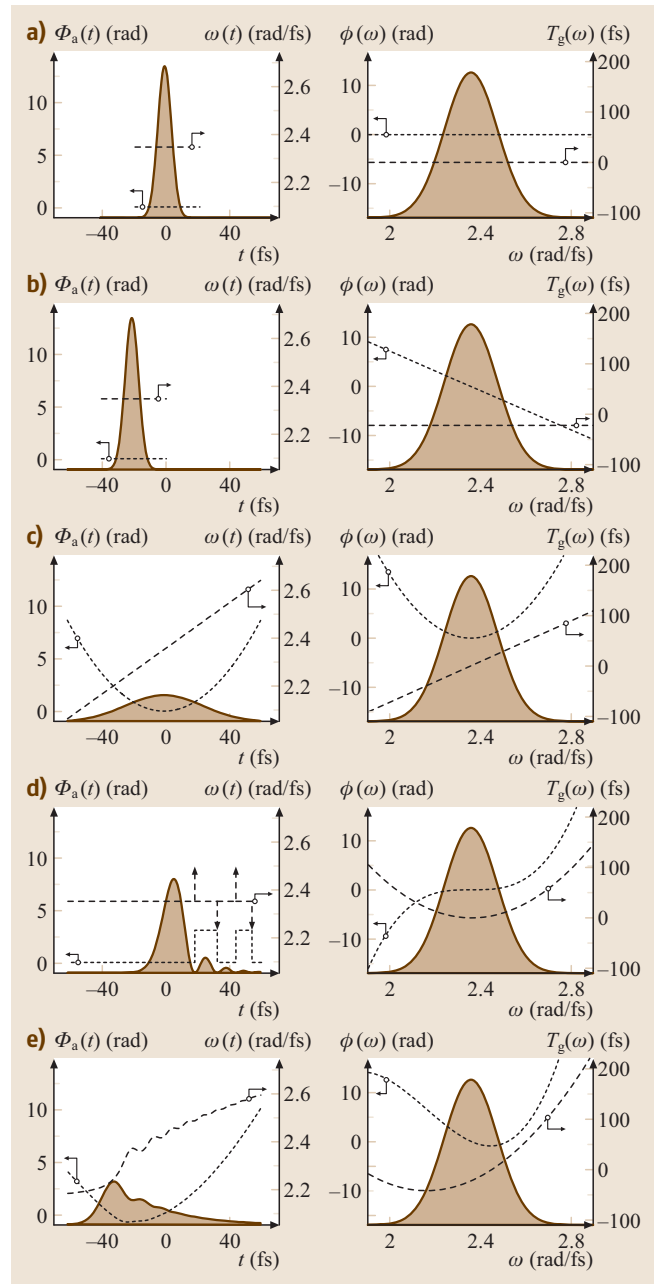
Fig. 12.3a–o Examples for changing the temporal shape of a 800 nm 10 fs pulse via the frequency domain (except (**n**)). *Left*: temporal intensity $I(t)$ (*shaded*), additional temporal phase $\Phi_a(t)$ (*dotted*), instantaneous frequency $\omega(t)$ (*dashed*), *right*: spectral intensity $I(\omega)$ (*shaded*), spectral phase $\phi(\omega)$ (*dotted*) and group delay $T_g(\omega)$ (*dashed*) for a: (**a**) bandwidth-limited Gaussian laser pulse of 10 fs duration; (**b**) bandwidth-limited Gaussian laser pulse of 10 fs duration shifted in time to -20 fs due to a linear phase term in the spectral domain ($\phi' = -20$ fs); (**c**) symmetrical broadened Gaussian laser pulse due to $\phi'' = 200$ fs^2; (**d**) third-order spectral phase ($\phi''' = 1000$ fs^3) leading to a quadratic group delay. The central frequency of the pulse arrives first, while frequencies on either side arrive later. The corresponding differences in frequencies cause beats in the temporal intensity profile. Pulses with cubic spectral phase distortion have therefore oscillations after (or before) a main pulse depending on the sign of ϕ'''. The higher the side pulses, the less meaningful the FWHM pulse duration; (**e**) combined action of all spectral phase coefficients (**a**)–(**d**). Phase unwrapping and blanking is employed when appropriate;

(**f**) π step at the central frequency; (**g**) π step displaced from central frequency; (**h**) sine modulation at central frequency with $\phi(\omega) = 1\sin[20\,\text{fs}(\omega - \omega_0)]$; (**i**) cosine modulation at central frequency with $\phi(\omega) = 1\cos[20\,\text{fs}(\omega - \omega_0)]$; (**j**) sine modulation at central frequency with $\phi(\omega) = 1\sin[30\,\text{fs}(\omega - \omega_0)]$. ▶

Amplitude modulation: (**k**) symmetrical clipping of spectrum; (**l**) blocking of central frequency components; (**m**) off center absorption.

Modulation in time domain: (**n**) self-phase modulation. Note the spectral broadening; (**o**) double pulse with pulse to pulse delay of 60 fs ▶

(12.8) the relation $-\phi(\omega) = \phi(-\omega)$ is obtained. As will be shown in Sect. 12.1.3 it is precisely the manipulation of this spectral phase $\phi(\omega)$ in the experiment which – by virtue of the Fourier transformation (12.11) – creates changes in the real electric field strength $E(t)$ (12.13) without changing $I(\omega)$. If the spectral intensity $I(\omega)$ is manipulated as well, additional degrees of freedom are accessible for generating temporal pulse shapes at the expense of lower energy.

Note that the distinction between positive- and negative-frequency parts is made for mathematical correctness. In practice only real electric fields and positive frequencies are displayed. Moreover, as usually only the shape and not the absolute magnitude of the envelope functions in addition to the phase function are the quantities of interest, all the prefactors are commonly omitted.


The temporal phase $\Phi(t)$ (12.4) contains frequency-versus-time information, leading to the definition of the instantaneous frequency $\omega(t)$ (12.5). In a similar fashion $\phi(\omega)$ contains time-versus-frequency information and we can define the group delay $T_g(\omega)$, which describes the relative temporal delay of a given spectral component

Part C | 12.1

(Sect. 12.1.3).

$$T_g(\omega) = \frac{d\phi}{d\omega} \,. \tag{12.18}$$

All quantities discussed so far are displayed in Fig. 12.2 for a pulse that initially appears to be complex. Usu-

ally the spectral amplitude is distributed around a center frequency (or carrier frequency) ω_0. Therefore – for *well-behaved* pulses – it is often helpful to expand the spectral phase into a Taylor series

$$\phi(\omega) = \sum_{j=0}^{\infty} \frac{\phi^{(j)}(\omega_0)}{j!} \cdot (\omega - \omega_0)^j$$

$$\text{with} \quad \phi^{(j)}(\omega_0) = \left. \frac{\partial^j \phi(\omega)}{\partial \omega^j} \right|_{\omega_0}$$

$$= \phi(\omega_0) + \phi'(\omega_0)(\omega - \omega_0)$$

$$+ \frac{1}{2}\phi''(\omega_0)(\omega - \omega_0)^2$$

$$+ \frac{1}{6}\phi'''(\omega_0)(\omega - \omega_0)^3 + \dots \tag{12.19}$$

The spectral phase coefficient of zeroth order describes in the time domain the absolute phase ($\Phi_0 = -\phi(\omega_0)$). The first-order term leads to a temporal translation of the envelope of the laser pulse in the time domain (the Fourier shift theorem) but not to a translation of the carrier. A positive $\phi'(\omega_0)$ corresponds to a shift towards later times. An experimental distinction between the temporal translation of the envelope via linear spectral phases in comparison to the temporal translation of the whole pulse is, for example, discussed in [12.20,21]. The coefficients of higher order are responsible for changes in the temporal structure of the electric field. The minus sign in front of the spectral phase in (12.17) is chosen so that a positive $\phi''(\omega_0)$ corresponds to a linearly up-chirped laser pulse. For illustrations see Figs. 12.2 and 12.3a–e.

There is a variety of analytical pulse shapes where this formalism can be applied to get analytical expressions in both domains. For general pulse shapes a numerical implementation is helpful. For illustrations we will focus on a Gaussian laser pulse $E_{in}^+(t)$ (not normalized to pulse energy) with a corresponding spectrum $\tilde{E}_{in}^+(\omega)$. Phase modulation in the frequency domain leads to a spectrum $\tilde{E}_{out}^+(\omega)$ with a corresponding electric field $E_{out}^+(t)$ of

$$E_{in}^+(t) = \frac{E_0}{2} e^{-2\ln 2 \frac{t^2}{\Delta t^2}} e^{i\omega_0 t} \,. \tag{12.20}$$

Here Δt denotes the FWHM of the corresponding intensity $I(t)$. The absolute phase is set to zero, the carrier frequency is set to ω_0, additional phase terms are set to zero as well. The pulse is termed an unchirped pulse in the time domain. For $\tilde{E}_{in}^+(\omega)$ we obtain the spectrum

$$\tilde{E}_{in}^+(\omega) = \frac{E_0 \Delta t}{2} \sqrt{\frac{\pi}{2\ln 2}} e^{-\frac{\Delta t^2}{8\ln 2}(\omega - \omega_0)^2} \,. \tag{12.21}$$

The FWHM of the temporal intensity profile $I(t)$ and the spectral intensity profile $I(\omega)$ are related by $\Delta t \Delta \omega = 4 \ln 2$, where $\Delta \omega$ is the FWHM of the spectral intensity profile $I(\omega)$.

Usually this equation, known as the time–bandwidth product, is given in terms of frequencies ν rather than circular frequencies ω and we obtain

$$\Delta t \Delta \nu = \frac{2 \ln 2}{\pi} = 0.441 . \tag{12.22}$$

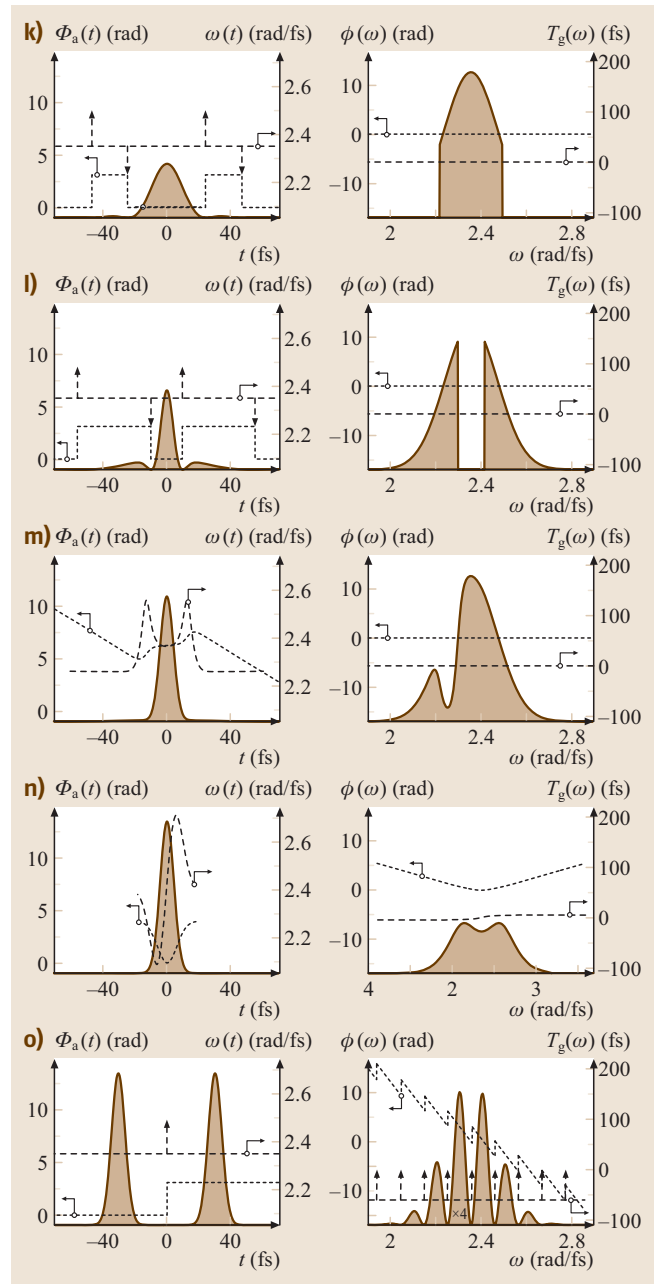
Several important consequences arise from this approach and are summarized before we proceed:

- The shorter the pulse duration, the larger the spectral width. A Gaussian pulse with $\Delta t = 10$ fs centered at 800 nm has a ratio of $\frac{\Delta \nu}{\nu} \approx 10\%$, corresponding to a wavelength interval $\Delta \lambda$ of about 100 nm. Taking into account the wings of the spectrum, a bandwidth comparable to the visible spectrum is "consumed" to create the 10 fs pulse.
- For a Gaussian pulse the equality in (12.22) is only reached when the instantaneous frequency (12.5) is time-independent, that is the temporal phase variation is linear. Such pulses are termed Fourier-transform-limited pulses or bandwidth-limited pulses.
- Adding nonlinear phase terms leads to the inequality $\Delta t \Delta \nu \geq 0.441$.
- For other pulse shapes a similar time-bandwidth inequality can be derived

$$\Delta t \Delta \nu \geq K . \tag{12.23}$$

Values of K for different pulse shapes are given in Table 12.1 and [12.22]

- Sometimes pulse durations and spectral widths defined by the FWHM values are not suitable measures. This is, for example, the case in pulses with substructure or broad wings causing a considerable part of the energy to lie outside the range given by the FWHM. In these cases one can use averaged values derived from the appropriate second-order moments [12.4, 23]. By this it can be shown [12.6, 24, 25] that, for any spectrum, the shortest pulse in time always occurs for a constant spectral phase $\phi(\omega)$. Taking a shift in the time domain also into account a description of a bandwidth-limited pulse is given by

$$\tilde{E}^{+}(\omega) = |\tilde{E}^{+}(\omega)| e^{-i\phi(\omega_0)} e^{-i\phi'(\omega_0)(\omega-\omega_0)} .$$


One feature of Gaussian laser pulses is that adding the quadratic term $\frac{1}{2}\phi''(\omega_0)(\omega-\omega_0)^2$ to the spectral phase function also leads to a quadratic term in the temporal phase function and therefore to linearly chirped pulses. This situation arises for example when passing an optical pulse through a transparent medium as will be

Table 12.1 Temporal and spectral intensity profiles and time bandwidth products ($\Delta \nu \Delta t \geq K$) of various pulse shapes; $\Delta \nu$ and Δt are FWHM quantities of the corresponding intensity profiles. The ratio $\Delta t_{\text{intAC}}/\Delta t$, where Δt_{intAC} is the FWHM of the intensity autocorrelation with respect to background (Sect. 12.3.2), is also given. In the following formulas employed in the calculations we set $\omega_0 = 0$ for simplicity.

Gaussian:

$$E^+(t) = \frac{E_0}{2} e^{-2\ln 2 \left(\frac{t}{\Delta t}\right)^2}$$

$$\tilde{E}^+(\omega) = \frac{E_0 \Delta t}{2} \sqrt{\frac{\pi}{2\ln 2}} e^{-\frac{\Delta t^2}{8\ln 2}\omega^2} ,$$

Sech:

$$E^+(t) = \frac{E_0}{2} \text{sech}\left[2\ln\left(1+\sqrt{2}\right)\frac{t}{\Delta t}\right]$$

$$\tilde{E}^+(\omega) = E_0 \Delta t \frac{\pi}{4\ln\left(1+\sqrt{2}\right)}$$

$$\times \text{sech}\left(\frac{\pi \Delta t}{4\ln\left(1+\sqrt{2}\right)}\omega\right) ,$$

Rect:

$$E^+(t) = \frac{E_0}{2} \quad t \in \left[-\frac{\Delta t}{2}, \frac{\Delta t}{2}\right], \text{ 0 elsewhere}$$

$$\tilde{E}^+(\omega) = \frac{E_0 \Delta t}{2} \text{sinc}\left(\frac{\Delta t}{2}\omega\right) ,$$

Single sided Exp.:

$$E^+(t) = \frac{E_0}{2} e^{-\frac{\ln 2}{2}\frac{t}{\Delta t}} \quad t \in [0, \infty], \text{ 0 elsewhere}$$

$$\tilde{E}^+(\omega) = \frac{E_0 \Delta t}{2i\Delta t\, \omega + \ln 2} ,$$

Symmetric Exp.:

$$E^+(t) = \frac{E_0}{2} e^{-\ln 2 \frac{t}{\Delta t}}$$

$$\tilde{E}^+(\omega) = \frac{E_0 \Delta t \ln 2}{\Delta t^2 \omega^2 + (\ln 2)^2} .$$

20	24.3	34.2	72.1	140.1	278.0	554.9	1109.2
40	40.6	42.3	52.9	80.0	144.3	280.1	556.0
80	80.1	80.3	81.9	87.2	105.9	160.1	288.6
160	160.0	160.0	160.2	160.9	163.9	174.4	211.7

shown in Sect. 12.1.3. The complex fields for such laser pulses are given by [12.26, 27]

$$\tilde{E}^+_{\text{out}}(\omega) = \frac{E_0 \Delta t}{2}$$
$$\times \sqrt{\frac{\pi}{2 \ln 2}} \, e^{-\frac{\Delta t^2}{8 \ln 2}(\omega - \omega_0)^2} \, e^{-i\frac{1}{2}\phi''(\omega_0)(\omega - \omega_0)^2} \tag{12.24}$$

$$E^+_{\text{out}}(t) = \frac{E_0}{2\gamma^{\frac{1}{4}}} \, e^{-\frac{t^2}{4\beta\gamma}} \, e^{i\omega_0 t} \, e^{i(at^2 - \varepsilon)} \tag{12.25}$$

with

$$\beta = \frac{\Delta t_{\text{in}}^2}{8 \ln 2} \quad \gamma = 1 + \frac{\phi''^2}{4\beta^2} \quad a = \frac{\phi''}{8\beta^2\gamma}$$

and

$$\varepsilon = \frac{1}{2}\arctan\left(\frac{\phi''}{2\beta}\right) = -\Phi_0 \, .$$

For the pulse duration Δt_{out} (FWHM) of the linearly chirped pulse (quadratic temporal phase function at^2) we obtain the convenient formula

$$\Delta t_{\text{out}} = \sqrt{\Delta t^2 + \left(4 \ln 2 \frac{\phi''}{\Delta t}\right)^2} \, . \tag{12.26}$$

The statistical definition of the pulse duration derived with the help of the second moment of the intensity distribution uses twice the standard deviation σ to characterize the pulse duration by

$$2\sigma = \frac{\Delta t_{\text{out}}}{\sqrt{2 \ln 2}} \, , \tag{12.27}$$

which is slightly shorter than the FWHM. These values are exact for Gaussian pulses considering only the ϕ'' part and can be used as a first estimate for temporal pulse broadening whenever ϕ'' effects are the dominant contribution (Sect. 12.1.3). Some values of the symmet-

ric pulse broadening due to ϕ'' are given in Table 12.2 and exemplified in Fig. 12.3c.

