FIGS. **31** and **32** show the first modification of the resin-formed body **320** for forming the ball circulation passage, which is described in the third embodiment.

In the first modification, the resin-formed body **320** for forming the ball circulation passage is composed of the first resin-formed frame **320**A, which is obtained by integrally connecting both of the ball passage forming portions **321, 321** and the resin pipes **323** at their ends with the direction changing passage-inner guide forming portions **322**A for one side, and the second resin formed frame **320**B, which is provided with the direction changing passage-inner guide forming portions **322**B for the other side and separately formed from the first resin-formed frame **320**A.

In this case, the ball passage forming portions **321, 321** are integrally connected with the direction changing passage-inner guide forming portions **322**A through the thin sheet portion **329**A as in the first embodiment.

The direction changing passage-inner guide forming portions **322**A are also integrally connected with the resin pipes **323** through the thin sheet portion **329**A. In this case, the resin pipe **323** is formed into a tubular integral body, although the half pipe members are used in the third embodiment. Accordingly, there exists no inserting hole s**34** in the thin sheet portion **329**A, and the ball returning passage **309** is exposed on the thin sheet portion **329**A.

The first resin-formed frame **320**A and the second resin-formed frame **320**B are connected, as shown in FIG. **32**, by means of a joint method using the combination of a recess and a projection to be inserted therein, such as a faucet joint method. In the illustrated example, a recess portion **336** of a dove-tail groove is formed in the second resin-formed frame **320**B, and an engaging projection **335** to be engaged with the recess portion **336** is formed, on the other hand, in the ball passage forming portions **321, 321**.

In this case, the resin pipe **323** of the first resin-formed frame **320**A is inserted in the through-hole **314** of the main body **313**, and the ball passage forming portions **321, 321** and the connecting plate portion **236** are inserted along the inner surface of the recess **307** of the main body **313**.

Then, the engaging projections **335** formed at the respective free end portions of the ball passage forming portions **321, 321** and the connecting plate portion **326** are engaged with the recess portions **336** formed on the thin sheet portion **329**B of the second resin-formed frame **324**B, which is arranged on the other end surface of the main body **313**.

The recess portions **336** may be formed on the first resin-formed frame **320**A and the engaging projections **335** may be formed on the second resin-formed frame **320**B. The connecting method is not limited to the method described above, and there may be used any conventional connecting method, in which the ends of the divided parts can be maintained in a proper connecting position and connected.

[Second Modification]

FIGS. **33** and **34** show the second modification of the resin-formed body **320** for forming the ball circulation passage, which is described in the third embodiment.

In the second modification, the resin-formed body **320** for forming the ball circulation passage, which has been obtained by integrally forming both of the ball passage forming portions **321, 321** and the resin pipes **323** as a returning passage forming portion with a pair of direction changing passage-inner guide forming portions **322, 322**, is divided at the middle portion of each of the ball passage forming portions **321, 321** and the ball returning passage forming portions **323** into two parts. More specifically, the ball passage forming portions **321, 321** and the ball returning passage forming portions **323** are divided at their middle portion into the respective two half parts, and each of the thus divided two half parts is integrally formed with the direction changing passage-inner guide forming portions **322, 322**, thus forming two resin-formed frames **320**C, **320**D having substantially the same shape.

Recess portions **338** and engaging projections **337** to be inserted therein are formed on the divided ends of the ball passage forming portions **321, 321**, the divided ends of the central connecting plate portion **326** and the divided ends of the resin pipes **323**.

[Third Modification]

FIG. **35** shows the third modification of the resin-formed body **320** for forming the ball circulation passage, which is described in the third embodiment.

In the third modification, there is not used the resin pipe **323** as a returning passage forming portion described in the first embodiment, and a resin-formed frame **320**E is obtained by integrally forming the ball passage forming portions, the connecting plate portions **326** with the thin sheet portions **329, 329** each having the pair of direction changing passage-inner guide forming portions **322, 322**. The ball returning passage **309** is composed as a through-hole formed in the main body **313**.

In this case, an engaging projection **339***a*, which is engageable with a tapered portion **315** formed in the opening end of the ball returning passage **309** may be formed in the opening end of the ball hole **339** of the thin sheet portion **329**. Such a construction permits to make a proper connection of the end of the ball returning passage **309** and the direction changing passage-inner guide forming portion **322**.

In the illustrated example, an arcuate engaging projection **348** is additionally formed on the connection portion of the outer guide groove **310***b* formed on the side cover plate **340** with the ball returning passage **309**. The engaging projection **48** can be engaged with the thin sheet portion **329**.

[Fourth Modification]

FIG. **36** shows the fourth modification of the resin-formed body **320** for forming the ball circulation passage, which is described in the third embodiment.

In the fourth modification, there is not used the resin pipe **323** described in the third modification, a resin-formed frame **320**F is obtained by integrally forming the ball passage forming portions **321** with the direction changing passage-inner guide forming portions **322** for the one side, the other resin-formed frame **320**G provided with the direction changing passage-inner guide forming portions **322** for the other side is separately formed from the above-mentioned resin-formed frame **320**F, and the resin-formed frames **320**F, **320**G are connected with each other by engagement of the engaging projection **335** with the recess **336**. The structure other than the above-mentioned construction is the same as that of the third modification.

In the third embodiment described above, there are used three sets of resin-formed bodies for forming the ball circulation passage, each of which is divided into two parts. Six sets of resin-formed bodies may however be used for the respective circulation passages. The single set of resin-formed body may also be used. In this case, the divisional method of the resin-formed body should be based on the first, second and fourth modifications described above, taking into consideration the difficulty of insertion of the resin-formed body into the main body of the outer tube.

[Modifications of the ball train]

In the third embodiment and the first to fourth modifications thereof, the ball spline has the angular contact type ball train. The present invention may also be applied to the ball spline having the radial contact type ball train as shown in FIG. **37**. In such a radial contact type ball train, the spline shaft has no projections on the outer periphery so as to reveal the circular cross-section, and the outer tube has no recesses on the inner periphery so as to reveal the hollow cylindrical shape. The radial contact type ball train has the smaller contact angle α than that of the angular contact type ball train. With respect to the divisional method of the resin-formed body **320** for forming the ball circulation passage, all the patterns described in the third embodiment and the first to fourth modifications thereof may be used.

In the example illustrated in FIG. **37**, six resin-formed bodies **320** for forming the ball circulation passage are separately provided from each other for the respective six ball trains. The two sets of resin-formed bodies **320** mentioned above may be integrally formed with each other so as to prepare three sets of resin-formed bodies **320** having the six ball circulation passages. The single resin-formed body having the six ball circulation passages may also be used.

[FOURTH EMBODIMENT]

FIGS. **38** and **39** illustrate the forth embodiment of the present invention. In the fourth embodiment, the present invention is applied to a roller spline, in which rollers are used as the rolling members.

The roller spline **401** as shown in FIG. **38** is composed of a spline shaft **402** as a guide member extending linearly, and

an outer tube **404** arranged so as to be movable along the spline shaft **402** through the rollers **403** as the rolling members.

The spline shaft **402** is formed into a long bar shape having a modified cross-section. The spline shaft **402** has on its outer periphery three projections **406**. Two roller running surfaces **405**, **405** are formed on the both sides of each of the projections **406**, so as to provide the total number of running surfaces of six.

The outer tube **404** has on its inner periphery three recesses **407** corresponding to the projections **406** of the spline shaft **402**, respectively. Roller running counter-surfaces **408**, **408** are formed at the both corners of each of the recesses **407**, so as to correspond to the above-mentioned roller running surfaces **405**, **405**.

In addition, the outer tube **404** has six roller returning passage **409**, **409**; **409**, **409**; **409**, **409**, which are in parallel with the six roller running counter-surfaces **408**, **408**; **408**, **408**; **408**, **408**, and six direction changing passages **410**, **410**; **410**, **410**; **410**, **410** formed into a U-shaped tube, which connect the ends of the above-mentioned roller running counter-surfaces **408**, **408**; **408**, **408**; **408**, **408** with the ends of the above-mentioned roller returning passage **409**, **409**; **409**, **409**; **409**, **409**. The outer tube **404** has six circulation passages in this manner.

The rollers **403** inserted in each of the circulation passages are connected with each other by means of the same roller retainer **412** as the roller retainer **212** shown in FIG. **19**, so as to form the train of the rollers **403**. The rollers **403** are guided by means of the roller retainer **412** and circulated in each of the circulation passages.

The outer tube **404** is composed of a tubular main body **413** having he roller running counter-grooves **408**, **408**; **408**, **408**; **408**, **408**, three resin-formed bodies **420**, **420**, **420** for forming the ball circulation passage, which are to be inserted in the main body **413**, and a pair of side cover plates **440**, **440** secured on the both ends of the main body **413** after the insertion of the resin-formed bodies **420**, **420**, **420** in the main body **413**.

In the fourth embodiment, the six circulation passages are formed by the three resin-formed bodies **420**, **420**, **420** as in the third embodiment.

Each of the resin-formed bodies **420** for forming the ball circulation passage has a pair of the roller passage forming portions **421**, **421** extending along the longitudinal side edges of the roller running counter-groove **408**, a pair of direction changing passage-inner guide forming portions **422**, **422** provided on the both ends of the main body **413**, and resin pipes **423** as a returning passage forming portion, which are inserted in through-holes formed in the main body **413**.

The roller passage forming portions **421**, **421** are provided with guide grooves for guiding the both side edges of the belt portion **412***b* of the roller retainer **412** in a loaded area. The guide grooves can prevent the roller retainer **412** not only from being swung during run of the roller, but also from being sagged by engaging the side edges of the belt portion **412***b* with the guide groove **421***a*, when the outer tube **404** is removed from the spline shaft **402**. The rollers **403** are supported by the roller retainer **412**. More specifically, the roller retainer **412** is supported by a jaw portion of the guide groove **421***a*, with the result that the rollers **403** are kept in its proper position so as not to come off the outer tube **404**.

Guide grooves **409***c*, **410***c* are also formed in the roller returning passage **409** and the direction changing passage **410** as non-loaded areas, in order to guide the side edges of the belt portion **412***b*. The guide grooves **409***c*, **410***c* are connected to the above-mentioned guide groove **421***a* in the loaded area so as to form an endless groove on the entire periphery.

When the roller retainer **412** is not used, the guide grooves **421***a*, **410***a*, **409***a* are not needed, and the jaw portions as shown in FIG. **20**(*h*) for supporting the ends of the roller are formed on the roller passage forming portions **421**.

In each of the resin-formed bodies **420** for forming the roller circulation passage, at least one of four connecting portions of the roller passage forming portions **421, 421** with the pair of the direction changing passage-inner guide forming portions **422, 422** are integrally connected with each other. The resin-formed body **420** is divided at the other portions into separate parts so as to be able to be inserted in the main body **413**.

The fundamental embodiment of the resin-formed body for forming the roller circulation passage, which is to be used for the spline unit is described in detail in the third embodiment. The structure of the resin-formed body for forming the roller circulation passage is described in detail in the second embodiment. Here, only the fundamental divisional pattern of the resin-formed body **420** for forming the roller circulation passage will be briefly described below with reference to FIG. **39**.

In FIG. **39**(*a*), the both ends of the four sets of roller passage forming portions **421, 421** are integrally connected with the respective one end of the pair of direction changing passage-inner guide forming portions **422, 422** to form a single resin frame **424**, and the both ends of each of the returning passage forming portions **423** are not connected with the other end of the direction changing passage-inner guide forming portion **422** so that these parts can be assembled into the main body **413**.

In FIG. **39**(*b*), the resin-formed body **420** for forming the roller circulation passage is composed of the first resin-formed frame **420**A, which is obtained by integrally connecting both of the roller passage forming portions **421, 421** and the resin pipes **423** as a returning passage forming portion at their ends with the direction changing passage-inner guide forming portions **422**A for one side, and the second resin-formed frame **420**B, which is provided with the direction changing passage-inner guide forming portions **422**B for the other side and separately formed from the first resin-formed frame **420**A.

In FIG. **39**(*c*), the resin-formed body **420** for forming the roller circulation passage, which has been obtained by integrally forming both of the roller passage forming portions **421, 421** and the resin pipes **423** as a returning passage forming portion with a pair of direction changing passage-inner guide forming portions **422, 422**, is divided at the middle portion of each of the roller passage forming portions **421, 421** and the returning passage forming portions **423** into two parts. More specifically, the roller passage forming portions **421, 421** and the resin pipes **423** are divided at their middle portion into the respective two half parts, and each of the thus divided two half parts is integrally formed with the direction changing passage-inner guide forming portions **422, 422**, thus forming two resin-formed frames **420**C, **420**D having substantially the same shape.

In FIG. **39**(*d*), there is not used the resin pipe **423** as shown in FIG. **39**(*a*), and a resin-formed frame **420**E is obtained by integrally forming both of the roller passage forming portions and the connecting plate portion **326** with the thin sheet portions **429, 429** each having the pair of direction changing passage-inner guide forming portions **422, 422**. The roller returning passage **409** is composed as a through-hole formed in the main body **413**.

In FIG. **39**(*e*), there is not used the resin pipe **423** as shown in FIG. **39**(*b*), and a resin-formed frame **420**F is obtained by integrally forming the roller passage forming portions **421** with the direction changing passage-inner guide forming portions **422** for the one side, the other resin-formed frame **420**G provided with the direction changing passage-inner guide forming portions **422** for the other side is separately formed from the above-mentioned resin-formed frame **420**F.

In FIGS. **39**(*a*) to **29**(*e*), the resin-formed frames are connected with each other by means of the conventional joint method such as a faucet joint, which uses engagement of the engaging projection with the recess.

[FIFTH EMBODIMENT]

FIGS. **40** to **44** show a linear motion guiding apparatus of the fifth embodiment of the present invention.

The linear motion guiding apparatus **501** is provided with a guide rail **502** as a guide member, which extends linearly, and a movable block **504** as a movable member, which is arranged so as to be movable along the guide rail **502** through a large number of balls **503** as rolling members.

The guide rail **502** is formed into a long bar shape having a rectangular cross-section. Two ball running grooves **505, 505** as a rolling member running track are formed on each of the right and left-hand side surfaces of the guide rail **502**, so as to provide a total number of grooves **505** of four. The guide rail **502** has on each of its side surfaces a projection **502***a*, on the upper and lower positions of which the ball running grooves **505, 505** are arranged.

The movable block **504** is formed as a block body having an inverse U-shaped cross-section, with its opening end being directed downwardly. The block body is provided with a horizontal portion **506**, which faces the upper surface of the guide rail **502** and with a pair of wing portions **507, 507**, which extend downwardly from the right and left ends of the horizontal portion **506** and face the right and left-hand side surfaces of the guide rail **502**, respectively. Each of the wing portions **507, 507** has on its inner surface two ball running counter-grooves **508, 508** as a rolling member running counter-track, which correspond to the ball running grooves **505, 505** formed on the right and left-hand side surfaces of the guide rail **502**.

Each of the right and left-hand wing portions **507, 507** of the movable block **504** has two ball returning passage forming portions **509, 509** formed therein, which extend in parallel with the ball running counter-grooves **508, 508**. At both the longitudinal ends of each of the wing portions **507, 507**, there are arranged direction changing passages **510, 510; 510, 510** for connecting the ends of the ball running counter-grooves **508, 508; 508, 508** with the ends of the ball returning passage **509, 509; 509, 509**. In summary, each of the wing portions **507, 507** of the movable block **504** has two endless circulation passages, in which the balls **503** are circulated, so as to provide the total number of passage of four.

In each of the four endless circulation passages in this embodiment, the balls **503** are retained in the form of train by means a ball retainer **512** as a rolling member retainer so that the balls **503** can be circulated while being guided by the ball retainer **512**.

As shown in FIGS. **44**(*c*) to **44**(*e*), the ball retainer **512** comprises a flexible belt portion **512***b*, which is provided with ball holes **512***a* for respectively receiving the balls **503**, and spacing portions **512***c* provided between the adjacent two balls **503, 503**. The belt portion **512***b* has a width longer than the diameter of the ball **503** so that the both side edges of the belt portion **512***b* extend outwardly from the ball **503**.

The spacing portion **512***c* is provided with a ball supporting spherical recess **512***d* corresponding to the spherical surface of the ball **503**. The ball **503** is supported on its both sides by a pair of supporting spherical recesses **512***d* so as to prevent the ball **503** from coming off the belt portion **512***b*. In this embodiment, the one end of the belt portion **512***b* is not connected to the other end thereof, thus forming a strip-shaped belt having the both ends. The one end of the belt portion **512***b* may be connected to the other end thereof so as to form an endless belt.

As shown in FIG. **41**, the movable block **504** is composed of a block body **513** having ball running counter-grooves **508, 508, 508, 508,** a pair of right and left-hand resin-formed bodies **520, 520** for forming ball circulation passages, which is inserted in the block body **513**, and a pair of side cover plates **540** (only one cover plate **540** is illustrated) secured to the both end surfaces of the block body **13**, in which the resin-formed bodied **520, 520** are inserted.

Each of the right and left-hand resin-formed bodies **520, 520** for forming the ball circulation passage forms two endless circulation passages. The right and left-hand resin-formed bodies **520, 520** have the symmetrical shape. One of them will be described below and the description of other thereof will be omitted.

More specifically, the resin-formed body **520** for forming the ball circulation passage is composed of a resin frame **524** obtained by integrally forming the ball passage forming portions **521, 521** extending along both longitudinal sides of the ball running counter-groove **508** with the pair of direction changing passage-inner guide forming portions **522, 522** (see FIG. **42**); and a pair of resin pipes **523, 523** as a returning passage forming portion, which are to be inserted in through-holes **514, 514** formed in the block body **513** (see FIG. **43**). The ball passage forming portions **521, 521** are integrally formed with the pair of direction changing passage-inner guide forming portions **522, 522** to form the resin frame **524** as an integral body, and the pair of resin pipes **523, 523** are separately formed from such an integral body, so that these parts can be assembled into the block body **513**.

As shown in FIG. **42**, the ball passage forming portions **521, 521** are provided with guide grooves for guiding the both side edges of the belt portion **512***b* of the ball retainer **512** in a loaded area. The guide grooves can prevent the ball retainer **512** not only from being swung during run of the ball, but also from being sagged by engaging the side edges of the belt portion **512***b* with the guide groove **521***a*, when the movable block **504** is removed from the guide rail **502**. The balls **503** are supported by the ball retainer **512**. More specifically, the ball retainer **512** is supported by a jaw portion of the guide groove **521***a*, with the result that the balls **503** are kept in its proper position so as not to come off the movable block **504**.

The distance between the pair of ball passage forming portions **521, 521** arranged in parallel with each other on the both longitudinal sides of the ball running counter-groove **508** is slightly smaller than the diameter of the ball **503**. In such a construction, it is possible to prevent the balls **503** from coming off the ball passage forming portions **521, 521** even when the ball retainer **512** is not used.

Guide grooves **509***c*, **510***c* are also formed, as shown in FIGS. **44**(*a*) and **44**(*b*), in the ball returning passage **509, 509** and the direction changing passage **510, 510** as non-loaded areas, in order to guide the side edges of the belt portion **512***b*. The guide grooves **509***c*, **10***c* are connected to the above-mentioned guide groove **521***a* in the loaded area so as to form an endless groove on the entire periphery.

The ball passage forming portions **521, 521; 521, 521** are composed, as shown in FIG. **42**(*a*), of the first connecting plate portion **525** extending longitudinally along the corner between the horizontal portion **506** and the wing portion **507** of the block body **513** in the longitudinal direction of the block body **513**; the second connecting plate portion **526** extending longitudinally between the ball running counter-grooves **508, 508** on the inner surface of each of the wing portions **507** of the block body **513**; and a pair of third connecting plate portions **527** extending along the under surface of the wing portion **507** of the block body **513** in the longitudinal direction thereof The upper edge of the first connecting plate portion **525** and the lower edge of the second connecting plate portion **526**, which face to each other, are placed on the opposite longitudinal sides of the upper ball running counter-groove **508** provided in the wing portion **507**, so as to form the ball passage forming portions **521, 521**. The lower edge of the second connecting plate portion **526** and the upper edge of the third connecting plate portion **527**, which face to each other, are placed on the opposite longitudinal sides of the lower ball running counter-groove **508** provided in the wing portion **507**, so as to form the ball passage forming portions **521, 521**.

As shown in FIGS. **44**(*a*), **44**(*b*) and **44**(*c*), the direction changing passage-inner guide forming portions **522** and the ball passage forming portions **521, 521** are connected by means of the thin sheet portion **529** through integral forming. The resin pipe **523** is inserted in a hole **534** formed on the thin sheet portion **529** so as to make a faucet joint, and fixed to the thin sheet portion **529**.

The thin sheet portion **529** has the direction changing passage-inner guide forming portions **522, 522**, which are formed so as to project corresponding to the two trains of balls **503, 503** on the side surface of the guide rail **502**. The both ends of the first, second and third connecting plate portions **525–527** are connected to the thin sheet portion **529** to be arranged on the end of the block body **513** so as to form the single resin frame **524**.

Each of the direction changing passage-inner guide forming portions **522** has a semi-cylindrical shape. On the outer periphery of the direction changing passage-inner guide forming portion **522**, there is formed an inner guide groove **510***a* having a semi-circular cross section so as to form the inner guide portion for the direction changing passage **510**. The one end of the inner guide groove **510***a* is connected to the end of the ball running counter-groove **508**. Accordingly, the one end of the inner guide groove **510***a* has the same cross-sectional shape as the ball running counter-groove **508** so as to make an alignment of the one end of the inner guide groove **510***a* with the end of the ball running counter-groove **508**. The other end of the inner guide groove **510***a* of the direction changing passage **510** is connected to the end of the ball returning passage **509**. Accordingly, the other end of the inner guide groove **510***a* has the same cross-sectional shape as the ball returning passage **509** so as to make an alignment of the other end of the inner guide groove **510***a* with the end of the ball returning passage **509**.

Cylindrical flange portions **533, 533** are formed on the both ends of the inner guide groove **510***a*. The distance between the respective outer surfaces of the cylindrical flange portions **533, 533** is larger than the width of the belt portion **512***b*. The cylindrical flange portions **533, 533** form a retainer-guide groove **510***c* for the ball retainer **512** in cooperation with a semi-circular recess portion having cutouts, which is formed on the inner periphery of the recess of the side cover plate **5040** described later.

The both ends of the inner guide groove **510***a* for the direction changing passage **510** extend to the contacting surface of the thin sheet portion **529** with the end surface of the block body **513** so as to be connected to the respective ends of the ball running counter-groove **508** and the ball returning passage **509**. Pipe inserting holes **534**, **534** having a semi-circular shape, in which the ends of the resin pipes **523** are to be inserted are formed on the thin sheet portion **529**.

As shown in FIG. **43**, the resin pipe **523** is composed of an outer peripheral side-half pipe member **523**b located in the outer peripheral side of the ball circulation passage, which is continuously connected to the outer guide groove **510**b for the direction changing passage **510** of the side cover plate **540**, and an inner peripheral side-half pipe member **523**a located in the inner peripheral side of the ball circulation passage, which is continuously connected to an inner guide groove **510**a for the direction changing passage **510** of the side cover plate **540**.

The inner peripheral side-half pipe member **523**a has a groove portion **509**a having a semi-circular cross section, and side edge portions **523**c extending longitudinally along the groove portion **509**a, as shown in FIGS. **43**(c) and **43**(d). The outer peripheral side-half pipe member **523**b is formed into a linear member having the same circular cross section as the outer guide groove **510**b for the direction changing passage, which is formed on the side cover plate **540**. The outer peripheral side-half pipe member **523**b has a groove portion **509**b, which is continuously connected to the outer guide groove **510**b, and side edge portions **523**d extending longitudinally along the groove portion **509**b. The side edge portions **523**d is provided on its outer edges with projections **523**e, which are to be brought into contact with the outer edges of the side edge portions **523**c of the inner peripheral side-half pipe member **523**a to form the retainer-guide groove **509**c for the ball retainer **512**.

The inner peripheral side-half pipe member **523**a of the resin pipe **523** has the same length of the block body **513**. The inner peripheral side-half pipe member **523**a is positioned so as to be brought into contact with the back surface of the direction changing passage-inner guide forming portion **522**.

The outer peripheral side-half pipe member **523**b of the resin pipe **523** has on the other hand a longer length than the block body **513** by a length corresponding to the thickness of the thin sheet portion **529**. The outer peripheral side-half pipe members **523**b are inserted in the inserting holes **534**. Longitudinal positional determination of the outer peripheral side-half pipe member **523**b is made by bringing the both ends of the outer peripheral side-half pipe member **523**b inserted in the inserting holes **534** into contact with the peripheral edge of the end portion of the outer guide grooves **510**b for the direction changing passage, which are formed on the side cover plate **540**. The projections **523**e formed on the both side edges of the outer peripheral side-half pipe member **523**b come into contact with the outer edges of the cylindrical flange portions **533** formed on the direction changing passage-inner guide forming portion **522** to form a part of the guide groove **510**c, and the outer peripheral side-half pipe member **523**b and the inner peripheral side-half pipe member **523**a are restricted to be turned in the inserting hole **514**.

The resin pipes **523** and the direction changing passage-inner guide forming portions **522** are accurately positioned through the inserting holes **534** formed on the thin sheet portion **529** and a proper assembling is carried out in this manner.

As shown in FIGS. **44**(f) and **44**(g), the side cover plate **540** is provided with an inserting recess portion **540**a, in which the thin sheet portion **529** is inserted, recess portions **541** having the outer guide grooves **510**b for the direction changing passage, into which portions the direction changing passage-inner guide forming portions **522** are fitted, and screw-fixing portions for securing the side cover plate **540** to the block body **513**. In the screw-fixing portions, the side cover plate **540** is fixed to the block body **513** by inserting bolts (not shown) into holes **543** formed on the side cover plate **540** and engaging the bolts with screwed holes **545** formed on the end surface of the block body **513**. The holes **543** are located at four positions, i.e., the position corresponding to the thin sheet portion **529** between the direction changing passage-inner guide forming portions **522**, **522** of each of the resin-formed bodies **520**, **520**, and the positions in the vicinity of the thin sheet portions **529**, **529** on the horizontal portion **506**.

As shown in FIG. **44**(g), the outer guide groove **510**b for the direction changing passage in the recess portion **541** has on its side edges larger-diameter arcuate recesses **546**, which form the retainer-guide groove **510**c in cooperation with the cylindrical flange portions **533** of the direction changing passage-inner guide forming portions **522** as shown in FIG. **44**(f), and a smaller-diameter arcuate recesses **547**, in which the cylindrical flange portions **533** are inserted. The direction changing passage-inner guide forming portion **522** provided with the inner guide groove **510**a for the direction changing passage is fitted into the recess portion **541** of the side cover plate **540**, and the thin sheet portion **529** is received in the inserting recess portion **540**a of the side cover plate **540**. The thin sheet portion **529** is held between the side cover plate **540** and the end surface of the block body **513** through a clamping force so as to be firmly fixed therebetween.

The direction changing passage-inner guide forming portions **522** and the ball passage forming portion **521** are connected through the thin sheet portion **529**, thus making it possible to maintain an accurate positional relationship of the end of the inner guide groove **510**a for the direction changing passage formed in the direction changing passage-inner guide forming portion **522** relative to the ball passage forming portions **521**, **521**, as well as an accurate positional relationship of the inner guide groove **510**a for the direction changing passage relative to the ball returning passage **509**.

The thin sheet portion **529** located in the vicinity of the direction changing passage-inner guide forming portion **522** is uniformly urged against the flat end surface of the block body **513** through a clamping force applied to the side cover plate **540** (see FIG. **44**). Even when the direction changing passage-inner guide forming portion **522** is not located in a correct position, the thin sheet portion **529** changes its shape on the end surface of the block body **513**, thus permitting the correct positioning of the direction changing passage-inner guide forming portion **522**. The thin sheet portion **529** is firmly clamped and fixed through a clamping force, which is applied to the side cover plate **540**, and frictional force caused by such a clamping step may prevent an unfavorable movement of the inner guide groove **510**a for the direction changing passage.

The side cover plate **540** is secured to the block body **513** so that the direction changing passage-inner guide forming portion **522** assembled to the block body **513** is fitted into the recess portion **541** of the side cover plate **40**. Such a fitting step permits to make an accurate positioning of the side cover plate **540** relative to the block body **513**.

Now, description will be given of assembling steps for the above-mentioned resin-formed bodies **520** for forming the ball circulation passage.

First, the inner peripheral side-half pipe member **523***a* of the resin pipe **523** is inserted in the through-hole **514** of the wing portion **507** of the block body **513**.

Then, the resin frame **524** obtained by integral forming is inserted in the recess of the block body **513**, while causing the thin sheet portions **529** at the both ends of the resin frame **524** to slide on the respective end surfaces of the wing portion **507** of the block body **513**. The first connecting plate portion **525** of the resin frame **524** comes into contact with the corner portion between the horizontal portion **506** and the wing portion **507**, thus making positional determination in the vertical direction of the resin frame **524**. The second connecting plate portion **526** and the third connecting plate portion **527** of the resin frame **524** come into contact with the respective inner surfaces of the wing portions **507** of the block body **513**, thus making positional determination of the ball passage forming portions **521, 521** and the direction changing passage-inner guide forming portions **522, 522**. At this time, the inserting holes **534, 534** of the thin sheet portion **529** are aligned with the through-holes **514, 514** of the block body **513**.

Then, the outer peripheral side-half pipe members **523***b*, **523***b* are inserted in the through-holes **514, 514** from the inserting holes **534, 534**, thus completing the assembling step of one of the resin-formed bodies **520, 520** for forming the ball circulation passage.

The assembling step of the other of the resin-formed bodies **520, 520** is carried out in the same manner.

Then, the one side cover plate **540** is secured to the one end surface of the block body **513** by a clamping step, the ball retainer **512** holding the balls is inserted, and the other side cover plate **540** is secured to the other end surface of the block body **513** by the same clamping step, thus completing the assembling step of the movable block **504**.

According to the present invention, the resin-formed bodies **520, 520** for forming the ball circulation passage are separately formed from the block body **513**. Even when the movable block **504** has a larger size, there is no restriction of flow of molten resin by the block body **513**, unlike the case where the block body **513** is integrally formed with the resin-formed bodies **520, 520**. Increase in number of gates formed on a die may ensure proper run of the molten-resin, thus improving the formability. Especially, the ball passage forming portions **521, 521** located at the opposite longitudinal sides of the ball running groove **508** are thin, with the result that molten resin may not reach every part of the space for forming the ball passage forming portions **521, 521**. It is therefore effective to form the resin-formed bodies **520, 520** separately from the block body **513** in accordance with the embodiment of the present invention.

In addition, since there are formed the right and left-hand resin-formed bodies **520, 520** for forming the ball circulation passage, each of which has two endless circulation passages, a proper run of molten resin is ensured even when the movable block **513** has a larger width.

The continuous circulation passage is formed by the resin-formed body **520**, and it is therefore possible to make positional determination of the inner guide groove **510***a* for the direction changing passage relative to the ball passage forming portions **521, 521**, as well as positional determination of the inner guide groove **510***a* for the direction changing passage relative to the ball returning passage **509**, thus ensuring continuity of the circulation passage so as to make smooth circulation of the balls **503**.

When the proper positional relationship of the inner guide groove **510***a* for the direction changing passage relative to the ball passage forming portions **521, 521**, is maintained, the ball passage forming portions **521, 521** are located at the longitudinal both sides of the ball running groove **508** so as to be aligned with the ends of the inner guide groove **510***a* for the direction changing passage.

When the proper positional relationship of the inner guide groove **510***a* for the direction changing passage relative to the ball returning passage **509** is maintained, the inner guide groove **510***a* for the direction changing passage can be aligned with the inner groove **523***a* of the ball returning passage **509**.

The connecting portion of the ball passage forming portions **521, 521** and the direction changing passage-inner guide forming portion **522** is obtained by integral forming, thus permitting omission of an assembling step of the connecting portion. Although the running direction of the balls **503** is changed in such a connecting portion, the above-mentioned integral structure may ensure continuity of the circulation passage, without being affected by assembling accuracy. It is therefore possible to make smooth run of the balls **503** from the ball running passage between the ball running groove **505** and the ball running counter-groove **508** to the direction changing passage **510**, as well as from the direction changing passage **510** to the ball returning passage **509**.

According to the present invention as described in detail, since the resin-formed body for forming the rolling member circulation passage is separately formed from the block body, even when the movable block has a larger size, increase in number of gates formed on a die may ensure proper run of the molten resin, thus improving the formability. It is therefore effective to form the resin-formed body separately from the block body in accordance with the present invention, taking into consideration the fact that the rolling member passage forming portions located at the opposite longitudinal sides of the rolling member running track are thin, with the result that molten resin may not reach every part of the space for forming the rolling member passage forming portions.

The continuous circulation passage is formed by the resin-formed body, and it is therefore possible to make positional determination of the inner guide groove for the direction changing passage relative to the rolling member passage forming portions, as well as positional determination of the inner guide groove for the direction changing passage relative to the rolling member returning passage, thus ensuring continuity of the circulation passage so as to make smooth circulation of the rolling members.

When the connecting portion of the rolling member passage forming portions and the direction changing passage-inner guide forming portion or the connecting portion of the direction changing passage-inner guide forming portion and the returning passage forming portion, in which portion the running direction of the rolling members is changed is obtained by integral forming, it is possible to omit an assembling step of the connecting portion and to ensure continuity of the circulation passage, without being affected by assembling accuracy.

The integral formation of the connecting portion of the rolling member passage forming portion with the direction changing passage-inner guide forming portion may cause the smooth running of the rolling members between the rolling member running track in the loaded area and the direction changing passage-inner guide forming portion, even when the returning passage forming portion formed of resin is not used.

When the rolling member retainer is used, it is possible to maintain a proper continuity on the entire periphery of the circulation passage in the retainer guide portion for guiding the rolling member retainer.

The thin retainer guide portion is formed without insertion of the body of the movable member in a die, and position of gates in the die can freely be determined without being restricted by the body of the movable member, with the result that molten resin can reach, during formation of the guide portion, the entire space therefor, which is formed in the die.

In addition, the formation of the right and left-hand resin-formed bodies for forming the rolling member circulation passage, each of which has two endless circulation passages may ensure a proper run of molten resin even when the body of the movable member has a larger width.

The connection of the direction changing passage-inner guide forming portion with the rolling member passage forming portion through the thin sheet portion makes it possible to maintain, through deformation of the thin sheet portion, a proper positional relationship between the direction changing passage-inner guide forming portion and the rolling member passage forming portion or a proper positional relationship between the direction changing passage-inner guide forming portion and the rolling member returning passage forming portion, thus making an accurate positional determination of the end of the direction changing passage-inner guide forming portion relative to the rolling member returning passage forming portion as well as an accurate positional determination of the direction changing passage-inner guide forming portion relative to the rolling member returning passage forming portion.

The thin sheet portion is urged against the flat end face of the body of the movable member by a clamping force, which is applied to the side cover plate. It is therefore possible to correct the position of the direction changing passage-inner guide forming portion through deformation of the thin sheet portion, even when the direction changing passage-inner guide forming portion is not correctly positioned relative to the end face of the body of the movable member.

In addition, the thin sheet portion can firmly be secured between the side cover plate and the body of the movable member by the clamping force, which is applied to the side cover plate, and it is therefore possible to prevent the direction changing passage-inner guide forming portion from being incorrectly placed.

What is claimed is:

1. A linear motion guiding apparatus comprising:

a guide member provided with a rolling member running track, and

a movable member arranged so as to be movable along the guide member through a large number of rolling members, said movable member being provided with (i) a rolling member running counter-track corresponding to the rolling member running track of said guide member, (ii) a rolling member returning passage arranged away from said rolling member running counter-track by a prescribed distance and in parallel therewith and (iii) a pair of direction changing passages for connecting the rolling member running counter-track and the rolling member returning passage to permit circulation of the rolling members

characterized in that:

a resin-formed body for forming a rolling member circulation passage comprises a pair of rolling member passage forming portions extending along both longitudinal sides of said rolling member running counter-track and a pair of direction changing passage-inner guide forming portions for forming inner peripheral guide portions of said direction changing passages, said resin-formed body being separately formed from a body of said movable member;

said rolling member returning passage is made by forming a through-hole in the body of said movable member; and

said pair of rolling member passage forming portions and at least one of said air of direction changing passage-inner guide forming portions are connected with each other through integral forming.

2. The apparatus as claimed in claim **1**, wherein:

a rolling member retainer is provided, said rolling member retainer being able to retain the rolling members in a train with a prescribed distance kept between adjacent two of the rolling members, and said rolling member retainer having side edge portions projecting from both sides of each of the rolling members; and

guide portions for guiding the side edge portions of the rolling member retainer are formed on an entire periphery of the rolling member circulation passage.

3. The apparatus as claimed in claim **1**, wherein:

each of said direction changing passage-inner guide forming portions has a thin sheet portion, which is to be brought into contact with an end face of the body of said movable member, and said each of said direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions or the returning passage forming portion by means of said thin sheet portion.

4. The apparatus as claimed in claim **1**, wherein:

said guide member comprises a guide rail;

said movable member comprises a movable block, which is provided with a horizontal portion, which faces an upper surface of said guide rail and a pair of wing portions, between which the guide rail is held at right and left-hand side surfaces thereof; and

two trains of the rolling members are arranged in a gap between the upper surface of the guide rail and a lower surface of the movable block, and a single train of the rolling members is arranged in each of gaps between the right and left-hand side surfaces of the guide rail and both of the wing portions, so as to provide a total number of trains of four.

5. The apparatus as claimed in claim **1**, wherein:

four direction changing passage-inner guide forming portions are formed corresponding to the four trains of the rolling members, respectively, and said four direction changing passage-inner guide forming portions are integrally connected with each other.

6. The apparatus as claimed in claim **1**, wherein:

each of said pair of rolling member passage forming portions are divided at a prescribed position in a longitudinal direction thereof into two parts.