Spectral phase coefficients of third order, i.e., a contribution to the phase function $\phi(\omega)$ of the form $\frac{1}{6}\phi'''(\omega_0) \cdot (\omega - \omega_0)^3$ are referred to as third-order dispersion (TOD). TOD applied to the spectrum given by (12.21) yields the phase-modulated spectrum

$$\tilde{E}^+_{\text{out}}(\omega) = \frac{E_0 \Delta t}{2}$$
$$\times \sqrt{\frac{\pi}{2 \ln 2}} \, e^{-\frac{\Delta t^2}{8 \ln 2}(\omega - \omega_0)^2} \, e^{-i\frac{1}{6}\phi'''(\omega_0) \cdot (\omega - \omega_0)^3} \tag{12.28}$$

and leads to asymmetric temporal pulse shapes [12.27] of the form

$$E^+_{\text{out}}(t) = \frac{E_0}{2}\sqrt{\frac{\pi}{2 \ln 2}}\frac{\Delta t}{\tau_0} Ai\left(\frac{\tau - t}{\Delta \tau}\right) e^{-\frac{\ln 2}{2} \cdot \frac{\frac{2}{3}\tau - t}{\tau_{1/2}}} e^{i\omega_0 t}$$
$$\text{with } \tau_0 = \sqrt[3]{\frac{|\phi'''|}{2}} \quad \phi^3 = 2(\ln 2)^2 \phi'''$$
$$\Delta \tau = \tau_0 \, \text{sign}(\phi''')$$
$$\tau = \frac{\Delta t^4}{16\phi^3} \quad \text{and} \quad \tau_{1/2} = \frac{\phi^3}{\Delta t^2} \tag{12.29}$$

where Ai describes the Airy function. Equation (12.29) shows that the temporal pulse shape is given by the product of an exponential decay with a half-life period of $\tau_{1/2}$ and the Airy function shifted by τ and stretched by $\Delta \tau$. Figure 12.3d shows an example of a pulse subjected to TOD. The pulse shape is characterized by a strong initial pulse followed by a decaying pulse sequence. Because TOD leads to a quadratic group delay the central frequency of the pulse arrives first, while frequencies on either side arrive later. The corresponding differences in frequencies cause beats in the temporal intensity profile explaining the oscillations after (or before) the main

Table 12.3 Dispersion parameters n, $\frac{dn}{d\lambda}$, $\frac{d^2n}{d\lambda^2}$, $\frac{d^3n}{d\lambda^3}$, T_g, GDD and TOD for common optical materials for $L = 1$ mm. pulse. The beating is also responsible for the phase jumps of π which occur at the zeros of the Airy function. Most of the relevant properties of TOD modulation are determined by the parameter $\Delta\tau$, which is proportional to $\sqrt[3]{|\phi'''|}$. The ratio $\Delta\tau/\Delta t$ determines whether the pulse is significantly modulated. If $|\Delta\tau/\Delta t| \geq 1$, a series of sub-pulses and phase jumps are observed. The sign of ϕ''' controls the time direction of the pulse shape: a positive value of ϕ''' leads to a series of post-pulses as shown in Fig. 12.3d whereas negative values of ϕ''' cause a series of pre-pulses. The time shift of the most intense sub-pulse with respect to the unmodulated pulse and the FWHM of the sub-pulses are on the order of $\Delta\tau$. For these highly asymmetric pulses, the FWHM is not a meaningful quantity to characterize the pulse duration. Instead, the statistical definition of the pulse duration

yields a formula similar to (12.26) and (12.27)

$$2\sigma = \sqrt{\frac{\Delta t^2}{2\ln 2} + 8(\ln 2)^2 \left(\frac{\phi'''}{\Delta t^2}\right)^2}. \tag{12.30}$$

It is a general feature of polynomial phase modulation functions that the statistical pulse duration of a modulated pulse is

$$2\sigma = \sqrt{\tau_1^2 + \tau_2^2}, \tag{12.31}$$

where $\tau_1 = \frac{\Delta t}{\sqrt{2\ln 2}}$ is the statistical duration of the unmodulated pulse [cf. (12.21)] and $\tau_2 \propto \frac{\phi^{(n)}}{\Delta t^{n-1}}$ a contribution only dependent on the nth-order spectral phase coefficient. As a consequence, for strongly modulated pulses, when $\tau_2 \gg \tau_1$, the statistical pulse duration increases approximately linearly with $\phi^{(n)}$.

It is not always advantageous to expand the phase function $\phi(\omega)$ into a Taylor series. Periodic phase functions, for example, are generally not well approximated by polynomial functions. For sinusoidal phase functions of the form $\phi(\omega) = A \sin(\omega \Upsilon + \varphi_0)$ analytic solutions for the temporal electric field can be found for any arbitrary unmodulated spectrum $\tilde{E}_{in}^+(\omega)$. To this end we consider the modulated spectrum (see also Sect. 12.1.3)

$$\tilde{E}_{out}^+(\omega) = \tilde{E}_{in}^+(\omega) e^{-iA \sin(\omega \Upsilon + \varphi_0)} , \qquad (12.32)$$

where A describes the amplitude of the sinusoidal modulation, Υ the frequency of the modulation function (in units of time) and φ_0 the absolute phase of the sine function. Making use of the Jacobi–Anger identity

$$e^{-A \sin(\omega \Upsilon + \varphi_0)} = \sum_{n=-\infty}^{\infty} J_n(A) e^{-in(\omega \Upsilon + \varphi_0)} , \qquad (12.33)$$

where $J_n(A)$ describes the Bessel function of the first kind and order n, we rewrite the phase modulation function

$$\tilde{M}(\omega) = \sum_{n=-\infty}^{\infty} J_n(A) e^{-in(\omega \Upsilon + \varphi_0)} \qquad (12.34)$$

to obtain its Fourier transform

$$M(t) = \sum_{n=-\infty}^{\infty} J_n(A) e^{-in \varphi_0} \delta(n\Upsilon - t) , \qquad (12.35)$$

where $\delta(t)$ describes the delta function. Since multiplication in the frequency domain corresponds to convolution in the time domain, the modulated temporal electrical field $E_{out}^+(t)$ is given by the convolution of the unmodulated field $E_{in}^+(t)$ with the Fourier transform of the modulation function $M(t)$, i.e., $E_{out}^+(t) = E_{in}^+(t) * M(t)$. Making use of (12.35) the modulated field reads

$$E_{out}^+(t) = \sum_{n=-\infty}^{\infty} J_n(A) E_{in}^+(t - n\Upsilon) e^{-in \varphi_0} . \qquad (12.36)$$

Equation (12.36) shows that sinusoidal phase modulation in the frequency domain produces a sequence of sub-pulses with a temporal separation determined by the parameter Υ and well-defined relative temporal phases controlled by the absolute phase φ_0. Provided the individual sub-pulses are temporally separated, i. e., Υ is chosen to exceed the pulse width, the envelope of each sub-pulse is a (scaled) replica of the unmodulated pulse envelope. The amplitudes of the sub-pulses are given by

$J_n(A)$ and can therefore be controlled by the modulation parameter A. Examples of sinusoidal phase modulation are shown in Fig. 12.3h–j. The influence of the absolute phase φ_0 is depicted in Fig. 12.3h and i, whereas Fig. 12.3j shows how separated pulses are obtained by changing the modulation frequency Υ. A detailed description of the effect of sinusoidal phase modulation can be found in [12.28].

12.1.3 Changing the Temporal Shape via the Frequency Domain

For the following discussion it is useful to think of an ultrashort pulse as being composed of groups of quasi-monochromatic waves, that is of a set of much longer wave packets of narrow spectrum all added together coherently. In vacuum the phase velocity $v_p = \omega/k$ and the group velocity $v_g = d\omega/dk$ are both constant and equal to the speed of light c, where k denotes the wave number. Therefore an ultrashort pulse – no matter how complicated its temporal electric field is – will maintain its shape upon propagation in vacuum. In the following we will always consider a bandwidth-limited pulse entering an optical system such as, for example, air, lenses, mirrors, prisms, gratings and combinations of these optical elements. Usually these optical systems will introduce dispersion, that is a different group velocity for each group of quasi-monochromatic waves, and consequently the initial short pulse will broaden in time. In this context the group delay $T_g(\omega)$ defined in (12.18) is the transit time for such a group of monochromatic waves through the system. As long as the intensities are kept low, no new frequencies are generated. This is the area of linear optics and the corresponding pulse propagation has been termed linear pulse propagation. It is convenient to describe the passage of an ultrashort pulse through a linear optical system by a complex optical transfer function [12.4, 25, 29]

$$\tilde{M}(\omega) = \tilde{R}(\omega) e^{-i\phi_d} , \qquad (12.37)$$

that relates the incident electric field $\tilde{E}_{in}^+(\omega)$ to the output field

$$\tilde{E}_{out}^+(\omega) = \tilde{M}(\omega) \tilde{E}_{in}^+(\omega) = \tilde{R}(\omega) e^{-i\phi_d} \tilde{E}_{in}^+(\omega) , \qquad (12.38)$$

where $\tilde{R}(\omega)$ is the real-valued spectral amplitude response describing for example the variable diffraction efficiency of a grating, linear gain or loss or direct amplitude manipulation. The phase $\phi_d(\omega)$ is termed the spectral phase transfer function. This is the phase ac-

cumulated by the spectral component of the pulse at frequency ω upon propagation between the input and output planes that define the optical system. It is this spectral phase transfer function that plays a crucial role in the design of ultrafast optical systems. Note that this approach is more involved when additional spatial coordinates have to be taken into account as, for example, in the case of *spatial chirp* (i.e., each frequency is displaced in the transverse spatial coordinates). Neglecting spatial chirp this approach can be taken as a first-order analysis of ultrafast optical systems. Although inside an optical system this condition might not be met, usually at the input and output all frequencies are assumed to be spatially overlapped for this kind of analysis. Note also that the independence of the different spectral components in this picture does not mean that the phase relations are random – they are uniquely defined with respect to each other. That means that the corresponding pulse in the time domain (by making use of (12.11) and (12.13)) is completely coherent [12.30] no matter how complicated the shape of the femtosecond laser pulse appears. In the first-order autocorrelation function a coherence time of the corresponding bandwidth-limited pulse would be observed. Only in the higher-order autocorrelations the uniquely defined phase relations show up (examples of second-order autocorrelations for phase- and amplitude-shaped laser pulses are given in Fig. 12.28). Figure 12.3f–j exemplifies the temporal intensity, spectral intensity and related phase functions for often employed phase functions. Figure 12.3k–m displays the same quantities for amplitude modulation. Figure 12.3n is an example for self-phase modulation and Fig. 12.3o shows a double pulse with pulse to pulse delay of 60 fs.

In the following discussion we will concentrate mainly on pure phase modulation and therefore set $\tilde{R}(\omega)$ constant for all frequencies and omit it initially. To model the system the most accurate approach is to include the whole spectral phase transfer function. Often however only the first orders of a Taylor expansion around the central frequency ω_0 are needed.

$$
\begin{aligned}
\phi_d(\omega) = {} & \phi_d(\omega_0) + \phi'_d(\omega_0)(\omega - \omega_0) \\
& + \frac{1}{2}\phi''_d(\omega_0)(\omega - \omega_0)^2 \\
& + \frac{1}{6}\phi'''_d(\omega_0)(\omega - \omega_0)^3 + \dots
\end{aligned}
\tag{12.39}
$$

If we describe the incident bandwidth-limited pulse by $\tilde{E}_{\mathrm{in}}^+(\omega) = |\tilde{E}^+(\omega)|\,\mathrm{e}^{-\mathrm{i}\phi(\omega_0)}\,\mathrm{e}^{-\mathrm{i}\phi'(\omega_0)(\omega-\omega_0)}$ then the over-

all phase ϕ_{op} of $\tilde{E}_{\mathrm{out}}^+(\omega)$ is given by

$$
\begin{aligned}
\phi_{\mathrm{op}}(\omega) = {} & \phi(\omega_0) + \phi'(\omega_0)(\omega - \omega_0) \\
& + \phi_d(\omega_0) + \phi'_d(\omega_0)(\omega - \omega_0) \\
& + \frac{1}{2}\phi''_d(\omega_0)(\omega - \omega_0)^2 \\
& + \frac{1}{6}\phi'''_d(\omega_0)(\omega - \omega_0)^3 + \dots
\end{aligned}
\tag{12.40}
$$

As discussed in the context of (12.19) the constant and linear terms do not lead to a change of the temporal envelope of the pulse. Therefore we will omit in the following these terms and concentrate mainly on the second-order dispersion ϕ'' [also termed the group velocity dispersion (GVD) or group delay dispersion (GDD)] and the third-order dispersion ϕ''' (TOD) whereas we have omitted the subscript d. Strictly they have units of [fs^2/rad] and [fs^3/rad^2], respectively, but usually the units are simplified to [fs^2] and [fs^3].

A main topic in the design of ultrafast laser systems is the minimization of these higher dispersion terms with the help of suitably designed optical systems to keep the pulse duration inside a laser cavity or at the place of an experiment as short as possible. In the following we will discuss the elements that are commonly used for the *dispersion management*.

Dispersion due to Transparent Media

A pulse traveling a distance L through a medium with index of refraction $n(\omega)$ accumulates the spectral phase

$$
\phi_{\mathrm{m}}(\omega) = k(\omega)L = \frac{\omega}{c}n(\omega)L \, ,
\tag{12.41}
$$

which is the spectral transfer function due to propagation in the medium as defined above.

The first derivative

$$
\frac{\mathrm{d}\phi_{\mathrm{m}}}{\mathrm{d}\omega} = \phi'_{\mathrm{m}} = \frac{\mathrm{d}(kL)}{\mathrm{d}\omega} = L\left(\frac{\mathrm{d}\omega}{\mathrm{d}k}\right)^{-1} = \frac{L}{v_{\mathrm{g}}} = T_{\mathrm{g}}
\tag{12.42}
$$

yields the group delay T_{g} and describes the delay of the peak of the envelope of the incident pulse. Usually the index of refraction $n(\omega)$ is given as a function of wavelength λ, i.e., $n(\lambda)$. Equation (12.42) then reads

$$
T_{\mathrm{g}} = \frac{\mathrm{d}\phi_{\mathrm{m}}}{\mathrm{d}\omega} = \frac{L}{c}\left(n + \omega\frac{\mathrm{d}n}{\mathrm{d}\omega}\right) = \frac{L}{c}\left(n - \lambda\frac{\mathrm{d}n}{\mathrm{d}\lambda}\right) .
\tag{12.43}
$$

As different groups of the quasi-monochromatic waves move with different group velocities the pulse will

be broadened. For second-order dispersion we obtain the group delay dispersion (GDD)

$$
\begin{aligned}
\text{GDD} = \phi''_\text{m} &= \frac{d^2\phi_\text{m}}{d\omega^2} = \frac{L}{c}\left(2\frac{dn}{d\omega} + \omega\frac{d^2n}{d\omega^2}\right) \\
&= \frac{\lambda^3 L}{2\pi c^2}\frac{d^2n}{d\lambda^2}\,.
\end{aligned}
\tag{12.44}
$$

For ordinary optical glasses in the visible range we encounter normal dispersion, i.e., red parts of the laser pulse will travel faster through the medium than blue parts. So the symmetric temporal broadening of the pulse due to ϕ'' will lead to a linearly up-chirped laser pulse as discussed in the context of (12.19) and Fig. 12.3c. In these cases the curvature of $n(\lambda)$ is positive (upward concavity) emphasizing the terminology that positive GDD leads to up-chirped pulses.

For the third-order dispersion (TOD) we obtain

$$
\begin{aligned}
\text{TOD} = \phi'''_\text{m} &= \frac{d^3\phi_\text{m}}{d\omega^3} = \frac{L}{c}\left(3\frac{d^2n}{d\omega^2} + \omega\frac{d^3n}{d\omega^3}\right) \\
&= \frac{-\lambda^4 L}{4\pi^2 c^3}\left(3\frac{d^2n}{d\lambda^2} + \lambda\frac{d^3n}{d\lambda^3}\right).
\end{aligned}
\tag{12.45}
$$

Empirical formulas for $n(\lambda)$ such as Sellmeier's equations are usually tabulated for common optical materials so that all dispersion quantities in (12.43–12.45) can be calculated. Parameters for some optical materials are given in Table 12.3 for $L = 1$ mm.

Note that in fiber optics a slightly different terminology is used [12.25]. There the second-order dispersion is the dominant contribution to pulse broadening. The β parameter of a fiber is related to the second-order dispersion by

$$
\beta = \frac{\left.\frac{d^2\phi_\text{m}}{d\omega^2}\right|_{\omega_0}}{L}\left[\frac{\text{ps}^2}{\text{km}}\right],
\tag{12.46}
$$

where L denotes the length of the fiber. The dispersion parameter D is a measure for the group delay dispersion per unit bandwidth and is given by

$$
D = \frac{\omega_0^2}{2\pi c}|\beta|\left[\frac{\text{ps}}{\text{nm km}}\right].
\tag{12.47}
$$

Angular Dispersion

Transparent media in the optical domain possess positive group delay dispersion leading to up-chirped femtosecond pulses. To compress these pulses, optical systems are needed that deliver negative group delay dispersion, that is systems where the blue spectral components travel faster than the red spectral components. Convenient devices for that purpose are based on angular dispersion delivered by prisms and gratings. We start our discussion again with the spectral transfer function [12.4]

$$
\phi(\omega) = \frac{\omega}{c}P_\text{op}(\omega)\,,
\tag{12.48}
$$

where P_op denotes the optical path length. Equation (12.48) is the generalization of (12.41). The group delay dispersion is given by

$$
\frac{d^2\phi}{d\omega^2} = \frac{1}{c}\left(2\frac{dP_\text{op}}{d\omega} + \omega\frac{d^2P_\text{op}}{d\omega^2}\right) = \frac{\lambda^3}{2\pi c^2}\frac{d^2P_\text{op}}{d\lambda^2}
\tag{12.49}
$$

and is similar to (12.44). In a dispersive system the optical path from an input reference plane to an output reference plane can be written

$$
P_\text{op} = l\cos\alpha\,,
\tag{12.50}
$$

where $l = l(\omega_0)$ is the distance from the input plane to the output plane for the center frequency ω_0 and α is the angle of rays with frequency ω with respect to the ray corresponding to ω_0. In general, it can be shown [12.4] that the angular dispersion produces negative group delay dispersion

$$
\frac{d^2\phi}{d\omega^2} \approx -\frac{l\omega_0}{c}\left(\left.\frac{d\alpha}{d\omega}\right|_{\omega_0}\right)^2.
\tag{12.51}
$$
Fig. 12.4a,b Prism sequences for adjustable group delay dispersion. **(a)** Two-prism sequence in double-pass configuration **(b)** four-prism sequence. Note that the spatial distribution of the frequency (spatial chirp) after the second prism can be exploited for phase and/or amplitude manipulations

For pairs of elements (prisms or gratings) the first element provides the angular dispersion and the second element recollimates the spectral components (see, for example, Fig. 12.4). Using two pairs of elements permits the lateral displacement of the spectral components (spatial chirp) to be canceled out and recovers the original beam profile.

Prism Sequences. Prism pairs [12.31] are well suited to introduce adjustable group delay dispersion (Fig. 12.4). Negative group delay dispersion is obtained via the angular dispersion of the first prism where the second prism is recollimating the beam. Recovering the original beam can be accomplished by either using a second pair of prisms or by using a mirror. Inside a laser cavity one can use either the four-prism arrangement or the two-prism arrangement for linear cavities together with a retroreflecting mirror. Outside a laser cavity the two-prism arrangement is often used, where the retroreflecting mirror is slightly off-axis to translate the recovered beam at the entrance of the system to be picked of by an additional mirror. There is also positive group delay dispersion in the system due to the material dispersion of the actual glass path the laser beam takes through the prism sequence. By translating one of the prisms along its axis of symmetry it is possible to change the amount of glass and therefore the amount of positive group delay dispersion. These devices allow a convenient continuous tuning of group delay dispersion from negative to positive values without beam deviation. The negative group delay dispersion via the angular dispersion can be calculated with the help of (12.48) and (12.50). In the case of minimum deviation and with the apex angle chosen so that the Brewster condition is satisfied (minimum reflection losses), the spectra phase introduced by a four-prism sequence $\phi_p(\omega)$ can be used to approximate the group delay dispersion by [12.4]

$$\frac{d^2\phi_p}{d\omega^2} \approx -\frac{4l_p\lambda^3}{\pi c^2}\left(\frac{dn}{d\lambda}\right)^2 \tag{12.52}$$

and the corresponding third-order dispersion yields approximately

$$\frac{d^3\phi_p}{d\omega^3} \approx \frac{6l_p\lambda^4}{\pi^2 c^3}\frac{dn}{d\lambda}\left(\frac{dn}{d\lambda} + \lambda\frac{d^2n}{d\lambda^2}\right). \tag{12.53}$$

In order to determine the total GDD and TOD of the four-prism sequence the corresponding contributions of the cumulative mean glass path L (12.44, 12.45) have to be added

$$\frac{d^2\phi_{four-prism}}{d\omega^2} \approx \frac{d^2\phi_m}{d\omega^2} + \frac{d^2\phi_p}{d\omega^2}$$
$$= \frac{\lambda^3 L}{2\pi c^2}\frac{d^2n}{d\lambda^2} - \frac{4l_p\lambda^3}{\pi c^2}\left(\frac{dn}{d\lambda}\right)^2, \tag{12.54}$$

$$\frac{d^3\phi_{four-prism}}{d\omega^3} \approx \frac{d^3\phi_m}{d\omega^3} + \frac{d^3\phi_p}{d\omega^3}$$
$$= \frac{-\lambda^4 L}{4\pi^2 c^3}\left(3\frac{d^2n}{d\lambda^2} + \lambda\frac{d^3n}{d\lambda^3}\right)$$
$$+ \frac{6l_p\lambda^4}{\pi^2 c^3}\frac{dn}{d\lambda}\left(\frac{dn}{d\lambda} + \lambda\frac{d^2n}{d\lambda^2}\right). \tag{12.55}$$

For a more-detailed discussion and other approaches to the derivation of the total GDD and TOD for a prism sequence see [12.31–35].

In principle one can get any amount of negative group velocity using this method. However a prism distance exceeding 1 m is often impractical. Higher amounts of positive group delay dispersion might be compensated for by the use of highly dispersive SF10 prisms but the higher third-order contribution prevent the generation of ultrashort pulses in the 10 fs regime. Fused quartz is a suitable material for ultrashort pulse generation with minimal higher-order dispersion. For example a four-prism sequence with $l_p = 50$ cm of fused quartz used at 800 nm yields roughly $\frac{d^2\phi_p}{d\omega^2} \approx -1000$ fs^2. Estimating a cumulative glass path of $L = 8$ mm when going through the apexes of the prisms yields $\frac{d^2\phi_m}{d\omega^2} \approx 300$ fs^2. In this way a maximum group delay dispersion of +700 fs^2 can be compensated.

Note that in such prism sequences the spatial distribution of the frequency components after the second prism can be exploited. Simple apertures can be used to tune the laser or to restrict the bandwidth. Appropriate phase or amplitude masks might be inserted as well.

Grating Arrangements. Diffraction gratings provide group delay dispersion in a similar manner to prisms. Suitable arrangements can introduce positive as well as negative group delay dispersion (see below). When introducing negative group delay dispersion the corresponding device is termed a *compressor*, while a device introducing positive group delay dispersion is termed a *stretcher*. Grating arrangements have the advantage of being much more dispersive but the disadvantage of introducing higher losses than prism arrangements. As intracavity elements they are used, for example, in

high-gain fiber lasers. Outside laser cavities gratings are widely used:

- To compensate for large amounts of dispersion in optical fibers;
- For ultrashort pulse amplification up to the petawatt regime with a technique called chirped pulse amplification (CPA) [12.36]: In order to avoid damage to the optics and to avoid nonlinear distortion of the spatial and temporal profile of the laser beam, ultrashort pulses (10 fs to 1 ps) are typically stretched in time by a factor of $10^3 – 10^4$ prior to injection into the amplifier. After the amplification process the pulses have to be recompressed, compensating also for additional phase accumulated during the amplification process. The topic is reviewed in [12.37];
- For pulse-shaping applications (Sect. 12.1.3);
- In combination with prism compressors to compensate third-order dispersion terms in addition to the group delay dispersion [12.38]. This was the combination employed to establish the long standing world record of 6 fs with dye lasers in 1987 [12.39].

In Fig. 12.5 the reflection of a laser beam from a grating is displayed. The spectrum of an ultrashort laser pulse will be decomposed after reflection into the first order according to the grating equation

$$\sin (\gamma) + \sin (\theta) = \frac{\lambda}{d} \, , \tag{12.56}$$

where γ is the angle of incidence, θ is the angle of the reflected wavelength component and d^{-1} is the grating constant. Blazed diffraction gratings have maximum transmission efficiency when employed in the Littrow
Fig. 12.5 Reflection from a grating: the spectrum of an ultrashort laser pulse will be decomposed after reflection ($\gamma =$ angle of incidence, $\theta(\lambda) =$ angle of reflection, $d^{-1} =$ grating constant)
Fig. 12.6 Grating compressor with parallel gratings and a mirror for beam inversion (cf. the corresponding prism setup in Fig. 12.4a). The red spectral components travel a longer optical path than the blue spectral components (l_g denotes the distance between the grating; l_0 denotes the optical path for the center wavelength λ_0 between two gratings; both lengths are used by different authors in deriving the group delay dispersion and the third order dispersion)

configuration, i.e., $\gamma = \theta(\lambda_0) =$ blaze angle. This has the additional advantage that astigmatism is minimized. Blazed gold gratings with an efficiency of 90–95% are commercially available with a damage threshold of $> 250 \, \mathrm{mJ/cm^2}$ for a 1 ps pulse. For higher efficiency and higher damage threshold dielectric gratings have been developed, for example, dielectric gratings with 98% efficiency at 1053 nm and a damage threshold $> 500 \, \mathrm{mJ/cm^2}$ for fs pulses are available.

A basic grating compressor (Fig. 12.6) consists of two parallel gratings in a double-pass configuration [12.40]. The first grating decomposes the ultrashort laser pulse into its spectral components. The second grating is recollimating the beam. The original beam is recovered by use of a mirror that inverts the beam. As in such a device the red spectral components experience a longer optical path than the blue spectral components, such an arrangement is suitable to compensate for material dispersion.

In Fig. 12.7 different grating configurations are displayed that produce: (a) zero, (b) positive and (c) negative group delay dispersion. Between the gratings an additional telescope is employed.

In Fig. 12.7a, a so-called zero-dispersion compressor is depicted. The system consists of a telescope that
Fig. 12.7a–c Different grating configurations that produce (**a**) zero, (**b**) positive and (**c**) negative group delay dispersion. Arrangement (**a**) corresponds to a zero-dispersion compressor, (**b**) to a stretcher and (**c**) to a compressor. The zero-dispersion compressor is often used in pulse-shaping devices. The *dashed line* in (**a**) indicates the Fourier-transform plane, whereas the stretcher and compressor are key components for chirped pulse amplification

images the laser spot on the first grating onto the second grating. All wavelength components experience the same optical path. In this manner zero net dispersion is obtained. Due to the finite beam size on the grating the components belonging to the same wavelength emerge as a parallel beam and are focused with the lens of focal length f spectrally into the symmetry plane thus providing a Fourier transform plane for pulse shaping, masking or encoding (Sect. 12.1.3 and Fig. 12.11).

Translating one of the gratings out of the focal plane closer to the telescope (Fig. 12.7b) results in an arrangement where the red components travel along a shorter optical path. The device introduces positive group delay dispersion (stretcher).

A compressor is realized by translating the grating away from the focal plane. (Fig. 12.7c).

The dispersion can be further modified by the use of a magnifying telescope. In order to avoid material dispersion in the lenses and to minimize aberration effects, reflective telescopes and especially Öffner telescopes are usually employed [12.41, 42].

The phase transfer function ϕ_g for these arrangements can be calculated with the help of a matrix formalism [12.43] and considering the case of finite beam size [12.44].

For a reflective setup (neglecting material dispersion) the group delay dispersion and the third-order dispersion of the three telescope arrangements (magnification = 1) in Fig. 12.7 can be described using a characteristic length L

$$\frac{d^2\phi_g}{d\omega^2} = -\frac{\lambda^3}{\pi c^2 d^2} \frac{1}{\cos[\theta(\lambda)]^2} L , \qquad (12.57)$$

$$\frac{d^3\phi_g}{d\omega^3} = \frac{d^2\phi_g}{d\omega^2} \frac{3\lambda}{2\pi c} \left\{ 1 + \frac{\lambda}{d} \frac{\tan[\theta(\lambda)]}{\cos[\theta(\lambda)]} \right\} . \qquad (12.58)$$

With the help of the grating equation (12.56) $\cos[\theta(\lambda)]$ is given by:

$$\cos[\theta(\lambda)] = \sqrt{1 - \left(\frac{\lambda}{d} - \sin\gamma \right)^2} . \qquad (12.59)$$

In reflective telescope setups usually only one grating is employed using suitable beam-folding arrangements. This reflects the situation when both gratings in Fig. 12.7 are moved out of the focal plane symmetrically. For the telescope arrangements we therefore obtain as the characteristic length $L = 2fa$. According to Fig. 12.7 the parameter a is determined by the distance of the grating to the lens

$$a = \frac{l_t}{f} - 1 \begin{cases} \text{Compressor: } l_t > f, \ a > 0 \\ \text{Zero-dispersion compressor: : } l_t = f, \\ \qquad\qquad\qquad\qquad\qquad a = 0 \\ \text{Stretcher: } l_t < f, \ a < 0 . \end{cases} \qquad (12.60)$$

For the grating compressor depicted in Fig. 12.6 the characteristic length L is given by

$$L = l_0 = \frac{l_g}{\sqrt{1 - \left(\frac{\lambda}{d} - \sin(\gamma) \right)^2}} , \qquad (12.61)$$

where l_0 is the optical path length of the center wavelength λ_0 between the gratings and l_g is the distance of the gratings.

For the compressor in Fig. 12.6 we obtain a group delay dispersion of $-1 \times 10^6 \ \text{fs}^2$ [$\lambda = 800 \ \text{nm}, d^{-1} =$

12001/mm, $l_0 = 300$ mm; $\gamma = 28, 6°$ (Littrow)] being orders of magnitude higher than the example given for the prism sequence.

Dispersion due to Interference (Gires–Tournois Interferometers and Chirped Mirrors)

The physics behind dispersion due to interference can be illustrated in the following way [12.25]. Periodic structures transmit or reflect waves of certain frequencies. Strong Bragg-type scattering usually occurs for wavelengths comparable to the periodicity of the struc-
Fig. 12.8 Schematic diagram of a Gires–Tournois interferometer (GTI)

ture. In this context the periodicity induces a resonance in the transfer function of the system, which then has dispersion associated with it.

A Gires–Tournois interferometer (GTI) [12.45] is a special case of a Fabry–Pérot interferometer in which one mirror (M1) is a 100% reflector and the top mirror (M2) is a low reflector, typically with a reflectivity of a few percent (Fig. 12.8). The group delay dispersion of such a device is given by (see for example [12.46] or [12.3] and references therein)

$$\frac{d^2\phi_{GTI}}{d\omega^2} = \frac{-2t_0^2(1-R)\sqrt{R}\sin\omega t_0}{(1+R-2\sqrt{R}\cos\omega t_0)^2} \ . \tag{12.62}$$

where $t_0 = (2nd\cos\theta)/c$ is the round-trip time of the Fabry-Pérot [12.47], n is the refractive index of the material between the two layers, d is the thickness of the interferometer and θ is the internal angle of the beam between the layers. In this formula material dispersion is neglected and R is the intensity reflectivity of the top reflector. The group delay dispersion can be conveniently tuned either by tilting the device or by changing the interferometer spacing. Increasing t_0 increases the dispersion, but at the same time reduces the frequency range over which the group delay dispersion is constant. These devices are typically used in applications employing pulses larger than 100 fs. For picosecond pulses
Fig. 12.9a,b Schematic of different types of chirped mirrors: (**a**) simple chirped mirror; the wavelength-dependent penetration depth is depicted. For a proper design, for example, an incoming up-chirped laser pulse can be transformed into a bandwidth-limited pulse after reflection. (**b**) double chirped mirror; impedance matching by an additional antireflection coating on top of the mirror and by a duty-cycle modulation inside the mirror

the mirror spacing is on the order of several mm, for femtosecond lasers the spacing has to be on the order of a few µm. In order to overcome the limitations for femtosecond applications, GTIs were constructed on the basis of dielectric multilayer systems [12.48]. The corresponding spectral transfer functions can be found in [12.4].

Nowadays specially designed dielectric multilayer mirrors offer a powerful alternative for dispersion management. Usually a dielectric mirror consists of alternating transparent pairs of high-index and low-index layers where the optical thickness of all layers is chosen to equal to 1/4 of the Bragg wavelength λ_B. Interference of the reflections at the index discontinuities add up constructively for the Bragg wavelength. If the opti-

cal thickness of the layers along the mirror structure is varied, then the Bragg wavelength depends on the penetration depth. Figure 12.9 shows an example where the red wavelength components penetrate deeper into the mirror structure then the blue wavelength components. An up-chirped pulse impinging on the mirror surface can be transformed into a bandwidth-limited pulse after reflection from this mirror. A gradual increase of the Bragg wavelength along the mirror producing a negative group delay dispersion was demonstrated by [12.49] and the corresponding mirror was termed a chirped mirror, allowing for the construction of compact femtosecond oscillators [12.50]. Of course the Bragg wavelength does not have to be varied linearly with the penetration depth. In principle chirp laws $\lambda_B(z)$ can be found for compensation of higher-order dispersion in addition. It was realized, that the desired dispersion characteristics of the chirped mirrors can be spoiled by spurious effects originating from multiple reflections within the coating stack and at the interface to the ambient medium, leading to dispersion oscillations (see the discussion on GTI). An exact coupled-mode analysis [12.51] was used to develop a so-called double-chirp technique in combination with a broadband antireflection coating, in order to avoid the oscillations in the group delay dispersion. Using accurate analytical expressions double chirped mirrors could be designed and fabricated with a smooth and custom-tailored group delay dispersion [12.52] suitable for generating pulses in the two cycle regime directly from a Ti:sapphire laser [12.53]. Double chirping has the following meaning: in conventional chirped mirrors, equal optical lengths of high-index (hi) and low-index (lo) material within one period are employed, i. e., $P_{lo} = P_{hi} = \lambda_B/4$. Double chirping keeps the duty cycle η as an additional degree of freedom under the constraint: $P_{lo} + P_{hi} = (1-\eta)\lambda_B/2 + \eta\lambda_B/2 = \lambda_B/2$. Dispersion oscillations could further be suppressed by a back-side-coated double-mirror design [12.54].

Pulse Shaping

The methods for dispersion management described so far are well suited to compensate higher-order dispersion terms in linear optical setups such as group delay dispersion and third-order dispersion. Much greater flexibility in dispersion management and the possibility of creating complex-shaped laser pulses with respect to phase, amplitude and polarization state is given with the help of (computer-controlled) pulse-shaping techniques (Fig. 12.10a). The issue was recently reviewed by *Weiner* [12.29, 55].

Fig. 12.10 (a) Pulse-shaping issues (schematic): creation of bandwidth-limited pulses from complex-structured pulses (*left to right*). Creation of *tailored* pulse shapes (*right to left*). (**b**) Adaptive femtosecond pulse shaping: a femtosecond laser system (not indicated) and a computer-controlled pulse shaper are used to generate specific electric fields that are sent into an experiment. After deriving a suitable feedback signal from the experiment a learning algorithm calculates a modified electric fields based on the information from the experimental feedback signal and the user-defined control objective. The improved laser pulse shapes are tested and evaluated in the same manner. Cycling through this loop many times results in iteratively optimized laser pulse shapes that finally approach the objective

A new class of experiments emerged in which pulse-shaping techniques were combined with some experimental signal embedded in a feedback learning loop [12.56–59]. In this approach a given pulse shape is evaluated in order to produce an improved pulse shape, which enhances the feedback signal (see Fig. 12.10b). These techniques have an impact on an increasing number of scientists in physics, chemistry, biology and engineering. This is due to the fact that primary light-induced processes can be studied and even actively controlled via adaptive femtosecond pulse shaping. For a small selection of work in various areas see [12.60–71].