(57) **ABSTRACT**

The linear movement guide apparatus according to the invention has features that two rows of ball rolling grooves are formed on an upper surface of a tracking base and one or two rows of ball rolling grooves are formed on both side surfaces thereof, respectively, on a concave portion of a sliding base are provided corresponding ball rolling grooves so as to face to the ball rolling grooves formed on the tracking base; the depth of each ball rolling groove about ½ of the diameter of balls to be held therein; and the distance between the ball rolling grooves formed on the upper surface of the tracking base and the distance between said ball rolling grooves and the ball rolling grooves formed on side surfaces are varied with respect to the distances between the corresponding ball rolling grooves formed on the sliding base. Thereby, the pitches between the ball rolling grooves on the tracking and sliding bases can be selected so as to obtain an optimum contact angles of balls for the load condition applied to the linear movement guide apparatus.

LINEAR MOVEMENT GUIDE APPARATUS AND METHOD FOR ASSEMBLING THE APPARATUS

TECHNICAL FIELD

The present invention relates to a linear movement guide apparatus, which is used to be applied to linear guide portions of, for instance, machine tools or robots for use in industrial purpose.

In such machine tools or robots, all kinds of load, i.e. load from a radial direction, load from a horizontal direction, load from a reversed-radial direction, and a moment load, are applied to the linear guide portion thereof, since the linear guide portion of the tools or robots is diversified. The present invention, particularly, relates to a linear movement guide apparatus and a method for assembling the apparatus, in which a common member is used to manufacture a tracking base and a sliding base of the apparatus without regard to the amount or the direction of load applied thereto, and suitable contact angles according to the directions, to which the loads are applied, can be obtained to give a maximum life time, a maximum stiffness and a maximum allowance of load to the apparatus.

BACKGROUND ART

First Prior Art

Such kind of linear movement guide apparatus is, for instance, disclosed in Japanese Utility Model Preliminarily Publication No. Hei 3-199710.

FIG. **23** is a schematic view showing an apparatus of the first prior art.

As shown in FIG. **23**, the linear movement guide apparatus **30** comprises a tracking base **31** having a square-shape cross-section, a sliding base **32** having a concave portion **32**, which also has a square-shaped cross section, for accepting said tracking base **31**, and four rows of indefinitely circulating balls **33**. On an upper surface of the tracking base **31** are provided two rows of ball rolling grooves **31***a*, and on each side surface of the tracking base **31** is arranged one row of ball rolling groove **31***b*, respectively. On an inside surface of said concave portion **32***c* of said sliding base **32**, are provided two rows of corresponding ball rolling grooves **32***a* so as to face to said two rows of ball rolling grooves **31***a* formed on the upper surface of the tracking base **31**, and one row of corresponding ball rolling groove **32***b* formed on each side surface thereof so as to face to the row of ball rolling groove **31***b* formed on the upper surface of the tracking base **31**, respectively. The ball rolling grooves **31***a* and **32***a*, which face to each other, are arranged as circular-ark shaped shallow grooves having a slightly larger dimension than that of the balls to be held therein. It should be noted that the ball rolling grooves **31***a* and **31***b*, which also face to each other, are arranged as Gothic ark-shaped grooves.

Holders **34** and **35** are provided in the apparatus in order to prevent that balls **33** are fallen down from the grooves when the sliding base **31** is taken off from the tracking base **32**.

Contact angles of balls, in the linear movement guide apparatus **30**, are arranged such that the contact angles in the upper two ball rows are substantially directed in a vertical direction, but in the lower two ball rows, the balls are made contact with the ball rolling grooves, which have their shapes of a combination of two circular-arks, at four points, i.e. at perspective upper points and perspective lower points, in a substantially even manner (hereinafter, such contact condition is called "complete four points contact"). In such a manner, above, in the linear movement guide apparatus **30**, the load applied from an upper direction is supported by the two rows of ball rolling grooves **31***a* and **32***a* having circular-ark shapes; and the load applied from a horizontal direction is supported by the ball rolling grooves **31***b* and **32***b* having Gothic-ark shapes by the complete four points contact.

Therefore, the apparatus has an excellent load supporting capability against the loads applied from not only an upper direction but also a lateral direction.

Second Prior Art

On the other hand, another linear movement guide apparatus **40** is disclosed in Japanese Utility Model Publication no. Sho 63-24258.

As shown in FIG. **24**, the linear movement guide apparatus **40** comprises a tracking base **41** having a square-shaped cross section, a sliding base **42** having a concave portion **42***c*, which also has a square-shaped cross section, for accepting the tracking base **41**, and four rows of infinite circulating balls **43**.

On side surfaces of the tracking base **41** are provided two rows of ball rolling grooves **41***a*, respectively; and on an inside surface of the concave portion **42***c* of the sliding base **42** are provided corresponding two rows of ball rolling grooves **42***a* so as to face to the ball rolling grooves **41***a* of the tracking base **42**. Therefore, four rows in total are formed in the apparatus. These ball rolling grooves **41**a and **42***a*, which face to each other, are designed as Gothic-ark shaped grooves, and the contact angle of balls in each ball row is arranged about 45 degrees with respect to a horizontal direction.

In the linear movement guide apparatus **40**, it is possible to have different constructions that the extended lines of the contact angles on the side surfaces of the tracking base **41** intersect with each other outside of the tracking base **41** (hereinafter, called as "DB structure"), or that the extended lines intersect with each other inside of the tracking base **41** (hereinafter, called as "DF structure"), by making a distance A between two rows of ball rolling grooves **41***a* and **41***a*, which are formed on the side surfaces of the tracking base **41**, larger or smaller than a distance B between the corresponding two rows of ball rolling grooves **42***a* and **42***a*, which are formed on the inside surface of the sliding base **42**.

In any way, in the linear movement guide apparatus **40**, when a small load is applied thereto from a vertical direction, the load is supported by one of the ball rows formed on the side surfaces, i.e. two ball rows in total; and when a large load is applied thereto from the vertical direction, the load is supported by two ball rows formed on the side surfaces, i.e. four ball rows in total. Since the number of ball rows for supporting the load is increased when a heavy load is applied, as stated in the above, a burden for the load in each ball rolling groove is reduced, so that the life time of the linear movement guide apparatus **40** becomes long.

Third Prior Art

Another linear movement guide apparatus, in which six ball rows in total are provided, is disclosed in, for instance, Japanese Patent Application Preliminarily Publication No.

Sho 62-141308. In this apparatus, two ball rows are formed on an upper surface side of a tracking base, and two ball rows are on the right and left side surfaces thereof, respectively.

As shown in FIG. **25**, the linear movement guide apparatus **100** comprises a tracking base **101**, a sliding base **102** having a concave portion **102***d* for accepting the tracking base **101** which is linearly guided along the tracking base **101**, and six rows of indefinite circulated balls **103** which are provided between the sliding base **102** and the tracking base **101** in a rotatable manner.

On an upper surface of the tracking base **101**, are provided a couple of ball rolling grooves **101***a*, and on each side surface thereof, are formed a couple of ball rolling grooves **101***b* and **101***c*, respectively. On the other hand, on an upper surface and each side surface of the concave portion **102***d* of the sliding base **102**, are formed corresponding ball rolling grooves **102***a*, **102***b* and **102***c*, facing to the ball rolling grooves **101***a*, **101***b* and **101***c* formed on the surface of the tracking base **101**, respectively.

In addition thereto, holders **107** and **108** are provided in the two ball rows **104** formed on the upper surface of the tracking base and in the two ball rows **105** and **106** formed on each side surface of the tracking base, respectively, in order to prevent that the balls **103** are fallen down when the sliding base **102** is taken off from the tracking base **101**.

In the linear movement guide apparatus **100**, the contact angles of balls in the ball rows **104** are arranged such that the contact angle a, which is defined as an angle formed by a contact line of the ball **103** held in the ball rolling groove **101***a* of the tracking base **101** with respect to a horizontal direction, is set at 90 degrees. And the contact angles are arranged in two ball rows **105**, **106** formed on each side surface of the tracking base such that a contact angle β, which is defined as an angle formed by contact lines of ball **103** in the upper and lower ball rolling grooves **101***b* and **101***c* with respect to the horizontal direction, is set at 45 degrees, which are inclined in upper and lower directions inside of the tracking base **101**, respectively. And thus, intersection points of these contact lines are located outside of the tracking base **101**.

In the thus constructed linear movement guide apparatus **100**, the vertical load applied from an upper direction against the sliding base **102** is supported by four ball rows in total, i.e. two ball rows **104** formed on the upper surface thereof and two ball rows **106** provided in the lower portion of side surfaces thereof.

Further, the lateral load applied from left and right directions is supported by either of upper two ball rows **105** or lower two ball rows **106** in accordance with the load applied direction. Furthermore, the load applied from a lower direction is supported by the upper two ball rows **105** formed on the side surfaces.

Fourth Prior Art

In Japanese Patent Preliminarily Publication No. Sho 64-53621, another linear movement guide apparatus **200** having six ball rows is further disclosed.

As shown in FIG. **26**, the linear movement guide apparatus **200** comprises a tracking base **201**, a sliding base **202** having a concave portion **202***d*, along which said tracking base **201** is guided, for accepting said tracking base **201**, and six indefinite circulated ball rows **203**, which are extended between the sliding base **202** and the tracking base **201** in a rotatable manner.

On each side surface of the tracking base **201**, are formed three rows of ball rolling grooves **201***a*, **201***b* and **201***c*; and on each inner side surface of the concave portion **202***d* of the sliding base **202** are provided corresponding three rows of ball rolling grooves **202***a*, **202***b* and **202***c* so as to face to the three rows of ball rolling grooves **201***a*, **201***b* and **201***c* of the tracking base **201**.

A holder **207** is provided in each ball row **204**, **205** and **206** formed on each side surface in order to prevent that the balls are fallen down when the sliding base **202** is taken from the tracking base **201**.

The contact angles of the balls **203** in the linear movement guide apparatus **200** are arranged such that the contact angles of the balls in the upper and middle rows are inclined in a lower direction toward inside of the tracking base **201** by about 45 degrees; and the contact angles of the balls in the lower rows are inclined in an upper direction toward inside of the tracking base **201** by about 45 degrees, so that the intersecting points **01** and **02** of the contact lines L1, L2 and L3 of the contact angles in upper, middle and lower rows are located inside of the tracking base **201**.

In the thus constructed linear movement guide apparatus **200**, since the contact lines L1 and L2 of the balls **203** in the upper and middle ball rows **204** and **205** are extended in a lower inside direction of the tracking base **201**, the radial load applied from the upper direction against the sliding base **202** is supported by the upper and middle ball rows **204** and **205**, and the reversed-radial load applied in the floating direction is supported by the lower ball rows **206**. Therefore, in this apparatus the stiffness for the radial load is much higher than that for the reversed-radial load. It is now defined that the stiffness means a performance that the bases are not apt to be deformed by the load effected between the sliding base and the tracking base, and are not apt to be unsteady. In the case of the fourth prior art, the apparatus is so designed as to make the stiffness for the load F applied in the radial direction large, to increase the capability to support a heavy load.

Fifth Prior Art

Furthermore, in Japanese Patent Preliminarily Publication No. Sho 64-53622, there is disclosed another linear movement guide apparatus **200'**, which is modified from the above-mentioned linear movement guide apparatus **200** in such a manner that the ball **203** in the middle ball rows **205** are arranged to be contact with the grooves at four points and the contact lines L21 and L22 are extended to lower inside and upper inside directions by about 45 degrees and intersect to each other at a portion inside of the tracking base **201**, as shown in FIG. **27**.

In the thus constructed linear movement guide apparatus **200'**, the radial load F is supported by the upper ball rows **204** and the reversed-radial load f is by the lower ball rows **206**.

On the other hand, the balls in the middle row of **205** are arranged to be made contact with the grooves at four points to support both the radial load and the reversed-radial load.

In the above-explained first to five conventional linear movement guide apparatuses, various performances are required to support the loads applied from all directions. That is to say, it is required to have a load supporting capability broken up with various ratios against the loads applied from upper, lower, left side and right side directions, in order to decrease vibration of machine, to which the apparatus is applied, by causing a differential sliding on the balls when a predetermined load or more is applied, or to roll the balls in a light manner in order to drive the apparatus in a high speed.

However, the conventional linear movement guide apparatuses mentioned in the above are designed to comply with only one of the requirements in such type of linear movement guide apparatuses, therefore the apparatuses can not satisfy all of the requirements mentioned in the above.

In the conventional apparatuses, the shapes of the tacking and sliding bases, the number of ball rows, and the contact angles are selected in accordance with the purpose of use of the apparatus, and the linear movement guide apparatuses are designed so as to obtain the performance to be required, manufactured in accordance with the design, and then supplied. The manufacturers accede to the various requirements of the users by manufacturing a large number of types of the linear movement guide apparatuses. However, it causes a lack of mass productivity and a low producing effect.

The present invention has been invented, taking the task of the prior arts into consideration; and has for its purpose to provide a linear movement guide apparatus having a suitable performance for supporting the load applied from each direction and a method for assembling the apparatus, in which pitches between the ball rolling grooves formed on the tracking base and the sliding base are changed in accordance with the load condition applied thereto in order to obtain ball rolling grooves having optimum contact angles.

DISCLOSURE OF INVENTION

A linear movement guide apparatus according to the present invention comprises a tracking base, a sliding base having a concave portion for accepting said tracking base and being linearly guided along said tracking base, and balls being held between said sliding base and said tracking base in a rotatable manner; said tracking base comprises at least one row of ball rolling groove on an upper surface thereof and at least one row of ball rolling groove on each side surface thereof; and said sliding base comprises corresponding ball rolling grooves, formed on upper and both side surfaces of said concave portion of the sliding base so as to face to the ball rolling grooves formed on said upper and side surfaces of said tracking base;

said apparatus is characterized in that a positional relationship of centers of the ball rolling grooves formed on the upper and side surfaces of either one of the tracking base or the sliding base are arranged to be coincident with or deviated from the corresponding ball rolling grooves formed on the corresponding tracking or sliding base, and the tracking base or the sliding base, in which said positional relationship of the centers of the grooves is coincident with or deviated from the corresponding ball rolling grooves, is mounted on the corresponding tracking base or the corresponding sliding base with an arbitrary combination.

The apparatus is characterized in that two rows of ball rolling grooves are provided on the upper surface of the tracking base and one row of ball rolling groove is provided on each of the left and right side surfaces of the tracking base, respectively.

The apparatus is further characterized in that a pair of rows of ball rolling grooves are provided on the upper surface of the tracking base and a pair of rows of ball rolling grooves are provided on the left and right side surfaces of the tracking base, respectively.

The apparatus is further characterized in that the tracking base has a square-shaped cross section, and a positional relationship of the centers of the ball rolling grooves formed on the tracking base and the sliding base is identified with each other or deviated from each other by changing a distance between the two rows of the ball rolling grooves formed on the upper surface of the tracking base and a distance between the ball rolling grooves formed on the upper surface and the ball rolling grooves formed on the side surfaces thereof with respect to the corresponding distances between the corresponding ball rolling grooves formed on the sliding base.

The apparatus is characterized in that the ball rolling grooves are arranged to have their depths by which the contact angles of balls to be held therein can be freely selected.

The apparatus is characterized in that the depths of the ball rolling grooves are arranged to be substantially ¼–½ of a diameter of ball to be held therein.

The apparatus is characterized in that the ball rolling grooves formed on the upper surface of the tracking base and the ball rolling grooves formed on the sliding base, which face to the grooves formed on the tracking base, have circular-ark shapes which are slightly larger than the ball to be mounted therein; and the ball rolling grooves formed on the side surfaces of the tracking base and the corresponding ball rolling grooves formed on the sliding base have their shapes that two circular-arks are combined.

The apparatus is characterized in that the ball rolling grooves formed on the upper surface of the tracking base and the corresponding ball rolling grooves formed on the sliding base facing thereto and the ball rolling grooves formed on side surfaces of the tracking base and the corresponding ball rolling grooves formed on the sliding base facing thereto have circular-ark shapes which are slightly larger than the balls to be mounted therein.

The apparatus is further characterized in that the ball rolling grooves formed on the upper surface of the tracking base and the corresponding ball rolling groove formed on the sliding base facing thereto, and the ball rolling grooves formed on side surfaces formed on the tracking base and the corresponding ball rolling grooves formed on the sliding base facing thereto have their shapes that two circular-arks are combined.

The apparatus is further characterized in that the ball rolling grooves formed on the upper surface of the tracking base and the corresponding ball rolling grooves formed on the sliding base to be facing thereto have their shapes that two circular arks are combined; but the ball rolling grooves formed on side surfaces of the tracking base and the corresponding ball rolling grooves formed on the sliding base facing thereto have circular-ark shapes which are slightly larger than the balls to be mounted therein.

The apparatus is further characterized in that the contact angles of the balls mounted in two rows of ball rolling grooves, which constitute a pair of rows mutually corresponding to each other, formed on the tracking an sliding bases are arranged to be 90 degrees with respect to a horizontal direction; and the contact angles of the balls mounted in two rows of ball rolling grooves, which constitute a pair of rows mutually corresponding to each other, formed on each surface side of the tracking and sliding bases are arranged to be about 45 degrees being inclined in an upper and inside direction of the tracking base with respect to a horizontal direction.

The apparatus is further characterized in that the contact angles of the balls mounted in two rows of ball rolling grooves, which constitute a pair of rows mutually corresponding to each other, formed on each side surface of the tracking and sliding bases are arranged to be substantially zero degrees with respect to a horizontal direction; and the contact angles of the balls mounted in two rows of the ball rolling grooves, which constitute a pair of rows mutually corresponding to each other, formed on the upper surfaces of the tracking and sliding bases, are arranged to be substantially 90 degrees with respect to a horizontal direction.

The apparatus is further characterized in that all of the ball rolling grooves formed on the tracking and sliding bases have their shapes of single circular-ark, which are slightly larger than the balls to be mounted therein, and at least one of the grooves has its cross section whose radius of curvature is set to be smaller than 0.52 of the diameter of the balls to be mounted in the groove.

The apparatus is further characterized in that said ball rolling grooves have their cross sections whose radius of curvature are set at about 0.51 of the diameter of the balls to be mounted in the grooves.

The method for assembling the linear movement guide apparatus according to the present invention is characterized in that the method comprises the following steps:

- a step for forming a first member having first ball rolling groove(s) on an upper surface thereof and second ball rolling groove(s) on left and right side surfaces thereof;
- a step for forming a plurality types of second members, which are arranged to be assembled to said first member in a slidable manner via a given number of ball rows, each member comprising third ball rolling groove(s), which are arranged such that a positional relationship of centers of the third ball rolling groove(s) is coincident with or deviated from the first ball rolling groove(s) formed on the first member, and fourth ball rolling groove(s), which are arranged such that a positional relationship of centers of the fourth ball rolling groove(s) is coincident with or deviated from the second ball rolling groove(s) formed on the first member; and
- a step for selecting a combination of the first and second members so as to obtain suitable contact angles for supporting loads applied from each direction and a moment load.

The assembling method is further characterized in that the method comprises the following steps:

- a step for forming a first member comprising a pair of first ball rolling grooves which are separated from each other in a width direction thereof by a first pitch, and a pair of second ball rolling grooves, which are separated from said first ball rolling grooves in a height direction thereof by a second pitch;
- a step for forming a plurality types of second members, which are arranged to be assembled to the first member in a slidable manner via four ball rows, comprising a pair of third ball rolling grooves, which are separated from each other in a width direction thereof by a third pitch, which is different from the first pitch, and a pair of fourth ball rolling grooves, which are separated from the third ball rolling grooves in a height direction by a fourth pitch, which is different from said second pitch; and
- a step for selecting a combination of said first and third pitches and said second and fourth pitches so as to obtain suitable contact angles for loads applied from each direction and a moment load.

The assembling method is further characterized in that depths of the ball rolling grooves are arranged such that the contact angles of the balls to be held therein can be freely selected.

The assembling method is further characterized in that the depths of the ball rolling grooves are arranged to be substantially ¼ to ½ of the diameter of balls to be mounted therein.

In the linear movement guide apparatus according to the present invention, it may be possible to arrange the ball rolling grooves so as to have circular-ark shapes which are slightly larger than the balls to be mounted therein, or Gothic-ark shapes; but the depths of the grooves should be in a range from about a quarter of the diameter of balls, which is suitable for the case that an angle deviation of the contact angles is small, to about a half of the diameter of the ball, which is suitable for the case that an angle deviation of the contact angles is large. Therefore, in the apparatus the balls are surely made contact with the circular ark-shaped ball rolling grooves at any portion, and thus it substantially allows to obtain all of the contact angles, which have been demanded in such type of conventional linear movement guide apparatuses.

The contact angle in each ball rolling groove can be set in an arbitrary manner by changing the pitch (distance) between the two rows of ball rolling grooves formed on the upper surface of the tracking base, and the pitch (distance) between said ball rolling grooves formed on the upper surface of the tracking base and the ball rolling grooves formed on side surfaces of the tracking base with respect to the pitch (distance) between the corresponding ball rolling grooves formed on the sliding base.

Particularly, in case that the ball rolling grooves are arranged to have circular-ark shapes which are slightly larger than the balls to be mounted therein, the contact angles are not limited to 45 degrees with respect to a horizontal direction but it is substantially possible to obtain the contact angles in an arbitrary manner.

Further, in case that the ball rolling grooves have their shapes of the combination of two circular-arks, it is possible to arrange such that the balls are made contact with the ball rolling grooves at two points, in order to cause a differential sliding for the first time that much more load beyond over the desired load is applied, or from the first.

There are provided balls between the ball rolling grooves formed on the upper and side surfaces of the tracking base and the corresponding ball rolling grooves formed on the sliding base. Therefore, it is possible to increase the stiffness of the linear movement guide apparatus by providing balls having dimensions slightly larger than the spaces between the ball rolling grooves to give a pre-load.

Further, since there are provided two rows of deep ball rolling grooves on the upper surface of the concave portion of the sliding base, it is possible to make the thickness of the upper portion of the sliding base large so that the stiffness of the block of the sliding base is increased.

Furthermore, since one row of the ball rolling groove is formed on each inside surface of the concave portion of the sliding base, it is possible to make the length of the side portion of the sliding base short to increase the stiffness of the linear movement guide apparatus. Therefore, the total height of the block of the sliding base becomes low and the height of the tracking base also becomes low because the position of the ball rows on the side surfaces thereof can be located in an upper portion. Therefore, the height of the linear movement guide apparatus as a whole becomes low and the size thereof compact.

Particularly, even in either cases that the grooves are designed as Gothic-ark style or as Circular ark style, a damping effect is improved by designing the depths of the grooves to be about 51% of the diameter of the balls to be held therein. Because, when the load, which is applied to the apparatus when the heavy machining is conducted, is applied, an amount of differential sliding is increased and thus the ball moves in the grooves in a mixed manner of the rolling movement and the sliding movement, causing that the rolling movement becomes like the sliding movement, and thus the damping effect (damping characteristic) is increased. Therefore, when the linear movement guide apparatus is used in machinery tools, it is possible to make the amount of slight waviness at machine as much as possible, and then the working accuracy is improved. Particularly, it is effective to set the contact angles of balls in the ball rotating grooves formed on the upper surfaces, at 90 degrees, which is an angle that the load is applied when the heavy cutting machining is conducted.

When the depths of the ball rolling grooves are set at 51% of the diameter of the balls to be held therein, the contact area of balls with respect to the general type of circular-ark shaped grooves becomes larger (the contact are becomes like that of the roller), so that the loading capacity for supporting a heavy load is rapidly increased in cooperation with the construction of said contacting angles, and a high stiffness and a stable linear movement can be obtained.

When the heavy machining is conducted, the apparatus works in a low speed. Therefore, even if some sliding is caused, the life time of the apparatus is not affected so much. Further, since the differential sliding is increased in proportion with the load to be applied, an extremely reasonable contact structure can be obtained.

BRIEF DESCRIPTION OF DRAWINGS

FIGS. **1** to **13** are schematic views showing embodiments of the linear movement guide apparatus according to the present invention, in which four ball rows are provided; and FIG. **1** is a perspective view having partially broken portion illustrating one of the embodiments of the apparatus.

FIG. **2** is a cross sectional view of FIG. **1** cut in a width direction

FIG. **3** is a schematic view for explaining a locational relationship of the ball rolling grooves in the linear movement guide apparatus shown in FIG. **1**.

FIG. **4** is a schematic view depicting one example of a machinery tool to which the linear movement guide apparatus according to the invention is applied.

FIG. **5** is schematic view illustrating directions of each load applied to the linear movement guide apparatus.

FIG. **6** is a schematic view for explaining a function in the linear movement guide apparatus according to the first embodiment of the present invention.

FIG. **7** is a schematic view for explaining a function in the linear movement guide apparatus according to the second embodiment of the present invention.

FIG. **8** is a schematic view for explaining a function in the linear movement guide apparatus according to the third embodiment of the present invention.

FIG. **9** is a schematic view for explaining a function in the linear movement guide apparatus according to the fourth embodiment of the present invention.

FIG. **10** is a schematic view for explaining a function in the linear movement guide apparatus according to the fifth embodiment of the present invention.

FIG. **11** is a schematic view for explaining a function in the linear movement guide apparatus according to the sixth embodiment of the present invention.

FIG. **12** is a schematic view for explaining a function in the linear movement guide apparatus according to the seventh embodiment of the present invention.

FIG. **13** is a schematic view for explaining a function in the linear movement guide apparatus according to the eighth embodiment of the present invention.

FIG. **14** is a schematic view for explaining a condition of the differential sliding caused in the apparatus having Gothic ark type grooves.

FIG. **15** is a schematic view for explaining a condition of the differential sliding caused in the apparatus having a circular ark type grooves.

FIG. **16** is a schematic view showing the other examples of the contact angle structure in the linear movement guide apparatus having four ball rows.

FIGS. **17** to **21** are schematic views showing the linear movement guide apparatuses according to the invention which have six ball rows, and FIG. **17** is a schematic view for explaining the ninth embodiment according to the invention.

FIG. **18** is a perspective view with partially broken portion illustrating a basic structure of the linear movement guide apparatus having six ball rows, shown in FIG. **17**.

FIG. **19** is a schematic view for explaining a function in the linear movement guide apparatus according to the tenth embodiment of the present invention.

FIG. **20** is a schematic view for explaining a function in the linear movement guide apparatus according to the eleventh embodiment of the present invention.

FIG. **21** is a schematic view for explaining a function in the linear movement guide apparatus according to the twelfth embodiment of the present invention.

FIGS. **22**(*a*) to (*c*) are schematic views showing each of other contact angle structures in the linear movement guide apparatus having six ball rows; and FIGS. **22**(*d*) and (*e*) are schematic views representing the linear movement guide apparatuses having other arrangements of ball rows.

FIGS. **23** to **27** are cross-sectional views cut in a width direction, illustrating constructions of the conventional linear movement guide apparatuses.

BEST MODE FOR CARRYING OUT THE INVENTION

The detail of the linear movement guide apparatus according to the present invention will be explained in the following with reference to the drawings.

FIGS. **1** and **2** are cross-sectional views, which are cut in a width direction, of one of the embodiments of the linear movement guide apparatus according to the invention.

The linear movement guide apparatus **10** according to the invention comprises a tracking base **11** having a square-shaped cross section, a sliding base **12** having a concave portion **12***c* for accepting said tracking base **11** and four ball rows **13** existing between the tracking base **11** and the sliding base **12** in a rotatable manner, as a summary.

The sliding base **12** comprises a sliding base block **14** having a high stiffness and side caps **15** which are fixed to both edge surfaces of said sliding base block **14**.

On an upper surface of the tracking base **11**, are provided two rows of ball rolling grooves **11**a and on each side surface thereof is formed one row of ball rolling groove **11***b*, respectively. On the other hand, on an inner surface of the concave portion **12***c* of the sliding base block **14** are formed corresponding ball rolling grooves **12***a* and **12***b*, respectively, so as to face to the rolling grooves **11***a* and **11***b*, and in the sliding base block **12** are formed ball relief bores **16**. In the side caps **15** are formed direction converting paths **17**, respectively, which connect the both ends of the ball paths formed between the ball rolling grooves **11***a*, **12***a* and **11***b*, **12***b* located in the load applied area and both ends of the ball relief bores **16**.

It should be noted that no retainer for preventing that the balls are fallen down when the sliding base **12** is taken off from the tracking base **11** is provided in the apparatus of the embodiment, due to the small space.

The ball rolling grooves **11***a*, **12***a* and **11***b*, **12***b*, which face to each other, may have so-called circular-ark type cross sections, consisting of a single circular-ark, as shown in FIG. **15**, or so-called Gothic ark type, consisting of a combination of two circular-arks, as shown in FIG. **14**; but the depths of the ball rolling grooves are set in such a manner that contacting angles of balls can be freely selected. In this embodiment, the depths of the ball rolling grooves are set at substantially half of the diameter of balls to be held therein. Thereby, the balls **13** should be made contact with any portion of the substantial semi-circular shaped ball rolling grooves **11***a*, **12***a* and **11***b*, **12***b*, respectively. Therefore, in the apparatus, almost all of the contact angles, which have been demanded in the conventional type of such linear movement guide apparatuses, can be obtained.

Particularly, when the circular-ark shaped ball rolling grooves are slightly larger than the balls to be held therein, the contact angles are not limited to 45 degrees with respect to a horizontal direction, but arbitrary angles can be obtained, substantially. When the variation of the contact angles is small, it is not necessary to make the depth of the ball rolling grooves about half of the diameter of the balls to be held therein. In such case, it may be possible to arrange the depths of the grooves to be about a quarter of the diameter of balls to be held therein.

Contrary to this, in the conventional linear movement guide apparatus **30** shown in FIG. **23**, the depths of the rolling grooves **31***a* and **32***a*, which are formed on the upper surface side of the sliding base and on the inner side of the concave portion of the corresponding tracking base, are arranged to be small and the circular-ark shapes of the grooves are designed to be slightly larger than the balls to be held therein. The apparatus **30** is not originally designed to have other contact angles excepting for the contact angle formed in a vertical direction. However, even if the contact angles extended in other directions than the vertical direction can be objected, the balls would be made contact with the ball rolling grooves at points located in the vicinity of edges of the ball rolling grooves. Therefore, the contact stress on the edge portions of the grooves would become extremely large, so that there would be a fear that ball rolling surfaces are destroyed.

According to the invention, it is possible to provide a linear movement guide apparatus as shown in FIG. **3** having various contact angles, shown in FIGS. **6** to **13**, by variably changing the pitch (distance) B1 between the two rows of ball rolling grooves formed on the upper surface of the tracking base **11**, and the pitch (distance) B2+B3 between said rows of the ball rolling grooves and the ball rolling grooves formed on the side surface of the tracking base, with respect to the pitches (distances) A1, A2, A3 between the corresponding ball rolling grooves formed on the sliding base. Such apparatuses have a suitable performance to support the load applied from each direction. It should be noted that only the tracking base, the balls and the contact angles are illustrated in a typical manner in FIGS. **6** to **13** in order to make the drawings much more understandable. The extending directions of the contact angles are shown by dotted broken lines in these figures. The lines connect the contact portions of balls in the ball rolling grooves facing to each other. Hereinafter, the lines will be called as contact angle lines.

All of the embodiments shown in the figures are basically designed so as to be able to support the loads applied from all directions being perpendicular to an axial direction of the tracking base **11**, which are represented by the loads applied from the four directions shown in FIG. **5**, i.e. a radial load PR applied from a direction, in which the sliding base **12** is urged against the tracking base **11** from an upper direction, a reversed radial load PL applied to a direction, in which the sliding base **12** is urged to be risen up against the tracking base **11**, and lateral loads PT applied to the sliding base **12** from left and right directions. Further, the apparatuses are designed so as to be basically able to support the moment Mc about the axial direction Z of the tracking base **11**, the moment Mb about a perpendicular axis Y, and the movement MA about a horizontal axis X. The apparatus is designed such that the stiffness in each direction is relatively varied in accordance to the specific load apply direction by selecting the proper contact angles of ball.

In the conventional linear movement guide apparatus **40** shown in FIG. **24**, the contact structure is also varied to be DB structure or to be DF structure by changing the distance A so as to become larger or smaller than the distance B. However, in this apparatus **40**, the contact angles per se are not varied, but keeping them about 45 degrees. Therefore, the conventional linear movement guide apparatus **40** does not have a performance for supporting the load applied from each direction, e.g. to change the load supporting capability in a width direction with respect to that in an upper and lower direction in an arbitrary manner.

In FIG. **6**, the linear movement guide apparatus according to the first embodiment of the present invention is illustrated.

In the first embodiment, the two rows of ball rolling grooves **11***a* formed on the upper surface of the tacking base **11** and the corresponding ball rolling grooves **12***a* formed on the sliding base **12** so as to face thereto, and one row of ball rolling grooves **11***b* formed on each side surface of the tracking base **11** and the corresponding ball rolling groove **12***b* on the sliding base **12** facing thereto, are designed to have circular-ark shapes consisting of a single circular-ark; and their depths are arranged to be substantially half of the diameter of balls to be held therein.

The contact angle lines in the upper ball rows are extended in a substantially vertical direction and the contact angle lines in the lower ball rows are inclined by 45 degrees with respect to the horizontal direction; and the contact angles lines of the lower ball rows intersect to each other at a point located on an upper side of the lower ball rows.

This type of the linear movement guide apparatus has a large load supporting capability for the main load, i.e. the load applied from an upper direction (radial load), and the apparatus is designed such that a large differential sliding is not caused so much. Therefore, this type of apparatus is suitably used when the apparatus is driven in a high speed. That is to say, in this apparatus, the radius of curvature of the cross-sections of the ball rolling grooves **11***a* and **12***a*; **11***b* and **12***b* are set at about 0.52 of the diameter of the balls to be held therein, which is a range for restricting the generation of the differential sliding small.

Further, when the radius of curvature of the ball rolling grooves having circular-ark shapes are arranged to be as almost the same size of the diameter of balls to be held therein, it becomes possible to obtain linear movement guide apparatuses having a various types of contact angles, in which the contact angles are varied only by slightly changing the pitches (distances) A1–A3 and B1–B3 between the ball rolling groove explained in the above.

It should be noted that the word of "differential sliding" means a sliding caused on the contact surface of balls held and rotated in the grooves. The sliding is caused by a difference between the inner contact diameter and the outer contact diameter of the circular-shaped contact surface of balls. The difference is generated when the balls are rolled because the balls are made contact with the ball rolling grooves in a circular-ark shaped condition. In the case of the ball rolling grooves having Gothic-ark type shapes, which are consisting of a combination of two circular-arks, the balls are made contact with the grooves at four points, as shown in FIG. **14**. When the balls are rolled in the grooves, being made contact with the grooves at four points, the difference between the inner contact diameter d**1** and the outer contact diameter d**2** becomes large; and further when the balls are rolled about the axis X, the difference between the inner contact point C and the outer contact point D becomes large, so that a large sliding is generated between the outer surface of the balls and the ball rolling grooves. Thereby, the balls are rolled in the grooves being slid, so that the rolling resistance, which is generated when the balls are rolled in the grooves, is increased. Therefore, when the sliding base **12** is moved along the tracking base **11**, a large friction resistance is generated. It should be noted that the reference symbol E in FIG. **14** represents an area where the balls and the rolling grooves are contacted to each other.

In case that the ball rolling grooves have circular-ark type shapes, which consist of only a single ark, the balls made contact with the grooves at tow points as shown in FIG. **15**. In this case, the contact width a is smaller in comparison with that of the Gothic-ark type ball rolling grooves. Therefore, it can be generally be said that only a small differential sliding is caused and thus the balls are rolled in the grooves in a preferred manner in the apparatus.

In FIG. **7**, there is depicted the linear movement guide apparatus according to the second embodiment of the present invention.

In the second embodiment, the two rows of ball rolling grooves **11***a* formed on the upper surface of the tracking base **11** and the corresponding ball rolling grooves **12***a* formed on the sliding base **12** facing thereto, and ball rolling grooves **11***b* formed on the side surfaces of the tracking base **11** and the corresponding ball rolling grooves **12***b* formed on the sliding base **12** facing thereto, are also designed as circular-ark type grooves having their depths of almost half of the diameter of balls to be held therein.

The contact angle lines in the upper ball rows are directed to a vertical direction and the contact angle lines in the lower ball rows are substantially extended into a horizontal direction.

The linear movement guide apparatus has a large load supporting capability for the main load, which is applied from the lateral directions; and is so designed that a differential sliding is not caused so much. Therefore, the apparatus is also suitably used when the apparatus is driven in a high speed.

When the tracking base and the sliding base are coupled so as to have the contact angles as shown in FIG. **7**(*a*), and a pre-load is given to the balls held in the ball rolling grooves, the contact angles of the balls are changed, and the contact angle lines are inclined as shown in FIG. **7**(*b*). Since the pre-load is applied to the balls with respect to a rotating direction of balls in the case that the sliding base is viewed from its axis direction, a linear movement guide apparatus having a high stiffness and no space in the rotating direction of balls can be obtained.

In FIG. **8**, a linear movement guide apparatus according to the third embodiment of the present invention is represented.

In the third embodiment, two rows of the ball rolling grooves **11***a* formed on the upper surface of the tracking base **11** and the corresponding ball rolling grooves formed on the sliding base **12** so as to face thereto, and the rows of the ball rolling grooves **11***b* formed on both the side surfaces of the tracking base **11** and the corresponding ball rolling grooves formed on the sliding base **12***b* facing thereto, are designed to have circular-ark shapes consisting of a single circular-ark, and to have depths of about half of the diameter of balls to be held therein.

In the apparatus shown in FIG. **8**, the contact angle lines in the upper ball rows are inclined by about 45 degrees with respect to the horizontal direction, respectively and intersect to each other at an upper point of the upper ball rows. Further, the contact angle lines in the lower ball rows are extended in a direction parallel to the contact angle lines of the upper ball rows.

The linear movement guide apparatus has a capability to support a large load applied from a lower direction (reversed radial load), and is designed such that the differential sliding is not caused so much. Therefore, the apparatus is suitably used when the apparatus is driven in a high speed.

When the tracking base is coupled with the sliding base having contact angles as shown in FIG. **8**(*a*) and a pre-load is given to the balls held between the ball rolling grooves, the contact angles are changed so that the angle formed by the contact angle lines in the grooves **11***a* and the angle formed by the contact angle lines in the grooves **11***b* and **11***b* become small. Since a pre-load is applied to the balls with respect to the rotating direction of balls when the sliding base is viewed from its axis direction, a linear movement guide apparatus having a high stiffness and no space in the ball rotating direction can be obtained. The pre-load can be applied to the balls by setting the distance between the ball rolling grooves, which are facing to each other, smaller than the diameter of the balls to be held therein. That is to say, when the pre-load is applied to the balls held in the grooves formed on the side surfaces of the bases, the tracking base is slightly deformed so as to be shrunk in a horizontal direction by a reaction force against the compression of the balls; but the sliding base is slightly deformed so as to be extended in a horizontal direction by the reaction force, so that the contact angles are changed.

In FIG. **9**, a linear movement guide apparatus according to the fourth embodiment of the present invention.

In the fourth embodiment, two rows of the ball rolling grooves **11***a* formed on the upper surface of the tracking base **11** and the corresponding ball rolling grooves **12***a* formed on the sliding base **12** so as to face thereto, and the rows of the ball rolling grooves **11***b* formed on the side surfaces of the tracking base **11** and the corresponding ball rolling grooves **12***b* formed on the sliding base **12** facing thereto, are designed to have circular-ark shapes consisting of a single circular-ark and to have their depths of half of the diameter of balls to be held therein.

In the fourth embodiment shown in FIG. **9**, the contact angle lines in the upper ball rows are inclined in a lower and inside direction with respect to the horizontal direction and intersect to each other at a lower point of the upper ball rolling grooves; and the contact angle lines in the lower ball rows are inclined to an upper and inside direction with respect to the horizontal line and intersect to each other at an upper point of the lower ball rolling grooves.

In this linear movement guide apparatus has a capability to support loads applied from all directions, i.e. radial load PR, lateral load PT applied from a horizontal direction, and reversed radial load PL applied from a lower direction, and is designed such that the differential sliding is not generated so much. Therefore, the apparatus is suitably used to be driven in a high speed.

In FIG. **10**, there is shown a linear movement guide apparatus according to the fifth embodiment of the present invention.

In the fifth embodiment, two rows of ball rolling grooves **11***a* formed on the upper surface of the tracking base **11**, and the corresponding ball rolling grooves **12***a* formed on the sliding base **12** facing thereto are arranged to have their depths about half of the diameter of balls to be held therein; and these grooves are designed as circular-ark type grooves having single circular-ark shaped cross section. Further, the rows of ball rolling grooves **11***b* formed on side surfaces of the tracking base **11** and the corresponding ball rolling grooves **12***b* formed on the sliding base **12** facing thereto are arranged to have their shapes that two circular-arks are combined, and the depths thereof are about half of the diameter of balls to be held therein.

In fifth embodiment shown in FIG. **10**, the contact angle lines in the upper ball rows are inclined by about 45 degrees with respect to the horizontal direction and the contact angle lines intersect to each other at an upper position of said ball rows. Further, the contact angle lines in the lower ball rows are also inclined to be substantially parallel to the lines in the upper ball rows, as like the embodiment shown in FIG. **8**.

This type of the linear movement guide apparatus has a large load supporting ability against the main load applied from the lower direction (reversed radial load); and is designed such that so-called differential sliding is not caused so much. Therefore, the apparatus can be suitably used to be driven in a high speed.

FIG. **11** depicts a linear movement guide apparatus according to the sixth embodiment of the present invention.

In this embodiment, two rows of ball rolling grooves **11***a* formed on the upper surface of the tracking base **11** and the corresponding ball rolling grooves **12***a* formed on the sliding base **12** facing thereto are arranged to have circular-ark shapes having depths of about half of the diameter of balls to be held therein; and the rows of ball rolling groove **11***b* formed on both side surfaces of the tracking base **11** and the corresponding ball rolling grooves **12***b* formed on the sliding base **12** facing thereto are arranged as Gothic-arc type grooves having their depths of almost half of the diameter of balls to be held therein.

In the sixth embodiment shown in FIG. **10**, the contact angle lines in the upper ball rows are directed in a substantially perpendicular direction and the contact angle lines in the lower ball rows are inclined by about 45 degrees with respect to the horizontal direction and then the lines intersect to each other in an upper position of the lower ball rows, as like as the embodiment shown in FIG. **6**.

This type of linear movement guide apparatus has a large load supporting ability against the main load applied from the upper direction (radial load). When a large radial load is applied to such linear movement guide apparatus, the balls held in the lower grooves are made contact with the grooves at four points, as shown in FIG. **11**(*b*).

In this apparatus, so-called differential sliding is caused thereby to decrease a mechanical vibration, which is generated when the working object W of the machinery tool is cut by a cutting tool TO shown in FIG. **4**. Therefore, the roughness of the cutting finish of the working object W and the accuracy of dimension thereof can be improved. Further, the thus caused differential sliding effects as a damper or a buffer means against a ball screw mechanism S. which is for driving the linear movement guide apparatus **10**, and a driving source therefor, i.e. a motor M. In FIG. **4**, an example is illustrated, in which the linear movement guide apparatus **10** according to the present invention is used in a movement guide section of a top table T for transporting the working object W.

In FIG. **12**, a linear movement guide apparatus according to the seventh embodiment of present invention is illustrated.

In this embodiment, two rows of ball rolling grooves **11***a* formed on the upper surface of the tracking base **11** and the corresponding ball rolling grooves **12***a* formed on the sliding base **12** facing thereto are arranged as Gothic arc type grooves having depths almost half of the diameter of balls to be held therein, but the rows of ball rolling groove **11***b* formed on both side surfaces of the tracking base **11** and the corresponding ball rolling grooves **12***b* formed on the sliding base **12** so as to face thereto are arranged to have circular-ark shapes, whose depths are almost half of the diameter of balls to be held therein.

In the seventh embodiment shown in FIG. **12**, the contact angle lines in the upper ball rows are inclined by about 45 degrees with respect to the horizontal direction and intersect to each other in an upper position of the upper ball rows; but the contact angle lines in the lower ball rows are directed in a substantially horizontal direction.

When a large load is applied to the linear movement guide apparatus from a horizontal direction, the balls held in one of the upper ball rows are made contact with the relevant groove at four points. Thereby, in this apparatus, so-called differential sliding is caused to decrease a mechanical vibration, which is generated when the working object of the machinery tool is subjected to be cut. Therefore, the roughness of cutting finish of the working object and the accuracy of dimension thereof can be improved. Further, the differential sliding effects as a damper or buffer means against a ball screw mechanism, which is for driving the linear movement guide apparatus **10** and a driving source therefor, i.e. a motor.

In FIG. **13**, a linear movement guide apparatus according to the eighth embodiment of the present invention is represented.

In this embodiment, not only two rows of ball rolling grooves **11***a* formed on the upper surface of the tracking base **11** and the corresponding ball rolling grooves **12***a* formed on the sliding base **12** so as to face thereto but also the rows of ball rolling groove **11***b* formed on side surfaces of the tracking base **11** and the corresponding ball rolling grooves **12***b* on the sliding base **12** so as to face thereto are arranged as Gothic-arc type grooves having their depths of almost half or less of the diameter of balls to be held therein.

In the eighth embodiment shown in FIG. **13**, the apparatus is designed such that the balls held in the ball rolling grooves **11***a* and **12***a* are made contact with the relevant ball rolling grooves formed on the tracking base **11** and **12** facing to each other at four points, when a large load is applied to the sliding base **12** from a lower direction.

Therefore, the apparatus is able to support a large load applied from the lower direction, and thus suitably used in a machinery, such as NC machinery or machining center, in which a comparatively heavy cutting process or a heavy grinding process is required.

In this apparatus, since the balls are made contact with the relevant ball rolling grooves formed in the tracking base **11** and the sliding base **12** at four points in a complete manner or at four points in an incomplete manner, in which the balls are made contact with the grooves with some deviation, an enough sliding resistance can be constantly obtained. The sliding resistance becomes larger, in response to the load applied from a lower direction. Therefore, the ball screw mechanism, for moving the sliding base **12** being applied a cutting load or a grinding lord, is not directly subjected to these loads. As a result, the apparatus has no drawback that the ball screw mechanism is damaged comparatively soon by a heavy cutting process or a heavy grinding process.

The sixth to eighth embodiments shown in FIGS. **11** and **13** in the above, the apparatuses are constructed such that the ball rolling grooves are designed as Gothic-arc type grooves consisting of a combination of two circular-arks and thus the balls are made contact with the relevant grooves at four points to obtain a differential friction when a heavy load is applied to the apparatus. However, even in case that the grooves are arranged as circular ark type grooves, consisting of a single circular-ark, it is possible to make the differential sliding large in order to increase the sliding resistance in the apparatus by the design that the radii of curvature of cross section of the grooves are close to the diameter of the balls to be held therein.

In this case, it is desired to set the radii of curvature R of the ball rolling grooves within a range smaller than about 0.52 of a diameter Da of ball to be held therein. However, if the radius of curvature is too small, a nimble rolling of balls, which is an inherent characteristic of such rolling guide apparatus, will be lost because the friction becomes too much large. Therefore, it is desired to set the radius of curvature in a range between 0.52 to 0.505, preferably at about 0.51.

In a rotary type ball and roller bearing, the radius of curvature of the cross section of the ball rolling groove is generally designed to be about 0.52 to 0.54 of a diameter of ball to be held therein, for the purpose of decreasing a rolling friction, which is caused on the rolling surface of the balls, particularly, for the purpose of preventing that a heat is generated when the balls are rolled in the grooves in a high speed. That is to say, when the radius of curvature of the ball rolling grooves becomes closer to 0.5 of the diameter of balls to be held therein, the contact width of the balls with respect to the ball rolling grooves becomes larger, so that a differential sliding between a center portion and the edge portions of the contact width becomes large. As a result, a friction resistance and the amount of heat generation also increase. Therefore, the radius of curvature of the groove is generally set at about 0.52 or more of the diameter of the ball to be held therein.

Further, in the case of a thrust ball bearing, the radii of curvature of cross sections of the ball rolling grooves formed on inner and outer races thereof are set at about 0.54 of the diameter of the balls to be held therein.

The basic idea of the linear rolling guide apparatus also exists on an extended line of this thinking. That is to say, the apparatus is generally designed in such a manner that the shapes of the cross sections of ball rolling grooves are arranged as so-called circular ark shaped grooves, which is consisting of a single circular-ark; and the radii of curvature of the cross sections thereof are generally set at about 0.52 to 0.54 of the diameter of balls to be held therein in order to restrain the increase of the friction resistance, as much as possible. In the above explained embodiments shown in FIGS. **3** to **11**, the radii of curvature of the cross section of the grooves are set within this range.

By converting this idea, the same effect as that of the Gothic arch type grooves, which are shown in FIGS. **11** and **13**, can be obtained. That is to say, the differential sliding caused in the ball rolling grooves having a cross section of a single circular-ark shapes is positively used to decrease the mechanical vibration, which is caused when the working object of the machinery tool is subjected to be cut.

That is to say, the cross sections of the grooves cut at a surface being perpendicular to an axis direction of the grooves have circular-ark shapes consisting of a single circular-ark, so that the all contact surfaces of the balls with respect to the ball rolling grooves become ellipse shaped circular ark surfaces whose longer axis is extended in a direction being perpendicular to the axis direction.

At each contact points along the longer axis of the ball contact surface, the distances from the rotating center axis of the balls are different from each other, and therefore, there are caused differential sliding on the ball contact surface. That is to say, when the balls are rotated, the balls are rolled and made contact with the grooves at some point on the longer axis of the ball contact surface without being slid, but at the other points, the balls are rolled and made contact with the grooves being slid. In the conventional apparatus, the differential sliding should be restricted as much as possible to decrease the friction. However, in the present invention, the differential sliding is used to control the friction caused in the axis direction, in order to obtain the stiffness and the damping, which are the characteristics required in the apparatus.

In other words, when the radius of curvature R of the ball rolling grooves is set at about 0.51 of the diameter D of the balls to be held therein, the differential sliding is increased therein by the load applied to the grooves when a heavy cutting is conducted; and thus the balls move in the grooves in a mixed condition of the rolling movement and the sliding movement. As a result, the rolling movement of the balls becomes like a sliding movement, so that the damping characteristic thereof is improved. Since the sliding and rolling phenomenon is generated between the balls and the ball rolling grooves and the movement of the balls becomes heavy, the damping characteristic is improved. Thus, it is possible to prevent that the amount of the slight waviness at machine is increased even when a heavy cutting is conducted.

Furthermore, in the apparatus having circular-ark type grooves, if the depths of the ball rolling grooves are set at 51% of the diameter of balls to be held therein, the contact area of balls becomes larger in comparison with the general circular ark type grooves. (In other words, the contact area becomes larger as like as that of rollers.) In this case, loading capability against a heavy load is rapidly improved, involving the construction of contact angles of balls explained in the above, and further a stable linear movement with a high stiffness can be obtained.

Next, a method for assembling linear movement guide apparatuses according to the first to eighth embodiment shown in FIGS. **6** to **13** will be explained in the above.

First, a common member is used to manufacture the tracking and sliding bases. These bases are manufactured by, for instance, a drawing method. On the other hand, dressers are prepared to form circular ark type grooves or Gothic-arc type grooves, whose depths are of about a quarter to a half of the diameter of balls to be held therein. It should be noted that pitches (distances) in width and height directions of each dresser are varied in accordance with the type of the contact angles of the linear movement guide apparatus.

That is to say, a pair of upper dressers, by which a predetermined-shaped grooves can be formed with a first pitch (distance) in its width direction, and a pair of lower dressers, by which a predetermined-shaped grooves can be formed to be separated from said upper dressers with a second pitch (distance) in a height direction, are used to manufacture the tracking base **11** from the common material having a square cross section. The thus manufactured tracking base **11** has a pair of ball rolling grooves **11***a*, **11***a* on an upper surface thereof, being separated from each other in its width direction by the first pitch (distance); and ball rolling grooves **11***b* on each side surface thereof being separated from said ball rolling grooves **11***a* by the second pitch (distance) in its height direction.

Next, a pair of upper dressers, by which a predetermined-shaped grooves can be formed being separated from each other by a third pitch (distance), which is different from said first pitch (distance), in its width direction, and a pair of lower dressers, by which a predetermined-shaped grooves can be formed being separated from said upper dressers in its height direction by a fourth pitch (distance), which is different from said second pitch (distance), are used to manufacture a plurality types of sliding bases **12** from the common member.

The thus manufactured sliding base **12** has a pair of ball rolling grooves **12***a*, **12***a* on an upper surface of a square shaped concave portion **12***c*, which are separated from each other by said third pitch (distance) in its width direction; and it also has ball rolling grooves **12***b*, which are separated from said ball rolling grooves **12***a* by said fourth pitch (distance) in its height direction on each side surface of said concave portion. It should be noted that these sliding bases are manufactured such that the third and fourth pitches (distances) are different from the first and second pitches formed on the tracking bases **11**; and a plurality types of sliding bases **12** having different pitches of the ball rolling grooves are manufactured with respect to one standard tracking base **11** by varying the differences between said third and fourth pitches from the first and second pitches.

Then, a suitable combination of the first and third pitches (distances) and the second and fourth pitches (distances) is selected so as to obtain suitable contact angles for loads applied from each direction or moment loads; and then the linear movement guide apparatus having desired contact angles and desired groove shapes is assembled.

In the assembling method of the linear movement guide apparatus mentioned in the above, a plurality types of sliding bases **12** are manufactured on the basis of one tracking base **11**. However, it may be possible to manufacture a plurality types of tracking bases **11** with respect to one basic sliding base **12**. The positional relationship of the ball rolling grooves should be as in the following. That is to say, the positional relationship between the centers of the grooves formed on the upper surface of the tracking base and the centers of the grooves formed on the side surfaces of the tracking base, and the positional relationship between the centers of the grooves formed on the upper surface of the sliding base and the centers of the grooves formed on the side surfaces of the sliding base are arranged to be coincident with each other or deviated from each other between the grooves facing to each other. It may be possible to set the standard surface for processing on the other surface than the upper surface of the tracking base.

FIGS. **16**(*a*) to (*e*), are illustrated the other types of constructions of the contact angles.

FIG. **16**(*a*) is one of the examples in which the contact angles of balls held in two rows of ball rolling grooves formed on the upper surface of the tracking base are set at about 90 degrees; and the contact angles of balls held in the rows of ball rolling grooves formed on the side surfaces of the tracking base are arranged such that the contact angle lines thereof are inclined in lower and inside direction with respect to a horizontal direction by a given degree. In this case, since the radial road is supported by not only the upper surface but also the side surfaces, the radial stiffness becomes large.

FIG. **16**(*b*) shows another example, in which the contact angles in upper ball rows of the tracking base are arranged such that the contact angle lines are inclined with respect to horizontal direction by about 45 degrees and intersect to each other at an upper point of the upper ball rows; and the contact angles of grooves formed on the side surfaces are arranged such that the contact angle lines are inclined in a lower and inside direction with respect to the horizontal direction by a given degree.

FIG. **16**(*c*) depicts another example, in which the contact angles in upper ball rows of the tracking base are arranged such that the contact angle lines are inclined with respect to horizontal direction by about 45 degrees and intersect to each other at a lower point of the upper ball rows; and the contact angles in both the side grooves are also arranged such that the contact angle lines are inclined in a lower and inside direction with respect to the horizontal direction by a given degree.

In the examples shown in FIGS. **16**(*b*) and (*c*), it is possible to support the load applied from lateral directions by the balls held in the grooves formed on the upper surfaces. Therefore, in these examples, the stiffness against the radial load and the load applied from the lateral directions is increased.

FIG. **16**(*d*) represents an embodiment, in which the contact angles in the upper ball rows of the tracking base are constructed such that both the contact angle lines are inclined in the same direction with 45 degrees being parallel to each other; and the contact angles in the side ball rows are arranged such that the contact angle lines are inclined by 45 degrees in a reversed direction of the lines in the upper ball rows, being parallel to each other.

FIG. **16**(*e*) illustrates another embodiment, in which the contact angles in the upper ball rows of the tracking base are constructed such that both the contact angle lines are inclined in the same direction by 45 degrees being parallel to each other; and the contact angles in the side ball rows are arranged such that both the contact angle lines are also inclined by 45 degrees in the same direction as the lines in the upper ball rows, being parallel to each other. In these embodiments shown in FIGS. **16**(*d*) and (*e*), since the contact angle lines in the upper ball rows are inclined to be parallel to each other, it is possible to support the load applied from the right side direction in the figures. And thus, the stiffness against the load applied from the right side direction in the figures particularly becomes high.

Furthermore, it may be possible to provide an apparatus in which the contact angle lines extended in the horizontal direction and the contact angle lines extended in the inclined direction are combined. Therefore, a various type of linear movement guide apparatuses having different contact angle constructions, by which the stiffness is made high in the relevant direction in accordance with the portion to be used, can be provided.

(Six Rows Type)

FIGS. **17** to **21** show six rows type linear movement guide apparatuses in which a pair of two rows of ball rolling grooves are formed on each surface of the tracking base, i.e.

on the upper surface, each side surface of the tracking base. Therefore, six ball rows in total are formed in the apparatus.

FIGS. **17** to **21** represent linear movement guide apparatuses according to the ninth to twelfth embodiments of the present invention. The basic construction of such linear movement guide apparatuses having six rows of ball rolling grooves will be first explained with reference to FIGS. **7** and **8**.

In these figures, the numerical reference **1** represents a linear movement guide apparatus as a whole, which comprises a tracking base **2** and a sliding base **3**. The sliding base **3** is so designed to be linearly guided along the tracking base **2** and to have a concave portion **3***d* for accepting the tracking base **2**. The apparatus comprises six ball rows, in which balls **4** are rotatable held in an endless manner, formed between the sliding base **3** and the tracking base **2**.

The tracking base **2** has a square-shaped cross section and is extended in a longitudinal direction. On the upper surface of the tracking base **2**, are provided a pair of two rows of ball rolling grooves **2***a* in a longitudinal direction; and a pair of two rows of ball rolling grooves **2***b* and **2***c* are extended on each side surface thereof.

The sliding base **3** comprises the concave portion **3***d* having a square-shaped cross section for accepting the tracking base **2**. The tracking base **2** also has a square shaped cross section. On upper and side surfaces of the concave portion **3***d*, are provided corresponding ball rolling grooves **3***a*, **3***b* and **3***c* so as to face to the ball rolling grooves **2***a*, **2***b* and **2***c*, of the tracking base **2**, respectively. It should be noted that the loads applied from the longitudinal and width directions are supported by these ball rolling grooves. The sliding base **3** is mounted on the tacking base **2** so as to traverse over the tracking base **2** by inserting the tracking base **2** into the concave portion **3***d*.

The sliding base **3** comprises a sliding base block **5** having a high stiffness, and side caps **6** fixed to each edge surface of the block **5**. And, the above said ball rolling grooves **3***a*, **3***b* and **3***c* and ball relief bores **7** are formed on the concave portion **3***d* of the sliding base block **5**. In the side caps **6**, are provided direction converting paths, by which both ends of the ball paths in load areas between the ball rolling grooves **2***a*, **3***a*, **2***b*, **3***b* and **2***c*, **3***c* facing to each other and both ends of the ball relief bores **7** are connected to each other.

Between the ball rolling grooves **2***a*, **2***b* and **2***c* on the tracking base **2** and the corresponding ball rolling grooves **3***a*, **3***b*, **3***c* on the sliding base **3**, which face to each other, a plurality of balls **4** are mounted in a rotatable manner. On the upper surface, are provided two ball rows **5**; and on each side surface, are provided two ball rows **6** and **7**, respectively. Therefore, six ball rows in total are provided in the apparatus.

Two ball rows **2***b*, **2***c* (or **3***b*, **3***c*) formed on both the side surfaces of either one of the tracking base **2** or the sliding base **3** are arranged such that the positional relationship between the center portions of the grooves are coincident with or deviated from the center portions of the corresponding ball rolling grooves **3***b*, **3***c* (or **2***b*, **2***c*) of either one of the tracking base or the sliding base **3** in upper and lower direction. Thus, the apparatus is constituted of the arbitrarily coupled tracking base **2** and sliding base **3**, in which the above stated positional relationships of the center portions of the grooves is coincident with each other or deviated from each other.

By coupling the tracking base **2** or the sliding base **3**, in which the corresponding positional relationship between the center portions of the grooves is coincident with or deviated from the corresponding tracking or sliding base in upper and lower directions, with the corresponding racking base **2** or the sliding base **3** in an arbitrary manner, as explained in the above, the contact angles of the balls **4** held in the ball rows **6** and **7** formed on the side surfaces can be adjusted. Thereby, the stiffness in upper and lower directions and right and left directions, which are required to support the loads applied from these directions, can be obtained, so that it is possible to provide a linear movement guide apparatus having a load supporting characteristic in accordance with the purpose of use thereof.

In order to adjust the above mentioned contact angles, it is preferred to design the ball rolling grooves as in the following.

That is to say, the ball rolling grooves **2***a*, **2***b*, **2***c*, **3***a*, **3***b* or **3***c* may be possible to have circular-ark type shapes or a Gothic-ark type shapes; however, it is desired to arrange such that at least each ball rolling groove **2***b*, **2***c* and **3***b*, **3***c* formed on side surfaces has its depth of about ½ of the diameter of balls **4** to be held therein. Thereby, the balls **4** held in the two ball rows **6** and **7**, which are formed on the side surfaces, are made contact with any place of the two rows of ball rolling grooves **2***b*, **2***c* or **3***b*, **3***c*, which have almost semi circular shapes. And thus, it is possible to obtain almost all contact angles. It should be noted that in case that the variation of the contact angles is small, it may be possible to arrange the depths of the grooves about ¼ of the diameter of balls **4**.

In the embodiments shown in FIGS. **17** to **21**, the linear movement guide apparatuses are constructed such that the positional relationship between the center portions of the grooves are coincident with or deviated from those of the corresponding grooves; and each type of contact angle construction is obtained by combining the tracking base **2** or the sliding base **3** with the corresponding tacking base **2** or the corresponding sliding base **3** in an arbitrary manner.

FIG. **17** is a schematic view showing the ninth embodiment according to the present invention. In the ninth embodiment, the centers OA of the ball rolling grooves **2***b* and **2***c* formed on side surfaces of the tracking base **2** are deviated from the centers OB of the corresponding ball rolling grooves **3***b* and **3***c* formed on the sliding base **3** in an upper direction, or the centers of OB of the ball rolling grooves **3***b* and **3***c* formed on side surfaces of the sliding base **3** are deviated from the centers OA of the corresponding ball rolling grooves **2***b* and **2***c* formed on the tracking base **2** in a lower direction; and thereby the contact angle lines of the balls **4** held in the ball rows **6** and **7** formed on the side surfaces are inclined by about 45 degrees in upper and inside direction of the tracking base **2** with respect to the horizontal direction. Such deviation can be obtained in the first to eighth embodiments by the same manner as in the above assembling method. In the ninth embodiment, the contact angles of balls **4** in the ball rows **5** formed on the upper surface, are arranged to be 90 degrees with respect to the horizontal direction.

In the ninth embodiment, the load applied from an upper direction against the sliding base **3** (radian load) PR is supported by the two ball rows **5** formed on the upper surface. And, the lateral load applied from left and right directions (horizontal direction load) PT is supported by either one of the two ball rows **6** and **7** formed on the side surfaces, according to the load applied direction. Further, the vertical load applied from the lower direction (reversed radial load) PL is supported by two ball rows **6** and **7** formed on the side surfaces.

Furthermore, the contact angles of the balls **4** in the two ball rows **6** and **7** formed on the side surfaces are arranged such that the contact angle lines are inclined in an upper and inside direction by 45 degrees with respect to the horizontal direction. Therefore, it is possible to support the load in a reversed radial direction and the load in a lateral direction in an even manner. Moreover, in such apparatus, the stiffness against the load applied from the lateral direction is much higher than that in the apparatus having only one ball row on each side surface.

Moreover, the load applied from the radial direction is supported by the two ball rows **5** formed on the upper surface, whose contact angles are about 90 degrees with respect to the horizontal direction. Therefore, a high stiffness can be obtained against the radial load.

Particularly, if the depths of the ball rolling grooves are set about 51% of the diameter of balls to be held therein, the contacting area of the balls against the general circular-ark type grooves becomes large (like a roller) and the supporting ability for the heavy load is rapidly improved, involving the construction of the contact angles, so that a high stiffness and a stable linear movement can be obtained.

That is to say, optimum and suitable combination of the tracking base and the sliding base can be obtained when the load are applied from a radial direction, a reversed direction and lateral (left and right) direction.

In FIG. **19**, is illustrated the linear movement guide apparatus according to the tenth embodiment of the present invention. In the linear movement guide apparatus **1***a*, the positional relationship between the centers of the grooves is arranged to be coincident with the corresponding grooves, i.e. the relationship between either one of two rows of ball rolling grooves **2***b* and **2***c* (or **3***b* and **3***c*) formed on side surfaces of the tracking base **2** or the sliding base **3** and the corresponding ball rolling grooves **3***b* and **3***c* (or **2***b* and **2***c*) formed on the tracking or sliding base **2** or **3**, so that the contact angles of balls **4** in the two ball rows **6** and **7** on the side surfaces become 0 degrees with respect to a horizontal direction. On the other hand, the contact angles of balls **4** in the two ball rows on the upper surface are arranged to be 90 degrees with respect to the horizontal direction.

In the tenth embodiment, the vertical load applied from the upper direction against the sliding base **3** (radial load) is supported by the two ball rows **5** formed on the upper surface. And the lateral load applied from left and right directions (horizontal direction load) is supported by two ball rows **6** and **7** formed on either of the side surfaces, according to the load applied direction.

Since the contact angles of balls **4** in the two ball rows on the side surfaces are arranged to be about 0 degrees with respect to the horizontal direction and the contact angles of balls **4** in the two ball rows **5** formed on the upper surface are arranged to be about 90 degrees with respect to the horizontal direction, a high stiffness can be obtained and it is possible to support the radial load and the lateral load in an even manner.

That is to say, the apparatus has a large stiffness against loads applied from not only the horizontal (left and right) direction but also the radial direction; and the combination of the tracking base and the sliding base is optimum in the case that the loads are applied from the radial direction and the horizontal (left and right) direction.

FIG. **20** is a schematic view showing a linear movement guide apparatus according to the eleventh embodiment of the present invention. In this embodiment, the contact angles of balls **4** in the upper ball rows **6** formed on the side surfaces are arranged to be about 45 degrees with respect to the horizontal direction and the contact angle lines in the upper ball rows intersect to each other at a point inside of the tracking base **2**; but the contact angles of the balls **4** in the lower ball rows **7** formed on the side surfaces are arranged to be about 0 degrees with respect to the horizontal direction.

On the other hand, the contact angles of balls **4** in the two ball rows formed on the upper surface are 45 degrees with respect to the horizontal direction and the intersecting point of the contact angle lines therein locate outside of the tracking base **2**.

Further, in FIG. **21**, is depicted a linear movement guide apparatus according to the twelfth embodiment according to the present invention. In this linear movement guide apparatus **1***c*, the relationship of the contact angles of balls in the ball rows **6** and **7** formed on the side surfaces are arranged to be reversed to that of the apparatus according to the eleventh embodiment. That is to say, the contact angles of balls **4** in the lower ball rows **7** of the side surfaces are arranged to be about 45 degrees with respect to the horizontal surface and the contact lines thereof intersect to each other at a point inside of the tracking base **2**; and the contact angles of the balls **4** in the upper ball rows **6** on the side surfaces are arranged to be about 0 degrees with respect to the horizontal direction.

Therefore, the combinations of the tracking base **2** and the sliding base **3** in the eleventh and twelfth embodiments are optimum for the case that a large load is applied from a reversed radial direction.

In FIGS. **22**(*a*) to (*c*), other examples of the constructions of contact angles of balls are shown. It should be noted that any other combination, which is not shown in these figures, are possible to be arranged.

In FIG. **22**(*d*), is provided another construction in which two ball rows are formed on one of the side surfaces but only one row is on the other side. In FIG. **22**(*e*), is provided still another construction in which two ball rows are formed on one of the side surfaces but only one is on the other side surface, in addition thereto, only one ball row is formed on the upper surface.

As stated in the above, it may be possible to combine the one ball row and two ball rows on the side surfaces, or to form only one ball row on each side surface and the upper surface. Furthermore, it may also be possible to arrange three ball rows or more on the side surfaces and the upper surface.

Further, in each embodiment explained in the above, no retainer for preventing that the balls **4** are fallen when the sliding base **3** is taken off from the tracking base **2** is provided. However, the present invention can be applied to the apparatus having such retainer.

Furthermore, in each embodiment, the tracking base has a square-shaped cross section and thus the concave portion formed in the sliding base also has a square-shaped cross section. However, the invention is not limited by the square-shaped bases.

According to the present invention, a necessary load supporting characteristic can be obtained in accordance with the amount and the direction of loads applied to the apparatus; and thus, it is possible to provide an apparatus having a large load supporting capacity in accordance with the purpose of use thereof.

INDUSTRIAL APPLICABILITY

In the linear movement guide apparatus according to the present invention, the contact angle in each ball rolling groove can be set arbitrarily by changing the distance between the two rows of ball rolling grooves formed on the upper surface of the tracking base and the distance between said ball rolling grooves and the ball rolling grooves formed on side surfaces of the tracking base, with respect to the distances between the corresponding ball rolling grooves formed on the sliding base. Therefore, it is possible to provide an apparatus having a suitable performance for the load applied thereto from each direction, by changing the pitches between the ball rolling grooves in accordance with the condition of load applied to the apparatus to form ball rolling grooves having the most optimum contact angles.

The cross sections of the ball rolling grooves may be possible to arrange as a single circular-ark shape or as a combination of two circular-arks, but the depth of the grooves should be set up so as to be able to select an arbitrary ball contact angles. It is preferred to set up the depth about ¼ to ½ of the balls to be held therein. In such construction, the balls held in the grooves surely made contact with any portion of the grooves, so that it is possible to obtain almost all contact angles, which have been required in the conventional linear movement guide apparatuses of this type.

According to the assembling method of the present invention, the common material can be used to manufacture the tracking base and the sliding base. And, a plurality types of linear movement guide apparatuses can be obtained only by changing the type of the dressers and pitches (distance) thereof, i.e. the pitches between the ball rolling grooves formed by the dressers, in accordance with the load condition. Then, the productivity of the apparatus is extremely improved.

What is claimed is:

1. A method of assembling a linear movement guide apparatus comprising the steps of:

forming a tracking base having substantially a square cross section and formed, at an upper surface thereof, with a pair of arcuate first ball rolling grooves separated from each other by a first pitch in a width direction thereof and each having a depth approximately half of a diameter of a ball as a rolling member and formed, at each of bilateral side surfaces thereof, with a pair of arcuate second ball rolling grooves separated from each other by a second pitch in a height direction thereof;

forming a plurality kinds of sliding bases formed with recessed portions in which said tracking base is mounted to be slidable with respect to the tracking base through six rows of rolling balls and provided with a pair of third ball rolling grooves separated from each other by a third pitch different from the first pitch in a width direction thereof and a pair of fourth ball rolling grooves separated from each other by a fourth pitch with respect to the third ball rolling grooves different from the second pitch in a height direction thereof; and

assembling a linear movement guide apparatus, by selecting a combination of said first and third pitches and a combination of said second and fourth pitches, having one of following first to fourth contact angle structures: first contact angle structure in which a contact angle of a ball disposed between said first and third ball rolling grooves is 90° with respect to a horizontal line and a contact angle of a ball disposed between said second and fourth ball rolling grooves is 45° in an upward oblique direction towards the tracking base with respect to the horizontal line; second contact angle structure in which a contact angle of a ball disposed between said first and third ball rolling grooves is 90° with respect to a horizontal line and a contact angle of a ball disposed between said second and fourth ball rolling grooves is 0°; third contact angle structure in which a contact angle of a ball disposed between said first and third ball rolling grooves is 45° in a downward oblique direction towards a central portion with respect to a horizontal line and a contact angle of a ball disposed between said second and fourth ball rolling grooves is 45° in an upward oblique direction towards the tracking base with respect to the horizontal line; and fourth contact angle structure in which a contact angle of a ball disposed between said first and third ball rolling grooves is 45° in an upward oblique direction towards a central portion with respect to a horizontal line and a contact angle of a ball disposed between said second and fourth ball rolling grooves is 45° in an upward oblique direction towards the tracking base with respect to the horizontal line.

2. A method of assembling a linear movement guide apparatus according to claim **1**, wherein said first to fourth ball rolling grooves each has a depth approximately corresponding to ¼ to ½ of the diameter of the ball.

3. A method of assembling a linear movement guide apparatus comprising the steps of:

forming a tracking base having substantially a square cross section and formed, at an upper surface thereof, with a pair of bilateral two arcuate first ball rolling grooves separated from each other by a predetermined pitch in a width direction thereof and each having a depth approximately half of a diameter of a ball as a rolling member and formed, at each of bilateral side surfaces thereof, with a pair of two arcuate second ball rolling grooves separated from each other by a predetermined pitch in a height direction thereof;

forming a plurality kinds of sliding bases formed with recessed portions in which said tracking base is mounted to be slidable with respect to the tracking base through six rows of rolling balls and provided with arcuate third ball rolling grooves composed of a pair of bilateral two ball rolling grooves in a manner of being disposed at an upper bottom surface of the recessed portions in the same manner as that for the first ball rolling grooves in the width direction or in a shifted manner with respect thereto and arcuate fourth ball rolling grooves composed of a pair of vertical two ball rolling grooves in a manner of being disposed at both inside surfaces of the recessed portions in the same manner as that for the second ball rolling grooves formed to both side surfaces of the tracking base or in a shifted manner with respect thereto; and

assembling a linear movement guide apparatus, by selecting a combination of phases of said first and third ball rolling grooves and a combination of phases of said second and fourth ball rolling grooves, having one of following first to fourth contact angle structures: first contact angle structure in which a contact angle of a ball disposed between said first and third ball rolling grooves is 90° with respect to a horizontal line and a contact angle of a ball disposed between said second and fourth ball rolling grooves is 45° in an upward oblique direction towards the tracking base with respect to the horizontal line; second contact angle structure in which a contact angle of a ball disposed between said first and third ball rolling grooves is 90° with respect to a horizontal line and a contact angle of a ball disposed between said second and fourth ball rolling grooves is 0°; third contact angle structure in which a contact angle of two ball rows disposed between said first and third ball rolling grooves is 45° in an upward oblique direction towards a central portion with respect to a horizontal line, a contact angle of upper two ball rows disposed between said second and fourth ball rolling grooves is 45° in an upward oblique direction towards the tracking base with respect to the horizontal line, and a contact angle of lower two ball rows disposed therebetween is 0° with respect to the horizontal line; and fourth contact angle structure in which a contact angle of two ball rows disposed between said first and third ball rolling grooves is 45° in an upward oblique direction towards a central portion with respect to a horizontal line, a contact angle of upper two ball rows disposed between said second and fourth ball rolling grooves is 0° with respect to the horizontal line and a contact angle of lower two ball rows disposed therebetween is 45° in an upward oblique direction towards the tracking base with respect to the horizontal line.

(57) **ABSTRACT**

A first invention of the subject application aims to smoothly circulate the rollers by integrally molding at least one member of the roller returning passage, the roller end surface guide wall and the direction changing portion with the block body.

Namely, at least one member of the roller returning passage forming member **91** for forming the roller returning passage **9**, the roller end surface guide wall **13** and the direction changing passage inner periphery portion forming member **12** for forming the direction changing passage inner periphery portion **10***b* is integrally molded by inserting the block body into a molding die.

A second invention of the subject application aims to realize a smooth circulation and movement of the rollers, and to prevent the running-out of the roller chain during the circulation of the roller.

LINEAR ROLLER GUIDE

TECHNICAL FIELD

The present invention relates to a linear motion guide device, and more particularly, to a linear roller guide device using rollers as rolling elements.

BACKGROUND ART

The conventional linear roller guide device of this type generally has a structure in which a movable block is movably supported on a track rail through a number of rollers. The guide device using rollers has an advantage of high rigidity and high load bearing ability in comparison with the guide device using balls. The movable block comprises a block body and side covers to be attached to both end portions of the block body. The block body is provided with a roller rolling surface and a roller returning passage for endlessly circulating a roller row, and the side cover is provided with a direction changing passage for connecting the roller rolling surface side to the roller returning passage.