Because of their short duration, femtosecond laser pulses cannot be directly shaped in the time domain. Therefore, the idea of pulse shaping is to modulate the incident spectral electric field $\tilde{E}_{in}^+(\omega)$ by a linear mask, i. e., the optical transfer function, $\tilde{M}(\omega)$ in the frequency domain. According to (12.38) this results in an outgoing shaped spectral electric field $\tilde{E}_{out}^+(\omega) = \tilde{M}(\omega)\tilde{E}_{in}^+(\omega) = \tilde{R}(\omega)e^{-i\phi_d}\tilde{E}_{in}^+(\omega)$. The mask may modulate the spectral amplitude response $\tilde{R}(\omega)$ and the spectral phase transfer function $\phi_d(\omega)$. Furthermore, polarization shaping has been demonstrated [12.72].

One way to realize a pulse shaper is the Fourier-transform pulse shaper. Its operation principle is based on optical Fourier transformations from the time domain into the frequency domain and vice versa. In Fig. 12.11 a standard design of such a pulse shaper is sketched. The incoming ultrashort laser pulse is dispersed by a grating and the spectral components are focused by a lens of focal length f. In the back focal plane of this lens – the Fourier plane – the spectral components of the original pulse are separated from each other, having minimum beam waists. By this means, the spectral components can be modulated individually by placing a linear mask into the Fourier plane. Afterwards, the laser pulse is reconstructed by performing an inverse Fourier transformation back into the time domain. Optically, this is realized by a mirrored setup consisting of an identical lens and grating. The whole setup – without the linear mask – is called a zero-dispersion compressor since it introduces no dispersion if the $4f$ condition is met (see also Fig. 12.7a). As a part of such a zero-dispersion compressor, the lenses separated by the distance $2f$, form a telescope with unitary magnification. Spectral modulations as stated by (12.38) can be set by inserting the linear mask.

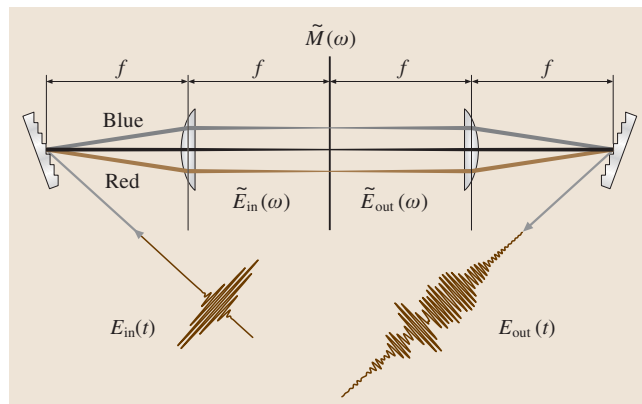
Due to the damage threshold of the linear masks used, cylindrical focusing lenses (or mirrors) are normally used instead of spherical optics. The standard design in Fig. 12.11 has the advantage that all optical


Fig. 12.11 Basic layout for Fourier-transform femtosecond pulse shaping
Fig. 12.12 Dispersion-optimized layout for Fourier transform femtosecond pulse shaping. The incoming beam is dispersed by the first grating (G). The spectral components go slightly out of plane and are sagitally focused by a cylindrical mirror (CM) via a plane-folding mirror (FM) in the Fourier plane (FP). Then the original beam is reconstructed by a mirrored setup

components are positioned along an optical line (grating in the Littrow configuration). For ultrashort pulses below 100 fs, however, spatial and temporal reconstruction errors become a problem due to the chromatic aberrations introduced by the lenses. Therefore, lenses are often replaced by curved mirrors. In general, optical errors are minimized if the tilting angles of the curved mirrors within the telescope are as small as possible. A folded, compact and dispersion optimized setup is de-
Fig. 12.13 Schematic diagram of an electronically addressed phase-only liquid-crystal spatial light modulator (LC-SLM). By adjusting the voltages of the individual pixels, the liquid-crystal molecules reorient themselves on average partially along the direction of the electric field. This leads to a change in refractive index and therefore to a phase modulation which can be independently controlled for different wavelength components

Fig. 12.14 Schematic illustration of shaping the temporal profile of an ultrashort laser pulse by retardation of the spectrally dispersed individual wavelength components in a phase only LC-SLM. The LC-SLM is located in the Fourier plane of the setups displayed in Fig. 12.11 and Fig. 12.12

picted in Fig. 12.12 [12.73]. For ultrashort pulses in the < 10 fs regime prisms have been employed as dispersive elements instead of gratings [12.74].

A very popular linear mask for computer-controlled pulse shaping in such setups is the liquid-crystal spatial light modulator (LC-SLM). A schematic diagram of an electronically addressed phase-only LC-SLM is depicted in Fig. 12.13. In the Fourier plane the individual wavelength components of the laser pulse are

spatially dispersed and can be conveniently manipulated by applying voltages at the separate pixels leading to changes of the refractive index . Upon transmission of the laser beam through the LC-SLM a frequency-dependent phase is acquired due to the individual pixel voltage values and consequently the individual wavelength components are retarded with respect to each other. Actual LC-SLMs contain up to 640 pixels [12.75]. In this way, an immensely large number of different spectrally phase modulated pulses can be produced. A phase-only LC-SLM does to a first approximation not change the spectral amplitudes and therefore the integrated pulse energy remains constant for different pulse shapes. By virtue of the Fourier transform properties, spectral phase changes result in phase- and amplitude-modulated laser pulse temporal profiles, as depicted schematically in Fig. 12.14.

If such an LC-SLM is oriented at 45° with respect to the linear polarization of the incident light field (either with the help of a wave plate or a suitably designed LC-SLM), polarization is induced in addition to retardance. A single LC-SLM together with a polarizer can be used therefore as an amplitude modulator. However, this also leads to phase modulation depending on the amplitude modulation level. For independent phase and amplitude control dual LC-SLMs are currently used. In such a setup a second LC-SLM is fixed back-to-back at −45° with respect to the linear polarization of light in front of the first LC-SLM and the stack is completed with a polarizer. For an early setup for independent phase and amplitude modulations see [12.76] whereas modern configurations are described in [12.55]. Alternatively, simple amplitude modulation functions $\tilde{R}(\omega)$ can be realized by insertion of absorbing material at specific locations in the Fourier plane, thus eliminating the corresponding spectral components within the pulse spectrum [12.77].

For polarization shaping [12.72] the polarizer is removed and spectral phase modulation can be imposed independently onto two orthogonal polarization directions. The interference of the resulting elliptically polarized spectral components leads to complex evolutions of the polarization state in the time domain. As any element between the LC-SLM stack and the experiment can modify the polarization evolution, dual-channel spectral interferometry and experimentally calibrated Jones matrix analysis have been employed for characterization [12.78]. A representation of a complex polarization shaped pulse is displayed in Fig. 12.15. Such pulses open up an immense range of applications, especially in quantum control, because vectorial proper-

Time evolves from left to right, and electric field amplitudes are indicated by the sizes of the corresponding ellipses. The momentary frequency can be indicated by colors, and the shadows represent the amplitude envelopes of the orthogonal electric field components. **(a)** A Gaussian-shaped laser spectrum supporting 80 fs laser pulses is taken for an illustrative theoretical example. **(b)** A complex experimentally realized polarization modulated laser pulse is shown. The width of the temporal window is 7.5 ps (After [12.78]) ▶

ties of multiphoton transitions can be addressed [12.79, 80].

Another possibility to realize phase-only pulse shaping is based on deformable mirrors consisting of a small number ($\sim$10) of electrostatically controlled membrane mirrors [12.81]. These devices are placed in the Fourier plane and by a slight out-of-plane tilt upon reflection half of the optics can be saved (see Fig. 12.16 for an illustration). The use of a micro-mirror array with 240×200 pixels used in reflection and a waveform update rate larger than 1 kHz has also been demonstrated [12.82].

Acousto-optic modulators (AOMs) can be used for programmable pulse shaping as well. Two different approaches exist.

One approach is depicted in Fig. 12.17 and is reviewed in [12.83, 84]. The AOM crystal is oriented at the Bragg angle to the Fourier plane of a zero-dispersion compressor. In the visible TeO_2 crystals are normally used whereas in the infrared InP crystals are employed. A programmable radio-frequency (RF) signal driving the piezoelectric transducer of the AOM creates an acoustic wave that propagates through the crystal. As light travels at orders of magnitude faster velocity, the acoustic wave can be considered as a fixed modulated grating at the moment the spatially dispersed laser beam hits the crystal. The amplitude and phase of the acoustic wave determine the diffraction efficiency and phase shift at each point in space. The beam is diffracted typically below 1° by the AOM via the photoelastic effect. AOMs can place in the order of thousand independent features onto the spectrum and have a significantly faster update rate than an LC-SLMs. On the other hand the optical throughput of such devices is well below 50% and typical mode-locked laser sources running at 100 MHz repetition rate in general cannot be pulse shaped because the acoustic wave is traveling several tens of microns in 10 ns. This is not a limitation for amplified ultrafast laser systems where the pulse repetition rate is usually slower than the acoustic aperture time, since this allows the
acoustic pattern to be synchronized to each amplifier pulse and to be refreshed before the next pulse arrives.

The other AOM approach is based on an acoustooptic programmable dispersive filter (AOPDF) and does not need to be placed in the Fourier plane of a 4f device [12.85–87]. A schematic of this device is shown in Fig. 12.18. Again, a programmable signal driving the piezoelectric transducer of the AOM creates an acoustic
Fig. 12.16 Schematic of a phase-only deformable-mirror pulse shaper
Fig. 12.17 Programmable pulse-shaping device based on the use of an acoustooptic modulator as the spatial light modulator
Fig. 12.18 Schematic of an acoustooptic programmable dispersive filter (AOPDF)

wave that propagates through the crystal and reproduces spatially the temporal shape of the RF signal. Two optical modes can be coupled efficiently by acoustooptic interaction only in the case of phase matching. If there is locally only one spatial frequency in the acoustic grating, then only one optical frequency can be diffracted at that position from the fast ordinary axis (mode 1) to the slow extraordinary axis (mode 2). The incident optical short pulse is initially in mode 1. Different groups of optical frequency components travel a different distance before they encounter phase-matched spatial frequencies in the acoustic grating. At that position part of the energy is diffracted onto mode 2. The pulse leaving the device at mode 2 will be made of all spectral components that have been diffracted at the various positions. If the velocities of the two modes are different, each frequency will

see a different time delay. The amplitude of specific frequency components of the output pulse is controlled by the acoustic power at the position where that frequency components are diffracted. With the help of a 2.5 cm-long TeO_2 crystal, a group delay range of 3 ps, 6.7 fs temporal resolution and 30% diffraction efficiency has been reported [12.86]. In general pulse shapers based on LC-SLMs or deformable mirrors have low transmission losses, are suitable also for high-repetition-rate mode-locked laser oscillators, do not impose additional chirp and have a low waveform update rate on the order of 10 Hz. Setups based on AOMs have high transmission losses and impose additional chirp, but they have a waveform update rate on the order of 100 kHz. Both AOMs and LC-SLMs can impose on the order of 1000 independent features onto the spectrum and are both suitable for amplitude and phase modulation. Programmable polarization shaping has been demonstrated so far only with LC-SLMs.

The programmable femtosecond pulse-shaping techniques described so far allow control of the temporal profile of an output waveform in phase, amplitude and polarization. This can be thought of as control over one spatial dimension, the direction of propagation. With that respect this *temporal-only* pulse shaping is one dimensional. Automated two-dimensional phase-only pulse shaping employing an optically addressed reflective two-dimensional SLM with negligible inter-pixel gaps allows real-space pulse shaping, in which a sample or device is irradiated with different tempo-

rally shaped waveforms at different locations [12.88]. The pulse-shaping arrangement is similar to conventional $4f$ spectral filtering arrangements, with the difference that the incoming beam is expanded in one dimension and the two-dimensional SLM is employed in a reflection geometry. Such a unit has been employed for two-dimensional shaping of surface polaritons [12.89].

12.2 Generation of Femtosecond Laser Pulses via Mode Locking

Femtosecond laser pulses can be generated directly from a wide variety of lasers with wavelengths ranging from the ultraviolet to the infrared. This range is greatly extended by the use of nonlinear frequency-conversion techniques. Continuous tuning is achieved, for example, via optical parametric oscillators followed by (cascaded) sum- and difference-frequency mixing. Tuning of amplified femtosecond laser systems is achieved via optical parametric amplifiers. The generation of a white-light continuum is also a standard technique for the generation of new wavelengths. With high-power femtosecond laser systems the X-ray region can be reached by focusing the radiation into a solid-state material or via high-harmonic generation whereas the latter technique also opens the door to the attosecond regime. The THz spectral region can be accessed via femtosecond lasers as well.

With very few exceptions the generation of ultrashort pulses relies on a technique known as mode locking. The topic has been covered in review articles (see, for example, [12.46, 90–93]), in several books devoted to ultrashort laser pulses (see, for example, [12.2–5, 94]) and in general laser text books (see, for example, [12.47, 95–97]). For a recent compilation of mode locking different laser systems ranging from solid-state lasers through fiber lasers to semiconductor lasers see, for example, [12.98].

Here we will limit the description to the basic concepts of mode locking.

A laser is typically constructed with a pair of mirrors separated by a distance L which enclose a gain medium and other components. In a continuous-wave (CW) laser or in a pulsed laser where the pulse duration is substantially greater then the cavity round-trip time T_{RT}

$$T_{RT} = \frac{2L}{c} \tag{12.63}$$

(c is the velocity of light and for simplicity the refractive index is taken as unity) the radiation energy is spread out fairly uniform between the mirrors. The generation of ultrashort laser pulses is based on the confinement of
Fig. 12.19 Simple snapshot representation of a mode-locked laser. The pulse is propagating back and forth between the end mirror (EM) and the output coupler (OC). The pulses in the output beam are separated by $2L$ in space (or $2L/c = T_{RT}$ in time). The *dashed box* represents the gain medium and other laser components

the energy in the cavity into a small spatial region. This single pulse bounces back and forth between the mirrors at the velocity of light. As indicated in Fig. 12.19 the output beam arises from partial transmission of the intracavity pulse through the output coupler and therefore consists of a train of replicas of the cavity pulse separated by $2L$ in space or by T_{RT} in time. A laser operating in this fashion is said to be mode locked for reasons that will become apparent soon.

In order to understand the physics behind mode locking a more precise discussion is necessary. Generally two conditions govern the frequency spectrum of a laser. On the one hand the overall envelope of the spectrum is determined by the emission profile of the lasing medium and by the characteristics of any wavelength selective element within the cavity. On the other hand for each transverse mode the cavity allows oscillations only at discrete frequencies ν_n the so-called *longitudinal* modes. Usually only one *transverse* mode namely the lowest-order mode having a Gaussian profile is permitted to oscillate in mode-locked laser systems. The corresponding set of longitudinal modes consists of a picket fence of regularly spaced modes – also termed the frequency comb – being separated by a frequency of $\delta\nu$

$$\delta\nu = \nu_{n+1} - \nu_n = \frac{c}{2L} = \frac{1}{T_{RT}} . \tag{12.64}$$

Part C | 12.2
Fig. 12.20 Longitudinal modes in a laser cavity. The spacing $\delta\nu$ of the modes is determined by the cavity length via $\delta\nu = c/2L = 1/T_{RT}$. Only those modes exceeding the loss line will lase. The FWHM of the spectral intensity function $\delta\nu$ is also indicated in addition. In lasers used for pulse generation below 10 fs the number of modes lasing is of the order 10^6

Taking both conditions together the emission spectrum of the laser will consist of those modes which have sufficient gain to lie above the threshold for lasing. The corresponding relationships are depicted in Fig. 12.20. The total electric field $E(t)$ resulting from such a multimode oscillation at a fixed point in space, say at one of the mirrors, is given by

$$E(t) = \sum_{n=0}^{N-1} E_n \sin[2\pi(\nu_0 + n\delta\nu)t + \varphi_n(t)] , \quad (12.65)$$

where N is the number of oscillating modes, $\varphi_n(t)$ is the phase of the nth mode and ν_0 is the lowest-frequency mode above the lasing threshold.

The average laser power output $P(t)$ is proportional to the square of the total electric field. Unless some method of fixing the relative phases $\varphi_n(t)$ of the modes is used they will generally vary randomly in time. This produces a random variation of the average laser power output $P(t)$ as a result of the random interference between modes.

If the phases are fixed with respect to each other $[\varphi_n(t) \to \varphi_n]$, it can be shown that $E(t)$ and accordingly $P(t)$ repeats with the period T_{RT}. In the case that the individual φ_n are randomly fixed, each *noise spike* in the random but periodic laser output power has a duration Δt roughly equal to $1/\Delta\nu$ with $\Delta\nu$ being the FWHM of the spectral intensity function (Fig. 12.23e, f). Within this approach the properties of perfectly mode-
Fig. 12.21 Superposition of four sine waves with equal amplitude E_0, differing in frequency by $\delta\nu$. The electric field of the individual waveforms, the total electric field $E(t)$, its envelope and the output power $P(t)$ as well as the average power $\bar{P}$ are shown

locked lasers are determined by a linear phase relation $\varphi_n = n\alpha$ amongst the modes, that is, a constant phase relation between two adjacent modes. This is the so-called mode-locking condition. To simplify the analysis of this case identical amplitudes $E_n = E_0$ for all modes are assumed corresponding to a square gain profile and for convenience α is set to zero. The summation of (12.65)

then yields

$$E(t) = E_0 \sin\left[2\pi\left(\nu_0 + \frac{N-1}{2}\delta\nu\right)t\right]\frac{\sin(N\pi\delta\nu t)}{\sin(\pi\delta\nu t)} .$$

$$(12.66)$$

The resulting electric field consists of a rapid oscillating part at the light central frequency $\nu_c = \nu_0 + \frac{N-1}{2}\delta\nu$ with the envelope $\left|\frac{\sin(N\pi\delta\nu t)}{\sin(\pi\delta\nu t)}\right|$ oscillating with $\delta\nu = 1/T_{RT}$. Averaging the fast oscillation ν_c the output power $P(t)$ is given by

$$P(t) = P_0\left[\frac{\sin(N\pi\delta\nu t)}{\sin(\pi\delta\nu t)}\right]^2$$

$$(12.67)$$

where P_0 is the average power of one wave.