Both sides of the roller rolling surface of the movable member are provided with a roller end surface guide wall for guiding an end surface of the roller, and each of the roller returning passage and the direction changing passage is also provided with a guide wall which is formed to be continuous to the roller end surface guide wall. whereby the end surfaces of the roller are guided in entire circulating passage so as to orderly circulate the rollers.

Conventionally, as to structural members such as the roller returning passage, the side cover and the roller end surface guide wall or the like, an attempt to reduce a manufacturing cost has been made by employing resin moldings as the structural members.

However, the above conventional linear roller guide devices entail drawbacks as described hereunder:

(1) The manufacturing process is complicated.

That is, each of the resin molded members is a molded member which is formed separately from the block body, so that a process of assembling the respective resin molded members is required after separately forming the respective members.

(2) The circulating defects of the roller at the roller rolling surface are liable to occur.

Namely, when assembled the resin molded members, irregularities are liable to occur at a connecting portion between the roller returning passage and the direction changing passage, and at a connecting portion between the roller rolling surface and the direction changing passage, so that there may be posed a problem, for example, that a smooth circulation of the rollers is obstructed and a problem of generation of an abnormal noise.

(3) The circulating defects of the roller at the roller end surface are liable to occur.

In particular, in case of the roller, it is required to prevent skew of the roller (i.e. blurring of a rotational axis of the roller). In order to prevent the skew, it is required to guide the end surface of the roller not only in a range of a loaded area of the roller rolling surface but also in all around of an endlessly circulating passage ranging from the direction changing passage to the non-loaded area of the roller returning passage.

FIG. **15**(*a*) shows a state that the roller **100** changes a rolling direction thereof form an unloaded area α to a loaded area β of the direction changing passage. At the time of direction changing of the roller **100**, for example, as schematically shown in FIGS. **15**(*b*) and **15**(*c*), when the roller **100** moves from the loaded area α, and then enters into the loaded area β in a skewed state, one end portion of the roller **100***a* of the roller **100** will firstly collide against the roller rolling surface **101** in the loaded area, so that the smooth movement of the roller **100** is obstructed. In addition, an edge load may occur at the end portion **100***a* of the roller **100** entering into the loaded area β, so that the roller **100** per se and the roller rolling surface **101** are damaged thereby to deteriorate durability of the guide device. Further, vibration of the roller and changes in rolling resistance during the circulation of the rollers will occur thereby to obstruct the smooth circulation of the rollers.

In order to prevent such problems, hitherto, the end surface of the roller is formed so as to be guided by the roller end surface guide wall provided at both sides of the roller rolling surface and passage walls provided at the direction changing passage and the roller returning passage. However, since the guide system is formed by connecting the discontinuous roller end surface guide wall, direction changing passage and roller returning passage, a sticking of the roller is liable to occur due to non-uniformity in a width of the respective passages and the irregularities of the connected portions thereby to also obstruct the smooth circulation of the rollers.

(4) A falling-out of the roller is required to be prevented.

On the other hand, hitherto, in order to prevent the roller from falling out from the movable block when the movable block is detached from the track rail, there is a well known structure in which a chamfered portion is provided at end portion of the roller and an engaging projection with which the chamfered portion is engaged is provided at the roller end surface guide wall formed along the roller rolling surface.

However, in case of such roller retaining system, when the engaging projection interferes with the roller during the circulation of the roller, the smooth circulation of the roller is obstructed. Therefore, when assembling the guide device, it is required to provide a small gap or clearance between the roller and the engaging projection so as not to interfere the engaging projection with the roller. However, it was difficult to provide the engaging projection to an accurate position.

In addition, the chamfered portion is required to be provided, so that an effective length for bearing the load is disadvantageously shortened in a length corresponding to the length of the chamfered portion, thereby to lower the load bearing ability.

On the other hand, there is also another well-known roller retaining system in which a number of rollers are retained in form of a chain by linking the rollers in a roller chain. However, in the case of such rollers retained in the roller chain, a problem of a running-out of the roller chain will arise during the circulation of the rollers. Therefore, it is necessary to guide the roller chain along the predetermined track. However, it was difficult to accurately guide the roller chain.

The first invention has been achieved for solving the problems described above, and an object of this invention is to provide a linear roller guide device enabling to reduce the assembling processes, to accurately position the structural members to a predetermined positions of the block body, and to secure the smooth circulation of the rollers by integrally forming at least one of the roller returning passage, roller end surface guide wall and direction changing passage with the block body.

An object of the second invention is, in addition to the object described above, to provide a linear roller guide device enabling to securely prevent the roller chain from running-out during the circulation of the rollers linked by the roller chain.

DISCLOSURE OF THE INVENTION

In order to achieve the afore-mentioned object, the first invention provides a linear roller guide device comprising a track rail and a movable block assembled to the track rail through a number of rollers,

the movable block comprising:

- a roller rolling surface on which the rollers roll;
- a block body having a roller returning passage corresponding to the roller rolling surface;
- a direction changing passage inner periphery portion formed to both end surfaces of the block body;
- a pair of roller end surface guide walls formed to both sides of the roller rolling surface of the block body and adapted to guide both the end surfaces of the roller; and
- side covers each having a direction changing passage outer periphery portion for forming a direction changing passage by fitting the side cover into the direction changing passage inner periphery portion formed to both end surfaces of the block body,
- the track rail including a roller rolling surface extending in an axial direction corresponding to the roller rolling surface of the block body, and
- the rollers circulating in an endless circulating passage constituted by a loaded area between the roller rolling surface of the block body and the roller rolling surface corresponding to the track rail, the direction changing passage and the roller returning passage,
- wherein at least one of a roller returning passage forming member for forming the roller returning passage, a roller end surface guide wall forming member for forming at least one of the paired roller end surface guide wall and a direction changing passage inner periphery portion forming member for forming the direction changing passage inner periphery portion is formed as a molded body integrally formed with the block body by inserting the block body into a molding die.

According to the structure described above, the assembling of the roller end surface guide wall forming member, the roller returning passage forming member and the direction changing passage inner periphery portion forming member is not required, thus eliminating the assembling process for the members.

In addition, the roller end surface guide wall, the roller returning passage and the direction changing passage inner periphery portion can be formed at accurate positions with respect to the block body.

After the rollers are rolled from a starting end to a terminal end of the roller rolling surface of the block body, the rollers are rolled and moved to the roller returning passage through the direction changing passage, moved along the roller returning passage, and thereafter, supplied to the starting end side of the roller rolling surface through the direction changing passage formed at the other side of the roller rolling surface.

When the direction changing passage inner periphery portion forming member is integrally formed with the block body, it becomes possible to eliminate the irregularities to be formed at the connected portion between the roller rolling surface and the direction changing passage inner periphery portion. In addition, as to the roller returning passage forming member, when it is integrally formed with the block body, it also becomes possible to eliminate the irregularities to be formed at the connected portion between the direction changing passage inner periphery portion and the roller returning passage.

Further, in one aspect of this invention, the device may have a structure in which the roller returning passage and the direction changing passage inner peripheral portion are provided with guide walls for guiding the end surface of the roller, the guide wall being continuous to the roller end surface guide wall, and the roller returning passage, the roller end surface guide wall of at least one of the paired roller end surface guide walls and the direction changing passage inner peripheral portion are integrally formed with the block body.

According to the structure described above, the roller end surface guide walls of the roller returning passage and the direction changing passage in an unloaded area and the roller end surface guide wall to be formed along the roller rolling surface in loaded area can be continuously molded, so that the irregularities are not formed at the connected portions in all around the endless circulating passage, thus enables the end surface of the roller to smoothly move.

In addition, the gap or clearance between the guide wall and the roller end surface can be formed with high accuracy in all around the endless circulating passage, so that the generation of the skew of the roller can be securely prevented.

In another aspect of this invention, the device may have a structure in which a chamfered portion is provided at least one end portion of the roller and an engaging projection with which the chamfered portion of the roller is engaged is provided at the roller end surface guide wall integrally molded with the block body so as to prevent the roller from falling out.

As described above, when such engaging projection is provided at the roller end surface guide wall to be integrally molded with the block body, the engaging projection can be accurately positioned with respect to the block body, so that the falling-out of the roller can be securely prevented even if the bearing block is detached from the track rail. In addition, there is not the slightest fear of interference of the block body with the roller during the circulation of the roller.

The guide device has a structure having four rows of rollers in total in which a pair of right and left rows of rollers are disposed to be rollable between the upper surface of the track rail and a lower surface of a horizontal portion of the block body and other two rows of the rollers each is disposed between the right and left side surfaces of the track rail and an inside surfaces of a suspending portion of the block body, respectively.

In this case, it is preferable that a contact angle line constituted by a line connecting two contact points of the roller disposed between the corresponding roller rolling surfaces formed to the upper surface of the track rail and the horizontal portion of the block body is set to vertically extend with an inclination angle of about with respect to a horizontal line, while a contact angle line of the roller disposed between the corresponding roller rolling surfaces formed to the right and left side surfaces of the track rail and the inside surfaces of the suspending portion of the block body is set to obliquely extend downwards and is formed so as to incline with an inclination angle of 30° with respect to a horizontal line.

In still another aspect of this invention, the guide device has a structure having four rows of rollers in total in which two rows of rollers are vertically disposed to be rollable between a right side surface of the track rail and a right inside surface of the suspending portion of the block body, and vertically disposed to be rollable between a left side surface of the track rail and a left inside surface of the suspending portion of the block body, respectively.

Among the two rows of the rollers arranged vertically at upper and lower portions, it is preferable that the upper row of rollers is formed so that a contact angle line of the roller is set to obliquely extend upwards from a side of the track rail to sides of the right and left suspending portions of the block body, and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line, while the lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards, and is formed so as to incline with an inclination angle of almost 45°, or that the upper row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards from a side of the track rail to sides of the right and left suspending portions of the block body, and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line, while the lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards, and is formed so as to incline with an inclination angle of almost 45°.

In particular, at a time of an insert molding, when a block supporting portion corresponding to the roller rolling surface of the block body is provided to an inner periphery of a molding die and the roller rolling surface is contacted to the block supporting portion, the block body can be effectively positioned in the molding die.

According to such structure, a pair of right and left roller rolling grooves (surfaces) of the block body will contact to the block supporting portion. As a result, the block body is supported by the paired right and left block supporting portions so that the block body is clamped from every four directions and supported by four points. Therefore, even if an injection pressure of a molding material is applied to the block body from every directions, the block body can be held unmoved, and the burr is not formed at a portion between the roller rolling surface and the block supporting portion.

In a second invention, there is provided a linear roller guide device comprising a track rail and a movable block assembled to the track rail through a number of rollers,

the movable block comprising:

a block body having a roller rolling surface and a roller returning passage corresponding to the roller rolling surface;

a direction changing passage inner periphery portion formed to both end surfaces of the block body; and

side covers each having a direction changing passage outer periphery portion for forming a direction changing passage by fitting the side cover into the direction changing passage inner periphery portion formed at both end surfaces of the block body,

the track rail including a roller rolling surface extending in an axial direction corresponding to the roller rolling surface of the block body,

the rollers circulating in an endless circulating passage constituted by a loaded area between the roller rolling surface of the block body and the roller rolling surface corresponding to the track rail, the direction changing passage and the roller returning passage, and the rollers are linked to each other by a roller chain inserted to be movable in the endless circulating passage,

wherein the roller returning passage and the direction changing passage inner periphery guide portion are provided with a roller chain guide portion for guiding a track of the roller chain onto a predetermined track,

wherein at least one of the roller returning passage forming member for forming the roller returning passage and the direction changing passage inner periphery portion forming member for forming the direction changing passage inner periphery portion is integrally molded by inserting the block body into a molding die.

According to the structure described above, the rollers can be smoothly rolled and moved in the endless circulating passage while being kept in a state where center axes of the respective rollers are retained in parallel to each other and intervals of adjacent rollers are retained in a predetermined distance, thus enabling to prevent the skew-generation.

In addition, the roller chain is guided onto the predetermined track by the roller chain guide portions formed to the roller returning passage and the direction changing passage, and the rollers shall be accurately guided by the roller chain guided by the roller chain guide portion. Further, a run-out of the roller chain can be prevented by the roller chain guide portion.

In addition, when the roller returning passage forming member for forming the roller returning passage and the direction changing passage inner periphery portion forming member for forming the direction changing passage inner periphery portion to which the roller chain guide portions are formed are integrally molded with the block body, the roller chain guide portions can be formed on accurate positions of the track.

In addition, when the direction changing passage inner periphery portion forming member is integrally formed with the block body, it becomes possible to eliminate the irregularities to be formed at the connected portion between the roller rolling surface and the direction changing passage inner periphery portion. Further, as to the roller returning passage, when it is integrally formed with the block body, it also becomes possible to eliminate the irregularities to be formed at the connected portion between the direction changing passage inner periphery portion and the roller returning passage. As a result, the rollers can be further smoothly circulated and moved in cooperation with the guiding function of the roller chain.

Furthermore, when the roller chain is formed so as to have an endless structure and is provided with a falling-out preventing portion for the rollers, the falling-out of the rollers can be prevented by the roller chain even if the movable block is detached from the track rail.

Further, the roller chain is preferably provided with a guide projecting portion so as to project from the end surface of the roller in an axial direction of the roller, while the roller returning passage and the direction changing passage inner peripheral portion are preferably provided with guide grooves with which the guide projecting portion is engaged. In addition, at least one side of the roller rolling surfaces formed to the block body is preferably provided with a guide wall having the guide groove extending in parallel to the roller rolling surface for guiding the guide projecting portion in parallel to the roller rolling surface. As to this guide wall, it is also preferable to integrally mold the guide wall with the block body by using an insert molding method and to continuously form the guide groove to the roller returning passage, the direction changing passage inner periphery portion and the guide wall so that the guide groove ranges to all around the endless circulating passage.

According to the structure described above, when the roller chain is circulated and moved, the guide projecting portion is engaged with the guide groove formed to the roller returning passage and the direction changing passage inner peripheral portion, so that the run-out of the roller chain is suppressed. As a result, the rollers can be rolled and moved in orderly arranged state in all around the endless circulating passage.

In addition, in a case where the roller chain is formed in a striped-shape having no connected portion at both ends thereof, when the movable block is detached from the track rail, the guide projecting portion is engaged with the guide groove, thus enabling to prevent a sagging or slack of an end portion of the roller chain. Further, also in a case of the roller chain having an endless structure, the sagging or slack of an intermediate portion of the roller chain can be prevented.

In still another aspect of this invention, the roller chain comprises spacer portions disposed between the adjacent rollers and connecting portions for connecting the respective spacer portions, and the guide projecting portion is provided to the connecting portion.

Accordingly, each of the rollers is arranged and circulated in a state where the rollers are retained by the spacer portions form back and forth in the arranging direction thereof.

Further, when a falling-out preventing portion for the roller is provided to the spacer portion so as to prevent the falling-out of the roller from back and forth of the roller, it becomes unnecessary to chamfer the end portion of the roller, so that an effective length of the roller for bearing the load can be increased.

Furthermore, since only the spacer portion is disposed between the adjacent rollers, a pitch of the rollers can be formed as small as possible, so that a number of the rollers to be disposed per unit length for bearing the load can be increased as many as possible, thus improving the load bearing ability of the roller.

In still another aspect of this invention, the connecting member and the spacer portion disposed between the adjacent rollers are formed as resin moldings, the roller is formed to have a hollow portion, and the roller is retained by inserting a resin portion into the hollow portion of the roller.

According to the structure described above, the falling-out of the roller can be surely prevented and a degree of parallelization between the adjacent rollers can be accurately maintained.

In addition, the roller may be retained in such a manner that a recessed portion is formed to both end portions of the roller and the resin portion is inserted into the recessed portion or in a manner that a grooved portion is formed to a center peripheral portion of the roller and the resin portion is fitted into the grooved portion.

When the roller chain moves at portion between the roller rolling surfaces and the unloaded roller rolling passage, the roller chain takes a linear shape. In contrast, when the roller chain moves in the direction changing passage, the roller chain is deformed from linear-shape to a curved-shape. As a result, the roller chain is repeatedly deformed in accordance with the movement of the movable block.

In view of this point, it is preferable to reinforce the roller chain by inserting a wire or thin plate into the connecting member.

In the guide device of the present invention, the number of rollers and arrangement thereof are optional. However, the following arrangements are more effective.

That is, the guide device may have a structure having four rows of rollers in total in which a pair of right and left rows of rollers are disposed to be rollable between the upper surface of the track rail and a lower surface of a horizontal portion of the block body, and one row of the roller is disposed between the right and left side surfaces of the track rail and inside surfaces of a suspending portion of the block body, respectively.

In this case, it is preferable that a contact angle line constituted by a line connecting two contact points of the roller disposed between the corresponding to the roller rolling surfaces formed to the upper surface of the track rail and the horizontal portion of the block body is set to vertically extend with an inclination angle of about 90° with respect to a horizontal line, while a contact angle line of the roller disposed between the corresponding roller rolling surfaces formed to the right and left side surfaces of the track rail and the inside surfaces of the suspending portion of the block body is set to obliquely extend downwards and is formed so as to incline with an inclination angle of 30° with respect to a horizontal line.

In addition, the guide device may have a structure having four rows of rollers in total in which two rows of rollers are vertically disposed at upper and lower portions to be rollable between a right side surface of the track rail and a right inside surface of the suspending portion of the block body, and vertically disposed to be rollable between a left side surface of the track rail and a left inside surface of the suspending portion of the block body, respectively.

Among the two rows of the rollers arranged vertically, it is preferable that the upper row of rollers is formed so that a contact angle line of the roller is set to obliquely extend upwards from a side of the track rail to sides of the right and left suspending portions of the block body and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line, while the lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards, and is formed so as to incline with an inclination angle of almost 45°; or that the upper row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards from a side of the track rail to sides of the right and left suspending portions of the block body and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line, while the lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards and is formed so as to incline with an inclination angle of almost 45°.

In particular, at a time of an insert molding, when a block supporting portion corresponding to the roller rolling surface of the block body is provided to an inner periphery of a molding die and the roller rolling surface is contacted to the block supporting portion, the block body can be effectively positioned in the molding die.

According to such structure, a pair of right and left roller rolling grooves (surfaces) of the block body will contact to the block supporting portion. As a result, the block body is supported by the paired right and left block supporting portions so that the block body is clamped from every four directions and supported by four points. Therefore, even if an injection pressure of a molding material is applied to the block body from every directions, the block body can be held unmoved, and the burr is not formed at a portion between the roller rolling surface and the block supporting portion.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a view showing one embodiment of a linear roller guide device according to the first invention.

BEST MODE FOR EMBODYING THE INVENTION

[The First Invention]

Hereunder, the first invention will be explained with reference to the accompanying drawings.

FIGS. **1** and **2** are views showing an embodiment of a linear roller guide device according to the first invention. The linear roller guide device **1** comprises a track rail **2**, four rows of rollers **3** in total of which two rows of rollers are disposed to an upper side surface of the track rail **2** and one row of rollers is disposed to both right and left side surfaces of the track rail **2** respectively, and a movable block **4** assembled to be movable through the four rows of rollers **3**.

The track rail **2** is an elongated member formed to have a rectangular shape in section, an upper portion of both the side surfaces of the track rail being formed to have tapered surfaces which gradually expand outwardly in upward direction, and each of the right and left tapered surfaces is provided with one row of roller rolling surface **5**, respectively. In addition, the upper surface of the track rail **2** is formed to be a plain surface of which both right and left end portions are provided with one row of roller rolling surface **6**, respectively, i.e., two rows of the roller rolling surfaces **6** in total.

The movable block **4** comprises a block body **40** formed of metal, and side covers **11** to be attached to both end surfaces of the block body **40**.

The block body **40** has a U-shaped cross section and high rigidity, and comprises a horizontal portion **41** opposing to the upper surface of the track rail **2**, a pair of suspending portions **42** and **42** suspending from the right and left end portions of the horizontal portion **41** so as to clamp both the right and left side surfaces of the track rail **2**. A lower surface of the horizontal portion **41** is provided with a pair of roller rolling surfaces **7, 7** corresponding to the paired roller rolling surfaces **6, 6** formed to the upper surface of the track rail **2**, while each of inner side surfaces of the right and left suspending portions **42, 42** is provided with a roller rolling surface **8** corresponding to the respective roller rolling surfaces **5, 5** formed to the right and left side surfaces of the track rail **2**.

A number of rollers **3** are disposed between four pairs of roller rolling surfaces **5, 8**; **6, 7**, corresponding to each other, that are formed to opposing surfaces between the track rail **2** and the movable block **4**, whereby roller rows for bearing a load to be applied to portions between the track rail **2** and the movable block **4** are assembled. A predetermined pre-load is applied to respective rollers **3**. The roller **3** is formed as a cylindrical roller. However, as shown in FIG. **3**(*d*), a barrel-shaped roller having a circular-arc shaped cross section in axial direction can be also available as the roller **3**.

Each of the rollers **3** linearly contacts to the roller rolling surfaces **5, 8**; **6, 7**. A contact angle line L1 constituted by a line connecting two contact portions of the roller disposed between the corresponding to the roller rolling surfaces **5, 8**; **6, 7** formed to the upper surface of the track rail **2** and the horizontal portion **41** of the block body **40** is set to vertically extend with an inclination angle of about 90° with respect to a horizontal line passing through a center of the roller **3**, while a contact angle line of the roller **3** disposed between the corresponding to the roller rolling surfaces formed to the right and left side surfaces of the track rail **2** and the inside surfaces of the right and left suspending portions **42, 42** of the block body **40** is set to obliquely extend toward a center of the track rail **2** and is formed so as to upwardly incline with a predetermined angle of α with respect to a horizontal line H passing through a center of the roller **3**, thereby to form a structure in which both the right and left corner portions **22, 22** of an upper portion of the track rail **2** are clamped by the two rows of rollers **3, 3** disposed to the right and left sides of the track rail **2** and by the two rows of rollers **3, 3** disposed to the upper surface side of the track rail **2**. In the embodiment shown in Figure, the angle of α is set to about 30°.

The block body **40** is provided with four rows of the roller returning passages **9** for circulating and guiding the four rows of rollers **3**. The roller returning passage **9** linearly extend in parallel to the respective roller rolling surfaces **5, 6** formed to the block body **40**. Two rows of the roller returning passages **9** are provided to the horizontal portion **41**, while two rows of the roller returning passages **9** are respectively provided to the right and left suspending portions of the block body **40**. The roller returning passage **9** is formed from a roller returning passage forming member **91** composed of resin.

The roller returning passage forming member **91** is integrally bonded to an inner peripheral portion of a penetration bore **43** penetrating through the horizontal portion **41** and the suspending portion **42** of the block body **40**. An outer peripheral shape of the roller returning passage forming member **91** is formed to have a cylindrical shape which conforms to an inner peripheral shape of the penetration bore **43**. The inner periphery of the roller returning passage forming member **91** is provided with a roller returning passage **9** having a rectangular cross section for guiding the roller **3**.

The roller returning passage **9** comprises a pair of unloaded roller guide surfaces **9***a*, **9***b* extending in parallel to each other for guiding a cylindrical outer periphery surface of the roller **3**, and a pair of unloaded roller end surface guide surfaces **9***c*, **9***c* extending in parallel to each other for guiding end surfaces of the roller **3**.

A gap or clearance between the paired unloaded roller guide surfaces **9***a*, **9***b* is set to slightly larger than a diameter of the roller **3** so as to form a small gap therebetween, while a gap or clearance between the paired unloaded roller end surface guide surfaces **9***c*, **9***c* is set to slightly larger than a length of the roller **3** so as to form a small gap therebetween, thus resulting in a structure enabling to smoothly move the rollers **3** (see FIG, **3**(*e*)).

FIG. **5** shows another embodiment of a roller returning passage forming member **92** to be formed to the suspending portion **42** of the block body **40**. Namely, the roller returning passage forming member **92** is integrally bonded to a recessed portion **44** formed to a lower end portion of the right and left suspending portions **42** of the block body **40**. The roller returning passage forming member **91** is integrally connected to a third loaded roller end surface guide wall forming member **143** provided to the inner peripheral side of the suspending portion **42**.

According to the structure described above, the block body **40** is required to be provided with only two penetration bores **43** to be formed to the horizontal portion **41**, thus enabling to simplify the manufacturing of the device.

In addition, as shown in FIGS. **1**(*b*), (*c*) and **2**, both end portions of the block body **40** are provided with side covers **11** constituting a direction changing passage **10** for changing the rolling direction of the roller **3** to the roller returning passage **9**, the roller **3** being disposed between the loaded roller rolling surfaces **5**, **8**; **6**, **7** formed to the track rail **2** and the block body **40**.

The direction changing passage **10** is formed to be a pipe having a U-shape. The side cover **11** is formed with only a direction changing passage inner periphery portion **10***a* of the direction changing passage **10**. while a direction changing passage inner periphery portion forming member **12** is integrally bonded to both end portions of the block body **40**.

This direction changing passage **10** has a rectangular shaped cross section, and both side portions of the direction changing passage outer periphery portion **10***a* and the inner periphery portion **10***b* for guiding the outer periphery surface of the roller **3** are provided with direction changing roller end surface guide walls **10***c*, **10***c* for guiding the end surfaces of the roller **3**. This direction changing roller end surface guide walls **10***c* together with the direction changing passage inner periphery portion **10***b* are formed to the direction changing passage inner periphery portion forming member **12**. Then, when the side cover **11** formed with the direction changing passage outer periphery portion **10***a* is fitted into the end surface of the block body **40** formed with the direction changing passage inner periphery portion **10***b* and the direction changing roller end surface guide walls **10***c*, the direction changing passage **10** having a U pipe shape is formed.

In this regard, the direction changing roller end surface guide walls **10***c*, **10***c* together with the direction changing passage outer periphery portion **10***a* may be provided to the side cover **11**. In another way, one direction changing roller end surface guide wall **10***c* together with the direction changing passage inner periphery portion **10***b* may be provided to a side of the direction changing passage inner periphery portion forming member **12**, while the other direction changing roller end surface guide walls **10***c* together with the direction changing passage outer periphery portion **10***a* may be provided to the side cover **11**.

In still another way, the direction changing roller end surface guide wall **10***c* is divided into two portions i.e. an inner periphery side portion and an outer periphery side portion, and then, the outer periphery side portion may be formed to the side cover **11**, while the inner periphery side portion may be provided to the direction changing passage inner periphery portion forming member **12**.

Further, as shown in FIG. **1**(*a*). along the respective four rows of roller rolling surfaces **7**, **8** of the block body **40**, there is provided with a loaded roller end surface guide wall **13** for guiding the end surfaces of the roller in the loaded area. In order to form the loaded roller end surface guide wall **13**, the block body **40** comprises a first end surface guide wall forming member **141** to be integrally bonded to a lower surface of the horizontal portion **40**, right and left second end surface guide wall forming members **142** to be integrally bonded to recessed corner portions between the horizontal portion **41** and the right and left suspending portions **42**, and right and left third end surface guide wall forming members **143** to be integrally bonded to a lower portion of inner side surface of the right and left suspending portions **42**.

The both end portions of the first end surface guide wall forming member **141** and an upper end portion of the second end surface guide wall forming members **142** are provided with loaded roller end surface guide walls **13**, **13**; **13**, **13** for guiding the end surfaces of the roller **3** rolling on the roller rolling surfaces **7**, **7** formed to the lower surface of the horizontal portion **41** of the block body **40**.

In addition, the lower end portions of the right and left second end surface guide wall forming member **142** and an upper end portion of the third end surface guide wall forming members **143** are provided with loaded roller end surface guide walls **13**, **13**; **13**, **13** for guiding the end surfaces of the roller **3** rolling on the roller rolling surfaces **8**, **8** formed to the suspending portion **42** of the block body **40**.

A gap or clearance between the paired loaded roller end surface guide walls **13**, **13** is set to slightly larger than a length of the roller **3** so as to form a small gap between the end surface of the roller **3** and the guide wall **13**.

Further, a first seal member **15** for sealing the gap formed between the horizontal portion **41** of the block body **40** and the upper surface of the track rail **2** is attached to the first end surface guide wall forming member **141**, while a second seal member **16** for sealing the gap formed between the suspending portion **42** of the block body **40** and the right and left side surfaces of the track rail **2** is attached to the third end surface guide wall forming member **143**.

In this embodiment, the loaded roller end surface guide walls **13** for guiding both end surfaces of the roller **3** is formed by the first to third end surface guide wall forming members **141**–**143** that are all composed of resin.

However, as shown in FIG. **3**(*a*), the loaded roller end surface guide walls **13** for guiding one end surface of the roller **3** may be formed by the block body **40** per se, while the loaded roller end surface guide wall **13** for guiding the other end surface of the roller **3** may be formed by the loaded roller end surface guide wall forming member **14**. In another way, as shown in FIG. **3**(*f*), both side of the loaded roller end surface guide walls **13** can be also formed by the block body **40**.

In this first embodiment, all of the roller returning passage forming member **91**, the roller end surface guide wall forming members **141**–**143** and the direction changing passage inner periphery portion forming member **12** are formed by integrally molding with the movable block.

Accordingly, the unloaded roller guide surfaces **9***a*, **9***b* of the roller returning passage **9** and both the inner and outer periphery portions **10***a*, **10***b* of the direction changing passage can be continuously and integrally molded. Further, the direction changing passage inner periphery portion **10***b* and the roller rolling surfaces **7**, **8** in the loaded area can be also integrally molded.

In addition, the roller end surface guide wall **9***c* of the roller returning passage **9**, the direction changing roller end surface guide wall **10***c* of the direction changing passage **10** and the loaded area roller end surface guide wall **13** are continuously formed by being integrally molded, so that the roller end surface guide wall can be continuously formed in all around the endless circulating passage.

According to the linear roller guide device of this invention, the assembling of the loaded roller end surface guide wall forming member **14**, the roller returning passage forming member **91** and the direction changing passage inner periphery portion forming member **12** is not required, thus enabling to omit the assembling process for the members.

In addition, the roller end surface guide wall **13**, the roller returning passage **9** and the direction changing passage inner periphery portion **10***b* can be provided at accurate positions with respect to the block body **40**.

As a result, after the rollers **3** are rolled from a starting end to a terminal end of the roller rolling surfaces **7**, **8** in the loaded area of the block body **40**, the rollers **3** are moved to the roller returning passage **9** through the direction changing passage **10** then moved along the roller returning passage **9**, and thereafter, supplied to the starting end side of the roller rolling surfaces **7**, **8** through the direction changing passage **10** formed at the other end of the roller rolling surfaces **7**, **8**,

When the direction changing passage inner periphery portion forming member **12** is integrally formed with the block body **40**, it becomes possible to eliminate the irregularities to be formed at the connected portion between the roller rolling surfaces **7**, **8** and the direction changing passage inner periphery portion **10***b*. In addition, as to also the roller returning passage forming member **91**, when the member **91** is integrally formed with the block body **40**, it also becomes possible to eliminate the irregularities to be formed at the connected portion between the direction changing passage inner periphery portion **10***b* and the roller returning passage **9**.

Further, when the roller returning passage forming member **91** and the direction changing passage inner peripheral portion forming member **12** are provided with unloaded roller end surface guide wall **9***c* and the direction changing roller end surface guide wall **10***c* for guiding the end surface of the roller, the guide walls being continuous to the loaded roller end surface guide wall **13** and these roller end surface guide walls are integrally formed with the block body **40**, the loaded roller end surface guide wall **13**, the direction changing roller end surface guide wall **10***c* and the unloaded roller end surface guide wall **9***c* can be continuously molded in all around the endless circulating passage without forming the irregularities at the connected portions of the guide walls, thus enabling the end surface of the roller to smoothly move.

In addition, the gaps or clearances between the the loaded roller end surface guide wall **13**, the direction changing roller end surface guide wall **10***c*, the unloaded roller end surface guide wall **9***c* and the roller end surfaces can be accurately maintained to constant values, so that the gaps or clearances can be limited to a small value, and the skew of the roller **3** can be securely prevented.

In addition, as shown in FIGS. **3**(*b*) and **3**(*c*), the device may have a structure in which a chamfered portion **3***a* is provided at least one end portion of the roller **3** while an engaging projection **13***a*, with which the chamfered portion **3***a* of the roller **3** is engaged, is provided at the loaded roller end surface guide wall **13** integrally molded with the block body **40** so as to prevent the roller **3** from falling out when the movable block **4** is detached from the track rail **2**. A small gap is formed between the engaging projection **13***a* and the roller **3** so that the engaging projection **13***a* would not interfere with the roller **3** when the rollers **3** roll and move between the roller rolling surfaces **6**, **7**; **5**, **8**.

As described above, when the engaging projection **13***a* is provided at the roller end surface guide wall **13** to be integrally molded with the block body **40**, the engaging projection **13***a* can be accurately positioned with respect to the block body **10**, and the gap between the engaging projection **13***a* and the chamfered portion **3***a* of the roller **3** can be accurately maintained to a constant value, whereby there is no fear of interference of the engaging projection **13***a* with the roller during the circulation of the roller **3**.

The integrally molding of the roller returning passage forming member **91**, the direction changing passage inner peripheral portion forming member **12** and the loaded roller end surface guide wall **13** with the block body **40** is performed in accordance with an insert molding method comprising the steps of disposing the block body **40** into a molding die **15** on the basis of the roller rolling surfaces **7**, **8** formed to the block body **40**, forming cavities corresponding to the respective resin molded portions to be formed between an inner wall of the molding die **15** and the block body **40**, and injecting a molding material into the respective cavities to form the resin molded portions.

FIG. **4** is a schematic view showing the block body **40** and states where the molding dies **15** are clamped or opened at the time of the insert molding. Namely, a fixed molding die **15***a* is provided with block supporting portions **15***b* to which the roller rolling surfaces **7**, **7**; **8**, **8** are fitted for positioning, while a movable molding die **15***c* is provided with pins **15***d* for forming the roller returning passage.

The block supporting portions **15***b* have plain shapes corresponding to the roller rolling surfaces **7**, **7**; **8**, **8** and linearly extend in parallel to each other. In this regard, FIGS. **4**(*b*) and **4**(*c*) show only a circumference of the roller returning passage **9** of a side of the suspending portion **42**.

Cavities **15***e* for forming the roller returning passage forming member **91** are provided to inside the penetration bores **43** formed in the horizontal portion **41** and the suspending portion **42** of the block body **40**, respectively. Further, cavities **15***f*–**15***h* for forming the first to third loaded roller end surface guide wall forming members **141**–**143** are provided to inner periphery portions of the horizontal portion **41** and the suspending portion **42**. respectively. Furthermore, cavities **15***i* for forming the direction changing passage inner periphery portion forming members **12** are provided to both front and back end portions of the block body **40**, respectively.

In this embodiment, the paired right and left roller rolling surfaces **7**, **7**: **8**, **8** of the block body **40** are supported at four points by the block supporting portions **15***b* of the molding die **15**. As a result, the block body **40** can be supported unmoved by the block supporting portions **15***b*, even if an injection pressure of a molding material is applied to the block body **40** from every directions, whereby the roller returning passage **9**, the direction changing inner periphery portion **10***b* and the first to third loaded roller end surface guide walls **131**–**133** can be accurately formed at predetermined positions.

In addition, since the block body **40** is stably positioned in the molding die **15**, the burr is not formed at portions between the roller rolling surfaces **7**, **7**; **8**, **8**.

It is preferable that the block supporting portions **15***b* closely contact to the roller rolling surfaces **7**, **8**. However, even the block supporting portions **15***b* and the roller rolling surfaces **7**, **8** are moved in a small distance due to a small gap formed therebetween, the small gap can be allowed as far as a dimension accuracy is within an allowable range and the resin material would not penetrate through the gap.

[Modifications of Roller Contact Angles]

Though the explanation described above has been made by taking an example of a case in which total four rows of rollers are disposed between corresponding portions i.e., the right and left two rows of rollers being disposed between the upper surface of the track rail **2** and the lower surface of the horizontal portion **41** of the block body **40** while one row of rollers being disposed between the right and left side surfaces of the track rail **2** and the inner side surfaces of the right and left suspending portions **42** respectively, a number and an arrangement of the roller rows are optional.

For example, as shown in FIGS. **6** and **7**, the device may have a structure having four rows of rollers in total of which right and left two rows of rollers are disposed between the right and left side surfaces of the track rail **2** and the inner side surfaces of the right and left suspending portions **42** of the block body **40**, respectively.

FIG. **6** shows an example having a structure in which the upper row of rollers **3** among the two rows of the rollers **3** arranged vertically is formed so that a contact angle line **L1** of the roller **3** is set to obliquely extend upwards from a side of the track rail **2** to the right and left suspending portions **42** of the block body **40** and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line H, while the lower row of rollers **3** is formed so that a contact angle line L2 of the roller **3** is set to obliquely extend downwards, and is formed so as to incline with an inclination angle of almost 45°.

FIG. **7** shows an example having a structure in which the upper row of rollers **3** among the two rows of the rollers **3** arranged vertically is formed so that a contact angle line **L1** of the roller **3** is set to obliquely extend downwards from a side of the track rail to sides of the right and left suspending portions **42**, **42** of the block body **40** and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line, while the lower row of rollers **3** is formed so that a contact angle line L2 of the roller **3** is set to obliquely extend upwards, and is formed so as to incline with an inclination angle of almost 45°.

In the case of this embodiment, the direction changing passages **10**A, **10**B of vertically arranged two rows of rollers **3** disposed to both end portions of the block body **40** are arranged alternately with a predetermined interval in an axial direction so as to intersect to each other. In this case, the direction changing passage inner peripheral portion forming member **12** formed to the end surface of the block body **40** is provided with the direction changing passage inner periphery portion **10***b* of the direction changing passage **10**A of a side close to the block body **40** and the direction changing roller end surface guide wall **10***c*, the inner periphery portion **10***b* and the guide wall **10***c* being integrally molded with the block body **40**.

As to the direction changing passage **10**B far from H the block body **40**, at least one portion of the loaded roller rolling surfaces **7**, **8** of an end surface side of the block body **40**, the direction changing passage inner periphery portion **10***b* of a part which is connected to an end portion of the roller returning passage **9** and the direction changing roller end surface guide wall **10***c* are integrally molded with the block body **40**. While, a round piece **10**C formed with the direction changing passage inner periphery portion **10***b* is attached to a part far from the direction changing passage **10**A. An inner periphery of this round piece **10**C is formed with a part of an outer periphery guide portion of the inside direction changing passage **10**A. The side cover **11** is formed with the direction changing passage outer peripheral portions **10***a*, **10***a* for both the direction changing passages **10**A, **10**B arranged vertically.