A discussion of this equation yields important insight into the properties of laser pulses generated via mode locking.

1. The power is emitted in the form of a train of pulses with a period corresponding to the cavity round-trip time $T_{RT} = \frac{1}{\delta\nu}$.
2. The peak power P_{Peak} increases quadratically with the number N of modes locked together: $P_{Peak} = N^2 P_0$. Mode locking is therefore useful to produce high peak powers and by focusing the laser beam to create high peak intensities; the average power $\bar{P}$ of both a mode-locked and a non-mode-locked laser is given by $\bar{P} = N P_0$.
3. The FWHM pulse duration Δt decreases linearly with the number N of modes locked together or equivalent is approximately the inverse of the gain bandwidth $\Delta\nu$:

$$\Delta t \approx \frac{T_{RT}}{N} = \frac{1}{N\delta\nu} = \frac{1}{\Delta\nu} .$$

This is why in the past dye lasers and nowadays solid-state lasers with large gain bandwidths are used to create femtosecond pulses. Ultrafast dye lasers generated pulses as short as 27 fs with around 10 mW of average power [12.99], whereas pulses around 5–6 fs with around 100 mW average power can be produced with Ti:sapphire lasers [12.53, 100]. In general the minimum pulse duration for a given gain profile can be estimated via the bandwidth product introduced in Sect. 12.1.2 and is summarized for various line shapes in Table 12.1.

The basic properties of mode locking are visualized with the help of Figs. 12.21–12.23. Figure 12.21 depicts the Fourier synthesis of a pulse obtained by the superposition of four sine waves with same amplitude and $\varphi_n(t) = 0$ according to (12.65, 12.66, 12.67).
Fig. 12.22 Comparison of the one, two-, four- and six-mode cases. An increase in the number of modes leads to a decrease in pulse duration. The peak power P_{peak} increases quadratically with the number N of modes locked together, whereas the average power $\bar{P}$ of both a mode-locked and a non-mode-locked laser scales linearly with N

In Fig. 12.22 the dependence of the pulse duration and peak power on the number of locked modes is illustrated for this case. Finally in Fig. 12.23 the shape of the average output power is displayed for $N = 10$ equally spaced modes with different relative amplitudes and phase angles according to (12.65).

In the following we will summarize some more-technical related considerations. Mode locking is essentially achieved by applying a periodic loss (or gain) modulation to the intracavity radiation whose period is matched to the cavity round trip time. The mechanisms can be described either in the frequency or time domain.

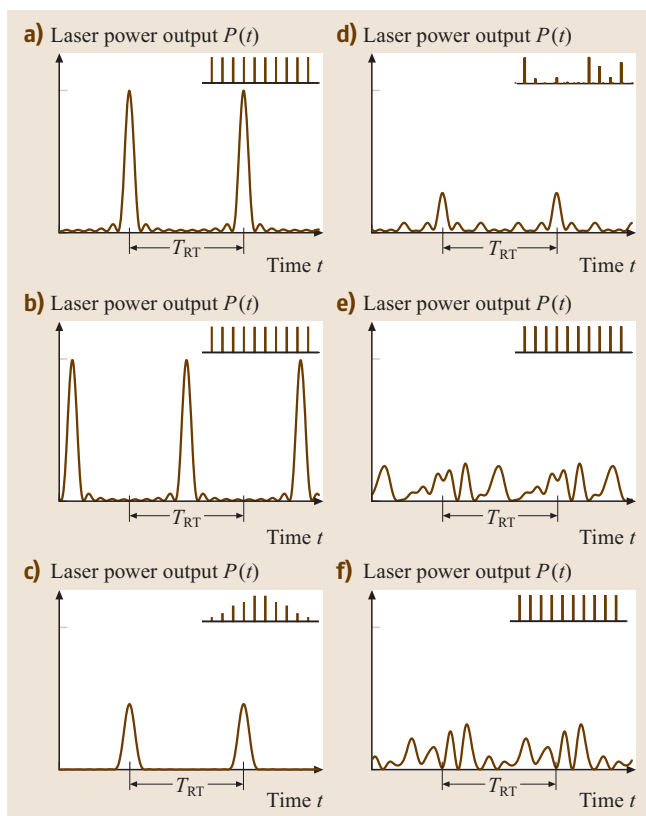
In the frequency domain one can start the consideration from the lowest-loss longitudinal mode. The periodic modulation at the frequency of the round-trip time leads to sidebands whose frequencies coincide with those of the adjacent longitudinal laser modes. In this


Fig. 12.23a–f Output power for 10 equally spaced modes with different relative amplitudes (as indicated in the *insets*) and phase angles (T_{RT} is the round-trip time): (**a**) linear phase relation $\varphi_n = n\alpha$ amongst the modes (i. e., a constant phase relation between two adjacent modes) with $\alpha = 0$, (**b**) linear phase relation $\varphi_n = n\alpha$ with $\alpha = \pi$, (**c**) Gaussian spectrum with five modes at FWHM and linear phase relation with $\alpha = 0$, (**d**) random spectrum and linear phase relation with $\alpha = 0$, (**e**) constant spectrum and random phase, (**f**) constant spectrum and different random phase

locked in phase. In the time domain, the periodic modulation can be visualized as an intracavity shutter that is open once per round trip time. Such a stationary time window of minimum loss will provide a higher net gain on each round trip for those photons that are concentrated in that time window.

Approaches for providing the periodic modulation are grouped into active and passive schemes, and hybrid schemes that make use of a combination of the two. Active mode locking is obtained with an active element within the laser cavity, for example an acoustooptic modulator, generating a loss modulation. The modulation has to be precisely synchronized with the cavity round trips. Modulating the gain is also possible and can be achieved by synchronous pumping. In this case the amplifying medium of the laser is pumped with the output of another mode-locked laser whereby the cavity round-trip times for both lasers have to be matched. Passive mode locking is obtained by the laser radiation itself that produces the modulation via the interaction with a nonlinear device in the laser cavity. Typical nonlinear devices are some type of saturable absorbers which exhibit an intensity dependent loss as they interact with the laser radiation. This modulation is thus automatically synchronized to the cavity round-trip frequency. Because pulse timing does not have to be externally controlled there is usually no need for synchronization electronics, making passive schemes conceptually simpler compared to active schemes. Originally organic dyes were used as real saturable absorbers, for example to generate picosecond pulses from solid-state lasers and pulses down to 27 fs from dye lasers [12.99]. The shortest pulses nowadays are generated in solid-state laser media, being passively mode-locked using the optical Kerr effect. This approach was originated by [12.101]. Pulses with less than 6 fs are nowadays generated directly from Ti:sapphire lasers with Kerr-lens mode locking [12.53, 100]. At a center wavelength of 800 nm a pulse duration of 5.4 fs contains only two optical cycles at full-width half-maximum of the pulse intensity.

way energy is shifted from one mode to adjacent modes and as a result all longitudinal modes become finally

12.3 Measurement Techniques for Femtosecond Laser Pulses

For energy, power, spectrum and spatial beam measurements of ultrashort laser pulses standard laser diagnostic techniques are employed [12.5, 47]. For a measurement of the pulse duration or more interesting of the time-dependent amplitude and phase of an ultrashort laser pulse, dedicated methods have been developed and are described in several textbooks and

references therein [12.4–6]. Here the basic ideas and underlying concepts are highlighted.

As the time and frequency domain are related by the Fourier transformation (12.6, 12.7, 12.11, 12.12) it should be sufficient to measure amplitude and phase in only one of the domains. Let us first shortly reflect on the frequency domain. All spectrometers no matter whether

diffraction-grating or Fourier-transform devices measure a quantity that is proportional to the spectral intensity (Sect. 12.3.3) and therefore the phase information is lost.

On the other hand direct electronic techniques for temporal pulse-width measurements, consisting of fast photodiodes and high-bandwidth (sampling) oscilloscopes, are limited to the several-picosecond regime. Fast photodiodes are therefore not suited to record the temporal profile of an ultrashort laser pulse. Often they are employed to check on the mode-locked operation of an ultrafast oscillator or to derive synchronization signals for amplification setups or synchronized experiments. The only detector that reaches a time resolution below one picosecond is the streak camera. However, a characterization of ultrashort pulses with respect to amplitude and phase requires optical correlation techniques, especially methods that operate in the time–frequency domain. The latter techniques will be described in more detail.

12.3.1 Streak Camera

The basic principle of a streak camera is depicted in Fig. 12.24. The ultrafast optical signal $I(t)$ to be analyzed is focused on a photocathode, where the signal is converted almost instantaneously into a number of electrons. The electrons then pass through a horizontal pair

of accelerating electrodes and hit a phosphor screen after passing an electron multiplier (MCP). The screen is then imaged with the help of a highly sensitive camera (not shown). The temporal resolution relies on the concept of transferring a temporal profile into a spatial profile. This is done by passing the electron pulse between a pair of vertical sweep electrodes. A high voltage is applied to the sweep electrodes at a timing synchronized to the incident light. During this high-speed sweep the electrons arriving at different times are deflected at different angles and consequently hit the MCP at different vertical directions. In this manner the vertical position on the phosphor screen serves as a time axis. The brightness of the signal is proportional to the intensity profile of the incident ultrashort optical signal. The horizontal direction of the image corresponds to the horizontal location of the incident light. For example if the streak camera is used in combination with a polychromator the time variation of the incident light with respect to wavelength can be measured. Time-resolved spectroscopy is therefore one of the application areas of these devices. Commercial devices [12.102, 103] are quoted with a temporal resolution of < 200 fs. Using different photocathode materials a spectral response can be achieved from 115 nm up to 1600 nm. X-ray streak cameras with a temporal resolution of 1.5 ps are quoted as well.
Fig. 12.24 Working principle (*top*) and timing (*bottom*) of a streak camera (After [12.102]). The spatial coordinate might be a wavelength coordinate after having dispersed the ultrashort optical signal with the help of a polychromator

12.3.2 Intensity Autocorrelation and Cross–Correlation

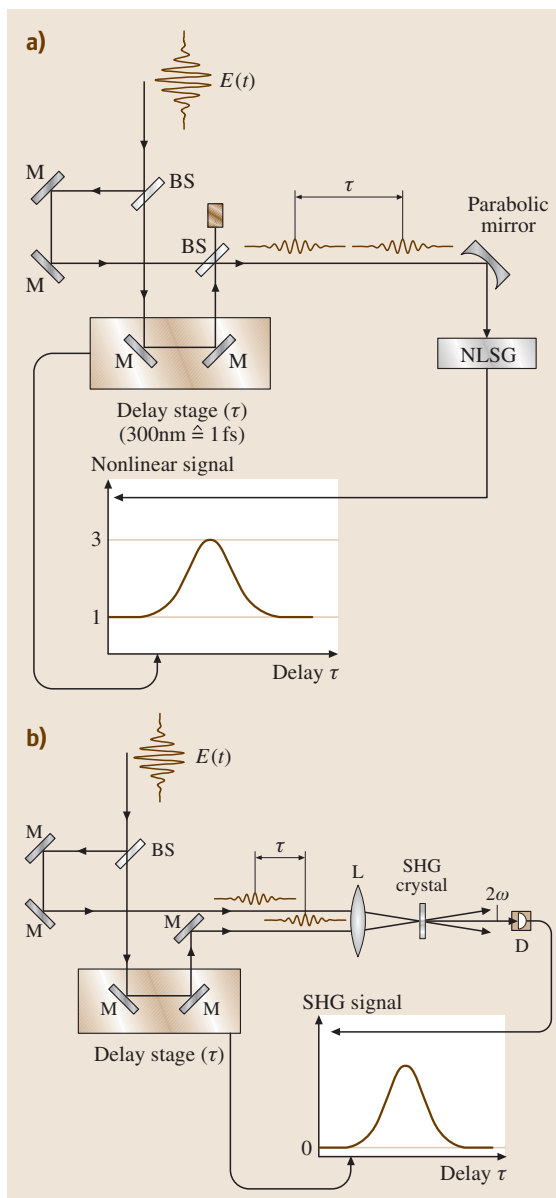
A widely used technique to estimate the pulse duration or to check whether a laser produces pulses rather than statistical intensity fluctuations is to measure the so-called intensity autocorrelation S_{intAC} [12.104]

$$S_{\text{intAC}}(\tau) = \int_{-\infty}^{\infty} I(t)I(t+\tau)\,\mathrm{d}t$$

$$= \int_{-\infty}^{\infty} I(t)I(t-\tau)\,\mathrm{d}t = S_{\text{intAC}}(-\tau)\,. \quad (12.68)$$

This is the time integral of one pulse intensity multiplied by the intensity of a time-shifted replica of the same pulse as a function of the time shift τ. The intensity autocorrelation has its maximum at $\tau = 0$ and is always symmetrical [see (12.68)]. In this fundamental arrangement one pulse serves as a gate to scan the other. It can be realized with any interferometer (for examples see Fig. 12.25) that splits the pulse into two pulses and recombines them with an adjustable time delay between them. Note within that context that, for example a 100 fs pulse duration, corresponds to a spatial extent of 30 μm, a dimension readily measurable with standard translation stages. Measuring the spatial overlap of the two pulses requires a nonlinear process to generate a detection signal proportional to the intensity product of the two pulses. Second-harmonic generation in thin crystals

Fig. 12.25a,b Optical layout for autocorrelation setups. **(a)** Collinear autocorrelator (dispersion minimized): the incoming pulse is split into two parts, where one is variably delayed with respect to the other. The pulses are recombined and focused on a nonlinear signal generator (NLSG). Second-harmonic generation in thin crystals and two-photon absorption in semiconductor photodiodes are commonly used for this purpose. Other second-order nonlinear effects can be used as well. The nonlinear signal is measured as a function of delay. If the measurement is performed with interferometric accuracy the interferometric autocorrelation is recorded. If the setup averages the fast oscillations of the light field (see (12.76)) the intensity autocorrelation with background is recorded, having a center-to-offset ratio of 3:1 (see (12.77)). **(b)** Non-collinear autocorrelator for recording the background free intensity autocorrelation (M = mirror; BS = beam splitter; SHG = second harmonic generation; D = detector; L = lens)

and two-photon absorption in semiconductor photodiodes [12.105, 106] are commonly used (in a *two-photon diode* the photon energy is within the band gap and only simultaneous two-photon absorption can lead to a signal). In the case of frequency-doubling crystals thin crystals have to be used in order to ensure that the ratio of the crystals phase-matching bandwidth to the pulse spectral bandwidth is large. For 100 fs pulses at 800 nm the beta-barium borate (BBO) crystal thickness should


not be thicker than $\approx 100\,\mu m$ and crystals as thin as $5\,\mu m$ have been used to measure few-fs pulses [12.6].

The intensity autocorrelation is obtained directly, when the two time-delayed laser pulses are not recombined collinearly but focused at a mutual angle into the thin nonlinear crystal. This leads to the so-called background free intensity autocorrelation. For the collinear setup the intensity autocorrelation is obtained by averaging the fast oscillations of the light field [(12.76) in Sect. 12.3.3].

The collinear intensity autocorrelation has a signal-to-background ratio of 3:1 [(12.77) in Sect. 12.3.3].

The intensity autocorrelation provides only limited information on the pulse shape, because there are infinitely many symmetric and asymmetric pulse shapes that lead to very similar symmetric autocorrelation traces. The procedure to estimate a pulse duration from intensity autocorrelations is to assume a pulse shape and then to calculate the FWHM pulse duration Δt from the known ratio with respect to the FWHM of the intensity autocorrelation Δt_{intAC}. In this approach generally Gaussian shapes or hyperbolic secant shapes are assumed. The ratio $\Delta t_{intAC}/\Delta t$ for various shapes [12.22] is given in Table 12.1.

If a pulse $I_1(t)$ is characterized, for example, in such a way it can be used to gate a second unknown pulse $I_2(t)$ by measuring the intensity cross-correlation S_{intCC} with a suitable nonlinear second-order signal like, for example, sum- or difference-frequency mixing or two-photon photodiodes

$$S_{intCC}(\tau) = \int_{-\infty}^{\infty} I_1(t)I_2(t+\tau)dt \,. \tag{12.69}$$

For Gaussian pulse shapes the corresponding FWHM quantities are related by

$$\Delta t_{intCC}^2 = \Delta t_1^2 + \Delta t_2^2 \,. \tag{12.70}$$

In general the second momenta of the individual pulses have to be considered [12.23].

For high-power femtosecond laser systems higher-order cross-correlations $S_{higher\ order\ int\ CC}$ are a very convenient and powerful tool to determine intensity profiles by making use of nonlinear optical processes of the order $n+1$ and $m+1$

$$S_{higher\ order\ intCC}(\tau) = \int_{-\infty}^{\infty} I_1^n(t)I_2^m(t+\tau)dt \,. \tag{12.71}$$
Fig. 12.26 (a) Optical layout for a single-shot autocorrelator. The delayed replicas of the incident pulse are focused with the help of a cylindrical lens (CL) onto a second-harmonic generation (SHG) crystal. The spatiotemporal overlap of the two spatially extended pulses is measured via SHG and recorded with a camera (M = mirror; BS = beam splitter). **(b)** Detail of **(a)**. In the region of spatiotemporal overlap, second-harmonic generation is induced via type I phase matching and the autocorrelation in time is transformed into a spatial intensity distribution along the x-axis. (After [12.5])

In this case the corresponding FWHM quantities assuming Gaussian pulse shapes are given by

$$\Delta t_{higher\text{-}order\ intCC}^2 = \frac{1}{n}\Delta t_1^2 + \frac{1}{m}\Delta t_2^2 \,. \tag{12.72}$$

The intensity autocorrelation does not necessarily have to be recorded by moving one interferometer arm as depicted in Fig. 12.25. In a so-called single-shot autocorrelator [12.107, 108] the two pulses are coupled non-collinearly into a thin frequency-doubling crystal (Fig. 12.26). Only in a small region within the crystal the pulses have spatiotemporal overlap. According to the geometry of the setup in Fig. 12.26b the delay time τ is related to the spatial coordinate x_0. Imaging the frequency-doubled signal yields an intensity autocorrelation as a function of the spatial coordinate

$$S_{\mathrm{intAC}}(x_0) = \int_{-\infty}^{\infty} I(x)I(x+x_0)\,\mathrm{d}x . \tag{12.73}$$

These single-shot devices are especially suited for high-intensity femtosecond laser pulses and are therefore convenient tools to adjust low-repetition femtosecond amplifiers. Phase-sensitive setups have also been reported [12.108, 109].