According to the first invention described above. the assembling of the roller end surface guide wall, the roller returning passage and the direction changing passage inner periphery portion is not required, thus eliminating the assembling process for the members.

In addition, the roller end surface guide wall, the roller returning passage and the direction changing passage inner periphery portion can be formed at accurate positions with respect to the block body.

When the direction changing passage inner periphery portion is integrally formed with the block body, it becomes possible to eliminate the irregularities to be formed at the connected portion between the roller rolling surface and the direction changing passage inner periphery portion. In addition, as to the roller returning passage, when it is integrally formed with the block body, it also becomes possible to eliminate the irregularities to be formed at the connected portion between the roller rolling changing passage inner periphery portion and the roller returning passage.

Further, when the roller returning passage and the direction changing passage inner peripheral portion are provided with guide walls for guiding the end surface of the roller, the guide wall being continuous to the roller end surface guide wall, and the roller returning passage. the roller end surface guide wall of at least one the paired roller end surface guide walls and the direction changing passage inner peripheral portion are integrally formed with the block body, so that the roller returning passage, the guide walls of the direction changing passage inner periphery portions and the roller end surface guide walls can be continuously molded, whereby irregularities are not formed at the connected portions, thus enabling the end surface of the roller to smoothly move.

In addition, the guide walls for the roller end surfaces can be integrally formed in continuous in all around the endless circulating passage and a gap between the guide wall and the end surface of the roller can be formed with a high accuracy, so that the skew of the roller can be securely prevented.

In addition, when the engaging projection for preventing the roller from falling out by engaging with the chamfered portion of the roller is provided at the roller end surface guide wall to be integrally molded with the block body, the engaging projection can be accurately positioned with respect to the block body, so that the falling-out of the roller can be surely prevented even if the bearing blocks is detached from the track rail. In addition, there is no fear of interference of the block body with the roller during the circulation of the roller.

In addition, at a time of an insert molding, when a block supporting portion having a shape obtained by cutting an outer peripheral portion of the roller with a cross section passing through a center axis of the roller is provided to an inner periphery of a molding die so as to correspond to the roller rolling surface of the block body and the block body is positioned in the molding die by contacting the roller rolling surface to the block supporting portion, the burr would not occur at the roller rolling surfaces.

In particular, when the paired right and left roller rolling surfaces of the block body are supported by the block supporting portions of the molding die, the block body is clamped from every four directions and supported by the paired right and left block supporting portions at four points. Therefore, even if an injection pressure of a molding material is applied to the block body from every directions, the block body can be held unmoved, and the block body can be accurately positioned.

[Second Invention]

Next, an embodiment of a second invention will be explained hereunder with reference to the accompanying drawings.

FIGS. **8** and **9** disclose embodiments of linear roller guide devices according to the second invention, respectively.

The linear roller guide device **201** comprises a track rail **202** and a movable block **204** assembled to be movable on an upper surface of the track rail **202** through four rows of rollers **203** in total of which two rows of rollers are disposed on an upper surface side of the track rail **202** and one row of rollers is disposed on the right and left side surface sides of the track rail **202**, respectively.

Each of the four rows of the rollers **203** circulates in an endless circulating passage constituted by the loaded area between the roller rolling surfaces **206, 207; 205, 208** of the block body **2040** and corresponding to the track rail **202**, the direction changing passage **210** and the roller returning passage **209**. In this regard, the embodiment of this second invention is different form that of the first invention in a point where the rollers **203** are linked to each other by a roller chain **218** inserted to be movable in the endless circulating passage.

The roller chain **218** is a resin molded product, as shown in FIGS. **9**(*c*)–(*e*), and comprises spacer portions **218***a* disposed between the adjacent rollers **203** and connecting bands (plates) **218***b* as connecting members for connecting the respective spacer portions **218***a*, the connecting bands **218***b* being flexible and having a thin plate-shape.

Both side surfaces of the spacer portion **218** is provided with a retaining recessed portion **218***c* for constituting the falling-out preventing portion having a circular-arc shape corresponding to a cylindrical surface of the roller **203**. The connecting plates **218***b* are positioned on a virtual surface connecting the center axes of the respective rollers **203**.

The spacer portion **218***a* is a member having a rectangular parallelepiped shape and a predetermined thickness so as to be disposed between the rollers **203** and has almost the same length in axial direction as that of the roller **203** and a width shorter than a diameter of the roller **203**. In addition, side surfaces in a thickness direction of the spacer portion **218***a* to which the roller **203** contacts are formed with retaining recessed portions **218***c* having a circular-arc shape corresponding to the shape of the roller **203**.

Both side end portions in axial direction of the roller of the connecting band **218***b* of the roller chain **218** project from the end surfaces of the roller in axial direction of the roller thereby to form guide projecting portions **2181**.

Each of the rollers **203** is retained from back and forth in an arranging direction by the respective spacer portions **218***a* of the roller chain **218**, so that it becomes unnecessary to form the chamfered portion to the end portion of the roller. As a result, a load can be supported by an entire length of the roller **203**, and an effective length of the roller **203** for bearing the load can be increased.

Furthermore, since only the spacer portion **218***a* is disposed between the adjacent rollers **203**, a pitch of the rollers **203** can be formed as small as possible, so that a number of the rollers **203** to be disposed per unit length for bearing the load can be increased as many as possible, thus improving the load bearing ability of the roller **203**.

FIG. **10**(*a*) shows an example of the roller chain **218** of a case where the roller **2031** has a hollow structure having a penetration bore **2032**. In the case of the roller **203** having the hollow structure, a pre-load can be easily applied in comparison with a case of a solid roller **203**, thus resulting in advantage.

A shaft portion **218***d* to be inserted into the penetration bore **2032** is formed to the roller chain **218**, whereby the roller chain **218** is integrated with the roller **203**. According to the structure described above, the falling-out of the roller **203** can be securely prevented, and the degree of parallelization between the respective rollers **203** can be accurately maintained.

FIG. **10**(*b*) shows an example of the roller chain **218** of a case where the roller **2034** has a structure having recessed portions **2033** at its both ends.

The roller chain **218** is provided with convex portions **218***e* to be rotatively inserted into the recessed portions **2033** formed to both the end portions of the roller **203**. According to this structure, the falling-out of the roller **2034** can be surely prevented, and the degree of parallelization between the respective rollers **2034** can be accurately maintained.

FIG. **10**(*c*) shows an example of the roller chain **218** of a case where the roller **2036** has a structure having a circular groove **2035** at a center of outer periphery of the roller **2036**.

The roller **203** is retained by fitting a ring member **218**f formed to the roller chain **218** into the circular groove **2035** of the roller chain **218**.

On the other hand. FIG. **10**(*d*) shows an example of the roller chain **218** of a case where the connecting plate **218***b* of the roller chain **218** is reinforced. Namely, the roller **218** is moved in the endless circulating passage having a track shape in accordance with the movement of the movable block **204**, and the roller chain **218** is repeatedly subjected to deformations from a linear-shape to a curved-shape, so that it is required to increase a fatigue strength of the roller chain **218**.

In view of this point, it is preferable to reinforce the connecting plate **218***b* for linking the roller **203** by inserting reinforcing members **218***g* such as wire, thin plate or the like into the connecting plate **218***b*.

The track rail **202** is an elongated member formed to have a rectangular shape in section, an upper portion of both the side surfaces of the track rail being formed to have tapered surfaces which gradually expand outwardly in upward direction, and each of the right and left tapered surfaces is provided with one row of roller rolling surface **205**, respectively. In addition, the upper surface of the track rail **202** is formed to be a plain surface of which both right and left end portions are provided with one row of roller rolling surface **206**, respectively, i.e., two rows of the roller rolling surfaces **206** in total.

The movable block **204** comprises a block body **2040** formed of metal, and side covers **211** to be attached to both end surfaces of the block body **2040**.

The block body **2040** has a U-shaped cross section and high rigidity and comprises a horizontal portion **2041** opposing to the upper surface of the track rail **202**, a pair of suspending portions **2042, 2042** suspending from the right and left end portions of the horizontal portion **2041** so as to clamp both the right and left side surfaces of the track rail **202**. A lower surface of the horizontal portion **2041** is provided with a pair of roller rolling surfaces **207, 207** corresponding to the paired roller rolling surfaces **206, 206** formed to the upper surface of the track rail **202**, while each of inner side surfaces of the right and left suspending portions **2042, 2042** is provided with roller rolling surface **208, 208** corresponding to the respective roller rolling surfaces **205, 205** formed to the right and left side surfaces of the track rail **202**.

A number of rollers **203** are disposed between four pairs of roller rolling surfaces **205, 208; 206, 207** corresponding to each other, that are formed to opposing surfaces between the track rail **202** and the movable block **204**, whereby roller rows for bearing a load to be applied to portions between the track rail **202** and the movable block **204** are assembled. A predetermined pre-load is applied to respective rollers **203**.

Each of the rollers **203** linearly contacts to the roller rolling surfaces **205, 208; 206, 207**. A contact angle a line L1 constituted by a line connecting two contact portions of the roller disposed between the corresponding roller rolling surfaces **205, 208; 206, 207** formed to the upper surface of the track rail **202** and the horizontal portion **2041** of the block body **2040** is set to vertically extend with an inclination angle of about 90° with respect to a horizontal line passing through a center of the roller **203**, while a contact angle line of the roller **203** disposed between the corresponding to the roller rolling surfaces formed to the right and left side surfaces of the track rail **202** and the inside surfaces of the right and left suspending portions **2042, 2042** of the block body **2040** is set to obliquely extend toward a center of the track rail **202** and is formed so as to upwardly incline with a predetermined angle of α with respect to a horizontal line H passing through a center of the roller **203**, thereby to form a structure in which both the right and left corner portions **2022, 2022** of an upper portion of the track rail **202** are clamped by the two rows of rollers **203, 203** disposed to the right and left sides of the track rail **202** and by the two rows of rollers **203, 203** disposed to the upper surface side of the track rail **202**. In the embodiment shown in Figure, the inclination angle of α is set to about 30°.

The block body **2040** is provided with four rows of the roller returning passages **209** for circulating and guiding the four rows of rollers **203**. The roller returning passage **209** linearly extend in parallel to the respective roller rolling surfaces **205, 206** formed to the block body **2040**. Two rows of the roller returning passages **209** are provided to the horizontal portion **2041**, while two rows of the roller returning passages **209** are respectively provided to the right and left suspending portions **2042** of the block body **2040**. The roller returning passage **209** is formed of a roller returning passage forming member **2091** composed of resin.

The roller returning passage forming member **2091** is integrally bonded to an inner peripheral portion of a penetration bore **2043** penetrating through the horizontal portion **2041** and the suspending portion **2042** of the block body **2040**. An outer peripheral shape of the roller returning passage forming member **2091** is formed to have a cylindrical shape which conforms to an inner peripheral shape of the penetration bore **2041**. The inner periphery of the roller returning passage forming member **2091** is provided with a roller returning passage **209** having a rectangular cross section for guiding the roller **203**.

The roller returning passage **209** comprises a pair of unloaded roller guide surfaces **209*a*, 209*b*** extending in parallel to each other for guiding a cylindrical outer periphery surface of the roller **203**, and a pair of unloaded roller end surface guide surfaces **209*c*, 209*c*** extending in parallel to each other for guiding end surfaces of the roller **203**.

A gap or clearance between the paired unloaded roller guide surfaces **209*a*, 209*b*** is set to slightly larger than a diameter of the roller **203** so as to form a small gap therebetween, while a gap or clearance between the paired roller end surface guide walls **209*c*, 209*c*** is set to slightly larger than a length of the roller **203** so as to form a small gap therebetween, thus resulting in a structure enabling to smoothly move the rollers **3**.

The unloaded roller end surface guide walls **209*c*, 209*c*** are formed with guide grooves **209*d*** with which the guide projecting portions **2181** of the roller chain **218** are engaged.

FIG. **11** shows another embodiment of a roller returning passage forming member **2092** to be formed to the suspending portion **2042** of the block body **2040**. Namely, the roller returning passage forming member **2092** is integrally bonded to a recessed portion **2044** formed to a lower end portion of the right and left suspending portions **2042** of the block body **2040**. The roller returning passage forming member **2091** is integrally connected to a third loaded roller end surface guide wall forming member **2143** provided to the inner peripheral side of the suspending portion **2042**.

According to the structure described above, the block body **2040** is required to be provided with only two penetration bores **2043** to be formed to the horizontal portion **2041**, thus making simple the manufacturing of the device.

In addition, as shown in FIGS. **8**, **9**(*a*) and **9**(*b*) both end portions of the block body **2040** are provided with side covers **211** constituting a direction changing passage **210** for changing the rolling direction of the roller **203** to the roller returning passage **209**, the roller **203** being disposed between the loaded roller rolling surfaces **205, 208; 206, 207** formed to the track rail **202** and the block body **2040**.

The direction changing passage **210** is formed to be a pipe having a U-shape. The side cover **211** is formed with only a direction changing passage inner periphery portion **210*a*** of the direction changing passage **210**, while a direction changing passage inner periphery portion forming member **212** is integrally bonded to both end portions of the block body **2040**.

This direction changing passage **210** has a rectangular shaped cross section, and both side portions of the direction changing passage outer periphery portion **210*a*** and the inner periphery portion **210*b*** for guiding the outer periphery surface of the roller **203** are provided with direction changing roller end surface guide walls **210*c*, 210*c*** for guiding the end surfaces of the roller **203**. This direction changing roller end surface guide walls **210*c*** together with the direction changing passage inner periphery portion **210*b*** are formed to the direction changing passage inner periphery portion forming member **212**. Then, when the side cover **211** formed with the direction changing passage outer periphery portion **210*a*** is fitted into the end surface of the block body **2040** formed with the direction changing passage inner periphery portion **210*b*** and the direction changing roller end surface guide walls **210*c***, the direction changing passage **210** having a U pipe shape is formed.

The direction changing roller end surface guide walls **210*c*, 210*c*** are formed with guide grooves **210*d*** with which the guide projecting portions **2181** of the roller chain **218** are engaged.

In this regard, the direction changing roller end surface guide walls **210*c*, 210*c*** together with the direction changing passage outer periphery portion **210*a*** may be provided to the side cover **211**. In another way, one direction changing roller end surface guide wall **210*c*** together with the direction changing passage inner periphery portion **210*b*** may be provided to a side of the direction changing passage inner periphery portion forming member **212**, while the other direction changing roller end surface guide walls **210*c*** together with the direction changing passage outer periphery portion **210***a* may be provided to the side cover **211**.

In still another way, the direction changing roller end surface guide wall **210***c* is divided into two portions i.e., an inner periphery side portion and an outer periphery side portion, and then, the outer periphery side portion may be formed to the side cover **211**, while the inner periphery side portion may be provided to the direction changing passage inner periphery portion forming member **212**.

Further, as shown in FIG. **8**(*a*) along the respective four rows of roller rolling surfaces **207**, **208** of the block body **240**, there is provided with a loaded roller end surface guide wall **213** for guiding the end surfaces of the roller in the loaded area.

The loaded roller end surface guide walls **213** are formed with guide grooves **213***a* with which the guide projecting portions **2181** of the roller chain **218** are engaged. In order to form the loaded roller end surface guide wall **213**, the block body **240** comprises a first end surface guide wall forming member **2141** to be integrally bonded to a lower surface of the horizontal portion **2040**, the right and left second end surface guide wall forming members **2142** to be integrally bonded to recessed corner portions between the horizontal portion **2041** and the right and left suspending portions **2042**, and right and left third end surface guide wall forming members **2143** to be integrally bonded to a lower portion of inner side surface of the right and left suspending portions **2042**.

Both the end portions of the first end surface guide wall forming member **2141** and an upper end portion of the second end surface guide wall forming members **2142** are provided with loaded roller end surface guide walls **213**, **213**; **213**, **213** for guiding the end surfaces of the roller **203** rolling on the roller rolling surfaces **207**, **207** formed to the lower surface of the horizontal portion **2041** of the block body **2040**.

In addition, the lower end portions of the right and left second end surface guide wall forming members **2142** and an upper end portion of the third end surface guide wall forming members **2143** are provided with loaded roller end surface guide walls **213**, **213**; **213**, **213** for guiding the end surfaces of the roller **203** rolling on the roller rolling surfaces **208**, **208** formed to the suspending portion **2042** of the block body **2040**.

A gap or clearance between the paired loaded roller end surface guide walls **213**, **213** is set to slightly larger than a length of the roller **203** so as to form a small gap between the end surface of the roller **203** and the guide wall **213**.

Further, a first seal member **216** for sealing the gap formed between the horizontal portion **2041** of the block body **2040** and the upper surface of the track rail **202** is attached to the first end surface guide wall forming member **2141**, while a second seal member **217** for sealing the gap formed between the suspending portion **2042** of the block body **2040** and the right and left side surfaces of the track rail **202** is attached to the third end surface guide wall forming member **2143**.

In this embodiment, the loaded roller end surface guide walls **213** for guiding both end surfaces of the roller **203** is formed by the first to third end surface guide wall forming members **2141**–**2143** that are all composed of resin.

However, as shown in FIG. **11**(*a*), the loaded roller end surface guide walls **213** for guiding one end surface of the roller **203** may be formed by the block body **2040** per se, while the loaded roller end surface guide wall **213** for guiding the other end surface of the roller **203** may be formed by the loaded roller end surface guide wall forming member **214**. In this case, the loaded roller end surface guide walls **213** may be formed with guide grooves with which the guide projecting portions **2181** of the roller chain **218** are engaged. In another way, as shown in FIG. **11**(*b*), a cutout **213***b* can be also formed in place of the guide groove.

In this second embodiment, all of the roller returning passage forming member **2091**, the roller end surface guide wall forming members **2141**–**2143** and the direction changing passage inner periphery portion forming member **212** is formed by integrally molding with the movable block **2040**.

Accordingly, the unloaded roller guide surfaces **209***a*, **209***b* of the roller returning passage **209** and both the inner and outer periphery portions **210***a*, **210***b* of the direction changing passage can be continuously and integrally molded. Further, the direction changing passage inner periphery portion **210***b* and the roller rolling surfaces **207**, **208** in the loaded area can be also integrally molded.

In addition, the roller end surface guide wall **209***c* of the roller returning passage **209**, the direction changing roller end surface guide wall **210***c* of the direction changing passage **210** and the loaded area roller end surface guide wall **213** are continuously formed by being integrally molded, so that the roller end surface guide wall can be continuously formed in all around the endless circulating passage. In addition, the guide groove for engaging with the guide projecting portion **2181** of the roller chain **218** can be continuously formed in all around the endless circulating passage.

According to the linear roller guide device of this invention, the roller returning passage forming member **2091** and the direction changing passage inner periphery portion forming member **212** are not required, thus enabling to omit the assembling process for the members. In addition, the roller returning passage **209** and the direction changing passage inner periphery portion **210***a* can be provided at accurate positions with respect to the block body **2040**.

When the direction changing passage inner periphery portion forming member **212** is integrally formed with the block body **2040**, it becomes possible to eliminate the irregularities to be formed at the connected portion between the roller rolling surfaces **207**, **208** and the direction changing passage inner periphery portion **210***b*. In addition, as to the roller returning passage **209**, when the member **91** is integrally formed with the block body **2040**, it becomes also possible to eliminate the irregularities to be formed at the connected portion between the direction changing passage inner periphery portion **210***b* and the unloaded roller guide surface **209***b* of the roller returning passage **209**.

On the other hand, the rollers **203** can be smoothly rolled and moved from the roller returning passage **209** in the unloaded area and the direction changing passage **210** to the loaded area between the roller rolling surfaces **206**, **207**; **205**, **208** while being held in a state where the center axes of the respective rollers **203** are retained in parallel to each other and intervals of adjacent rollers **203** are retained in a predetermined distance by the roller chain **218**.

In particular, when the roller chain **218** is circulated and moved, the guide projecting portions **218***a* formed to the roller chain **218** are guided in all around the circulating passage by the guide grooves **209***d*, **210***d* and **213***a* formed to the guide walls **213** provided to both sides of the roller returning passage **209**, the direction changing inner periphery portion **210***b* and the roller rolling surfaces **207**, **208**, so that the run-out of the roller chain **218** during the circulation can be suppressed in all around the circulating passage. Accordingly, the roller chain **218** can circulate and move on a predetermined track in all around the endless circulating passage. As a result, the rollers **203** can accurately roll and move, thus preventing the skew-generation of the rollers **203**.

Furthermore, in this embodiment, the gaps between the guide walls **213**, the direction changing roller end surface guide wall **210***c* in the loaded area and the unloaded roller end surface guide wall **209***c* and the roller end surfaces can be accurately maintained to a predetermined value, so that the gap can be reduced to a sufficiently small value. As a result, the skew of the rollers **203** can be securely prevented in cooperation with the retaining function of the roller chain **218**.

Furthermore, when the movable block **204** is detached from the track rail **202**, the rollers **203** are retained by the roller chain **218**.

The integrally molding of the roller returning passage forming member **2091**, the direction changing passage inner peripheral portion forming member **212** and the loaded roller end surface guide wall **213** with the block body **2040** is performed in accordance with an insert molding method comprising the steps of disposing the block body **2040** into a molding die **215** on the basis of the roller rolling surfaces **207**, **208** formed to the block body **2040**, forming cavities corresponding to the respective resin molded portions to be formed between an inner wall of the molding die **215** and the block body **2040**, and injecting a molding material into the cavities to form the resin molded portions.

FIG. **12** is a schematic view showing the block body **2040** and states where the molding dies **215** are clamped or opened at the time of the insert molding. Namely, a fixed molding die **215***a* is provided with block supporting portions **215***b* to which the roller rolling surfaces **207**, **207**; **208**, **208** are fitted for positioning, while a movable molding die **215***c* is provided with pins **215***d* for forming the roller returning passage. The block supporting portions **215***b* and the pins **215***d* are formed with projecting portions **215***b***1**, **215***d***1** corresponding to the guide projecting portion **2181** of the roller chain **218**.

The block supporting portions **215***b* have plain shapes corresponding to the roller rolling surfaces **207**, **207**: **208**, **208** and linearly extend in parallel to each other. In this regard, FIGS. **12**(*b*) and **12**(*c*) shows only a circumference of the roller returning passage **209** of a side of the suspending portion **2042**.

Cavities **215***d* for forming the roller returning passage forming member **2091** are provided inside the penetration bores **2043** formed in the horizontal portion **2041** and the suspending portion **2042** of the block body **2040**, respectively. Further, cavities **215***e* for forming the first to third loaded roller end surface guide wall forming members **213** are provided to inner periphery portions of the horizontal portion **2041** and the suspending portion **2042**, respectively. Furthermore, cavities **215***f* for forming the direction changing passage inner periphery portion forming members **212** are provided to both front and back end portions of the block body **2040**, respectively.

In this embodiment, the paired right and left roller rolling surfaces **207**, **207**; **208**, **208** of the block body **2040** are supported at four points by the block supporting portions **215***b* of the molding die **215**. As a result, the block body **2040** can be supported unmoved by the block supporting portions **215***b*, even if an injection pressure of a molding material is applied to the block body **2040** from every directions, whereby the roller returning passage **209**, the direction changing inner periphery portion **210***b* and the first to third loaded roller end surface guide walls **2131**–**2133** can be accurately formed at predetermined positions.

In addition, since the block body **2040** is stably positioned in the molding die **215**, the burr is not formed at portions between the roller rolling surfaces **207**, **207**; **208**, **208**.

It is preferable that the block supporting portions **215***b* closely contact to the roller rolling surfaces **207**, **208**. However, even the block supporting portions **215***b* and the roller rolling surfaces **207**, **208** are moved in a small distance due to a small gap formed therebetween, the small gap shall be allowed as far as a dimension accuracy is within an allowable range and the resin material would not penetrate through the gap.

[Modifications of Roller Contact Angles]

Though the explanation described above has been made by taking into consideration an example of a case in which total four rows of rollers are disposed between corresponding portions i.e., the right and left two rows of rollers being disposed between the upper surface of the track rail **202** and the lower surface of the horizontal portion **2041** of the block body **2040** while one row of rollers being disposed between the right and left side surfaces of the track rail **202** and the inner side surfaces of the right and left suspending portions **2042** respectively, a number and an arrangement of the roller rows are optional.

For example, as shown in FIGS. **13** and **14**, the device may have a structure having four rows of rollers in total in which right and left two rows of rollers are disposed between the right and left side surfaces of the track rail **202** and the inner side surfaces of the right and left suspending portions **2042** of the block body **2040**, respectively.

FIG. **13** shows an example having a structure in which the upper row of rollers **203** among the two rows of the rollers **203** arranged vertically is formed so that a contact angle line of the roller **203** is set to obliquely extend upwards from a side of the track rail **202** to the right and left suspending portions **2042** of the block body **2040** and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line, while the lower row of rollers **203** is formed so that a contact angle line of the roller **203** is set to obliquely extend downwards and is formed so as to incline with an inclination angle of almost 45°.

FIG. **14** shows an example having a structure in which the upper row of rollers **203** among the two rows of the rollers **203** arranged vertically is formed so that a contact angle line L1 of the roller **203** is set to obliquely extend downwards from a side of the track rail to sides of the right and left suspending portions **2042**, **2042** of the block body **2040** and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line H, while the lower row of rollers **203** is formed so that a contact angle line L2 of the roller **203** is set to obliquely extend upwards and is formed so as to incline with an inclination angle of almost 45°.

In the case of this embodiment, the direction changing passages **210**A, **210**B of vertically arranged two rows of rollers **3** disposed to both end portions of the block body **2040** are arranged alternately with a predetermined interval in an axial direction so as to intersect to each other. In this case, the direction changing passage inner peripheral portion forming member **212** formed to the end surface of the block body **2040** is provided with the direction changing passage inner periphery portion **210***b* of the direction changing passage **210**A of a side close to the block body **2040** and the direction changing roller end surface guide wall **210***c*, the inner periphery portion **210***b* and the guide wall **210***c* being integrally molded with the block body **2040**.

As to the direction changing passage **210**B far from the block body **2040**, at least one portion of the loaded roller rolling surfaces **207**, **208** of an end surface side of the block body **2040**, the direction changing passage inner periphery portion **210***b* of a part which is connected to an end portion of the roller returning passage **209** and the direction changing roller end surface guide wall **210***c* are integrally molded with the block body **2040**. While, a round piece **210**C formed with the direction changing passage inner periphery portion **210***b* is attached to a part far from the direction changing passage **210**A. An inner periphery of this round piece **210**C is formed with a part of an outer periphery guide portion of the inside direction changing passage **210**A. The side cover **211** is formed with the direction changing passage outer peripheral portions **210***a*, **210***a* for both the direction changing passages **210**A, **210**B arranged vertically.

According to the second invention described above, since the rollers are circulated in a state of being retained by the roller chain, the rollers are rolled and moved in a state where center axes of the respective rollers are retained in parallel to each other by the roller chain. Therefore, the generation of skew can be prevented and the rollers can be smoothly rolled and moved,

In addition, since the roller chain is guided on a predetermined track through the roller chain guide portions formed to the roller returning passage and the direction changing passage, the rollers retained by the roller chain can be also accurately guided.

In addition, the running-out of the roller chain can be prevented by the roller chain guide portions.

In particular, when the roller returning passage to be formed with the roller chain guide portions, the roller returning passage forming member to be formed with the direction changing inner periphery portion and the direction changing passage inner periphery portion forming member are integrally molded with the block body, the roller chain guide portions can be accurately formed on the track.

In addition, when the direction changing passage inner periphery portion forming member is integrally formed with the block body, it becomes possible to eliminate the irregularities to be formed at the connected portion between the roller rolling surface and the direction changing passage inner periphery portion. In addition, as to the roller returning passage, when it is integrally formed with the block body, it also becomes possible to eliminate the irregularities to be formed at the connected portion between the direction changing passage inner periphery portion and the roller returning passage, whereby the rollers can be further smoothly circulated and moved in cooperation with the guiding function of the roller chain.

Furthermore, when the roller chain is formed so as to have an endless structure and is provided with a falling-out preventing portion for the rollers, the falling-out of the rollers can be prevented by the roller chain even if the movable block is detached from the track rail.

In addition, the roller chain is provided with a guide projecting portion, while the roller returning passage and the direction changing passage inner peripheral portion are provided with guide grooves. In addition, a side of the roller rolling surface in the loaded area is provided with a guide wall having the guide groove, and the guide wall is integrally molded with the block body by using an insert molding method, so that the roller chain can be accurately guided in all around the endless circulating passage, thus enabling the rollers to further smoothly circulate and move.

According to the structure described above, when the roller chain is circulated and moved, the guide projecting portion is engaged with the guide groove formed to the roller returning passage and the direction changing passage inner peripheral portion, so that the run-out of the roller chain during the circulation is suppressed. As a result, the rollers can be rolled and moved in orderly arranged state in all around the endless circulating passage.

In addition, in a case where the roller chain is formed in a striped-shape having no connected portion at both ends thereof, when the movable block is detached from the track rail, the guide projecting portion is engaged with the guide groove, thus enabling to prevent a sagging or slack of an end portion of the roller chain. Further, a also in the case of the roller chain having an endless structure, the sagging or slack of an intermediate portion of the roller chain can be prevented.

When the roller chain comprises spacer portions disposed between the adjacent rollers and connecting members for connecting the respective spacer portions, each of the rollers is arranged and circulated in a state where the rollers are retained by the spacer portions from back and forth in the arranging direction thereof.

Further, when a falling-out preventing portion for the roller is provided to the spacer portion so as to prevent the roller falling-out from back and forth of the roller, it becomes unnecessary to chamfer the end portion of the roller, so that an effective length of the roller for bearing the load can be increased, thus enabling to improve the load bearing ability.

Furthermore, since only the spacer portion is disposed between the adjacent rollers, a pitch of the rollers can be formed as small as possible, so that a number of the rollers required to be disposed per unit length for bearing the load can be increased as many as possible, thus further improving the load bearing ability of the roller.

In addition, when the roller is formed to have a hollow structure and the roller is retained by inserting a resin portion into the hollow portion of the roller, the falling-out of the roller can be securely prevented and a degree of parallelization between the adjacent rollers can be accurately maintained.

In addition, as an example of a case where the hollow portion does not penetrate, the roller may be retained in such a manner that a recessed portion is formed to both end portions of the roller and the resin portion is inserted into the recessed portion or in a manner that a grooved portion is formed to a center peripheral portion of the roller and the resin portion is fitted into the grooved portion.

In addition, when the roller chain is reinforced by inserting a wire or thin plate into the connecting member for linking the rollers, a fatigue strength and life duration of the roller chain can be increased.

In addition, at a time of the insert molding, when a block supporting portion having a shape obtained by cutting an outer peripheral portion of the roller with a cross section passing through a center axis of the roller is provided to an inner periphery of a molding die so as to correspond to the roller rolling surface of the block body, and the block body is positioned in the molding die by contacting the roller rolling surface to the block supporting portion, the burr would not occur at the roller rolling surfaces.

In particular, when the paired right and left roller rolling surfaces of the block body are supported by the block supporting portions of the molding die, the block body is clamped from every four directions and supported by the paired right and left block supporting portions at four points. Therefore, even if an injection pressure of a molding material is applied to the block body from every directions, the block body can be held unmoved, thus the block body can be accurately positioned.

INDUSTRIAL APPLICABILITY

As described above, the linear roller guide device according to the present invention is widely applicable to linear guide mechanisms for various industrial equipments such as machine tool, robot operating system, measuring apparatus or the like.

What is claimed is:

1. A linear roller guide device comprising a track rail and a movable block assembled to the track rail through a number of rollers, said movable block comprising:

a roller rolling surface on which said rollers roll;

a block body having a roller returning passage corresponding to the roller rolling surface;

a direction changing passage inner periphery portion formed to both end surfaces of the block body;

a pair of roller end surface guide walls formed to both sides of the roller rolling surface of the block body and adapted to guide both the end surfaces of the roller; and

side covers each having a direction changing passage outer periphery portion for forming a direction changing passage by fitting the side cover into the direction changing passage inner periphery portion formed to both end surfaces of the block body,

said track rail including a roller rolling surface extending in an axial direction corresponding to the roller rolling surface of the block body, and

said rollers circulating in an endless circulating passage constituted by a loaded area between the roller rolling surface of the block body and the roller rolling surface corresponding to the track rail, the direction changing passage and the roller returning passage,

wherein at least one of a roller returning passage forming member for forming the roller returning passage, which is of one-piece construction with a guide wall guiding a roller end surface, a direction changing passage inner periphery portion forming member for forming the direction changing passage inner periphery portion, which is of one-piece construction with the guide wall and a roller end surface guide wall forming member for forming at least one of the paired roller end surface guide walls, is formed as a molded body integrally formed with the block body by inserting the block body into a molding die.

2. A linear roller guide device according to claim **1**, wherein said roller returning passage forming member and said direction changing passage inner peripheral portion forming member are provided with guide walls for guiding the end surfaces of the rollers, the guide walls being continuous to the roller end surface guide wall, and said roller returning passage forming member, said roller end surface guide wall forming member of at least one of the paired roller end surface guide wall forming members and said direction changing passage inner peripheral portion forming member are integrally molded with the block body.

3. A linear roller guide device according to any one of claims **1** and **2**, wherein a block supporting portion having a shape obtained by cutting an outer peripheral portion of the roller with a cross section passing through a center axis of the roller is formed to an inner periphery of a molding die so as to correspond to the roller rolling surface of the block body at a time of an insert molding, and the block body is positioned in the molding die by contacting the roller rolling surface to the block supporting portion.

4. A linear roller guide device according to any one of claims **1**, **2** and **6** wherein said device has a structure having four rows of rollers in total in which a paired right and left rows of rollers are disposed to be rollable between the upper surface of the track rail and a lower surface of a horizontal portion of the block body and two rows of the rollers each is disposed between the right and left side surfaces of the track rail and inside surfaces of a suspending portion of the block body, respectively.

5. A linear roller guide device according to claim **4**, wherein a contact angle line constituted by a line connecting two contact points of said roller disposed between the roller rolling surfaces formed to the upper surface of the track rail and the horizontal portion of the block body is set to vertically extend with an inclination angle of approximately 90° with respect to a horizontal line, while a contact angle line of the roller disposed between the roller rolling surfaces formed to the right and left side surfaces of the track rail and the inside surfaces of the suspending portion of the block body is set to obliquely extend downwards and is formed so as to incline with an inclination angle of approximately 30° with respect to a horizontal line.

6. A linear roller guide device according to claim **1**, wherein said roller is provided with a chamfered portion formed to at least one end portion of the roller, and an engaging projection with which said chamfered portion of the roller is engaged is provided at the roller end surface guide wall integrally molded with the block body so as to prevent the roller from falling-out.

7. A linear roller guide device according to any one of claims **1**, **2** and **6**, wherein said guide device has a structure having four rows of rollers in total in which two rows of rollers are vertically disposed to be rollable at upper and lower portions between a right side surface of the track rail and a right inside surface of the suspending portion of the block body, respectively, while the remaining two rows of rollers are vertically disposed to be rollable at upper and lower portions between a left side surface of the track rail and a left inside surface of the suspending portion of the block body, respectively.

8. A linear roller guide device according to claim **7**, wherein said upper row of rollers is formed so that a contact angle line of the roller is set to obliquely extend upwards from a side of the track rail to sides of the right and left suspending portions of the block body and is formed so as to incline with an inclination angle of approximately 45° with respect to a horizontal line, while said lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards and is formed so as to incline with an inclination angle of approximately 45° with respect to a horizontal line.

9. A linear roller guide device according to claim **7**, wherein said upper row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards from a side of the track rail to sides of the right and left suspending portions of the block body, and is formed so as to incline with an inclination angle of approximately 45° with respect to a horizontal line, while the lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line.

(57) **ABSTRACT**

An object of this invention is to provide a linear motion guide device and a table guide device having an automatic controllability and to realize a load bearing structure having a high rigidity. The device is characterized in that a movable block **(4)** is formed to provide an L-shape in section, rolling ball rows (B1–B4) are disposed to be rollable between ball rolling grooves formed to an upper surface of a track rail **(1)** and a horizontal portion of the movable block **(4)** and between ball rolling grooves formed to a side surface of the track rail **(1)** and a suspending portion **(3)**, wherein each of the ball rolling grooves has a circular-arc-shape in section having a deep-groove shape having a groove depth of approximately ⅓ to ½ of a diameter of the rolling ball.

LINEAR MOTION GUIDE UNIT AND TABLE GUIDE APPARATUS UTILIZING THE SAME

TECHNICAL FIELD

The present invention relates to a linear motion guide device using rolling balls and to a table guide device using the linear motion guide device.

BACKGROUND ART

As examples of the conventional linear motion guide device of this type, for example, the devices disclosed in Japanese Patent Laid-Open Publication No. SHO 55-46045 and No. SHO 55-46046 are well known. That is, each of the devices comprises a track rail and a movable block having an L-shape in section, and the movable block further comprises a horizontal portion opposing to an upper surface of the track rail and a suspending portion opposing to one side surface of the track rail.

Two rows of rolling balls were disposed to be rollable between two opposing surfaces of the upper surface of the track rail and the horizontal portion of the movable block, and between two opposing surfaces of the one side surface of the track rail and the suspending portion of the movable block, respectively.

The conventional linear motion guide device of this type has a following contact-angle structure. Namely, in the two rows of rolling balls provided on the upper surface of the track rail, a contact angle line constituted by a line connecting the two contact points of the rolling balls to the ball rolling grooves corresponding to the respective ball rows is set to extend toward the track rail and is formed so as to incline toward a side of the suspending portion with respect to a vertical line passing a center of the rolling ball in a case of the ball row positioned close to the suspending portion side, while the other contact angle line in a case of a ball row positioned at the other side of the suspending portion is set to extend toward the track rail and is formed so as to incline toward an opposing side of the suspending portion.

In contrast, in the pair of rolling balls provided on the side surface of the track rail, a contact angle line constituted by a line connecting the two contact points of the rolling balls to the ball rolling grooves corresponding to the respective ball rows is set to extend toward the track rail and is formed so as to incline toward a side of the horizontal portion with respect to a horizontal line passing a center of the rolling ball in a case of the ball row positioned close to a side of the horizontal portion, while the other contact angle line in a case of a ball row positioned at the other side of the horizontal portion is set to extend toward the track rail and is formed so as to incline toward an opposing side of the horizontal portion.