Fig. 12.27a–e Quadratic interferometric autocorrelation **(a)** and the isolated components S_{f0}, S_{f1} and S_{f2} in the time domain **(b)**–**(d)** for a bandwidth-limited Gaussian pulse of 10 fs pulse duration. Note that the offset in **(a)** introduces an additive value at $\omega = 0$ and **(e)** is therefore the Fourier transform of the offset-corrected curve. $\Delta t_{\mathrm{quadratic\ interferometric\ AC}}$ is indicated in **(a)** in addition (in the figure qiAC is used as a shorthand notation for quadratic interferometric AC)

12.3.3 Interferometric Autocorrelations

We will now discuss the case of a collinear autocorrelation in more detail. The simplest interferometric signal is that from a linear detector that records the intensity of the recombined pulses. For identical electric fields E of the two pulses, the signal $S_{\mathrm{linear\ interferometric\ AC}}$ as a function of their relative delay τ is

$$
\begin{aligned}
S_{\mathrm{linear\ interferometric\ AC}}(\tau) &= \int_{-\infty}^{\infty} [E(t)+E(t+\tau)]^2 \,\mathrm{d}t \\
&= 2\int_{-\infty}^{\infty} I(t)\,\mathrm{d}t \\
&\quad + 2\int_{-\infty}^{\infty} E(t)E(t+\tau)\,\mathrm{d}t
\end{aligned}
\tag{12.74}
$$

where we have skipped the prefactors defined in Sects. 12.1.1 and 12.1.2. The signal consists of an offset given by the summed intensity of the two pulses and the interference term that is described by an autocorrelation of the electric field. The Wiener–Khintchine theorem states that the Fourier transformation of the autocorrelation of the electric field yields the spectral density [12.110] – a quantity that is proportional to the spectral intensity $I(\omega)$, which is the basis for Fourier spectroscopy. A linear autocorrelation therefore contains no information beyond the amplitude of the spectrum and the total intensity of the pulse.

A solution to this problem is a nonlinear detector that is sensitive to the squared intensity and yields the signal $S_{\mathrm{quadratic\ interferometric\ AC}}$

$$
\begin{aligned}
S_{\mathrm{quadratic\ interferometric\ AC}}(\tau) \\
= \int_{-\infty}^{\infty} \left\{[E(t)+E(t+\tau)]^2\right\}^2 \mathrm{d}t .
\end{aligned}
\tag{12.75}
$$

Taking the electric field as $E(t) = \mathrm{Re}[A(t)\,\mathrm{e}^{\mathrm{i}\Phi_{\mathrm{a}}(t)}\,\mathrm{e}^{\mathrm{i}\omega_0 t}]$ and defining $S_0 = \int_{-\infty}^{\infty} A^4(t)\,\mathrm{d}t$ in order to normalize

one obtains, similar to [12.4, 111],

$$S_{\text{quadratic interferometric AC}}(\tau) = \frac{1}{S_0}\left\{S_{f0} + S_{f1} + S_{f2}\right\}$$

with

$$S_{f0} = \int_{-\infty}^{\infty}\left\{A^4(t) + 2A^2(t)A^2(t+\tau)\right\}\mathrm{d}t \, ,$$

$$S_{f1} = 2\,\mathrm{Re}\left\{ \mathrm{e}^{\mathrm{i}\omega_0\tau}\int_{-\infty}^{\infty} A(t)A(t+\tau) \right.$$

$$\left. \times\left(A^2(t) + A^2(t+\tau)\right)\mathrm{e}^{\mathrm{i}(\Phi_{\mathrm{a}}(t+\tau)-\Phi_{\mathrm{a}}(t))}\,\mathrm{d}t\right\},$$

$$S_{f2} = \mathrm{Re}\left\{\mathrm{e}^{\mathrm{i}2\omega_0\tau}\int_{-\infty}^{\infty} A^2(t)A^2(t+\tau)\right.$$

$$\left. \times\,\mathrm{e}^{\mathrm{i}2(\Phi_{\mathrm{a}}(t+\tau)-\Phi_{\mathrm{a}}(t))}\,\mathrm{d}t\right\}, \qquad (12.76)$$

where Re denotes the real part. According to (12.48) the signal $S_{\text{quadratic interferometric AC}}$ can be decomposed into three frequency components, S_{f0}, S_{f1} and S_{f2}, at $\omega \approx 0$, $\omega \approx \pm\omega_0$, and $\omega \approx \pm 2\omega_0$, respectively, as illustrated in Fig. 12.27.

S_{f0} corresponds to an intensity correlation with background. It can be obtained either by Fourier filtering or by averaging the fast oscillations in the experiment directly. With (12.76) it follows that this intensity autocorrelation has a center-to-offset ratio of

$$\frac{S_{f0}(0)}{S_{f0}(\infty)} = \frac{\displaystyle\int_{-\infty}^{\infty} 3A^4(t)\,\mathrm{d}t}{\displaystyle\int_{-\infty}^{\infty} A^4(t)\,\mathrm{d}t} = \frac{3}{1}\,. \qquad (12.77)$$

S_{f1} is a sum of two mutual symmetric cross-correlations and depends explicitly on the temporal phase $\Phi_{\mathrm{a}}(t)$.

S_{f2} represents an autocorrelation of the second harmonic field and is therefore related to the spectral intensity of the second-harmonic spectrum. It also depends on the temporal phase $\Phi_{\mathrm{a}}(t)$. Note that phase-modulated pulses having the same spectral intensity can have very different spectral intensities after frequency doubling (Fig. 12.28). This has been exploited in recent experiments [12.21, 112, 113]. Making use of a pulse shaper (Sect. 12.1.3) that scans calibrated phase functions and at the same time measuring the second-harmonic spectrum is a noninterferometric method to characterize the spectral phase of ultrashort laser pulses [12.114]. All

three components add constructively at $\tau = 0$ and yield a center to background ratio of 8:1. This can be directly seen from (12.75)

$$\frac{S_{\text{quadratic interferometric AC}}(0)}{S_{\text{quadratic interferometric AC}}(\infty)}$$

$$= \frac{\displaystyle\int_{-\infty}^{\infty}(E+E)^4\,\mathrm{d}t}{\displaystyle\int_{-\infty}^{\infty}E^4\,\mathrm{d}t + \int_{-\infty}^{\infty}E^4\,\mathrm{d}t} = \frac{16\displaystyle\int_{-\infty}^{\infty}E^4\,\mathrm{d}t}{2\displaystyle\int_{-\infty}^{\infty}E^4\,\mathrm{d}t} = \frac{8}{1}\,.$$

$$(12.78)$$

The center-to-background ratios are used in experiments to check the proper alignment of the interferometer. In order to derive phase information analytical functions, for example Gaussians, can be fitted to the $S_{\text{quadratic interferometric AC}}$ [12.111]. Taking the knowledge of the spectrum into account iterative algorithms that make no assumptions about the underlying pulse shapes have been reported [12.115, 116]. Both approaches deliver meaningful results only for linear chirps and in the case of nearly no noise. The influence of noise on autocorrelation measurements is discussed in [12.4, 117]. This is an important point as most often measurements are performed over an average of pulse trains. Other sources of systematic error in autocorrelation measurements are discussed in [12.6].

The ratio $\Delta t_{\text{intAC}}/\Delta t$ is only valid for the intensity autocorrelation of a bandwidth-limited pulse. For bandwidth-limited Gaussian pulses the FWHM of a quadratic interferometric autocorrelation signal (taken at 4 in a 8:1 plot as displayed in Fig. 12.27a) relates to the pulse duration by

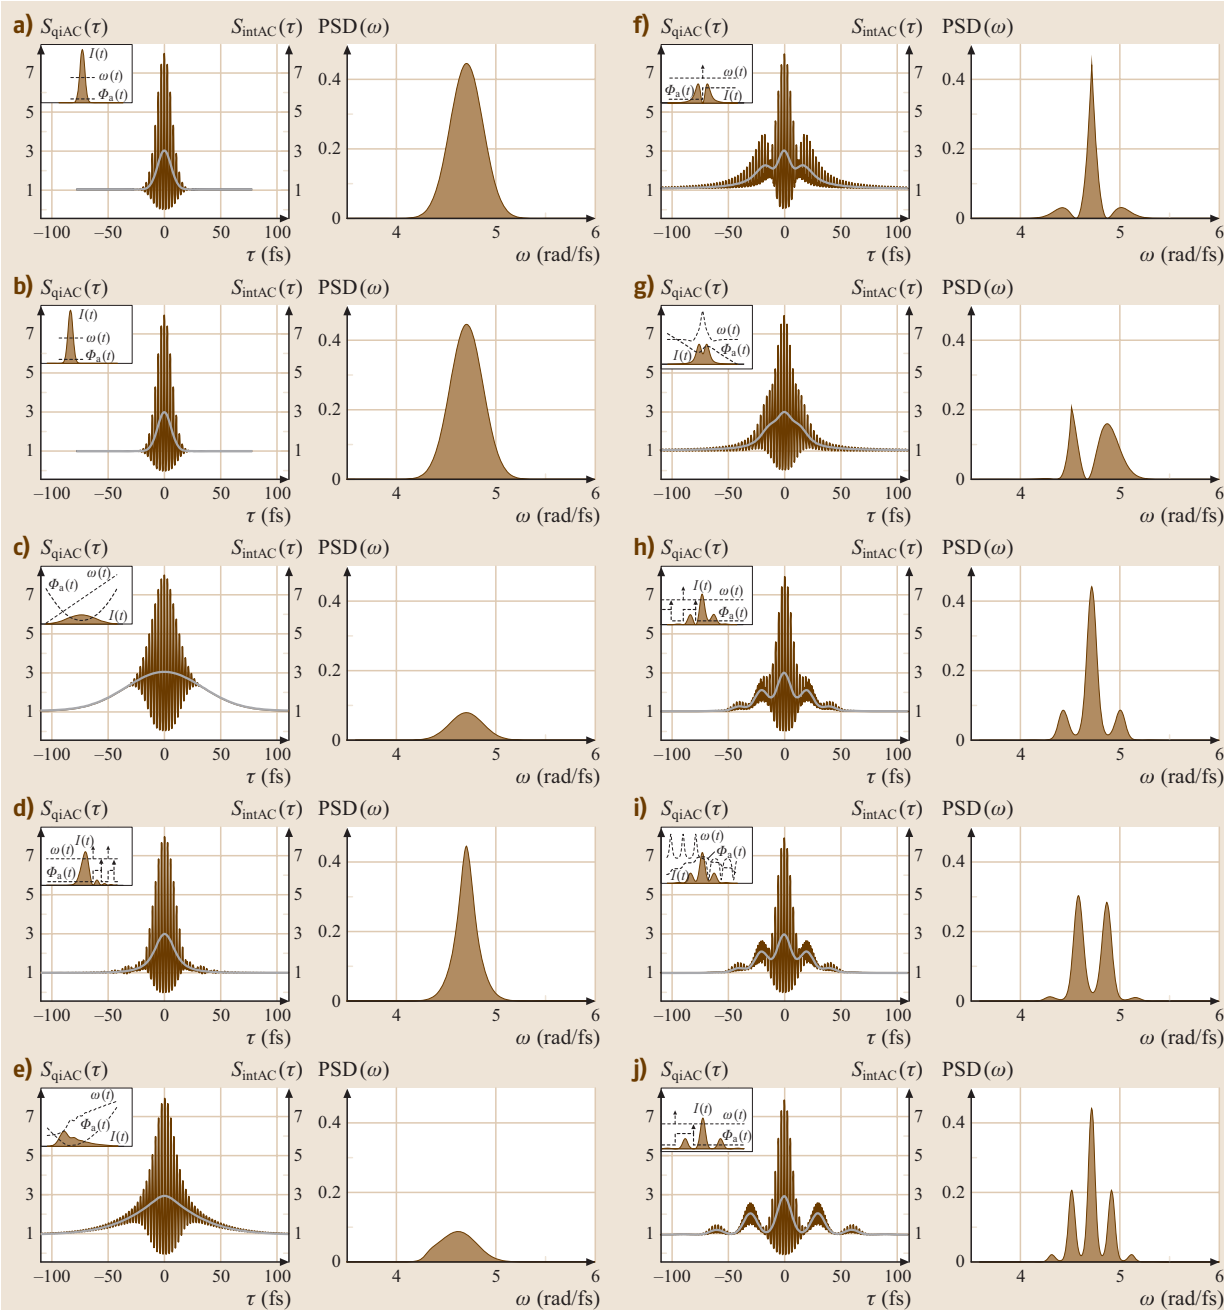
$$\frac{\Delta t_{\text{quadratic interferometric AC}}}{\Delta t} = 1.6963 \qquad (12.79)$$

for bandwidth-limited Gaussian pulses. Figure 12.28 compiles for different pulses the resulting interferometric autocorrelation traces together with the intensity autocorrelation and the spectrum at the second harmonic of the fundamental.

12.3.4 Time–Frequency Methods

As described above, the interferometric autocorrelation, even together with the independently measured spectrum, does not give sufficient information to characterize arbitrary-shaped ultrashort laser pulses with respect to their temporal amplitude $A(t)$ or temporal intensity $I(t)$ and the temporal phase function $\Phi_{\mathrm{a}}(t)$ or their frequency-domain counterparts (Sect. 12.1.2).

Techniques have emerged that operate not in the time or frequency domain but in the *joint time–frequency domain*, involving both temporal resolution and frequency resolution simultaneously [12.24, 118] and being able to completely determine the pulse shape [12.6].

For illustration purposes we start with an example from music: in order to describe a line of music we use notes. The frequency is indicated by the pitch of the note and the duration of the note indicates how long the frequency has to be held. The sheet of music will


tell us in what order the notes have to be played and additional information like *piano* and *forte* is given to indicate the intensity to be played. The first few notes of Beethoven's fifth symphony are given as an example in Fig. 12.30a. If an orchestra is playing the music and we wish to graphically record the music, a spectrogram $S_{spectrogram}(\omega, \tau)$ is a useful quantity. A spectrogram of a function $f(t)$ is defined as the energy density spectrum of a short-time Fourier transform STFT(ω, τ)

$$S_{spectrogram}(\omega, \tau) \equiv |\text{STFT}(\omega, \tau)|^2$$

$$= \left| \int_{-\infty}^{\infty} f(t)g(t - \tau) e^{-i\omega t} \, dt \right|^2 .$$

(12.80)

Fig. 12.28a–o *Left*: quadratic interferometric autocorrelation $S_{quadratic\ interferometric\ AC}(\tau)$ (*black*) and intensity autocorrelation $S_{int\ AC}(\tau)$ (*grey*) for the pulse shapes of Fig. 12.3 with a central wavelength of 800 nm. The temporal intensity $I(t)$, the additional temporal phase $\Phi_a(t)$ and the instantaneous frequency $\omega(t)$ are shown in the *insets*. *Right*: corresponding power spectrum density PSD(ω) of $S_{qiAC}(\tau)$ displayed in the region of the second harmonic. Note that for pulses (**a**) to (**j**) the linear spectrum remains unchanged. (**a**) bandwidth-limited Gaussian laser pulse of 10 fs duration, (**b**) bandwidth-limited Gaussian laser pulse of 10 fs duration shifted in time to −20 fs due to a linear phase term in the spectral domain ($\phi' = -20$ fs), (**c**) symmetrical broadened Gaussian laser pulse due to $\phi'' = 200$ fs^2, (**d**) third-order spectral phase ($\phi''' = 1000$ fs^3) leading to a quadratic group delay, (**e**) combined action of all spectral phase coefficients (**a**)-(**d**), (**f**) π step at the central frequency, (**g**) π step displaced from the central frequency, (**h**) sine modulation at the central frequency with $\phi(\omega) = 1 \sin[20\,\text{fs}(\omega - \omega_0)]$, (**i**) cosine modulation at the central frequency with $\phi(\omega) = 1 \cos[20\,\text{fs}(\omega - \omega_0)]$, (**j**) sine modulation at the central frequency with $\phi(\omega) = 1 \sin[30\,\text{fs}(\omega - \omega_0)]$, (**k**) symmetrical clipping of spectrum, (**l**) blocking of the central frequency components, (**m**) off-center absorption, (**n**) self-phase modulation. Note the spectral broadening, (**o**) double pulse, with a pulse-to-pulse delay of 60 fs. Note that the second harmonic field $E^2(t) = A^2(t) e^{2i\Phi_a(t)} e^{2i\omega_0 t}$ gives rise to the autocorrelation function S_{f2} is related to the second harmonic PSD, i.e. squared modulus of the Fourier transform of $E^2(t)$ as displayed in the right column. Hence, the shape of the second harmonic PSD is determined by phase modulation of the linear spectrum and can be used to efficiently control two-photon resonant processes [12.21, 112, 113] ◄ ►

where $g(t - \tau)$ denotes the gate (or window) function. The concept behind it is simple and powerful. If we want to analyze what is happening at a particular time, we just use a small portion of the signal centered at that time, calculate its spectrum and do it for each instant of

is retrieved in amplitude and phase there are other time – frequency distributions in use for displaying the data like for example the Wigner [12.24, 119–122] and Husimi representations [12.123, 124]. A quantity closely related to the spectrogram is the sonogram $S_{\mathrm{sonogram}}(\omega, \tau)$

$$S_{\mathrm{sonogram}}(\omega, \tau) \equiv \left| \int_{-\infty}^{\infty} \tilde{f}(\omega')\tilde{g}(\omega-\omega')e^{+i\omega'\tau}\,d\omega' \right|^2 ,$$

(12.81)

where $\tilde{g}(\omega-\omega')$ is a frequency gate in analogy to the time gate $g(t-\tau)$ used in the spectrogram. If $\tilde{g}(\omega)$ is the Fourier transform of $g(t)$ then it can be shown that the sonogram is equivalent to the spectrogram [12.6].

In ultrafast optics, the gate to record the spectrogram or the sonogram is usually the pulse itself.

Spectrogram–Based Methods

Recording a spectrogram is accomplished experimentally by gating the pulse with a variable delayed replica of the pulse in an instantaneous nonlinear optical medium followed by spectrally resolving the gated pulse. The basic optical layout of such a device is almost the same as a non-collinear autocorrelation setup depicted in Fig. 12.25b. Only the detector has to be replaced by a spectrometer and camera system in order to spectrally resolve the gated pulse. The corresponding

time. A spectrogram corresponding to the beginning of Beethoven's fifth symphony is shown in Fig. 12.30b.