Due to an employment of such contact-angle structure, a load-bearing capacity against loads to be applied from various directions including vertical and horizontal directions can be enhanced. In particular, it becomes possible to increase a supporting rigidity against a moment in a direction for rotating the movable block around the track rail.

In the prior art technics described above, however, since the supporting rigidity against the moment in the direction for rotating the movable block around the track rail is high, there were posed following problems. Namely, when the movable block in a state having a working error in attaching surfaces thereof is fixed to a table and then the track rail is fixed to a fixed bed, a misalignment is caused between the track rail and the movable block and an excessive force is

applied to the track rail and the movable block, thus resulting in increasing of sliding resistance and promoting early wear of the ball rolling grooves and rolling balls per se. Such misalignment will be avoided by increasing working precision of the respective members of the device. However, the working precision has a limit itself and involves a cost increasing.

The present invention is achieved for solving the afore-mentioned problems and an object of the present invention is to provide a linear motion guide device and a table guide device using the linear motion guide device which has an automatic controllability and enables to realize a supporting structure having a high rigidity.

DISCLOSURE OF THE INVENTION

In order to achieve the afore-mentioned object, the present invention provides a linear motion guide device comprising:

a track rail having a rectangular-shape in section and at least one ball rolling groove formed respectively to an upper surface and one side surface of the track rail;

a movable block having a L-shape in section, comprising a horizontal portion provided with ball rolling grooves corresponding to ball rolling grooves formed to the upper surface of the track rail and a suspending portion provided with ball rolling grooves corresponding to ball rolling grooves formed to the one side surface of the track rail; and

a row of rolling balls disposed to be rollable between corresponding ball rolling grooves formed to the upper surface of the track rail and the horizontal portion of the movable block and between corresponding ball rolling grooves formed to the side surface of the track rail and the suspending portion of the movable block, respectively;

wherein each of the ball rolling grooves has a circular-arc-shape in section having a deep-groove shape having a groove depth set to approximately ⅓ to ½ of a diameter of the rolling ball.

According to the present invention, the movable block is formed in L-shape in section and has a supporting construction in which only the upper surface and one side surface of the track rail are supported by the horizontal portion and the suspending portion at a right angle, so that it becomes possible to increase a degree of freedom in a direction for inclining the horizontal portion and the suspending portion around a corner portion between the horizontal portion and the suspending portion. Therefore, even if the track rail and the movable block are formed with a working error or the device is formed with an error in a degree of parallelism between a mating surface to which the track rail is attached and a mating surface to which the movable block is fixed, a position of the movable block can be automatically adjusted and controlled by displacements of the contact points of the rolling balls rolling in the ball rolling grooves.

In addition, each of the ball rolling grooves is formed so as to have a deep-grooved shape. Therefore, even if the contact points of the rolling balls are displaced by the automatically controlling function, the rolling ball contacts to intermediate portions of an inner circumferential surface of the ball rolling groove, the intermediate portions being far deep positions from a side peripheral edge portion of the ball rolling groove. As a result, a load to be applied to the rolling ball can be dispersed and supported by the inner circumferential surface of the ball rolling groove, and there is no fear of edge-load being applied to the side peripheral edge portion of the ball rolling groove, thus achieving a high automatic controllability.

Further, the movable block is formed to be opened at one side thereof, so that the movable block can be subjected to a grinding work using a large-sized grinding stone to form the ball rolling grooves. In addition, even in a case of the deep-grooved type, the grinding work can be performed at a high efficiency, thus improving the productivity of the device.

Furthermore, the movable block is formed in an L-shape and has no under-cut portion, and the track rail is also formed in a simple rectangular-shape in section, so that the movable block can be easily formed by a drawing operation and the productivity can be improved.

In one aspect of this invention, there can be also provided a linear motion guide device in which a contact angle line constituted by a line connecting the two contact points of the rolling ball disposed between the corresponding ball rolling grooves formed to the horizontal portion of the movable block and the upper surface of the track rail is set to extend toward the track rail and is formed so as to incline toward a side of the suspended portion with respect to a vertical line passing a center of the rolling ball, and

a contact angle line constituted by a line connecting the two contact points of the rolling ball disposed between the corresponding ball rolling grooves formed to the suspending portion of the movable block and the side surface of the track rail is set to extend toward the track rail and is formed so as to incline toward a side of the horizontal portion with respect to a horizontal line passing a center of the rolling ball.

Due to an employment of such contact-angle structure described above, a load in a horizontal direction for moving the suspending portion close to the side surface of the track rail is supported by the rolling balls disposed at the side surface of the track rail, while a load in a horizontal direction for moving the suspending portion away from the side surface of the track rail is supported by the rolling balls disposed at the upper surface of the track rail.

Further, a load in a direction for pressing the suspending portion on to the track rail from an upper direction is supported by the rolling balls disposed at the upper surface of the track rail, while a load in a direction for lifting the suspending portion from the track rail is supported by the rolling balls disposed at the side surface of the track rail.

In another aspect of this invention, each of the upper surface and the side surface of the track rail is arranged with at least two rows of rolling balls, respectively, and the respective at least two rows of the rolling balls disposed at the upper surface and the side surface of the track rail have a contact-angle structure in which the contact angle lines of the respective rolling balls are inclined in the same direction.

According to this construction, the load bearing ability can be increased without impairing the automatic controllability.

In another aspect of this invention, the horizontal portion of the movable block may be provided with a skirt portion having a length shorter than that of the suspending portion, the skirt portion being formed at a side surface opposing to the side surface of the horizontal portion to which the suspending portion is formed, and a row of rolling balls is disposed to be rollable between corresponding a pair of ball rolling grooves formed to the skirt portion and the side surface of the track rail.

According to such construction described above, even if a load in a direction for lifting the movable block from the track rail is applied to the device, the movable block is firmly supported by not only one side surface but also both side surfaces of the track rail, so that the load bearing ability against the lifting load can be increased.

The movable block may also be constructed so as to comprise a movable block body having a loaded ball rolling groove and a ball returning passage for returning the ball in the loaded ball rolling groove from one end to the other end of the loaded ball rolling groove and side covers provided for both end portions of the movable block body, the side cover constituting a ball turning passage for changing the ball rolling direction by receiving the ball from the loaded ball rolling groove and then guiding the ball to the ball returning passage,

wherein at least one of a return passage constituting the ball returning passage structure and an inner circumferential portion constituting an inner circumferential structure of the ball turning passage is formed of a molding-shaped portion which is integrally formed to the movable block body by an insert molding method in which the mold-shaping is performed by inserting the movable block body into a shaping mold.

According to this construction, the mold-shaping operation of the movable block can be easily performed.

In another aspect of this invention, the device is characterized in that the horizontal portion of the movable block is provided with two rows of ball rolling grooves while the suspending portion is also provided with two rows of ball rolling grooves, and bolt holes for inserting attaching-bolts are formed to both central portions between the two rows of the ball rolling grooves of the horizontal portion and the suspending portion, respectively.

When the horizontal portion and the suspending portion are fastened to a table in a manner described above, the movable block is reinforced by the table, so that the rigidity of the device can be increased.

In another aspect of this invention, the device is characterized in that a plural rows of ball rolling grooves to be formed on the upper surface of the track rail are locally disposed close to one side surface side of the track rail and a bolt hole for inserting the attaching bolt is formed to a region on the upper surface of the track rail close to the other side surface side of the track rail.

As described above, when the position of the ball rolling grooves to be formed on the upper surface of the track rail is set to one side and the bolt inserting hole for fastening the track rail is formed at the other side portion, it can be possible to prevent an extraneous substance from invading into the ball rolling grooves.

On the other hand, a table guide device according to the present invention is characterized by comprising a fixed bed, a pair of linear motion guide devices arranged in parallel with the fixed bed and table to be assembled through the paired linear motion guide devices;

wherein the linear motion guide device described above is used as the linear motion guide device, the paired track rails of the paired linear motion guide devices are symmetrically disposed on the upper surface of the fixed bed so that the side surfaces of the track rails to which the ball rolling grooves are formed are faced to inside or outside to each other, the side surface of the track rail opposing to the side surface to which the ball rolling grooves are formed is set to be a reference surface for attachment, and the fixed bed is formed to have a reference wall for supporting the reference surface for attachment of the track rail.

In addition, the device is characterized in that a height of the reference wall is set to a height corresponding to that of the ball rolling groove formed to the side surface opposing to the reference surface of attachment.

According to the table guide device of this invention, a pair of right and left movable blocks are fixed to the table, so that the device, as a whole, has a structure in which the side surfaces of the right and left track rails are clamped by the suspending portions of the respective right and left movable blocks. Therefore, as a whole, the rigidity in the direction for rotating the movable blocks around the track rails is increased, and there can be realized a table guide device having a high load bearing performance against the loads in every direction including horizontal and vertical directions.

Further, even if the working errors or the like are caused to attaching surfaces of the track rails and the movable blocks, the automatic controlling function of the linear motion guide device is effected as described above, so that the misalignment between the track rail and the movable block is absorbed and automatically controlled by the displacements of the contact points of the balls rolling within the ball rolling grooves. As a result, the table can be smoothly guided.

In addition, the ball rolling grooves can be simultaneously formed by a grinding operation in a state where the two rows of track rails are fixed in parallel to each other, so that the parallel tracks and grooves having a high accuracy can be obtained.

Furthermore, when the table is provided with supporting walls for supporting rear surfaces of the suspending portions of the respective right and left movable blocks, the load in a horizontal direction applied to the table is directly transferred to the movable blocks not through the attaching bolts but through the supporting walls, and then transferred from the movable blocks to the track rails thereby to be directly supported by the reference walls of the fixed bed. Accordingly, the load in a horizontal direction would not apply from a shearing direction to the attaching bolt for fastening the movable block or the attaching bolt for fastening the track rail, so that there can be provided a table guide device with a structure having an extremely high rigidity.

In addition, the table guide device in another aspect of this invention may comprise a preload controlling mechanism provided between at least one of the supporting walls and the suspending portion of the movable block, the preload controlling mechanism is constructed in a manner that the movable block is forcibly pressed to the track rail side by utilizing the supporting wall as a supporting member so as to increase a preload of the balls disposed between the movable blocks and track rails, a reaction force applied to the supporting wall as a reaction force of the pressing force is applied to another supporting wall through the table, then a suspending portion of another movable block is pressed to another track rail by the reaction force thereby to increase the preload of the balls. When the preload controlling mechanism described above is provided to the table guide device, the supporting rigidity of the whole of the table can be increased.

In particular, when a tapered gib formed of a block body to be face-contacted to the rear surface of the suspending portion is used as the preload controlling mechanism and disposed between the supporting wall and the suspended portion of the movable block, it is possible to uniformly impart the preload to the ball rows. In addition, the rigidity between the suspending portion and the supporting wall can also be maintained to a high level.

Further, in another aspect of this invention, the linear motion guide device is characterized in that the track rail is provided with at least one ball rolling groove to be formed to the upper surface and another side surface of the track rail, respectively, and the movable block defined in claim **1** is

assembled to right and left corner portions between the upper surface and lateral side surfaces of the track rail.

That is, the linear motion guide device is characterized by comprising:

a track rail provided with at least one ball rolling groove formed to right and left half portions of an upper surface and lateral side surfaces of the track rail, respectively;

a pair of movable blocks provided on a right and a left corner portions between the upper surface and the lateral side surfaces of the track rail, each of the movable blocks having an L-shape cross section and further comprising a horizontal portion provided with a ball rolling groove corresponding to the ball rolling groove formed to the right and left half portions of the upper surface of the track rail and a suspending portion provided with a ball rolling groove corresponding to the ball rolling groove formed to the lateral side surfaces of the track rail;

a row of rolling balls disposed to be rollable between the ball rolling grooves formed to the upper surface of the track rail and the horizontal portions of the paired movable blocks; and

a row of rolling balls disposed to be rollable between the ball rolling grooves formed to the lateral side surfaces of the track rail and the suspended portions of the paired movable blocks;

wherein each of the ball rolling grooves is formed to be a deep-grooved shape having a circular-arc-shape in section, and a groove depth is set to approximately ⅓ to ½ of a diameter of the rolling ball.

In another aspect of this invention, there can be also provided a linear motion guide device in which a contact angle line constituted by a line connecting the two contact points of the rolling ball disposed between the corresponding ball rolling grooves formed to the horizontal portions of the paired movable blocks and the upper surface of the track rail is set to extend toward the track rail and is formed so as to incline toward the respective suspending portions of the paired movable blocks with respect to a vertical line passing a center of the rolling ball, and

a contact angle line constituted by a line connecting the two contact points of the rolling ball disposed between the corresponding ball rolling grooves formed to the suspending portions of the paired movable blocks and the side surfaces of the track rail is set to extend toward the track rail and is formed so as to incline toward a side of the horizontal portion of the respective movable blocks with respect to a horizontal line passing a center of the rolling ball.

Further, the linear motion guide device is characterized in that each of the ball rows disposed at the right and left half portions of the upper surface and right and left side surfaces of the track rail consists of two rows of rolling balls and the respective two rows of rolling balls have a contact angle arrangement so that the contact angle lines thereof are inclined to the same direction to each other.

Furthermore, the linear motion guide device is characterized in that the track rail is a rail having a wide width.

Furthermore, the table guide device is characterized by comprising a fixed bed and a linear motion guide device formed by combining aforementioned one track rail and the paired movable blocks, wherein the track rail of the linear motion guide device is fixed to the fixed bed and a table is fixed to the paired first and second movable blocks.

According to the arrangement described above, even in a case of assembling the table guide device, a pair of guide rails are not required and it is sufficient to prepare only one track rail, whereby an applicable range of the table guide device can be broadened. In particular, in a case where a pair of the track rails are used, the paired track rails are required to have a high attaching performance. However, the requirement for such attaching accuracy can be neglected in this case, because of using one track rail.

Further, it is preferable to use a rail having a wide width as the track rail, because the stability of the device can be improved by using such wide-width track rail. In addition, due to the wide-width track rail, the load bearing ability with respect to an angular moment around a center axis of the track rail can be increased.

The characteristics and functions of the features that the movable block is formed to provide an L-shape in section and the ball rolling groove is formed to be a deep-grooved shape have been described hereinabove.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a view showing one embodiment of a linear motion guide device according to the present invention, in which FIG. **1** (*a*) is a cross sectional view of the linear motion guide device, FIG. **1** (*b*) is a side view of the linear motion guide device and FIG. **1** (*c*) is a partially sectional view showing a ball recirculating passage of the linear motion guide device.

FIG. **2** is a cross sectional view showing one embodiment of a table guide device according to the present invention in which the linear motion guide device shown in FIG. **1** is used.

FIG. **3** is a cross sectional view showing another embodiment of a table guide device according to the present invention in which the linear motion guide device shown in FIG. **1** is used.

FIG. **4** is a cross sectional view showing another embodiment of a linear motion guide device according to the present invention.

FIG. **5** is a cross sectional view showing one embodiment of a table guide device according to the present invention in which the linear motion guide device shown in FIG. **4** is used.

FIG. **6** is a cross sectional view showing further embodiment of a linear motion guide device according to the present invention.

BEST MODE FOR EMBODYING THE INVENTION

In order to explain the present invention in more detail, the preferred embodiments of the invention will be be described hereunder with reference to the accompanying drawings.

FIG. **1** is a view showing a first embodiment of a linear motion guide device according to the present invention. The linear motion guide device comprises a track rail **1** having a rectangular shape in section, a movable block **4** having an L-shape in section, the movable block **4** further comprising a horizontal portion **2** opposing to an upper surface of the track rail **1** and a suspending portion **3** opposing to one side surface of the track rail **1** and ball rows B**1**, B**2**, B**3** and B**4** each consisting of two rows of a number of rolling balls disposed to be rollable between the upper surface of the track rail **1** and the horizontal portion **2** of the movable block **4** and between the side surface of the track rail **1** and the suspending portion **3**.

The track rail **1** is formed to provide a rectangular shape in section so that each of upper and lower surfaces and lateral right and left side surfaces of the track rail **1** has a plain surface. Two rows of ball rolling grooves **51** to **54** are formed to the upper surface and one side surface of the track rail **1**, respectively. The ball rolling grooves **51** and **52** formed to the upper surface are provided at portions close to the lateral right and left end portions so as to be symmetric with respect to a center of the track rail **1**. At the center portion of the track rail **1**, there is formed a bolt inserting hole **7** for inserting an attaching bolt for fixing the track rail **1** so as to vertically pass through the track rail **1**. Ball rolling grooves **53** and **54** are also formed to the side surface of the track rail **1** so as to be symmetric in vertical direction. An interval of adjacent ball rolling grooves **53** and **54** formed to the side surface of the track rail **1** is smaller than that of the ball rolling grooves **51** and **52** formed to the upper surface of the track rail **1**.

At a lower surface of the horizontal portion **2** of the movable block **4** is provided with two rows of ball rolling grooves **61** and **62** corresponding to the ball rolling grooves **51** and **52** formed to the track rail **1**, while the suspending portion **3** is provided with two rows of ball rolling grooves **63** and **64** corresponding to the ball rolling grooves **53** and **54** formed to the one side surface of the track rail **1**. A bolt hole **8** for fixing the movable block **4** is respectively formed to a portion between the two rows of ball rolling grooves **61** and **62** of the horizontal portion **2** and at an upper portion of the suspending portion **3**.

Each of the ball rolling grooves **51**–**54** and **61**–**64** of the track rail **1** and the movable block **4** has a circular-arc shape in section and formed to provide a deep-grooved shape having a groove depth of approximately ⅓ to ½ of a diameter of the rolling ball.

In addition, each of the contact angle lines S**1** and S**2** each constituted by a line connecting two contact points of the ball rows B**1** and B**2** disposed between the corresponding ball rolling grooves **51**, **61**; **52**, **62** formed to the horizontal portion **2** of the movable block **4** and the upper surface of the track rail **1** is set to extend toward the track rail **1** and is formed so as to incline toward a side of the suspending portion **3** with respect to a vertical line V passing a center of the rolling ball. When the ball diameter of the respective ball rows B**1** and B**2** is set to a large diameter larger than a distance between the two contact points of the rolling ball which contacts to the respective ball rolling grooves, a preload can be imparted to the rolling balls of the respective ball rows B**1** and B**2**.

On the other hand, each of the contact angle lines S**3** and S**4** each constituted by a line connecting the two contact points of the ball rows B**3** and B**4** disposed between the corresponding ball rolling grooves **53**, **63**; **54**, **64** formed to the suspending portion **3** of the movable block **4** and the side surface of the track rail **1** is set to extend toward the track rail **1** and is formed so as to incline toward a side of the horizontal portion **2** of the movable block **4** with respect to a horizontal line H passing a center of the rolling ball. Further, in this case, when the ball diameter of the respective ball rows B3 and B4 is set to a diameter larger than a distance between the two contact points of the rolling ball which contacts to the respective ball rolling grooves **53**, **63**; **54**, **64**, a preload can be imparted to the rolling ball of the respective ball rows B1 and B2.

The movable block **4** comprises a movable block body **41** having loaded ball rolling grooves **61**–**64** and ball return passages **71**–**74** for returning the balls from one end to the other end of the loaded ball rolling grooves **61**–**64** and side covers **42** and **42** provided at both end portions of the movable block body **41**, each of the side covers **42** and **42** constituting ball rolling direction turning passages **81**–**84** for receiving the ball B from the loaded ball rolling grooves **61**–**64** and then guiding the ball B to the ball return passages **71**–**74**.

In addition, at least one of return passage members **71***a*–**74***a* constituting the ball return passages **71**–**74** and an inner circumferential portion member **81***b*–**84***b* constituting inner peripheral guide portions **81***a*–**84***a* of the ball rolling direction turning passages **81**–**84** is formed of a molding-shaped portion which is integrally formed with the movable block body **41** by an insert-molding method in which the mold-shaping operation is performed by inserting the movable block body **41** into a shaping mold.

Under certain circumstances, there may be a case where a ball retainer (not shown) is provided at a side peripheral portion of the loaded ball rolling grooves **61**–**64** so as to prevent the ball B from dropping off from the movable block **4** when the movable block **4** is detached from the track rail **1**. In this case, the ball retainer may also be integrally formed with the movable block body **41** together with the inner peripheral guide portion members **81***b*–**84***b* and the ball returning passage members **71***a*–**74***a*.

According to the present invention, a load FXR in the horizontal direction for moving the suspending portion **3** close to the side surface of the track rail **1** is born by the two rows of rolling balls B3 and B4 disposed at the side surface of the track rail **1**, while a load FXL in a horizontal direction for moving the suspending portion **3** away from the side surface of the track rail **1** is born by the two rows of rolling balls B1 and B2 disposed at the upper surface of the track rail.

Further, a load FYD in the vertical direction for pressing the movable block **4** onto the upper surface of the the track rail **1** from an upper direction is born by the two rows of rolling balls B1 and B2 disposed at the upper surface of the track rail **1**, while a load FYU in the vertical direction for lifting the movable block **4** from the track rail **1** is born by the two rows of rolling balls B3 and B4 disposed at the side surface of the track rail **1**. Accordingly, the loads in four directions can be born by one movable block **4**.

On the other hand, the movable block **4** is formed to have a load bearing construction in which the upper surface and the one side surface of the track rail **1** are born by the horizontal portion **2** and the suspending portion **3** of the movable block **4** at a right angle, and both of the contact angle lines S1 and S2 of the two rows of rolling balls B1 and B2 disposed at the upper surface are formed to extend toward the track rail **1** and to incline toward a side of the suspending portion **3** with respect to a vertical line V, while both of the contact angle lines S3 and S4 of the two rows of the rolling balls B3 and B4 disposed at the side surface are are formed to extend toward the track rail **1** and to incline toward a side of the horizontal portion **2** with respect to a horizontal line H. Therefore, the rigidity in the direction for rotating the movable block **4** around a center axis of the track rail **1** is small.

Accordingly, even if the track rail **1** and the movable block **4** are formed with a working error or the device is formed with an angular error between a mating surface to which the track rail **1** is attached and a mating surface to which the movable block **4** is fixed, a position of the movable block **4** can be automatically controlled by displacements of the contact points of the rolling balls B rolling in the ball rolling grooves **51**–**54** and **61**–**64**.

In addition, each of the ball rolling grooves **51**–**54** and **61**–**64** is formed so as to have a deep-groove shape. Therefore, even if the contact points of the rolling balls B are displaced by the automatically controlling function, the rolling balls B1–B4 contact to intermediate portions of an inner circumferential surface of the ball rolling grooves **51**–**54** and **61**–**64**, the intermediate portions being far deep positions from a side peripheral edge portions of the ball rolling grooves **51**–**54** and **61**–**64**. As a result, a load to be applied to the rolling ball B can be dispersed and born by the inner circumferential surface of the ball rolling grooves **51**–**54** and **61**–**64**, and there is no fear of the ball contacting to the side peripheral edge portion of the ball rolling grooves **51**–**54** and **61**–**64**, thus achieving a high automatic controllability.

Further, the movable block **4** is formed to be opened at one side thereof, so that the movable block **4** can be subjected to a grinding work using a large-sized grinding stone to form the ball rolling grooves **61**–**64**. In addition, even in a case of the deep-groove type, the grinding work can be performed at a high efficiency, thus improving the productivity of the device.

Furthermore, the movable block **4** is formed in an L-shape in section and has no under-cut portion, and the track rail **1** is also formed in a simple rectangular-shape in section, so that the movable block **4** can be easily formed by a drawing operation, thus improving the productivity.

FIG. **2** is a view showing a table guide device in which aforementioned linear motion guide device is used.

This table guide device comprises a fixed bed **20**, a pair of linear motion guide devices **10** and **10** arranged in parallel with the fixed bed **20** and a table **30** to be assembled through the paired linear motion guide devices **10** and **10**.

The linear motion guide device described above is used as the linear motion guide devices **10** and **10** and a pair of track rails **1** and **1** of the paired linear motion guide devices **10** and **10** are symmetrically arranged on the upper surface of the fixed bed **20** so that the side surfaces of the track rails **1** and **1** to which the ball rolling grooves **53** and **54** are formed are faced to outside to each other. The side surfaces of the respective track rails **1** and **1** opposing to the side surfaces, to which the ball rolling grooves **53** and **54** are formed, are set as reference surfaces **56** and **56** for attachment, and the fixed bed **20** is formed with a pair of parallel reference walls **21** and **21** for supporting the reference surfaces **56** and **56** for attaching the track rails **1** and **1**. Each of heights of the reference walls **21** and **21** is set to a height corresponding to that of the ball rolling grooves **53** and **54** formed to the side surfaces opposing to the reference surfaces **56** and **56** for attachment. Accordingly, the reference surfaces **56** and **56** for attaching the track rails **1** and **1** can be set to an almost the same height of the movable block **4**, thus assembling the table structure in sufficiently small size.

According to the table guide device of the present invention, a pair of right and left movable blocks **4** and **4** are fixed to the table **30**, so that the device as a whole has a structure in which the side surfaces of the right and left track rails **1** and **1** are clamped by the suspending portions **3** and **3** of the respective right and left movable blocks **4** and **4**. Therefore, as a whole, the rigidity in the direction for rotating the movable blocks **4** and **4** around the track rails **1** and **1** is increased. As a result, there can be realized a table guide device having a high load bearing performance against the loads in every direction including horizontal and vertical directions.

Further, even if there is caused a working error or the like to attaching surfaces of the track rail **1** and the movable block **4**, the automatic controlling function of the linear motion guide device is effected as described above, so that the misalignment between the track rail **1** and the movable block **4** is absorbed and automatically controlled by the displacements of the contact points of the balls B rolling within the ball rolling grooves **51–54** and **61–64**. As a result, the table **30** can be smoothly guided.

In addition, the ball rolling grooves **51–54** can be simultaneously formed by a grinding operation in a state where the two rows of track rails **1** and **1** are fixed in parallel to each other, so that the parallel tracks having a high accuracy can be obtained.

Furthermore, the table **30** is provided with supporting walls **31** and **31** for supporting rear surfaces of the suspending portions **3** and **3** of the respective right and left movable blocks **4** and **4**. The supporting walls **31** and **31** support the respective suspending portions **3** and **3** in an entire range corresponding to a height of the suspending portion **3**, and are constructed so as to oppose to the reference wall **21** of the fixed bed **20** through the suspending portions **3**, **3** and the track rails **1**, **1** in the horizontal direction at the same height as that of the reference wall **21**.

Since the supporting wall **31** is provided, the load in a horizontal direction applied to the table **30** is directly transferred to the movable block **4** not through the attaching bolt **32** but through the supporting wall **31**, and then transferred from the movable blocks **4**, **4** to the track rails **1**, **1** thereby to be directly supported by the reference wall **21** of the fixed bed **20**. Accordingly, the load in a horizontal direction would not apply from a shearing direction to the attaching bolt **32** for fastening the movable block **4** or the attaching bolt **11** for fastening the track rail **1**, so that there can be provided a table guide device with a construction having an extremely high rigidity.

In addition, the suspending portion **3** of the movable block **4** is reinforced by the supporting wall **31**, so that a bending deformation of the suspending portion **3** due to a moment load can be sufficiently prevented.

On the other hand, the table guide device is provided with a preload controlling mechanism installed between one side of the supporting wall **31** of the table **20** and the suspending portion **3** of the movable block **4**, the preload controlling mechanism being constructed in a manner that the movable block **4** is forcibly pressed to a side of the track rail **1** by utilizing the supporting wall **31** as a supporting member so as to increase a preload to be applied to the ball rows B**3** and B**4** disposed between the movable block **4** and track rail **1**, a reaction force applied to the supporting wall **31** as a reaction force of the pressing force is applied to another supporting wall **31** through the table **30**, and then a suspending portion **3** of another movable block **4** is pressed to another track rail **1** by the reaction force thereby to increase the preload of the ball rows B**3** and B**4**.

As the preload controlling mechanism described above, various constructions will be applicable. In this embodiment, a tapered gib **51** composed of a block body face-contacting to a rear surface of the suspending portion **3** is provided between the supporting wall **31** of the table **30** and the suspending portion **3** of the movable body **4**.

That is, the preload controlling mechanism **50** comprises the tapered gib **51**, a tapered groove **52** having a tapered surface into which the tapered gib **51** is inserted and a bolt **53** for fixing the tapered gib **51**. The tapered gib **51** is composed of the block body having a high rigidity, one side surface thereof is formed to be a plain vertical surface **51***a* face-contacting to the rear surface of the suspending portion **3** of the movable block **4**, while the other side surface thereof is formed to be a tapered surface **51***b* of which width decreases along an upper direction as viewed. In contrast, the tapered groove **52** provided to the supporting wall **31** of the table **30** is formed to have an inclined surface against which the tapered surface **51***b* of the tapered gib **51** abuts.

When the tapered gib **51** face-contacting to the suspending portion **3** is used, it becomes possible to uniformly impart the preload to the ball rows B**3** and B**4**. In addition, the rigidity between the suspended portion **3** and the supporting wall **31** can also be maintained to a high level.

In this regard, in the embodiment of the table guide device described above, the paired linear motion guide devices are arranged so that the suspending portions **3** and **3** of the respective movable blocks are positioned outside the track rails **1** and **1**. However, as shown in FIG. **3**, the paired linear motion guide devices can also be arranged so that the suspending portions **3** and **3** of the paired movable blocks **4** and **4** are positioned inside the track rails **1** and **1**, this arrangement being reverse to that of the embodiment described above.

In this case, the reference wall **21** of the fixed bed **20** is positioned outside the respective track rails **1** and **1**, while the supporting wall **31** of the table **30** is formed inside of the respective movable blocks **4** and **4**. In addition, the preload controlling mechanism **50** is also provided inside the movable blocks **4** and **4**.

OTHER EMBODIMENTS

FIGS. **4–9** show the other embodiments of the linear motion guide device and the table guide device using the linear motion guide device according to the present invention.

Further, in the following explanations, only the points different from those of the above embodiment will be explained. Namely, detailed explanations regarding to the same constitutional elements or parts as those in the embodiment will be omitted by adding the same reference numerals to the corresponding elements or parts.

In the embodiment of the linear motion guide device shown in FIG. **4**, the horizontal portion **2** of the movable block **4** is provided with two rows of ball rolling grooves **61** and **62** while the suspending portion **3** is also provided with two rows of ball rolling grooves **63** and **64**, and bolt holes **2***a* and **3***a* for inserting attaching-bolts are provided at corresponding central portions between the two rows of the ball rolling grooves **61** and **62** of the horizontal portion **2** and the suspending portion **3**, respectively.

FIG. **5** shows a construction of a table guide device to which the linear motion guide device of this type is applied so that the suspending portions **3** and **3** of the paired right and left movable blocks **4** and **4** are positioned inside the track rails **1** and **1**. As like this case, when the horizontal portion **2** and the suspending portion **3** are fastened to the table **30**, the movable block **4** is reinforced by the table **30**, so that the rigidity of the device can be increased.

As a matter of course, it is also possible to adopt a construction in which the suspending portion **3** of the movable block **4** is positioned outside the track rail **1**.

FIG. **6** shows a construction of a linear motion guide device in which a plurality rows of the ball rolling grooves **61** and **62** to be formed to the upper surface of the track rail **1** are collectively positioned at the upper surface close to the one side surface to which the ball rolling grooves **63** and **64** are formed, and a bolt hole **8** for inserting the attaching bolt is formed at a region on the upper surface close to the other side surface of the track rail **1**.

As like this manner, when the positions of the ball rolling grooves **61** and **62** are arranged to one side of the upper surface of the track rail **1** and the bolt hole **8** for fastening the track rail **1** is formed at the other side portion, it becomes possible to prevent an extraneous substance from invading into the ball rolling grooves **61** and **62**.

FIG. **7** shows a structure of a table guide device to which the linear motion guide device of this type is applied so that the suspending portions **3** and **3** of the paired right and left movable blocks **4** and **4** are positioned inside the track rails **1** and **1**. As a matter of course, the suspending portions **3** and **3** of the movable blocks **4** and **4** can be also positioned outside the track rail **1**.

FIG. **8** shows a structure of a linear motion guide device in which the horizontal portion **2** of the movable block **4** is provided with a skirt portion **13** having a length shorter than that of the suspending portion **3**, the skirt portion **13** being formed at a side surface opposing to the side surface of the horizontal portion to which the suspending portion **3** is formed, and a row of rolling balls B**5** is disposed to be rollable between corresponding a pair of ball rolling grooves **55** and **65** formed to the skirt portion **13** and the side surface of the track rail **1**.

According to such structure described above, even if a load in a direction for lifting the movable block **4** from the track rail **1** is applied to the device, the movable block **4** is firmly born by not only one side surface but also both side surfaces of the track rail **1**, so that the load bearing ability against the lifting load can be increased.

FIG. **9** shows a construction of a table guide device to which the linear motion guide device of this type is applied so that the suspending portions **3** and **3** of the paired right and left movable blocks **4** and **4** are positioned inside of the track rails **1** and **1**. As a matter of course, the suspending portions **3** and **3** of the movable blocks **4** and **4** can be also positioned outside of the track rail **1**.

FIG. **10** shows a construction of a table guide device in which the paired track rails of the linear motion guide devices shown in FIG. **2** are replaced with a track rail **100** having a wide width. It is to be noted that the structure of the movable block **4** is substantially the same as that of the movable block **4** shown in FIG. **1**, so that the detailed structure of the device shall be referred to FIG. **1** and corresponding explanations, if necessary. In such case, the explanations shall be read upon replacing the term "track rail **1**" with "track rail **100**".

That is, the device is constructed by comprising a track rail **100** having a wide width and rectangular shape in section to which at least one row of ball rolling groove, i.e., two rows of ball rolling grooves in this case as shown in FIG. **10**, are formed at right and left half portions of the upper surface and the right and left side surfaces of the track rail **100** and a pair of movable blocks **4** and **4** to be assembled to both right and left corner portions of the track rail **100**.

That is, the linear motion guide device comprises:

a track rail provided with at least one ball rolling groove, i.e., a pair of two rows of ball rolling grooves **51**, **52**, **53** and **54** formed to the right and left half portions of the upper surface and the right and left side surfaces of the track rail **100** having a wide width, respectively;

a pair of movable blocks **4** and **4** provided on right and left corner portions between the upper surface and the right and left side surfaces of the track rail **100**, each of the movable blocks **4** and **4** having an L-shaped cross section and further comprising a horizontal portion **2** provided with ball rolling grooves **61** and **62** corresponding to the ball rolling grooves **51** and **52** formed to the right and left half portions of the upper surface of the track rail **100** and a suspending portion **3** provided with ball rolling grooves **63** and **64** corresponding to the ball rolling grooves **53** and **54** formed to the right and left side surfaces of the track rail **100**;

rows of rolling balls B**1** and B**2** disposed to be rollable between the upper surface of the track rail **100** and the ball rolling grooves **51** and **64** formed to the horizontal portions **2** and **2** of the paired movable blocks **4** and **4**; and

rows of rolling balls B**3** and B**4** disposed to be rollable between the right and left side surfaces of the track rail **100** and the ball rolling grooves **54** and **64** formed to the suspending portions **3** and **3** of the paired movable blocks **4** and **4**.

In addition, each of the ball rolling grooves **51**, **61**; **52**, **62**; **53**, **63**; **54**, **64** is formed to provide a deep-grooved shape having a circular-arc-shape in section, and a groove depth is set to approximately ⅓ to ½ of a diameter of the rolling ball.

In addition, each of the contact angle lines S**1** and S**2** each constituted by a line connecting the two contact points of the rolling ball disposed between the corresponding ball rolling grooves **51**, **61**; **52**, **62** formed to the horizontal portions **2** and **2** of the paired movable blocks **4** and **4** and the upper surface of the track rail **100** is set to extend toward the track rail **100** and is formed so as to incline toward a side of the respective suspending portions **3** and **3** of the paired movable blocks **4** and **4** with respect to a vertical line V passing a center of the rolling ball, while each of the contact angle lines S**3** and S**4** each constituted by a line connecting the two contact points of the rolling balls B**3** and B**4** disposed between the corresponding ball rolling grooves **53**, **63**; **54**, **64** formed to the suspending portions **3** and **3** of the paired movable blocks **4** and **4**, and the side surfaces of the track rail **100** is set to extend toward the track rail **100** and is formed so as to incline toward a side of the horizontal portion **2** of the respective movable blocks **4** and **4** with respect to a horizontal line H passing a center of the rolling ball.

Further, each of the right and left half portions of the upper surface and the right and left side surfaces of the track rail **100** is provided with two rows of ball rows B**1**, B**2**; B**3**, B**4** which has a contact angle arrangement so that the contact angle lines thereof are inclined to the same direction to each other.

In addition, bolt holes **8** and **8** for inserting attaching-bolts are provided at corresponding central portions between the two rows of the ball rolling grooves **61** and **62** of the horizontal portions **2** and **2**, and the bolt holes **8** and **8** are also provided at base portions of the suspending portions **3** and **3**, respectively.

As described above, the structure of the movable blocks **4** and **4** is substantially the same as that of the movable block **4** shown in FIG. **1**, and the movable blocks **4** and **4** can be subjected to a grinding work using a large-sized grinding stone with a high efficiency to form the deep-groove type ball rolling grooves **61–64**.

In addition, the track rail **100** is fixed to the fixed bed **20**, and the the table **30** is fixed to the paired movable blocks **4** and **4**. The track rail **100** is a rail having a wide width thereby to increase the stability of the device.

Further, due to an employment of the track rail **100** having wide width, the load bearing ability with respect to an angular moment around a center axis of the track rail **100** can be increased.

Furthermore, even in a case of assembling the table guide device, a pair of guide rails are not required and it is sufficient to prepare only one track rail **100**, whereby an applicable range of the table guide device can be broadened. In particular, in a case where a pair of the track rails are used, the paired track rails are required to have a high attaching performance. However, the requirement for such attaching accuracy can be neglected in this case because of using one track rail.

Further, in a case where such paired movable blocks **4** and **4** are assembled to one track rail **100**, as a matter of course, the movable block shown in FIGS. **4** and **6** will also be applicable to the device as the movable blocks **4**.