Figure 12.29 shows the concept of STFT on a complicated electric field of a laser. Once an electric field

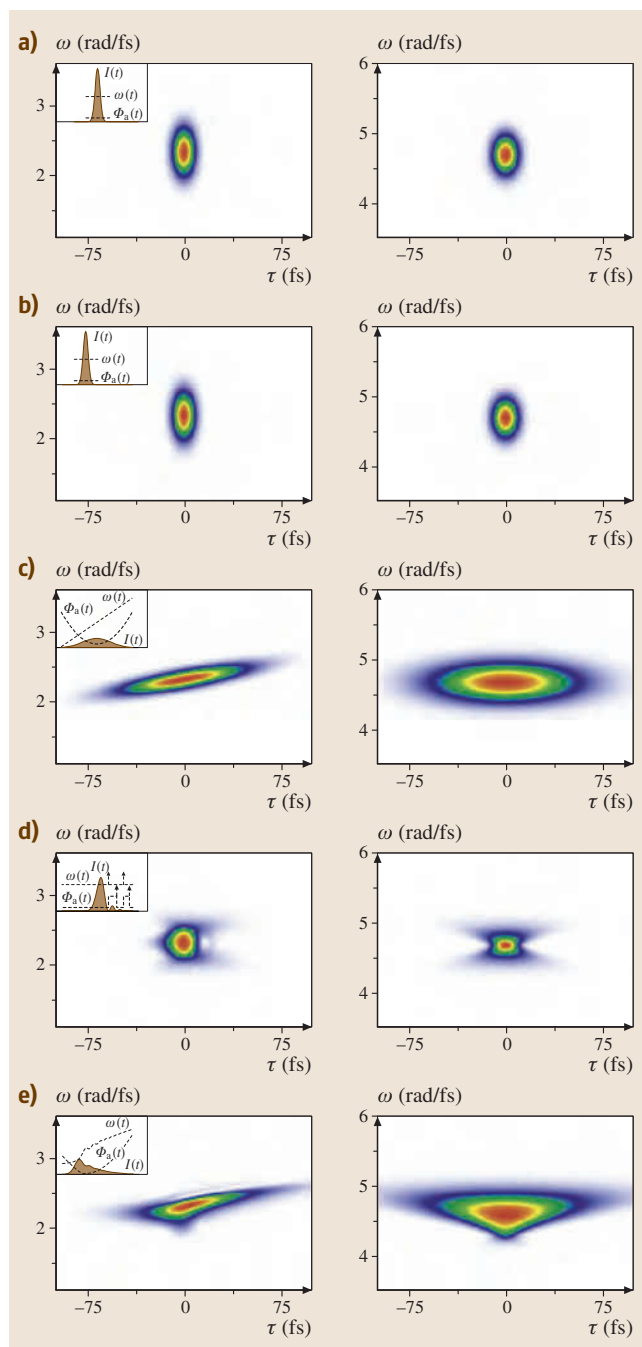
technique has been termed frequency-resolved optical gating (FROG) and is described in great detail in [12.6, 125] and references therein.

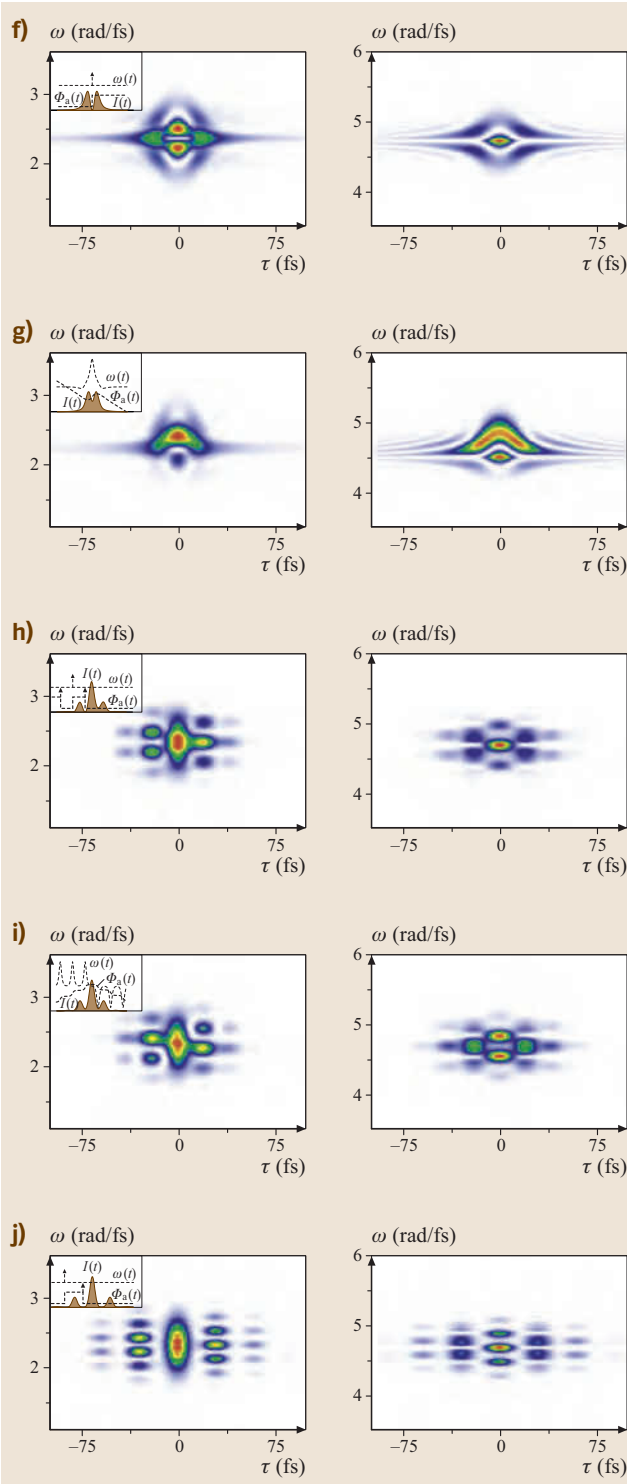
Depending on the instantaneous nonlinear optical effect used to gate the pulse in FROG, several different FROG geometries have been investigated [the setup of Fig. 12.25b) would correspond to a second-harmonic-generation (SHG) FROG]. These geometries can also be implemented as single-shot devices, similar to the single-shot autocorrelator depicted in Fig. 12.26. The FROG trace $I_{\text{FROG}}(\omega, \tau)$, that is a plot of frequency (wavelength) versus delay, is a spectrogram of the complex amplitude E_c [see (12.15)]. Neglecting any prefactors, different nonlinear optical effects yield the following expressions according to [12.6, 125].

Polarization–Gate (PG) FROG.

$$I_{\text{FROG}}^{\text{PG}}(\omega, \tau) = \left| \int_{-\infty}^{\infty} E_c(t)\, |E_c(t-\tau)|^2\, e^{-i\omega t}\, dt \right|^2 .$$

(12.82)

In a crossed-polarizer arrangement for the probe pulse this technique makes use of induced birefringence in


fused silica in the presence of the gate pulse. The third-order optical nonlinearity is the electronic Kerr effect. The FROG traces obtained by this method are very intuitive (Fig. 12.31).


Self–Diffraction (SD) FROG.

$$I_{\mathrm{FROG}}^{\mathrm{SD}}(\omega, \tau) = \left| \int\limits_{-\infty}^{\infty} E_{\mathrm{c}}(t)^2 E_{\mathrm{c}}^*(t - \tau) \mathrm{e}^{-\mathrm{i}\omega t} \, \mathrm{d}t \right|^2 .$$

(12.83)

In this approach the two beams (with the same polarization) generate a sinusoidal intensity pattern in the nonlinear medium (for example, fused silica) and hence introduce a material grating, which diffracts each beam. One of the diffracted beams is then the signal beam sent to the spectrometer.

Transient–Grating (TG) FROG.

$$I_{\mathrm{FROG}}^{\mathrm{TG}}(\omega, \tau)$$
$$= \left| \int\limits_{-\infty}^{\infty} E_{\mathrm{c}1}(t) E_{\mathrm{c}2}^*(t) E_{\mathrm{c}3}(t - \tau) \mathrm{e}^{-\mathrm{i}\omega t} \, \mathrm{d}t \right|^2 . \quad (12.84)$$

This is a three-beam setup, where two pulses are overlapped in time and space at the optical Kerr medium (for example fused silica), producing a refractive index grating similar as in SD FROG. In a TG a third pulse is variably delayed and overlapped in the fused silica and is diffracted by the induced grating, producing the signal beam for the spectrometer. The beams in the TG geometry (three input and one output) are kept nearly collinear and form a so-called boxcars arrangement, where the four spots appear in the corners of a rectangle when placing a card into the beams after the nonlinear medium. As TG is a phase-matched process, the sensitivity is higher compared to the SD approach. Depending on which pulse is variably delayed – with the other two coincident in time – the TG FROG trace is mathematically equivalent to the PG FROG (pulse one or three is delayed) or to the SD FROG (pulse two is delayed).

Third–Harmonic–Generation (THG) FROG.

$$I_{\mathrm{FROG}}^{\mathrm{THG}}(\omega, \tau) = \left| \int\limits_{-\infty}^{\infty} E_{\mathrm{c}}(t - \tau)^2 E_{\mathrm{c}}(t) \mathrm{e}^{-\mathrm{i}\omega t} \, \mathrm{d}t \right|^2 .$$

(12.85)

This method makes use of third-harmonic generation as the nonlinear process.

Second–Harmonic–Generation (SHG) FROG.

$$I_{\text{FROG}}^{\text{SHG}}(\omega, \tau) = \left| \int_{-\infty}^{\infty} E_c(t) E_c(t - \tau) e^{-i\omega t} \, dt \right|^2 .$$

(12.86)

SHG FROG involves spectrally resolving a standard SHG-based non-collinear intensity autocorrelator, which always yields symmetric traces, resulting in a direction of time ambiguity for the SHG FROG. This ambiguity can experimentally be removed, for example, by placing a piece of glass in the beam before the beam splitter to introduce positive chirp or to create satellite pulses via surface reflections. Because of its high sensitivity and as it is based on a standard SHG autocorrelator, this method is widely employed. Examples of SHG FROG traces for various pulse shapes are given in Fig. 12.31.

A comparison of the different approaches is given in Table 12.4. Various calculated traces for common ultrashort pulse distortions for the PG and the SHG FROG geometries are given in Fig. 12.31. Calculated FROG traces for the other beam geometries are given in [12.125]. Measured FROG traces for different geometries are compiled in [12.6].

It is important to note that knowledge of the spectrogram (or sonogram) of the electric field of an ultrashort laser pulse is sufficient to completely determine the electric field in amplitude and phase (besides some ambiguities such as the absolute phase) because a spectrogram is equivalent to the two-dimensional phase-retrieval problem in image science and astronomy [12.126]. In general, phase retrieval is the problem of finding a function knowing only the magnitude (but not the phase) of its Fourier transform. Phase retrieval for a function of one variable is impossible. For example, knowledge of a pulse spectrum does not fully determine the pulse as infinitely many different pulses have the same spectrum (Fig. 12.3a–j). However, phase retrieval for a function of two variables is possible and the FROG trace can be rewritten as the squared magnitude of a two-dimensional Fourier transform [12.125]. Very sophisticated iterative retrieval procedures, which can rapidly retrieve the pulse from the FROG trace with update rates up to several Hz, exist [12.127].

In the following some additional attributes of FROG techniques, which also partially hold for sonogram methods, are summarized:

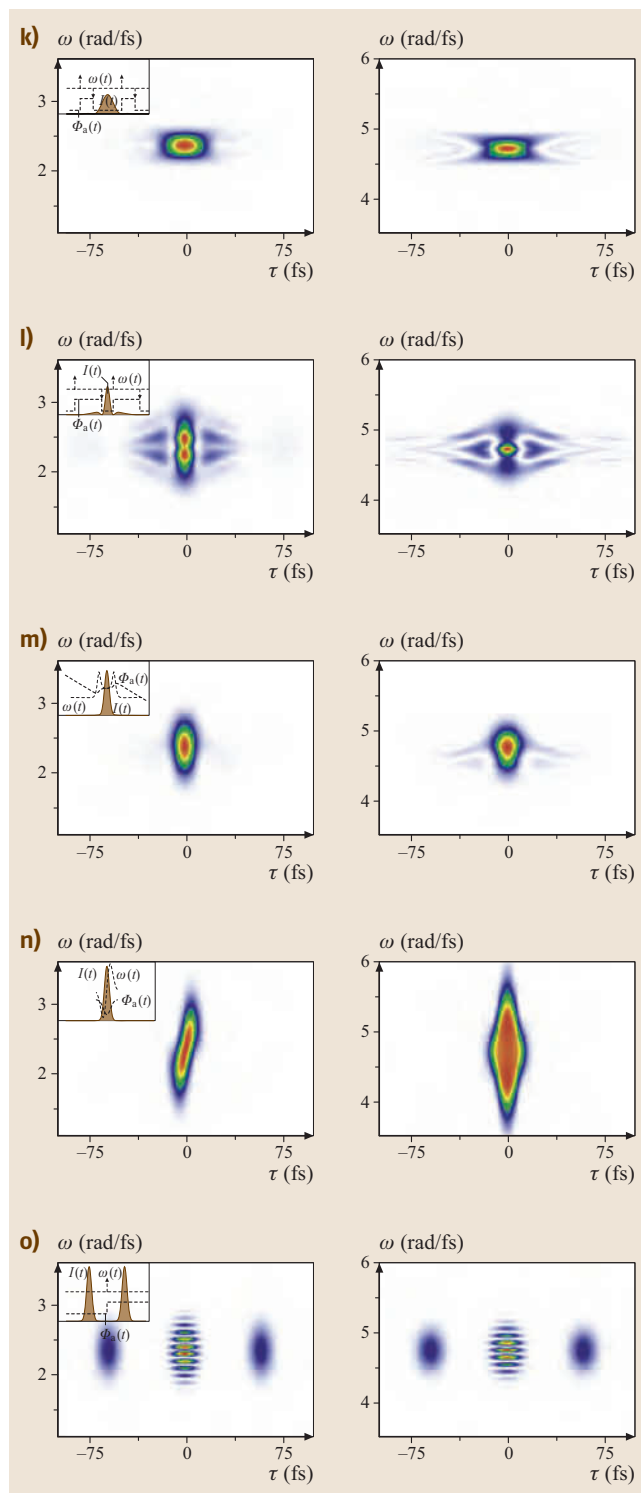
- As the FROG trace consists of $N \times N$ points, while the intensity and phase on the other hand only have


Table 12.4 Comparison of different FROG geometries (PG = polarization gate; SD = self-diffraction; TG = transient grating; THG = third-harmonic generation; SHG = second-harmonic generation). Sensitivities are only approximate and assume 800 nm 100 fs pulses focused to about 100 μm (10 μm for THG) to be measured. In the schematics only the part involving the nonlinear optical effect characterized by its nonlinearity is displayed. Not shown are delay lines and various lenses, as these are common to all setups and are similar to the optical layouts shown in Fig. 12.25b and Fig. 12.26. Solid lines indicate input pulses; dashed lines indicate signal pulses. The frequencies shown (ω, 2ω, 3ω) are the carrier frequencies of the pulses taking part and indicate whether the signal pulse has the same carrier frequency as the input pulse or is shifted as in SHG and THG. D denotes a detector being composed of a spectrometer and camera system. (WP = wave plate; P = polarizer) (after [12.6])

Geometry	PG	SD	TG	THG	SHG
Nonlinearity	$\chi^{(3)}$	$\chi^{(3)}$	$\chi^{(3)}$	$\chi^{(3)}$	$\chi^{(2)}$
Sensitivity (single shot) (μJ)	≈ 1	≈ 10	≈ 0.1	≈ 0.03	≈ 0.01
Sensitivity (multi shot) (nJ)	≈ 100	≈ 1000	≈ 10	≈ 3	≈ 0.001
Advantages	Intuitive traces; automatic phase matching	Intuitive traces; deep UV capability	Background–free; sensitive; intuitive traces; deep UV capability	Sensitive; very large bandwidth	Very sensitive
Disadvantages	Requires polarizers	Requires thin medium; not phase matched	Three beams	Unintuitive traces; very short λ signal	Unintuitive traces; short λ signal
Ambiguities	None known	None known	None known	Relative phase of multiple pulses $\phi, \phi +/- 2\pi/3$	Relative phase of multiple pulses $\phi, \phi + \pi$; direction of time
Schematics					

2N points, the FROG trace overdetermines the pulse. This gives rise to an increased robustness of the two-dimensional methods and to an improved immunity towards measurement noise. The nonconvergence of the FROG algorithm therefore can be a hint of the presence of systematic errors.

- Other than autocorrelation techniques, FROG offers a built-in consistency check to detect systematic errors. It involves computing the *marginals* of the FROG trace, that is, integrals of the trace with respect to delay or frequency. The marginals can be compared to the independently measured spectrum or autocorrelation. For an SHG FROG the time marginal yields the intensity autocorrelation and the frequency marginal yields the second-harmonic spectrum. The marginals of the SHG FROG traces in

Fig. 12.31 are therefore given in the corresponding pictures of Fig. 12.28.

- FROG can also be used in a cross-correlation variant named XFROG [12.128]. In this case a known pulse is used to gate an unknown pulse (usually derived from the known one), where no spectral overlap between the pulses is required. Via sum- or difference-frequency generation or other nonlinear processes, pulses in the ultraviolet (UV) and infrared (IR) spectral range can be characterized. The technique has been refined for measuring pulses in the attojoule (per pulse) regime and is capable of measuring pulses with poor spatial coherence and random phase, such as fluorescence [12.129].

- In the sub-10 fs range SHG FROG has been demonstrated down to 4.5 fs pulse durations with the help

of type I phase matching in a 10 μm-thick BBO crystal [12.130]. In this regime the non-collinear beam geometry can also introduce beam smearing artefacts. Type II phase matching allows the use of a collinear SHG FROG geometry, which is free of geometrical smearing [12.131, 132]. The FROG traces generated in this arrangement do not contain the optical fringes associated with interferometric autocorrelations and, therefore, can be processed by existing SHG FROG algorithms.

- Making use of a thick SHG crystal as a frequency filter [12.134, 135] allows for the construction of an extremely simple and robust FROG setup that has been demonstrated for 800 nm pulses in the range from 20 fs to 5 ps for different spectral widths of the ultrashort pulses. The device was termed grating-eliminated no-nonsense observation of ultrafast incident laser light E-fields (GRENOUILLE) [12.6]. Spatial temporal distortions such as spatial chirp and pulse front tilt can also be measured via GRENOUILLE [12.136, 137] [spatial chirp: each frequency is displaced in the transverse spatial coordinates, often resulting from misaligned prism pairs and tilted windows; pulse front tilt: the pulse group fronts (intensity contours) are tilted with respect to the perpendicular to the propagation direction, resulting from residual angular dispersion after pulse compressor or stretcher units].