According to the present invention as described above, the movable block is formed in an L-shape in section and has a load bearing structure in which only the upper surface and one side surface of the track rail are supported by the horizontal portion and the suspending portion at a right angle, so that it becomes possible to increase a degree of freedom in a direction for inclining the horizontal portion and the suspending portion around a corner portion between the horizontal portion and the suspending portion. Therefore, even if the track rail and the movable block are formed with a working error or the device is formed with an error in a degree of parallelism between a mating surface to which the track rail is attached and a mating surface to which the movable block is fixed, a position of the movable block can be automatically controlled or adjusted by displacing the contact points of the rolling balls rolling in the ball rolling grooves.

In addition, each of the ball rolling grooves is formed so as to have a deep-grooved shape. Therefore, even if the contact points of the rolling balls are displaced by the automatically controlling function, the rolling balls will contact to intermediate portions of an inner circumferential surface of the ball rolling groove, the intermediate portions being far deep positions from a side peripheral edge portion of the ball rolling groove. As a result, a load to be applied to the rolling ball can be dispersed and supported by the inner circumferential surface of the ball rolling groove, and there is no fear of edge-load being applied to the side peripheral corner portion of the ball rolling groove, thus achieving a high automatic controllability.

Further, the movable block is formed to be opened at one side thereof, so that the movable block can be subjected to a grinding work using a large-sized grinding stone to form the ball rolling grooves. In addition, even in a case of the deep-groove type, the grinding work can be performed at a high efficiency, thus improving the productivity of the device.

Furthermore, the movable block is formed in an L-shape and has no under-cut portion, and the track rail is also formed in a simple rectangular-shape in section, so that the movable block can be easily formed by a drawing operation and the productivity can be improved.

On the other hand, a contacting direction of the ball row disposed at the ball rolling grooves formed to the upper surface of the track rail is set to extend toward the track rail and is formed so as to incline toward a side of the suspending portion of the movable block with respect to a vertical line passing a center of the rolling ball, while a contact direction of the ball row disposed at the side surface of the track rail is set to extend toward the track rail and is formed so as to incline toward a side of the horizontal portion of the movable block with respect to a horizontal line passing a center of the rolling ball. Due to the structure described above, a load to be applied in four directions can be born by a single movable block.

In addition, when each of the upper surface and the side surface of the track rail is arranged with at least two rows of rolling balls respectively and at least two rows of the rolling balls arranged at the upper surface and the side surface of the track rail have a contact-angle structure in which the contact angle lines of the respective rolling balls are inclined in the same direction, the load bearing ability can be increased without impairing the automatic controllability between the track rail and the movable block.

In addition, when at least one of a return passage constituting the ball returning passage structure and an inner circumference guide portion constituting an inner circumferential guide structure of the ball rolling direction turning passage is formed of a molding-shaped portion which is integrally formed to the movable block body by an insert molding method in which the mold-shaping operation is performed by inserting the movable block body into a shaping mold, the mold-shaping of the movable block can be easily performed.

In addition, when the horizontal portion and the suspended portion are fastened to a table, the movable block is reinforced by the table, so that the rigidity of the device can be increased.

Further, when the position of the ball rolling grooves to be formed on the upper surface of the track rail is arranged to one side portion and the bolt inserting hole for fastening the track rail is formed at the other side portion, it can be possible to prevent an extraneous substance from invading into the ball rolling grooves.

Furthermore, when the horizontal portion of the movable block is provided with a skirt portion having a length shorter than that of the suspending portion, the skirt portion being formed at a side surface opposing to the side surface of the horizontal portion to which the suspending portion is formed, and a row of rolling balls are disposed to be rollable between corresponding a pair of ball rolling grooves formed to the skirt portion and the side surface of the track rail, even if a load in a direction for lifting the movable block from the track rail is applied to the device, the movable block is firmly supported by not only one side surface but also both side surfaces of the track rail, so that the load bearing ability against the lifting load can be increased.

On the other hand, according to the table guide device of this invention, a pair of right and left movable blocks are fixed to the table, so that the device as a whole has a construction in which the side surfaces of the right and left track rails are clamped by the suspended portions of the respective right and left movable blocks. Therefore, as a whole, the rigidity in the direction for rotating the movable blocks around the track rails is increased, and there can be realized a table guide device having a high load bearing performance against the loads in every direction including the horizontal and vertical directions.

Further, even if there are working errors or the like to attaching surfaces of the track rails and the movable blocks, the automatic controlling function of the linear motion guide device is effected as described above, so that the misalignment between the track rail and the movable block is absorbed and automatically controlled by the displacements of the contact points of the balls rolling within the ball rolling grooves. As a result, the table can be smoothly guided.

In addition, the ball rolling grooves can be simultaneously formed by a grinding operation in a state where the two rows of track rails are fixed in parallel to each other, so that the parallel tracks and grooves having a high accuracy can be obtained.

Furthermore, when the table is provided with supporting walls for supporting rear surfaces of the suspending portions of the respective right and left movable blocks, the load in a horizontal direction applied to the table is directly transferred to the movable blocks not through the attaching bolts but through the supporting walls, and then the load is transferred from the movable blocks to the track rails thereby to be directly supported by the reference walls of the fixed bed. Accordingly, the load in a horizontal direction would not apply from a shearing direction to the attaching bolt for fastening the movable block or the attaching bolt for fastening the track rail, so that there can be provided a table guide device with a structure having an extremely high rigidity.

In addition, a preload controlling mechanism is provided between at least one of the supporting walls and the suspending portion of the movable block, the preload controlling mechanism being constructed in a manner that the movable block is forcibly pressed to a side of the track rail by utilizing the supporting wall as a supporting member so as to increase a preload of the balls disposed between the movable blocks and track rails, a reaction force applied to the supporting wall as a reaction force of the pressing force is applied to another supporting wall through the table, then a suspending portion of another movable block is pressed to another track rail by the reaction force, thereby to increase the preload of the balls. When the preload controlling mechanism described above is provided for the table guide device, the supporting rigidity of the whole table can be increased.

In particular, when a tapered gib formed of a block body face-contacting to the rear surface of the suspending portion is used as the preload controlling mechanism and disposed between the supporting wall and the suspending portion of the movable block, it is possible to uniformly impart the preload to the ball rows. In addition, the rigidity between the suspending portion and the supporting wall can also be maintained to a high level.

INDUSTRIAL APPLICABILITY

As described above, the linear motion guide device and the table guide device using the linear motion guide device according to the present invention are valuable as a linear guide mechanism for various industrial equipments such as machine tool, inspection instrument, robot operating system or the like.

What is claimed is:

1. A linear motion guide device comprising:

a track rail having a rectangular-shape in section and at least one ball rolling groove formed to both an upper surface and one side surface of the track rail, respectively;

a movable block having an L-shape in section, comprising a horizontal portion provided with ball rolling grooves corresponding to ball rolling grooves formed to the upper surface of the track rail and a suspending portion provided with ball rolling grooves corresponding to ball rolling grooves formed to the one side surface of the track rail; and

a row of rolling balls disposed to be rollable between corresponding ball rolling grooves formed to the upper surface of the track rail and the horizontal portion of the movable block and between corresponding ball rolling grooves formed to the side surface of the track rail and the suspending portion of the movable block, respectively;

wherein each of the ball rolling grooves has a circular-arc-shape in section having a deep-groove shape having a groove depth of approximately ⅓ to ½ of a diameter of the rolling ball.

2. A linear motion guide device according to claim **1**, wherein a contact angle line constituted by a line connecting two contact points of the rolling ball disposed between the corresponding ball rolling grooves formed to the horizontal portion of the movable block and the upper surface of the track rail is set to extend toward the track rail and is formed so as to incline toward a side of the suspended portion with respect to a vertical line passing a center of the rolling ball, and

a contact angle line constituted by a line connecting the two contact points of the rolling ball disposed between the corresponding ball rolling grooves formed to the suspending portion of the movable block and the side surface of the track rail is set to extend toward the track rail and is formed so as to incline toward a side of the horizontal portion with respect to a horizontal line passing a center of the rolling ball.

3. A linear motion guide device according to claim **2**, wherein said upper surface and the side surface of the track rail are arranged with at least two rows of rolling balls respectively, and said at least two rows of the rolling balls disposed at the upper surface and the side surface of the track rail have a contact-angle structure in which the contact angle lines of the respective rolling balls are inclined in the same direction.

4. A linear motion guide device according to claim **3**, wherein said horizontal portion of the movable block is provided with a skirt portion having a length shorter than that of the suspending portion, the skirt portion being formed at a side surface opposing to the side surface of the horizontal portion to which the suspending portion is formed, and a row of rolling balls is disposed to be rollable between a pair of ball rolling grooves formed to the opposing surfaces of the skirt portion and the side surface of the track rail.

5. A linear motion guide device according to any one of claims **1**, **2** and **3**, wherein said movable block comprise a movable block body having a loaded ball rolling groove and a ball returning passage for returning the ball in the loaded ball rolling groove from one end to the other end of the loaded ball rolling groove and side covers provided for both end portions of the movable block body, the side cover constituting a ball turning passage for changing a ball rolling direction by receiving the rolling ball from the loaded ball rolling groove and then guiding the rolling ball to the ball returning passage,

wherein at least one of a ball returning passage constituting the ball returning passage structure and an inner circumferential portion constituting an inner circumferential structure of the ball turning passage is formed of a molding-shaped portion which is integrally formed to the movable block body by an insert molding method in which the mold-shaping operation is performed by inserting the movable block body into a shaping mold.

6. A linear motion guide device according to any one of claims **1**, **2**, **3** and **4**, wherein said horizontal portion of the movable block is provided with two rows of ball rolling grooves while said suspending portion is also provided with two rows of ball rolling grooves, and bolt holes for inserting attaching-bolts are formed to both central portions between said two rows of the ball rolling grooves of the horizontal portion and the suspending portion, respectively.

7. A linear motion guide device according to any one of claims **1**, **2**, **3** and **4**, wherein said plural rows of ball rolling grooves to be formed on the upper surface of the track rail are locally disposed to one side surface side of the track rail and a bolt hole for inserting the attaching bolt is formed in a region on the upper surface of the track rail close to the other side surface of the track rail.

8. A table guide device comprising a fixed bed, a pair of linear motion guide devices arranged in parallel with the fixed bed and a table to be assembled through said paired linear motion guide devices,

wherein each of said linear motion guide devices comprises: a track rail having a rectangular-shape in section and at least one ball rolling groove formed to both an upper surface and one side surface of the track rail to be fixed to said fixed bed; a movable block having an L-shape in section, comprising a horizontal portion provided with ball rolling grooves corresponding to ball rolling grooves formed to the upper surface of the track rail and a suspending portion provided with ball rolling grooves corresponding to ball rolling grooves formed to the one side surface of the track rail; and a row of rolling balls disposed to be rollable between corresponding ball rolling grooves formed to the upper surface of the track rail and the horizontal portion of the movable block and between corresponding ball rolling grooves formed to the side surface of the track rail and the suspended portion of the movable block, respectively, in which each of said ball rolling grooves has a circular-arc-shape in section having a deep-groove shape having a groove depth of approximately ⅓ to ½ of a diameter of the rolling ball; and

wherein said paired track rails of said paired linear motion guide devices are symmetrically disposed on the upper surface of said fixed bed so that the side surfaces of the track rails to which the ball rolling grooves are formed are faced to inside or outside to each other, said side surface of the track rail opposing to the side surface to which the ball rolling grooves are formed is set to be a reference surface for attachment, and said fixed bed is provided with a reference wall for supporting said reference surface for attachment of the track rail.

9. A table guide device according to claim **8**, wherein said reference wall is formed so as to have a height corresponding to a height of said ball rolling groove formed to the side surface opposing to the reference surface for attachment.

10. A table guide device according to claim **8**, wherein a contact angle line constituted by a line connecting two contact points of said rolling ball disposed between the corresponding ball rolling grooves formed to the horizontal portion of said movable block and the upper surface of said track rail is set to extend toward the track rail and is formed so as to incline toward a side of the suspended portion of the movable block with respect to a vertical line passing a center of the rolling ball, and

a contact angle line constituted by a line connecting the two contact points of the rolling ball disposed between the corresponding ball rolling grooves formed to the suspending portion of the movable block and the side surface of the track rail is set to extend toward the track rail and is formed so as to incline toward a side of the horizontal portion of the movable block with respect to a horizontal line passing a center of the rolling ball.

11. A table guide device according to any one of claims **8**, **9** and **10** wherein said table is provided with supporting walls for supporting rear surfaces of said suspending portions of the respective right and left movable blocks.

12. A table guide device according to claim **11**, wherein said table guide device further comprises a preload controlling mechanism provided between at least one of said supporting walls and said suspending portion of the movable block, the preload controlling mechanism being constructed in a manner that the movable block is forcibly pressed to a side of the track rail by utilizing the supporting wall as a supporting member so as to increase a preload of the balls disposed between the movable blocks and track rails, a reaction force applied to the supporting wall as a reaction force of the pressing force is applied to another supporting wall through the table, then a suspending portion of another movable block is pressed to another track rail by the reaction force thereby to increase the preload of the balls.

13. A table guide device according to claim **12**, wherein said preload controlling mechanism is disposed between said supporting wall and said suspending portion of the movable block and is composed of a tapered gib formed of a block body face-contacting to a rear surface of said suspending portion.

14. A table guide device according to claim **8**, wherein each of said upper surface and said side surface of the track rail is provided with at least two rows of rolling balls, and the respective two rows or more of rolling balls formed to the upper surface and the side surface of said track rail have a contact angle arrangement so that the contact angle lines thereof are inclined to the same direction to each other.

15. A table guide device according to claim **8**, wherein said horizontal portion of the movable block is provided with a skirt portion having a length shorter than that of the suspending portion, said skirt portion being formed at a side surface opposing to the side surface of said horizontal portion to which the suspending portion is formed, and a row of rolling balls is disposed to be rollable between corresponding a pair of ball rolling grooves formed to said skirt portion and the side surface of the track rail.

16. A linear motion guide device comprising:

a track rail provided with at least one ball rolling groove formed respectively to right and left half portions of an upper surface and lateral right and left side surfaces of said track rail;

a pair of movable blocks provided on right and left corner portions between the upper surface and lateral side surfaces of said track rail, each of said movable blocks having an L-shaped cross section and further comprising a horizontal portion provided with ball rolling grooves corresponding to the ball rolling grooves formed to the right and left half portions of the upper surface of said track rail and a suspending portion provided with ball rolling grooves corresponding to the ball rolling grooves formed to said lateral side surfaces of the track rail;

a row of rolling balls disposed to be rollable between the ball rolling grooves formed to the upper surface of said track rail and the horizontal portions of the paired movable blocks and between the ball rolling grooves formed to the lateral side surfaces of the track rail and the suspending portions of the paired movable blocks;

wherein each of said ball rolling grooves is formed to be a deep-grooved shape having a circular-arc-shape in section, and a groove depth is set to approximately ⅓ to ½ of a diameter of the rolling ball.

17. A linear motion guide device according to claim **16**, wherein a contact angle line constituted by a line connecting two contact points of the rolling ball disposed between the corresponding ball rolling grooves formed to the horizontal portions of the paired movable blocks and the upper surface of the track rail is set to extend toward the track rail and is formed so as to incline toward a side of the respective suspending portions of the paired movable blocks with respect to a vertical line passing a center of the rolling ball, and

a contact angle line constituted by a line connecting two contact points of the rolling ball disposed between the corresponding ball rolling grooves formed to the suspending portions of the paired movable blocks and the side surface of the track rail is set to extend toward the track rail and is formed so as to incline toward a side of the horizontal portion of the respective movable blocks with respect to a horizontal line passing a center of the rolling ball.

18. A linear motion guide device according to claim **17**, wherein each of right and left half portions of said upper surface and said lateral right and left side surfaces of the track rail is provided with at least two rows of rolling balls, and the respective two rows or more of rolling balls formed to said upper surface and the lateral side surfaces of said track rail have a contact angle arrangement so that the contact angle lines thereof are inclined to the same direction to each other.

19. A linear motion guide device according to any one of claims **16**, **17** and **18**, wherein said track rail is a rail having a wide width.

20. A table guide device comprising a fixed bed to which a track rail of a linear motion guide device according to any one of claims **16** to **18** having a first and a second movable blocks is fixed and a table fixed to the first and second movable blocks.

(57) **ABSTRACT**

A movable table unit capable of carrying out an operation for rotating a movable table at a position other than an original point and an operation for moving it in parallel after rotating at a predetermined angle by a simple control, capable of moving the rotation center linearly along two axes easily, and further moving the movable table largely along a single axis, is provided. The movable table unit for achieving this object comprises a table base plate, a movable table supported movably on the table base plate, a plurality of moving members joined to a bottom surface of the movable table, a plurality of two-axis guiding systems for guiding each of the moving members along two axes intersecting with each other on the table base plate and for guiding largely along an axis, rotation systems for supporting the movable table or moving members rotatably relative to each of the two-axis guiding systems and a plurality of driving systems for moving each of the moving members selectively along any one of the two axial directions so as to provide the movable table with a linear motion along the two axes and for providing the movable table with a rotation motion around an axis perpendicular to the table base plate.

MOVABLE TABLE UNIT

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a movable table unit for use in a precision printing machine, a precision processing machine, a precision manufacturing machine or the like, and more specifically to a movable table unit which is mounted movably relative to a table base plate along two axes intersecting each other and rotatably relative to an axis perpendicular to a plane formed by the two axes.

2. Description of the Related Art

As a movable table unit for use in the aforementioned precision printing machine, a precision processing machine, a precision manufacturing machine or the like, so-called XY table in which a movable table is mounted movably relative to a table base plate along two axes intersecting each other has been often used.

Conventionally, as a movable table unit for use in the precision printing machine, the precision processing machine, the precision manufacturing machine or the like, so-called XY table in which a movable table is mounted movably along two axes intersecting each other with respect to a table base plate has been often used. In this XY table, a work placed on the movable table is moved along two axes, X and Y axes independently. In the precision printing machine or the like, not only an operation for moving a printing work placed on the movable table along the two axes, but also an operation for rotating it around an axis perpendicular to a plane formed by the two axes are required depending on the case.

Therefore, as the movable table for use in the precision printing machine or the like, an apparatus called "XYθ table" has been used, in which the movable table is not only mounted movably along the two axes intersecting each other with respect to the table base plate but also rotatably around an axis perpendicular to a plane formed by the two axes.

The technology relating to this XYθ table has been already disclosed in, for example, Unexamined Published Japanese Patent Application No.HEI8-99243, Unexamined Published Japanese Patent Application No.HEI1-240246, Unexamined Published Japanese Patent Application No.HEI1-242989, Unexamined Published Japanese Patent Application No.HEI4-210347, Unexamined Published Japanese Patent Application No.HEI8-211173, Unexamined Published Japanese Patent Application No.HEI8-252733, Unexamined Published Japanese Patent Application No.HEI9-42405, Unexamined Published Japanese Patent Application No.HEI9-155666, Unexamined Published Japanese Patent Application No.HEI9-216138, Unexamined Published Japanese Utility Model Application No.2515316, Unexamined Published Japanese Patent Application No.HEI4-354637, Unexamined Published Japanese Patent Application No.HEI6-31563, Unexamined Published Japanese Patent Application No.HEI7-219636, Unexamined Published Japanese Patent Application No.HEI5-77125, Unexamined Published Japanese Patent Application No.HEI4-2435, Unexamined Published Japanese Patent Application No.HEI3-56895, Unexamined Published Japanese Patent Application No.HEI2-202031, Unexamined Published Japanese Patent Application No.SHO62-282294 and the like.

The XYθ tables will be explained about a typical example thereof. In the longitudinally/laterally moving rotation table unit according to Unexamined Published Japanese Patent Application No.HEI8-99243, a movable table is supported on a base movably in all directions through three XY linear guide systems and a driving force is applied to moving blocks possessed by these XY linear guide systems through an independent ball screw unit. A upper rail possessed by each XY linear guide system is fixed to a bottom surface of the movable table. Upper and lower blocks possessed by the XY linear guide system are connected to each other with pins and bearing such that they are freely rotatable.

In the movable table according to Unexamined Published Japanese Utility Model No.2515316, the movable table is supported freely movably in all directions through a thrust bearing on a base. Three driving units are mounted in directions perpendicular to each other and output shafts of these driving units are connected to the movable table through a joint.

However, the above described conventional arts have the following problems. That is, in case of the longitudinally/laterally moving rotation table unit according to the Unexamined Published Japanese Patent Application No.HEI8-99243, a movable table is supported freely movably in all directions through three XY linear guide systems on the base and a driving force is applied to each of moving blocks possessed by these XY linear guide systems through an independent ball screw unit. Therefore, to rotate the movable table at a position other than an original point or move the movable table in parallel after it is rotated by a predetermined angle, the three XY linear guide systems have to be moved by different amounts mutually relating to one another, so that the table motion control becomes complicated. Also, in case of the longitudinally/laterally moving rotation table unit according to Unexamined Published Japanese Patent Application No.HEI8-99243, there is another problem, because the rotation center of the movable table is deviated due to motions thereof in the XY directions; it is difficult to carry out such a processing as printing or the like on a work placed on the movable table by rotating the movable table while moving it linearly along an axis after the movable table is positioned in the XY plane. Additionally, in case of the longitudinally/laterally moving rotation table unit according to the aforementioned Unexamined Published Japanese Patent Application No.HEI8-99243, the movable table is supported freely movably in all directions through three XY linear guide systems. Thus, further problem is that when a work is mounted or dismounted on/from the movable table, the movable table cannot be moved largely along a single axis even if it is requested.

On the other hand, in case of the movable table according to the aforementioned Unexamined Published Japanese Utility Model Application No.2515316, the movable table is supported movably in all directions through a thrust bearing on the base and three driving units intersecting each other are mounted on the base. Then, output shafts of the driving units are connected to the movable table through a joint. To rotate the movable table at a position other than an original point or move the movable table in parallel after it is rotated by a predetermined angle, the three driving units have to be moved by different amounts mutually relating to one another, so that the table motion control becomes complicated. Further, this invention has a problem that the rotation center of the movable table is deviated because of motions thereof in the XY directions and further has a problem that the movable table cannot be largely moved along an axis.

OBJECT AND SUMMARY OF THE INVENTION

Accordingly, the present invention has been made to solve the above described problems, and therefore, it is an object of the invention to provide a movable table unit capable of carrying out an operation for rotating a movable table at a position other than an original point and an operation for moving it in parallel after rotating by a predetermined angle by a simple control, capable of moving the rotation center linearly along two axes easily, and further moving the movable table largely along a single axis.

To achieve the above object, the present invention provides a movable table unit comprising: a table base plate; a movable table supported movably on the table base plate; a plurality of moving members joined to a bottom surface of the movable table; a plurality of two-axis guiding systems for guiding each of the moving members along two axes intersecting with each other on the table base plate and for guiding it largely along an axis; rotation systems for supporting the movable table or moving members rotatably relative to each of the two-axis guiding systems; and a plurality of driving means for moving each of the moving members selectively along any one of the two axial directions so as to provide the movable table with a linear motion along the two axes and for providing the movable table with a rotation motion around an axis perpendicular to the table base plate.

According to the above technological means, a plurality of the moving members are joined to a bottom surface of the movable table and each of these moving members is guided freely movably along two axes intersecting each other on the table base plate by the two-axis guiding system. Thus, by moving each of the moving members selectively along any one of the two axes by the driving means, the movable table can be moved linearly along each axis.

By combining the plural moving members to be moved by the driving means or selecting a direction of the motion thereof, a rotation moment force is applied to the movable table so as to provide the table with a rotation motion around an axis perpendicular to the table base plate.

Further, because the two-axis guiding system for guiding the moving member on the table base plate is so constructed that the moving member is guided largely along an axis, when a work to be placed on the moving table is mounted or dismounted, the movable table can be moved largely along an axis.

According to the present invention, an operation for rotating the movable table at a position other than an original point or an operation for moving the movable table in parallel after it is rotated by a predetermined angle can be carried out by a simple control, and an operation for moving the rotation center linearly along an axis can be carried out easily. Additionally, a movable table unit capable of moving the movable table largely along an axis can be provided.

According to the present invention, as the two-axis guiding system, for example, a system in which the movable member is guided movably along the X axis and Y axis which are perpendicular to each other, is used. However, the two axes guided by the two-axis guiding system are not restricted to the X-axis and Y-axis directions which are perpendicular to each other, but any two axes are permitted as long as they cross each other at a predetermined angle.

This two-axis guiding system, for example, comprises a track rail formed in a linear shape and a moving block formed to have a substantially C-shaped cross section and mounted movably to the track rail through a plurality of rolling bodies. That is, by stacking two two-axis guiding systems such that the track rails thereof intersect each other, the movable table can be guided in two directions which are perpendicular to each other. This is the same as the known

XY table. Further, it is permissible to employ a linear motion guide system which comprises a wide track rail formed in channel shape and a moving block mounted movably within a channel of the track rail through a plurality of rolling bodies.

Any rotation system may be used as long as the movable table or the moving member joined thereto is supported rotatably relative to each two-axis guiding system. For example, it is permissible to provide the rotation system between the movable table and moving member or it is also permissible to incorporate the rotation system in the two-axis guiding system for guiding the moving member.

However, in case where the rotation system is provided between the movable table and moving member, a force for driving the movable table is transmitted directly through the rotation system. Therefore, the driving force can be transmitted in a substantially parallel direction to a gravity center of the movable table. When the movable table is driven, unbalanced moment load is never applied to the rolling bodies or the like incorporated in the rotation system, so that the movable table can be moved smoothly.

Any two-axis guiding system may be used as long as it is capable of receiving a load in the lateral direction. Not only other type of linear bearing using the rolling guide but also the sliding bearing can be used.

Further, the driving means is constituted of, for example, a screw feeding (ball screw or the like) mechanism and the nut portion meshing with the feeding screw shaft is provided in the two-axis guiding system or moving member. If the driving means is constituted of a screw feeding mechanism, a position in the direction of the screw shaft is determined when the screw shaft is stopped. This driving means is not restricted to the screw feeding mechanism, but for example, an actuator (e.g., made by ORIENTARU MOTOR Co.) in which a shaft reciprocates linearly can be used. Meanwhile, although the driving means is mounted on the table base plate which is a fixed side, it may be also mounted to the movable table which is a movable side.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a plan view showing a first embodiment of a movable table of the present invention;

FIG. **2** is a partially broken-away side view showing the movable table unit according to the first embodiment;

FIG. **3** is a front sectional view showing the two-axis guiding system;

FIG. **4** is a side sectional view showing the two-axis guiding system;

FIG. **5** is a perspective view showing the two-axis guiding system;

FIG. **6** is a front view showing a cross section of a first concave portion of the two-axis guiding system;

FIG. **7** is a sectional view showing arrangement of balls in the first concave portion of the two-axis guiding system;

FIG. **8** is a front view showing a cross section of a second concave portion of the two-axis guiding system;

FIG. **9** is a sectional view showing arrangement of balls in the second concave portion of the two-axis guiding system;

FIG. **10** is a partially broken-away perspective view showing a rotation system;

FIG. **11** is a sectional view of major portions showing a mounting condition of the rotation system;

FIG. **12** is a plan view showing a case in which the movable table according to the first embodiment has been moved in the Y-axis direction;

FIG. **13** is a plan view showing a case in which the movable table according to the first embodiment has been moved in the X-axis direction;

FIG. **14** is a plan view showing a case in which the movable table according to the first embodiment has been rotated;

FIG. **15** is an explanatory view showing forces to be applied to the movable table according to the first embodiment;

FIG. **16** is an explanatory view showing a rotation angle of the movable table according to the first embodiment of the present invention;

FIG. **17** is a plan view showing a second embodiment of the movable table of the present invention;

FIG. **18** is a partially broken-away side view showing the movable table according to the second embodiment;

FIG. **19** is a front sectional view showing the two-axis guiding system according to the fourth embodiment of the movable table unit of the present invention; and

FIG. **20** is a side sectional view showing the two-axis guiding system according to the fourth embodiment of the movable table of the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Hereinafter, a movable table unit of the present invention will be described in detail with reference to the accompanying drawings.

Embodiment 1

FIGS. **1** and **2** are construction diagrams showing a first embodiment of the movable table unit of the present invention.

As shown in FIGS. **1** and **2**, the movable table unit **1** of the first embodiment comprises a table base plate **2**, a movable table **3**, moving members **13**, **14**, **15** joined to a bottom face of this movable table, three two-axis guiding systems $\mathbf{4}_1$, $\mathbf{4}_2$, $\mathbf{4}_3$ for guiding movably these moving members **13**, **14**, **15** along both X and Y axes perpendicular to each other and guiding them largely movably along the Y axis, a rotation system **31** for joining the aforementioned movable table **3** to the moving members **13**, **14**, **15** freely rotatably, a first driving means **5** for driving the moving member **13** guided by the first two-axis guiding system $\mathbf{4}_1$ along the Y-axis, and two secondary driving means **6**, **7** for driving the moving members **14**, **15** guided by the second and third two-axis guiding systems $\mathbf{4}_2$, $\mathbf{4}_3$ independently along the X-axis.

As shown in FIGS. **1** and **2**, the aforementioned table base plate **2** is formed in the shape of a flat rectangular plate and the movable table **3** is formed in the shape of a disk having a slightly smaller diameter than the width of the table base plate **2**. Three two-axis guiding systems $\mathbf{4}_1$, $\mathbf{4}_2$, $\mathbf{4}_3$ are disposed at each predetermined position on the table base plate **2**. As shown in FIG. **1**, in an initial state before the driving is started, the positions P_1, P_2, P_3 of rotation shafts of the first, second and third two-axis guiding systems $\mathbf{4}_1$, $\mathbf{4}_2$, $\mathbf{4}_3$ for supporting the movable table **3** rotatably are disposed so as to be located on a single circle C formed around an original position **0**. The first, second and third two-axis guiding systems $\mathbf{4}_1$, $\mathbf{4}_2$, $\mathbf{4}_3$ are joined to the movable table **3** freely rotatably under a positional relation shown in FIG. **1**. That is, the first two-axis guiding system $\mathbf{4}_1$ is joined to the movable table **3** at the position P_1 intersecting the circle C on the X-axis with respect to the rotation center O of the movable table **3**, and the other second and third two-axis guiding systems $\mathbf{4}_2$, $\mathbf{4}_3$ are joined to the movable table **3** at the positions P_2, P_3 on the circle C which are symmetrical relative to the X axis.

As shown in FIG. **1**, the track rail **8** in the Y-axis direction for the first two-axis guiding system $\mathbf{4}_1$ is installed near an end in the width direction (X-axis direction) of the table base plate **2** such that it spans an entire length of the table base plate **2** along the length direction (Y-axis direction) thereof. Of the aforementioned three two-axis guiding systems, the second and third two-axis guiding systems $\mathbf{4}_2$, $\mathbf{4}_3$ use the track rail **9** in the Y-axis direction commonly, and the track rail **9** in the Y-axis direction is installed near the other end in the width direction of the table base plate **2** so that it spans an entire length of the table base plate **2** along the length direction thereof and it is parallel to the track rail **8** of the first two-axis guiding system $\mathbf{4}_1$.

The three two-axis guiding systems $\mathbf{4}_1$, $\mathbf{4}_2$, $\mathbf{4}_3$ are constructed in the same way, comprising the track rails **8**, **9** in the Y-axis direction with a long span installed on the table base plate **2**, moving blocks **10**, **11**, **12** mounted to the track rails **8**, **9** in the Y-axis direction freely movably through a plurality of balls as rolling bodies, and short X-axis direction track rails **13**, **14**, **15** mounted freely movably in a direction perpendicular to the track rails **8**, **9** through a plurality of balls as rolling bodies to the moving blocks **10**, **11**, **12**. These short track rails **13**, **14**, **15** are joined to the moving table as a moving member.

Further, a structure of the two-axis guiding systems $\mathbf{4}_1$, $\mathbf{4}_2$, $\mathbf{4}_3$ will be described in detail. As shown in FIGS. **3**, **4**, the two-axis guiding systems $\mathbf{4}_1$, $\mathbf{4}_2$, $\mathbf{4}_3$ is a linear guiding system comprising the track rails **8**, **9** in the Y-axis direction, the moving blocks **10**, **11**, **12** and the track rails **13**, **14**, **15** in the X-axis direction for guiding the movable table **3** freely movably along two axes (XY axes) intersecting each other and supporting the movable table **3** freely rotatably. As shown in FIG. **3**, a guiding portion **16** is formed on a upper portion of the track rails **8**, **9** in the Y-axis direction such that it is protruded in a trapezoidal shape to both the sides thereof. Two ball rolling grooves **18** in which a plurality of balls **17** as rolling bodies roll are formed on corner portions located up and down of the right and left guide portions **16**, totaling four ball rolling grooves. As shown in FIG. **3**, a first concave portion **19** having a C-shaped cross section in which each of the track rails **8**, **9** in the Y-axis direction is inserted, is provided in a bottom face of the moving blocks **10**, **11**, **12** and as shown in FIG. **4**, a second concave portion **20** having a C-shaped cross section in which each of the track rails **13**, **14**, **15** in the X-axis direction is inserted, is provided in a top face of the moving blocks **10**, **11**, **12** such that the second concave portion **20** intersects the first concave portion **19**. Further, as shown in FIG. **6**, four ball rolling grooves **21** are provided in right and left inner faces of the first concave portion **19** of the moving blocks **10**, **11**, **12** opposing the right and left side faces of the track rails **8**, **9** in the Y-axis direction such that they are located at positions corresponding to the right and left ball rolling grooves of the track rails **8**, **9** in the Y-axis direction.

As shown in FIGS. **5**, **6**, four ball escaping paths **22** are provided corresponding to the four ball rolling grooves **21** of the first concave portion **19** in the lower portion of the moving blocks **10**, **11**, **12** such that they are in parallel to each other. In the lower portion of the moving blocks **10**, **11**, **12**, as shown in FIG. **7**, side lids **24** containing four direction changing paths **23** for connecting the ball rolling grooves **21** of the moving blocks **10**, **11**, **12** with the ball escaping paths **22** on both ends are provided on both end portions in the length direction of the first concave portion **19**.

The contact directions of the four rows of the balls **17** interposed between the track rails **8**, **9** in the Y-axis direction and the first concave portion **19** are inclined at a predetermined angle α with respect to a horizontal line H passing through the center of the upper and lower ball rows, such that they are symmetrical thereto, as shown in FIG. **6**. In this embodiment, an outward opening contact structure is applied, in which the contact angle line L connecting the center of each ball **17** and a contact point thereof with the ball rolling groove **21** is closed in an inward direction of the first concave portion **19** and opened in an outward direction which is opposite to the first rolling groove **21**. Consequently, an appropriate preliminary pressure is applied to the balls **17**. Of course, an inward opening contact structure which is opened in an inward direction of the first concave portion **19** may be utilized.

On the other hand, as shown in FIGS. **5**, **8**, two ball rolling grooves **26** in which balls **25** roll are provided on each of the right and left sides of the track rails **13**, **14**, **15** in the X-axis direction and totally four ball rolling grooves **26** are provided. Four ball rolling grooves **27** corresponding to the ball rolling grooves **26** of the track rails **13**, **14**, **15** in the X-axis direction are provided on the right and left inner faces of the second concave portion **20** of the moving blocks **10**, **11**, **12** opposing the right and left side faces of the track rails **13**, **14**, **15** in the X-axis direction.

Further, in the upper end portion of the moving blocks **10**, **11**, **12**, four ball escaping paths **28** corresponding to the four ball rolling grooves **27** of the second concave portion **20** are provided in parallel to each other. As shown in FIG. **9**, side lids **30** containing four direction changing paths **29** for connecting both ends of each ball rolling grooves **27** of the moving blocks **10**, **11**, **12** and both ends of the ball escaping paths **28** are provided on both end portions of the second concave portion **20** of the moving blocks **10**, **11**, **12**.

Further, as shown in FIG. **8**, contact directions of four rows of the balls **25** interposed between the track rails **13**, **14**, **15** in the X-axis direction and the second concave portion **20** are inclined at a predetermined angle α with respect to the horizontal line H passing through the center of the ball rolling grooves **26** of the upper and lower rows, such that they are symmetrical thereto. In this embodiment, outward opening contact structure is employed, in which a contact angle line L connecting the center of the ball **25** with a contact point of the ball rolling groove **26** is closed in an inward direction of the second concave portion **20** and opened in an outward direction of the second concave portion **20**. Of course, inward opening contact structure which is opened in an inward direction of the second concave portion **20** may be utilized. An appropriate preliminary pressure is applied to the balls **25**.

A rotation system **31** for supporting the movable table **3** freely rotatably with respect to the track rails **13**, **14**, **15** in the X-axis direction of the three two-axis guiding systems 4_1, 4_2, 4_3 will be described in detail.

As shown in FIGS. **3**, **4**, **10**, **11**, the rotation system **31** contains inner track ring **32** and outer track ring **33**, which are formed in a circular shape. These inner and outer track rings **32**, **33** are disposed concentrically such that they engage each other. In this embodiment, the track ring fixed to the track rails **13**, **14**, **15** in the X-axis direction is the inner track ring **32** and the track ring fixed to the movable table **3** is the outer track ring **33**. A plurality of rollers **34** as rolling bodies are disposed between both the track rings **32** and **33**.

As shown in FIGS. **3**, **4**, the aforementioned inner track ring **32** is joined to the linear track rails **13**, **14**, **15** in the X-axis direction through a joint member **70**. This joint member **70** comprises a first joint plate **71** to which the track rails **13**, **14**, **15** in the X-axis direction are fixed and a disc-shaped second joint plate **72** to which the inner track ring **32** is fixed, and the first joint plate **71** and the second joint plate **72** are fixed to each other with a bolt **73**. A step concave portion **74** is provided on an outer periphery of the second joint plate **72** and the inner track ring **32** is mounted on this step concave portion **74** from upward. A pressing member **75** is fixed to a top end face of the step concave portion **74** by screwing a bolt, so that the inner track ring **32** is fixed in a condition in which it is nipped from up and down between the pressing member **75** and a step portion **74*a*** located at the root of the step concave portion **74**.