- The wavelength limitation due to nonlinear optical processes can be circumvented by the use of multi-photon ionization as a nonlinearity. Measurements of interferometrically recorded energy-resolved photoelectron spectra generated by above-threshold ionization were demonstrated to yield FROG-type time–frequency distributions that were used to characterize ultrashort laser pulses [12.138]). This approach is potentially applicable to the XUV wavelength region.

Sonogram–Based Methods

Recording the sonogram involves slicing the frequency spectrum and measuring the arrival time of the frequency components. Experimentally this can be achieved, for example, by cross-correlation of a pulse with a frequency-filtered replica of the pulse in an instantaneous nonlinear medium (Fig. 12.32). The corresponding technique is known as frequency-domain phase measurement (FDPM) and is described in [12.139]. The method gives information on the group delay and an integration can be performed that gives the spectral phase function without any iterative al-
Fig. 12.32 Schematic of a frequency-domain phase measurement (FDPM) or spectrally and temporally resolved upconversion technique (STRUT) apparatus

Fig. 12.34 Experimental setup for real-time spatial–spectral interference (SSI) measurements. (After [12.133])

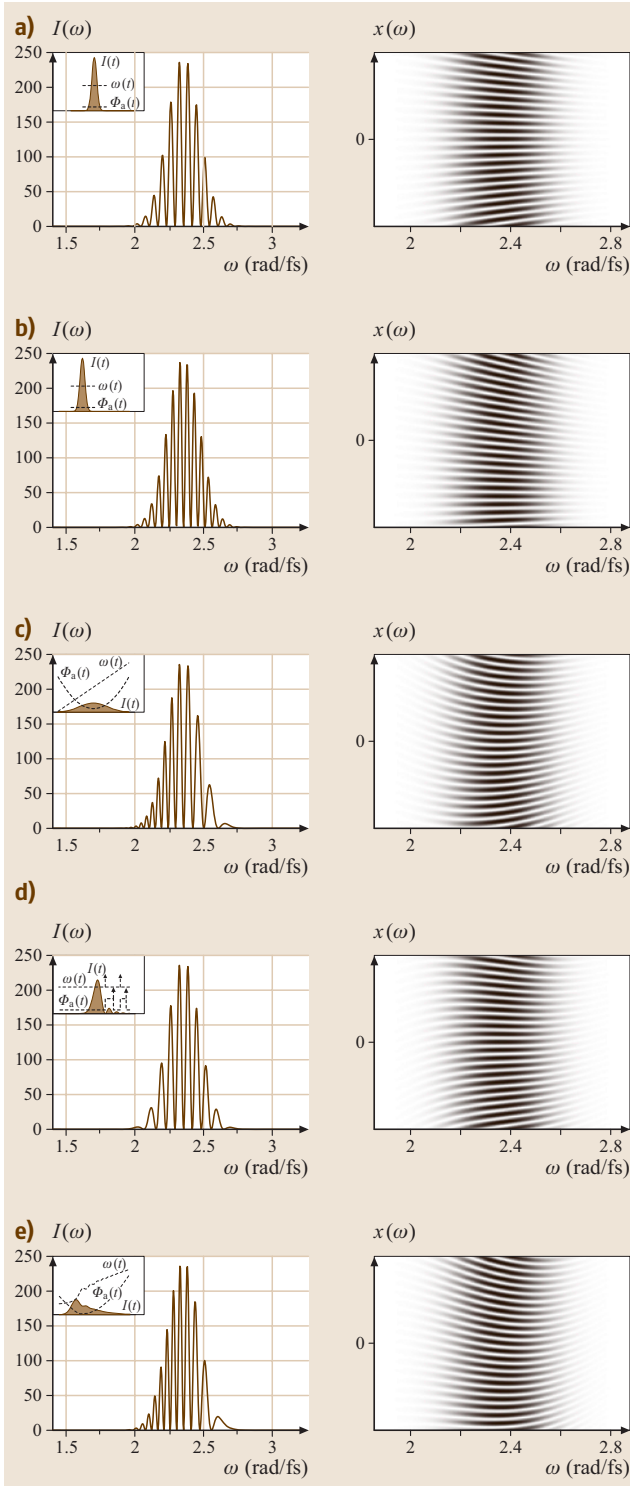
gorithm. An experimental realization has been termed spectrally and temporally resolved upconversion technique (STRUT) [12.140] and also exists in a single-shot


Fig. 12.35a–o Calculated spectral interference (SI) and spatial–spectral interference (SSI) traces for various ultrashort pulse shapes with a central wavelength of 800 nm according to the pulses displayed in Fig. 12.3. *Left – SI*: the time delay between both pulses is 100 fs. *Right*: SSI the angle 2Θ between both beams is $2°$. The temporal intensity $I(t)$, the additional temporal phase $\Phi_a(t)$ and the instantaneous frequency $\omega(t)$ are shown in the *insets* as a reminder. **(a)** bandwidth-limited Gaussian laser pulse of 10 fs duration, **(b)** bandwidth-limited Gaussian laser pulse of 10 fs duration shifted in time to -20 fs due to a linear phase term in the spectral domain ($\phi' = -20$ fs), **(c)** symmetrical broadened Gaussian laser pulse due to $\phi'' = 200$ fs^2, **(d)** third-order spectral phase ($\phi''' = 1000$ fs^3) leading to a quadratic group delay, **(e)** combined action of all spectral phase coefficients, **(a)**-**(d)(f)** π step at the central frequency, **(g)** π step displaced from the central frequency, **(h)** sine modulation at the central frequency with $\phi(\omega) = 1\sin[20\,\text{fs}(\omega - \omega_0)]$, **(i)** cosine modulation at the central frequency with $\phi(\omega) = 1\cos[20\,\text{fs}(\omega - \omega_0)]$, **(j)** sine modulation at the central frequency with $\phi(\omega) = 1\sin[30\,\text{fs}(\omega - \omega_0)]$, **(k)** symmetrical clipping of spectrum, **(l)** blocking of the central frequency components, **(m)** off-center absorption, **(n)** self-phase modulation, (note the spectral broadening) **(o)** double pulse, with a pulse-to-pulse delay of 60 fs ◄, ►►

version [12.141]. As the sonogram and the spectrogram are mathematically equivalent FROG retrieval algorithms (being in principle somewhat slower) can also be used in this approach [12.141]. From a practical point of view the method is experimentally more involved than a FROG setup and it is less sensitive, because energy is lost at the filter before the nonlinear medium. In the SHG version, the STRUT apparatus and the FROG apparatus are identical when removing the frequency filter and using a spectrometer as the detector in Fig. 12.32.

12.3.5 Spectral Interferometry

The techniques described so far make use of nonlinear optical processes in order to determine the amplitude and phase of ultrashort laser pulses. Although, with the help of SHG FROG, pulses down to the picojoule regime can be measured in a multishot setup, shaped ultrashort laser pulses might spread out their energy over a time scale of picoseconds and thus prevent characterization with the help of nonlinear processes. However, as these pulses are usually created from an oscillator or an amplifier a well-characterized reference pulse is often available. This allows to make use of highly sensi-

tive linear techniques to determine the amplitude and phase of an ultrashort laser pulse. The technique is named spectral interferometry (SI), frequency-domain interferometry or Fourier-transform spectral interferometry [12.6, 142–145]. The basic SI setup is depicted in Fig. 12.33. A well-characterized reference pulse $E_{ref}(t)$ and a modified signal pulse $E(t)$ derived from an experiment or a pulse shaper are directed collinearly into a spectrometer. The measured SI spectrum $S_{SI}(\omega)$ is proportional to the square of the Fourier transform of the sum of the two fields:

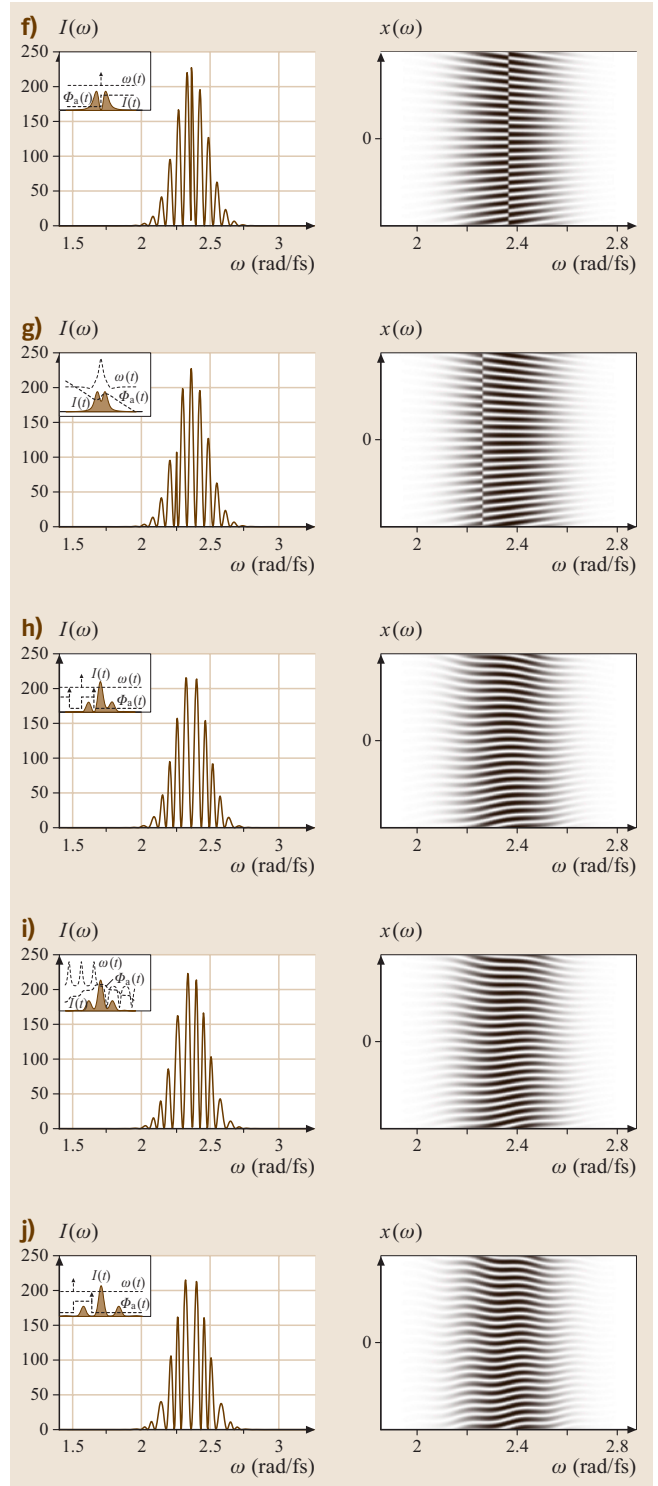
$$S_{SI}(\omega) \propto |\text{Fouriertransform}\{E_{ref}(t) + E(t-\tau)\}|^2$$
$$\propto |\tilde{E}_{ref}(\omega) + \tilde{E}(\omega)e^{-i\omega\tau}|^2$$
$$\propto |\sqrt{I_{ref}(\omega)}e^{-i\phi_{ref}(\omega)} + \sqrt{I(\omega)}e^{-i\phi(\omega)-i\omega\tau}|^2$$
$$= I_{ref}(\omega) + I(\omega) + \sqrt{I_{ref}(\omega)}\sqrt{I(\omega)}$$
$$\times (e^{i\phi_{ref}(\omega)-i\phi(\omega)-i\omega\tau} + c.c.)$$
$$= I_{ref}(\omega) + I(\omega) + 2\sqrt{I_{ref}(\omega)}\sqrt{I(\omega)}$$
$$\times \cos(\phi_{ref}(\omega) - \phi(\omega) - \omega\tau). \quad (12.87)$$

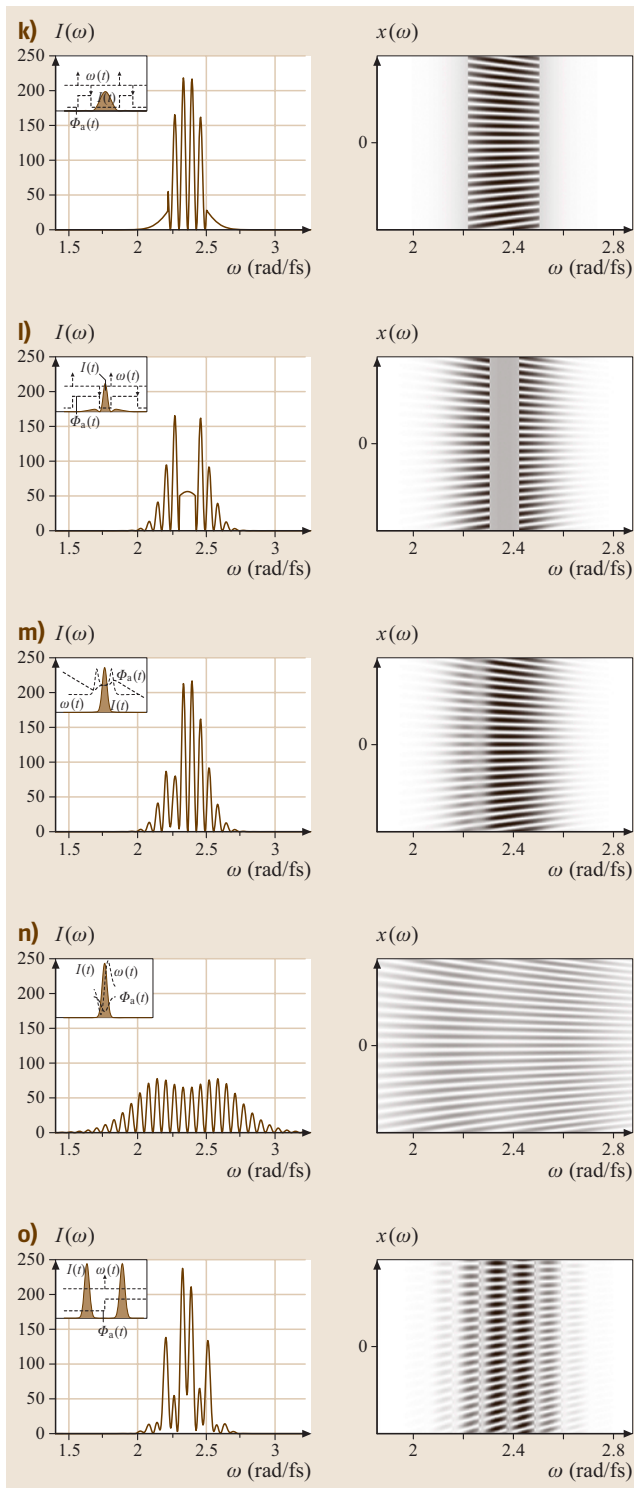
The phase difference

$$\Delta\phi(\omega) = \phi_{ref}(\omega) - \phi(\omega) \quad (12.88)$$

can be extracted from the measured $S_{SI}(\omega)$. Using the arcos function is not recommended because experimental noise can lead to large phase errors [12.145]. Commonly a Fourier-transform technique is used [12.145, 146] where the phase difference is extracted by the Fourier transform of the measured spectrum, ignoring the negative and zero-frequency components and shifting the positive-frequency components to direct current (DC) in order to remove the delay term $e^{-i\omega\tau}$. An inverse Fourier transform then yields the phase difference $\Delta\phi(\omega)$. With the help of the known reference phase $\phi_{ref}(\omega)$, $\phi(\omega)$ is finally obtained.

In the following some attributes of SI are summarized:

- SI requires the spectrum of the reference pulse to contain completely the spectrum of the unknown pulse.
- If the reference pulse and the signal pulse are identical, the phase difference is zero. The remaining oscillations on the spectrum due to the delay term are a convenient tool to adjust, for example, interferometric autocorrelator setups.
- Using the FROG technique for characterization of the reference pulse, the combined technique was termed temporal analysis by dispersing a pair of light E-fields (TADPOLE) [12.6, 147].




- SI is a heterodyne technique and amplifies the generally weak signal pulse [see (12.87)]. With the help of TADPOLE, pulse trains with an energy per pulse in the zeptojoule (zepto $= 10^{-21}$) regime have been analyzed [12.147].

- Once the reference phase is known, phase retrieval does not require an iterative procedure and is therefore fast. This allows, for example, for the synthesis of arbitrary laser pulse shapes with the help of feedback-controlled femtosecond pulse shaping techniques [12.148]. Together with its high sensitivity, TADPOLE is well suited to the characterization of complex-shaped femtosecond laser pulses. Furthermore, in a dual-channel setup SI has been used to characterize complex polarization-shaped femtosecond laser pulses [12.78]. The setup for the characterization of time-dependent polarization profiles has been called polarization-labeled interference versus wavelength for only a glint (POLLIWOG) [12.149].

- SI can also be implemented in a spatial variation, where the reference pulse and the signal pulse propagate at an angle of 2Θ with respect to each other (Fig. 12.34). The frequency components of the optical fields of the two propagating pulses are mapped in one dimension by a diffraction grating and a cylindrical lens and interfere at the focal plane of the lens. The technique is called spatial–spectral interference (SSI). The corresponding device is a convenient tool for optimizing various setups such as pulse shapers and compressors as the fringe patterns are displayed in real time and the information is encoded in an intuitively interpretable pattern [12.133]. A comparison of calculated SI and SSI traces for various ultrashort pulse distortions is given in Fig. 12.35.

- There also exists a self-referencing variant of SI that does not require separate characterization of the reference pulse. This technique is called spectral phase interferometry for direct electric field reconstruction (SPIDER) [12.17, 150] and involves appropriate temporal stretching of a reference pulse followed by sum-frequency generation with two well-displaced copies of the unstretched input pulse. This technique has been successfully demonstrated for the characterization of ultrashort pulses in the few-cycle regime [12.151]. Due to the nonlinear process involved, SPIDER is less sensitive than TADPOLE. A comparison of SHG FROG and SPIDER for sub-ten-femtosecond pulse characterization is given in [12.152]. A spatially resolved version of SPIDER has also been demonstrated [12.153]. A setup that is

capable of characterizing a pulse at the interaction point of an experiment, called zero additional phase (ZAP) SPIDER, has been demonstrated for visible and sub-20-femtosecond ultraviolet pulses [12.154].