On the other hand, the movable table **3** to which the outer track rail **33** is to be fixed includes a circular opening portion **76**, in which the pressing member **75** of the inner track ring **32** can be inserted from up and a circular step concave portion **77** is provided on a lower edge of the internal periphery of the opening portion **76**. The outer track ring **33** is mounted on this step concave portion **77**. Further, a pressing member **78** for pressing the outer track ring **33** is fixed to an opening edge of the step concave portion **77** by tightening a bolt **73**, so that the outer track ring **33** is held between this pressing member **78** and the step portion **77*a*** of the step concave portion **77** in a condition in which it is nipped from up and down.

As shown in FIG. **11**, a first track groove **37** constituted of upper and lower roller rolling surfaces **35**, **36** which are opened outward in the radius direction at a substantially 90° is formed on an outer peripheral face of the inner track ring **32**. On the other hand, a second track groove **40** constituted of two upper and lower roller rolling surfaces **38**, **39** which are opened inward in the radius direction at an angle of substantially 90° opposing the first track groove **37** is formed on an inner peripheral face of the outer track ring **33**.

As shown in FIG. **10**, a part of the rollers **34** interposed between the first track groove **37** and the second track groove **40** are interposed between a upper roller rolling face **35** of the first track groove **37** and a lower roller rolling face **36** of the second track groove **40** such that they are freely rotatable. The remaining rollers **34** are interposed between a lower roller rolling face **36** of the first track groove **37** and a upper roller rolling face **38** of the second track groove **40** such that they are freely rotatable.

The rollers **34** interposed between the upper roller rolling surface **35** of the first track groove **37** and the lower roller rolling surface **39** of the second track groove **40** such that they are freely rotatable, and the rollers **34** interposed between the lower roller rolling face **36** of the first track groove **37** and the upper roller rolling face **38** of the second track groove **40** such that they are freely rotatable, are so constructed in so-called "cross rotor type", in which both of the rollers **34** are arranged such that they intersect each other alternately. As shown in FIG. **10**, a spacer retainer **41** is interposed between the rollers **34**.

As for the arrangement of the rollers **34**, the rollers **34** may be arranged not such that their rotating axes intersect each other alternately, but such that their rotating axes change their directions every two or three rollers. The rollers **34** may be arranged in various ways. A plurality of the rollers **34** interposed between the inner track ring **32** and outer track ring **33** are supplied with a preliminary pressure. As for application of the preliminary pressure, according to this embodiment, as shown in FIG. **11**, the inner track ring **32** is divided to the upper and lower portions **32*a***, **32*b***, and a gap is formed between the upper and lower portions **32*a*** and **32*b*** of the inner track ring **32** in a condition that the upper and lower roller rolling faces **35**, **36** are in a free contact with the roller **34**, and then the upper and lower portions **32*a***, **32*b*** are tightened vertically until the gap therebetween is eliminated, thereby compressing each roller **34** by a predetermined amount to apply the preliminary pressure thereto.

As other structure for applying the preliminary pressure to the rollers **34**, it is permissible to provide a circumference of the outer track ring **33** with a slit (not shown), so that when the outer track ring **33** is mounted on the step concave portion **42** of the movable table **3**, the slit in the outer track ring **33** is narrowed to reduce the diameter thereof, thereby pressing the rollers **34** from the right and left sides to apply the preliminary pressure.

By constructing the rotation system **31** with a structure in which the rollers **34** are interposed between the inner track ring **32** and outer track ring **33**, it is possible to obtain a supporting structure having a high stiffness against a load from every direction including a load for compressing in the rotation axis direction, a load for pulling in the rotation axis direction, a load to be applied in a direction perpendicular to the rotation axis, a moment load for inclining the rotation axis and the like. Therefore, a light, highly stiff supporting structure can be obtained.

The movable table unit **1** according to the first embodiment, as shown in FIG. **1**, comprises a first driving means **5** for driving the moving block **10** of the first two-axis guiding system $\mathbf{4}_1$ along the Y axis having a large moving amount, and the second driving means **6**, **7** for driving the track rails **14**, **15** of the second and third two-axis guiding systems $\mathbf{4}_2$, $\mathbf{4}_3$ independently along the X axis.

As shown in FIGS. **1**, **2**, the first driving means **5** comprises a driving motor **45** such as a servo motor, stepping motor or the like and a feeding screw mechanism **46** for converting a rotating motion of the driving motor **45** to a linear motion. The aforementioned feeding screw mechanism **46** comprises a nut **48** joined to the moving block **10** of the first two-axis guiding system $\mathbf{4}_1$ through two brackets **47**, a long screw shaft **49** meshing with this nut **48**, double row angular contact type bearing **50** for supporting each end of this screw shaft **49** freely rotatably and a bearing support **51** for supporting this bearing **50**. The aforementioned driving motor **45** is fixed to an end portion in the length direction of the table base plate **2** through a bracket **52** and a motor shaft **53** is joined to a shaft end of the screw shaft **49** through a joint member **54**. The long screw shaft **49** of the feeding screw mechanism **46** is disposed in parallel near an end in the width direction of the table base plate **2** and along the track rail **8** in the Y-axis direction of the first two-axis guiding system $\mathbf{4}_1$.

The second driving means **6**, **7** are constructed in the same way, and as shown in FIGS. **1**, **2**, comprise a driving motor **55**, **56** such as a servo motor, stepping motor and the like, and a feeding screw mechanism **57**, **58** for converting a rotating motion of the driving motor **55**, **56** to linear motion. The aforementioned feeding screw mechanisms **57**, **58** each comprise a nut **61**, **62** joined to the moving block **11**, **12** of the second, third two-axis guiding system $\mathbf{4}_2$, $\mathbf{4}_3$ through a bracket **59**, **60** and a short screw shaft **63**, **64** which meshes with the nut **61**, **62**. The driving motors **55**, **56** are fixed to the track rails **14**, **15** in the X-axis direction of the second, third two-axis guiding system $\mathbf{4}_2$, $\mathbf{4}_3$ through brackets **65**, **66** and the short screw shafts **63**, **64** are directly connected to a motor shaft (not shown). In the aforementioned two second driving means **6**, **7**, the driving motors **55**, **56**, screw shafts **63**, **64** and the like are disposed symmetrically relative to the X axis in FIG. **1**.

In the movable table unit according to the first embodiment having the above described structure, turning the movable table at a position other than the original point, moving the movable table in parallel after turning it at a predetermined angle and the like can be carried out by a simple control, and further moving the rotation center linearly along the two axes can be carried out easily, and additionally moving the movable table largely along an axis can be carried out.

That is, in the movable table unit **1** according to the first embodiment, the movable table **3** is stopped at a position shown in FIG. **1** in an initial state before the movable table **3** is moved. For example, in case where the movable table **3** is moved in parallel to the Y axis from this state without changing the posture of the movable table **3**, the driving motor **45** of the first driving means **5** for driving the moving block **10** of the first two-axis guiding system $\mathbf{4}_1$ along the Y axis is driven in a predetermined direction so as to rotate the long screw shaft **49** joined to the motor shaft **53** of the driving motor **45**. Then, because the nut **48** meshing with the screw shaft **49** is fed in the Y-axis direction with a rotation of the screw shaft **49**, the moving block **10** of the first two-axis guiding system $\mathbf{4}_1$ fixed to the nut **48** meshing with the screw shaft **49** through a bracket **47** is also moved along the Y axis as shown in FIG. **12**. Consequently, the movable table **3** joined to the moving block **10** of the first two-axis guiding system $\mathbf{4}_1$ is moved at a predetermined distance y along the Y axis together with the track rail **13** of the first two-axis guiding system $\mathbf{4}_1$.

In case where the movable table **3** is moved in parallel to the X axis, the driving motors **55**, **56** of the second driving means **6**, **7** for driving the track rails **14**, **15** in the X-axis direction of the second, third two-axis guiding systems $\mathbf{4}_2$, $\mathbf{4}_3$ are driven in the same rotation direction so as to rotate the screw shafts **63**, **64** joined to motor shafts (not shown) of the driving motors **55**, **56** in the same direction. Then, because the nuts **61**, **62** meshing with the screw shafts **63**, **64** are joined to the moving blocks **11**, **12** of the second and third two-axis guiding systems $\mathbf{4}_2$, $\mathbf{4}_3$ which do not move along the X axis, through the brackets **59**, **60**, the screw shafts **63**, **64** meshing with the nuts **61**, **62** are moved in the same direction along the X axis with rotations thereof as shown in FIG. **13**. Thus, the driving motors **55**, **56** joined to the screw shafts **63**, **64** are moved in the same direction along the X axis (for example, leftward direction of FIG. **13**) with the screw shafts **63**, **64**. As a result, the movable table **3** joined to the track rails **14**, **15** in the X-axis direction freely rotatably through the rotation system **31** is moved by a predetermined amount along the X axis, together with the track rails **14**, **15** in the X-axis direction of the second, third two-axis guiding systems $\mathbf{4}_2$, $\mathbf{4}_3$ joined to the driving motors **55**, **56** through the brackets **65**, **66**.

In case where the movable table **3** is turned with respect to a rotating axis **0** perpendicular to a plane formed by the X and Y axes, the driving motors **55**, **56** of the second driving means **6**, **7** for driving the track rails **14**, **15** in the X-axis direction of the second, third two-axis guiding systems $\mathbf{4}_2$, $\mathbf{4}_3$ are driven in opposite directions to each other, so as to rotate the screw shafts **63**, **64** connected to motor shafts (not shown) of the driving motors **55**, **56** in opposite directions to each other. If the movable table **3** is rotated in a counterclockwise direction, as shown in FIG. **14**, the track rail **14** in the X-axis direction of the second two-axis guiding system $\mathbf{4}_2$ is moved leftward in the Figure, while the track rail **15** in the X-axis direction of the third two-axis guiding system $\mathbf{4}_3$ is moved rightward in the same Figure. On the other hand, in case where the movable table **3** is turned in a clockwise direction, the track rail **14** in the X-axis direction of the second two-axis guiding system $\mathbf{4}_2$ is moved rightward in FIG. **14**, while the track rail **15** in the X-axis direction of the third two-axis guiding system 4_3 is moved leftward in the same Figure. In case where the movable table **3** is turned in a counterclockwise direction, the moving block **10** of the first two-axis guiding system 4_1 is moved upward as viewed in FIG. **14** by a predetermined amount, while the movable table **3** is turned in a clockwise direction, the moving block **10** of the first two-axis guiding system 4_1 is moved downward as viewed in FIG. **14** by a predetermined amount.

Because the nuts **61, 62** meshing with the screw shafts **63, 64** of the second driving means **6, 7** are joined to the moving blocks **11, 12** of the second, third two-axis guiding systems 4_2, 4_3 which are not moved in the X-axis direction through the brackets **59, 60**, the screw shafts **63, 64** meshing with the nuts **61, 62** are moved in opposite directions to each other along the X axis with rotations thereof. Therefore, the driving motors **55, 56** joined to the screw shafts **63, 64** are moved by the same amount in opposite directions to each other along the X axis as shown in FIG. **14**. Consequently, the track rails **14, 15** in the X-axis direction of the second, third two-axis guiding systems 4_2, 4_3 joined to the driving motors **55, 56** through the brackets **65, 66** are also moved in opposite directions to each other along the X axis by the same amounts $-\Delta x$, $+\Delta x$.

The screw shaft **49** is driven by the driving motor **45** of the first driving means **5** so that the nut **48** meshing with the screw shaft **49** is moved by a predetermined amount in the Y-axis direction with a rotation of the screw shaft **49**. Therefore, the moving block **10** of the first two-axis guiding system 4_1 fixed to the nut **48** meshing with the screw shaft **49** through the bracket **47** is moved by a predetermined amount $+\Delta y$ along the Y axis.

As described above, according to the first and second driving means **5, 6, 7**, the moving block **10** of the first two-axis guiding system 4_1 is moved by a predetermined amount $+\Delta y$ along the Y axis and at the same time, the track rails **14, 15** in the X-axis direction of the second, third two-axis guiding systems 4_2, 4_3 are moved in opposite directions to each other by the same amounts $-\Delta x$, $+\Delta x$ along the X axis. Then, in the movable table **3** guided by the first-third two-axis guiding systems 4_1, 4_2, 4_3 freely movably along the two axes, X axis and Y axis and supported freely rotatably, as shown in FIGS. **14, 15**, a point P_2 supported by the second two-axis guiding system 4_2 is moved leftward in FIG. **14** by the second driving means **6**, a point P_3 supported by the third two-axis guiding system 4_3 is moved rightward by the second driving means **7** and a point P_1 supported by the first two-axis guiding system 4_1 is moved upward with respect to FIG. **14** by the first driving means **5**. As a result, forces F_1, F_2, F_3 are applied to the points P_1, P_2, P_3 supported rotatably of the movable table **3** by the first and second driving means **5, 6, 7**, as shown in FIG. **15**. Components of force $F\theta_1$, $F\theta_2$, $F\theta_3$ in the circumferential direction of the forces F_1, F_2, F_3 serve for rotation moments for rotating the movable table **3** so that the movable table **3** is rotated in the counterclockwise direction of FIG. **15**.

To rotate the movable table **3** at an angle θ, as shown in FIG. **16**, the track rail **13** of the first two-axis guiding system 4_1 is moved by a predetermined amount $+\Delta y = R\tan\theta$ along the Y axis by the first driving means **57** and the track rails **14, 15** in the X-axis direction of the second and third two-axis guiding systems 4_2, 4_3 are moved by the same amounts $-\Delta x = -R\tan\theta\cdot\cos\beta$, $+\Delta x = +R\tan\theta\cdot\cos\beta$ respectively, in opposite directions to each other along the X axis. Where R is a radius from the rotation center O of the movable table **3** to the points P_1, P_2, P_3 for supporting the movable table **3** freely rotatably and β is an angle formed by a line connecting the rotation axis O with the point P_2 before the movable table **3** is rotated, with respect to the Y axis.

Further, the movable table **3** may be rotated not only around the rotation axis O but also around an arbitrary rotation axis at a desired rotation radius as shown by an arrow R in FIG. **14**. That is, to rotate the movable table **3** around an arbitrary rotation axis at a desired rotation radius, the first two-axis guiding system 4_1 is moved by a predetermined amount Δy along the Y axis by the first driving means **5**, and simultaneously the second and third two-axis guiding systems 4_2, 4_3 are moved by different predetermined amounts $+\Delta x$, $-\Delta x'$ respectively, in opposite directions along the X axis by the second driving means **6, 7**. Consequently, the movable table **3** is rotated at a rotation radius determined depending on the moving amounts $+\Delta x$, $-\Delta x'$, Δy of the first-third two-axis guiding systems 4_1, 4_2, 4_3 around a desired rotation axis. Because the moving amounts $+\Delta x$, $-\Delta x'$, Δy of the first-third two-axis guiding systems 4_1, 4_2, 4_3 are determined geometrically, if a relational expression is memorized in a control unit preliminarily, the amounts $+\Delta x$, $-\Delta\Delta x'$, Δy and rotation amounts of the respective rotation motors are calculated by specifying a rotation center and rotation angle, so as to control the first and second driving means **5, 6, 7**. A change of positions in which the two-axis guiding systems 4_1, 4_2, 4_3 supports the movable table **3** freely rotatably, accompanied by a motion of the first-third two-axis guiding systems 4_1, 4_2, 4_3 is absorbed by free motions of the track rail **13** in the X-axis direction and the moving blocks **11, 12** of the two-axis guiding systems 4_1, 4_2, 4_3.

In the movable table unit **1**, if the movable table **3** is moved in an arbitrary direction on the XY plane and simultaneously rotated in the direction θ around the rotation axis O, a motion for moving the movable table **3** in the X-axis direction, a motion for moving the movable table **3** in the Y-axis direction and a motion for rotation the movable table **3** along the direction θ are combined in an arbitrary way. However, by carrying out these three motions independently of each other, the control for moving the movable table **3** to a predetermined position and at a predetermined angle can be carried out more easily.

That is, in case where in the movable table unit **1**, the movable table **3** is moved in an arbitrary direction on the XY plane and further rotated in the direction θ around the rotation axis O, the movable table **3** is moved at a desired amount along the Y axis by driving the first driving means **5**, and then by driving the second driving means **5, 6** in the same direction, the movable table **3** is moved at a desired amount along the X axis. After that, by driving the second driving means **5, 6** in opposite directions to each other and simultaneously driving the first driving means **5**, the movable table **3** is rotated at a desired angle in the direction θ around the rotation axis O. That is, the motion controls in the X axis, Y axis and direction θ can be carried out independently of each other, so that the motion control of themovable table **3** can be further facilitated.

As described above, in the movable table unit **1** of the first embodiment, an operation for rotating the movable table **3** at a position other than the original point or an operation for rotating it at a predetermined angle and then moving it in parallel can be carried out by a simple control. In the movable table unit **1**, by driving only the first driving means **5**, the movable table **3** can be moved linearly in the Y axis easily and further by driving only the second driving means **6** in the same direction, the movable table **3** can be moved linearly in the X-axis direction. Further, because the track rail **8** in the Y-axis direction of the first two-axis guiding system 4_1 to be driven by the first driving means **5** is formed in a long length, the movable table can be moved largely along an axis.

Even if yawing occurs in the movable table unit **1** according to the first embodiment when the movable table **3** is moved along the Y axis by the first driving means **5**, by driving the second driving means **6**, **7** which are driving means for the X axis and direction θ, the yawing can be corrected so as to be able to move the movable table **3** to a predetermined position always with an appropriate posture.

Although in the movable table unit **1** according to the first embodiment, a case in which the movable table **3** is formed in a circular shape has been described, the movable table **3** may be so constructed that a center portion thereof is bored in a circular shape, because the three two-axis guiding systems are disposed on a circle around a rotation axis, thereby realizing a pass-through work and reduction of weight.

Although, in the first embodiment, the feeding screw mounted to the table base plate and the nut portions mounted to the moving block of the first two-axis guiding system are used as driving means, it is permissible to fix the feeding screw on the moving table and fix the nut portions on the moving block of the first two-axis guiding system.

Although in the first embodiment, a case in which the first and second driving means are provided independently for the first-third two-axis guiding systems has been described, the present invention is not restricted to this example, but it is permissible to provide the moving blocks or the like of the first and second driving means with the nut portions integrally and dispose the feeding screw inside the moving blocks or the like integrally. In this case, because the first and second driving means can be integrated with the first-third two-axis guiding systems, the size of this unit can be further reduced.

Second Embodiment

FIGS. **17**, **18** show a second embodiment of the present invention and the same reference numerals are attached to the same components as the first embodiment. According to the second embodiment, five two-axis guiding systems are provided. A two-axis guiding system provided with the first driving means is disposed in the center of rotation of the moving table and two two-axis guiding systems provided with the second driving means are disposed concentrically with the rotation center of the moving table and on a diameter along the Y axis.

That is, in the movable table unit **1** according to the second embodiment, as shown in FIG. **17**, five two-axis guiding systems 4_1, 4_2, 4_3, 4_4, 4_5 are disposed on each predetermined position on the table base plate **2**. As for these five two-axis guiding systems 4_1, 4_2, 4_3, 4_4, 4_5, as shown in FIG. **17**, the position P_1 in which the first two-axis guiding system 4_1 supports the movable table **3** freely rotatably is disposed so as to be located in the center O of a circle C in an initial state before the driving is started, and the positions P_2, P_3, P_4, P_5 in which the second-fifth two-axis guiding systems 4_2, 4_3, 4_4, 4_5, support the movable table **3** freely rotatably are disposed so as to be located on the same circle C around the rotation center O. The second and third two-axis guiding systems 4_2, 4_3 are disposed on the circle C formed with respect to the rotation axis O around which the movable table **3** rotates and at positions different by 180° on the Y axis. The fourth and fifth two-axis guiding systems 4_4, 4_5 are disposed on the circle C concentric with the rotation center of the movable table **3** and at positions different by 180° on the X axis.

Of the aforementioned five two-axis guiding systems, the first-third two-axis guiding systems 4_1, 4_2, 4_3 use a track rail **80** in the Y-axis direction in common and this track rail **80** in the Y-axis direction is mounted so as to span an entire length (Y-axis direction) of the table base plate **2**, in the center with respect to the width direction (X-axis direction) of the table base plate **2**. In the fourth two-axis guiding system 4_4, the track rail **81** in the Y-axis direction is mounted near an end in the width direction of the table base plate **2** in such a condition that it is shorter than the track rail **80** of the first two-axis guiding system 4_1 and parallel thereto. Further, in the fifth two-axis guiding system 4_5, the track rail **82** in the Y-axis direction is mounted near the other end in the width direction of the table base plate **2** and along the length direction of the table base plate **2** in such a condition that it is shorter than the track rail **80** of the first two-axis guiding system 4_1 and parallel thereto.

The five two-axis guiding systems 4_1, 4_2, 4_3, 4_4, 4_5 are constructed in the same way, comprising the track rails **80**, **81**, **82** in the Y-axis direction mounted on the table base plate **2** as described above, moving blocks **83**, **84**, **85**, **86**, **87** mounted to the track rails **80**, **81**, **82** movably in the Y-axis direction through a plurality of the balls as rolling bodies, and shorter track rails **88**, **89**, **90**, **91**, **92** in the X-axis direction mounted on the moving blocks **83**, **84**, **85**, **86**, **87** through a plurality of the balls as the rolling bodies in a direction perpendicular to the aforementioned track rails **80**, **81**, **82**.

The two-axis guiding systems 4_1, 4_2, 4_3, 4_4, 4_5 are constructed in the same manner as the first embodiment, and comprise the track rails **80**, **81**, **82** in the Y-axis direction, moving blocks **83**, **84**, **85**, **86**, **87** and track rails **88**, **89**, **90**, **91**, **92** in the X-axis direction. They are linear guiding systems for guiding the movable table **3** movably along two axes (XY axes) which are perpendicular to each other and supporting the movable table **3** rotatably. The track rails **88**, **89**, **90**, **91**, **92** in the X-axis direction of the two-axis guiding systems 4_1, 4_2, 4_3, 4_4, 4_5 support the movable table **3** rotatably through the rotation systems **31**.

The movable table unit **1** according to the second embodiment comprises the first driving means **5** for driving the track rail **88** of the first two-axis guiding system 4_1 along the Y axis ensuring a large traveling amount and two second driving means **6**, **7** for driving the track rails **89**, **90** of the second and third two-axis guiding system 4_2, 4_3 independently along the X axis.

As shown in FIGS. **17**, **18**, the first and second driving means **5**, **6**, **7** comprise driving motors **45**, **55**, **56** and feeding screw mechanisms **46**, **57**, **58** for converting rotation of the driving motors **45**, **55**, **56** to linear motion like the first embodiment. Meanwhile, the fourth and fifth two-axis guiding systems 4_4, 4_5 have no driving means.

In the movable table unit according to the second embodiment having such a structure, operations for rotating the movable table at a position other than the original point and moving it in parallel after rotating at a predetermined angle can be carried out by a simple control. Also, an operation for moving the rotation center linearly along two axes can be carried out and further, the movable table can be moved largely along a single axis.

That is, in the movable table unit **1** according to the second embodiment, the movable table **3** is stopped at a position shown in FIG. **17** for example, in an initial state before the movable table **3** is moved. For example, in case where the movable table **3** is moved in parallel along the Y axis without changing the posture thereof, the driving motor **45** of the first driving means **5** for driving the moving block

84 of the first two-axis guiding system 4_1 along the Y-axis is driven in a predetermined direction so as to rotate the long screw shaft **49** joined to the motor shaft **53** of the driving motor **45**. Then, the nut **48** meshing with this screw shaft **49** is moved in the Y-axis direction with rotations of the screw shaft **49**, so that the moving block **10** of the first two-axis guiding system 4_1 fixed to the nut **48** meshing with the screw shaft **49** through the brackets **47** is also moved in the Y-axis direction. As a result, the movable table **3** joined to the moving block **10** of the first two-axis guiding system 4_1 is moved by only a predetermined amount y along the Y axis with the moving block **10** of the first two-axis guiding system 4_1.

Next, in case where the movable table **3** is moved in parallel along the X axis, as shown in FIG. **17**, by driving the driving motors **55**, **56** of the second driving means **6**, **7** for driving the track rails **89**, **90** in the X-axis direction of the second and third two-axis guiding systems 4_2, 4_3, along the X axis, in the same direction, the screw shafts **63**, **64** joined to motor shafts (not shown) of the driving motors **55**, **56** are rotated. Then, because the nuts **61**, **62** meshing with the screw shafts **63**, **64** are joined to the moving blocks **84**, **85** of the second and third two-axis guiding systems 4_2, 4_3 which are not moved in the X-axis direction, through the brackets **59**, **60**, conversely the screw shafts **63**, **64** meshing with the nuts **61**, **62** are moved in the same direction along the X axis with rotations thereof. Consequently, the driving motors **55**, **56** joined to the screw shafts **63**, **64** are also moved in the same direction along the X axis with the screw shafts **63**, **64**. As a result, the movable table **3** joined to the track rails **89**, **90** in the X-axis direction rotatably through the rotation systems **31** is moved by only a predetermined amount x in the same direction along the X axis, together with the track rails **89**, **90** in the X-axis direction of the second and third two-axis guiding systems 4_2, 4_3 joined to the driving motors **55**, **56** through the brackets **65**, **66**.

Further, in case where the movable table **3** is rotated around a rotation axis perpendicular to a plane formed by the X and Y axes, by driving the driving motors **55**, **56** of the second driving means **6**, **7** for driving the track rails **89**, **90** in the X-axis direction of the second and third two-axis guiding systems 4_2, 4_3 in opposite directions to each other, the screw shafts **63**, **64** joined to motor shafts (not shown) of the driving motors **55**, **56** are rotated in opposite directions to each other.

Because the nuts **61**, **62** meshing with the screw shafts **63**, **64** of the second driving means **6**, **7** are joined to the moving blocks **84**, **85** of the second and third two-axis guiding systems 4_2, 4_3 which are not moved in the X-axis direction through the brackets **59**, **60**, conversely, the screw shafts **63**, **64** meshing with the nuts **61**, **62** are moved in opposite directions to each other along the X axis with rotations thereof. Thus, the driving motors **55**, **56** joined to the screw shafts **63**, **64** are moved in opposite directions to each other along the X axis together with the screw shafts **63**, **64**. As a result, the movable table **3** joined to the track rails **89**, **90** in the X-axis direction rotatably through the rotation systems **31** is moved by only a predetermined amount x in opposite directions along the X axis, together with the track rails **89**, **90** in the X-axis direction of the second and third two-axis guiding systems 4_2, 4_3 joined to the driving motors **55**, **56** through the brackets **65**, **66**.

As described above, the movable table **3** is guided movably along the two axes, X and Y axes and supported rotatably by the five two-axis guiding systems 4_1, 4_2, 4_3, 4_4, 4_5. For example, the point P_2 supported by the second two-axis guiding system 4_2 is moved leftward in FIG. **11** by the second driving means **6** and the point P_3 supported by the third two-axis guiding system 4_3 is moved leftward in FIG. **11** by the third driving means **7**. Because the second and third two-axis guiding systems 4_2, 4_3 are disposed on the circle C formed relative to the rotation axis O around which the movable table **3** is rotated and at positions different by 180° on the Y axis. Therefore, forces applied to the points P_2, P_3 in which the second and third two-axis guiding systems 4_2, 4_3 support the movable table **3** rotatably become rotation moment forces for directly rotating the movable table **3**. Thus, in the movable table **3** mentioned above, rotation moment forces for rotating the movable table **3** are applied to the points P_2, P_3 supported rotatably, by the second driving means **6**, **7** as shown in FIG. **17**. As a result, the movable table **3** is rotated in a counterclockwise direction in FIG. **17**.

In case where the movable table **3** is moved in an arbitrary direction on the XY plane and simultaneously rotated in the direction θ around the rotation axis O in the movable table unit **1**, an operation for moving the movable table **3** in the X-axis direction, an operation for moving the movable table **3** in the Y-axis direction and an operation for rotating the movable table **3** in the direction θ may be combined.

That is, in case where the movable table **3** is moved in an arbitrary direction on the XY plane and simultaneously rotated in the direction θ around the rotation axis O in the movable table unit **1**, first of all, the first driving means **5** is driven so as to move the movable table **3** in the Y-axis direction, then second driving means **5**, **6** are driven in the same direction so as to move the movable table **3** in the X-axis direction and after that, the second driving means **6**, **7** are driven in opposite directions to each other so as to rotate the movable table **3** by a predetermined amount around the rotation axis O. As a result, the motion control in the X-axis direction, Y-axis direction and in the direction θ can be carried out independently thereby facilitating the motion control of the movable table **3**.

As described above, in the movable table unit **1** according to the second embodiment, an operation for rotating the movable table **3** at a position other than the original point and an operation for moving it in parallel after rotating at a predetermined angle can be carried out by a simple control. Further, in the movable table unit **1**, by driving only the first driving means **5**, the movable table **3** can be moved linearly in the Y-axis direction easily. By driving the second driving means **6**, **7** in the same direction, the movable table **3** can be moved linearly in the X-axis direction easily. Further, because the track rail **80** in the Y-axis direction of the first two-axis guiding system 4_1 driven by the first driving means **5** is formed in a long length, the movable table **3** can be moved largely along a single axis.

In the second embodiment, when rotating the movable table **3**, only two second driving means **6**,**7** have to be driven and it is not necessary to drive the first driving means **5** in addition to the two second driving means **6**, **7** unlike the first embodiment. Thus, the rotation of the movable table **3** can be carried out further easily.

Further, according to the second embodiment, as plural two-axis guiding systems, the fourth and fifth two-axis guiding systems are disposed on the right and left sides of the first-third two-axis guiding systems. Thus, the movable table can be supported across an entire width thereof and the motion of the movable table can be further stabilized. This is particularly effective for use of a wide table or increasing the load capacity or the like.

Although the second embodiment has been described about a case in which as plural two-axis guiding systems, the fourth and fifth two-axis guiding systems are disposed on the right and left sides of the first-third two-axis guiding systems, the present is not restricted to this example, but it is possible to eliminate the fourth and fifth two-axis guiding systems by using a wide track rail in the Y-axis direction for the first-third two-axis guiding systems or narrowing the width of the movable table.

Because the structure and operation are the same as the first embodiment, a description thereof is omitted.

Third Embodiment

FIGS. **19**, **20** show a third embodiment of the present invention and the same reference numerals are attached to the same components as the first embodiment. Although this third embodiment is the same as the first embodiment in the structures of the first track rail, moving block and the second track rail, the rotation system is not provided between the movable table and two-axis guiding system, and therefore this point is different from the first embodiment.

That is, the movable table unit **1** of the third embodiment comprises first moving block **10***a* and second moving block **10***b*, which are upper and lower divisions of the two-axis guiding system **4**. The aforementioned rotation system **31** is disposed between the first moving block **10***a* and second moving block **10***b*. The other structure and operation are the same as the first embodiment, and therefore a description thereof is omitted.

What is claimed is:

1. A movable table unit comprising:

a table base plate;

a movable table supported movably on said table base plate;

a first track rail installed on the table base plate along an Y axial direction;

a plurality of rotating and two-axis guiding systems guided by the first track rail, for guiding the movable table along a different direction from the Y axial direction and supporting the movable table rotatably;

a first driving means fixed to the table base plate for driving at least one of the rotating and two-axis guiding systems along the Y axial direction; and

a plurality of second driving means fixed to the rotating and two-axis guiding systems for driving the movable table independently along the different direction from the Y axial direction,

wherein each of the rotating and two-axis guiding systems comprises a moving block guided by the first track rail, a second track rail guided by the moving block along an X axial direction and a rotation system for supporting the movable table rotatably relative to the moving block, and

wherein the rotation system is arranged between the movable table and the second track rail.

2. A movable table unit as claimed in claim **1**, wherein a rotation center of each of the rotating and two-axis guiding systems are disposed on a rotation center of the movable table.

3. A movable table unit as claimed in claim **1**, wherein the plurality of rotating and two-axis guiding systems are guided by the same first track rail.

4. A movable table unit as claimed in claim **1**, wherein the first track rail is substantially fixed on a full length of the table base plate.

5. A movable table unit as claimed in claim **1**, wherein the second track rails of the guiding systems are arranged parallel to each other.

[57] **ABSTRACT**

This invention relates to a sliding guide apparatus for, for example, a linear guiding apparatus, curved guiding apparatus, swiveling bearing or the like for infinite sliding motion, and more particularly to a sliding guide apparatus wherein an end-present rolling element chain for supporting a linear motion or rotary motion is inserted in a full track. The sliding guide apparatus comprises a track rail having a rolling path for rolling elements extending in the length direction of the sliding guide apparatus, a moving body which contains a loaded rolling path facing the aforementioned rolling path and an unloaded rolling path which circulates the rolling elements from one end to the other end of the loaded rolling path and moves along the aforementioned track rail, and a plurality of rolling elements which roll between the moving body and track rail while being loaded with a load and circulate in a full track composed of the loaded rolling path and unloaded rolling path of the aforementioned moving body. The rolling elements are disposed in line at predetermined intervals in a single or plurality of flexible connecting belts such that they can roll freely and incorporated in the full track of the sliding member together with the connecting belts. The connecting belts circulate with the balls in the full track of the sliding member while both end portions thereof are opposed to each other.

SLIDE GUIDE AND ITS ROLLER CHAIN WITH ENDS

FIELD OF THE INVENTION

This invention relates to a sliding guide apparatus for, for example, a linear guiding apparatus, curved guiding apparatus, swiveling bearing or the like for infinite sliding motion, and more particularly to a sliding guide apparatus wherein an end-present rolling element chain for supporting a linear motion or rotary motion is inserted in a full track.

BACKGROUND ART

In various sliding guide apparatuses containing bearing, by using rolling motion of rolling elements such as balls or rollers interposed between a track rail and a moving body, relative linear motion or rotary motion between the track rail and moving body is enabled. To (1) prevent the rolling elements from falling out of the moving body when the moving body is separated from the track rail, (2) reduce frictional resistance by avoiding relative contact between respective rolling elements, and (3) arrange the rolling elements at predetermined positions so as to secure a smooth motion or the like, generally a plurality of the rolling elements are incorporated between the track rail and moving body while being held by rolling element retainer or rolling element cage made of metallic thin plate or synthetic resin.

However, in a sliding guide apparatus using a conventional rolling element retainer, this rolling element retainer is incorporated in the moving body and then the rolling elements are incorporated in a rolling path formed for the rolling elements. Then, the moving body is installed on the track rail. Particularly if this sliding guide apparatus contains a full track of the rolling elements, assembly work for this sliding guide apparatus using the rolling element retainer requires experienced skill, so that automation thereof is difficult.

In the sliding guide apparatus using the conventional rolling element cage, the rolling element cage has a plurality of pockets such that respective rolling elements are rotatably held in these pockets. Thus, assembly work for incorporating the plurality of the rolling elements into the sliding guide apparatus is easy. However, because it is necessary to incorporate the plurality of the rolling elements in the respective pockets of the rolling element cage and hold them so that they do not slip out, it takes time and labor to produce this rolling element cage itself.

Therefore, to solve such problem, various ball chains which are produced by injection molding of resin with balls being disposed as inner ring on a substantially flat plane in a mold so that they are incorporated without an end in a full track of a moving body have been proposed (Japanese Examined Patent Publication No. Hei 6-56181, Japanese Unexamined Patent Application No. Hei 5-52217, Japanese Unexamined Patent Application No. Hei 5-126149, Japanese Unexamined Patent Application No. Hei 5-196036, Japanese Unexamined Patent Application No. Hei 5-196037).

In this conventional ball chain, after the ball chain is incorporated in a full track of a moving body, both end portions thereof are connected to each other so as to form an endless ball chain. However, this connecting work is very troublesome.

In such a sliding guide apparatus, following so-called ball selective engagement method has been applied to support four directional loads including radial, reverse radial and

right/left direction loads between the moving body and track rail, and further improve accuracy of reciprocation of the moving body relative to the track rail and stiffness thereof. That is, pre-pressure is applied to each ball of the ball chain interposed between the moving body and track rail or this pre-pressure may be sometimes adjusted. To apply the pre-pressure and adjust it, as a general easy method, a ball having a slightly larger size than a dimension of a gap between the loaded rolling path of the moving body and a rolling path of the track rail is selected and engaged. At this time, its sliding resistance and stiffness are measured so as to determine the size of a ball for use.

However, in the sliding guide apparatus using the aforementioned conventional ball chain, when this ball selective engagement is carried out, if the ball chain first incorporated in the moving body and connected endlessly has not achieved a desired sliding resistance and stiffness due to its ball diameter, this endless connection of the ball chain must be released so as to create ends thereof and that ball chain having the ends must be removed from the moving body. Then, another ball chain having ends and a different ball diameter is incorporated in the moving body and connected endlessly. Whether or not this incorporated ball chain has achieved its desired sliding resistance and stiffness is investigated. Until the ball diameter of the ball chain incorporated in the moving body achieved its desired sliding resistance and stiffness, the same procedure must be repeated. As a result, the ball selective engagement method which is essentially a simple method for application of pre-pressure and adjustment thereof, conversely becomes a very complicated method.

DISCLOSURE OF THE INVENTION

The present invention has been proposed in viewpoints of this problem. It therefore is an object thereof to provide a sliding guide apparatus and an end-present rolling element chain thereof, which are easy to handle without slip-out of the rolling elements and incorporate in a full track of the sliding guide apparatus while automation of such procedures is also easy, and wherein not only the ball selective engagement method for application of pre-pressure and adjustment thereof can be applied without making its operation complicated, but also the operation of the ball selective engagement method is further made easy to facilitate handling of the rolling elements so that they do not slip out.

According to the present invention, there is provided a sliding guide apparatus containing a track rail, a moving body which moves along the track rail and a plurality of rolling elements which roll between the moving body and track rail while being loaded with a load, the track rail having a rolling path on which the rolling elements roll, the moving body comprising a main unit having a loaded rolling path in which loaded rolling elements roll facing the rolling path of the track rail and an unloaded rolling path in which unloaded rolling elements roll, and a pair of lid portions which are mounted on front and rear ends in advancement direction and in which direction changing paths for the rolling elements for connecting the loaded rolling path and the unloaded rolling path are formed, the loaded rolling path and unloaded rolling path of the moving body, direction changing path and rolling path of the track rail facing the loaded rolling path of the moving body forming full tracks for the rolling elements, the plurality of rolling elements being connected by flexible resin connecting body having interposed portions which are interposed between the respective rolling elements and connecting portions for connecting the respective interposed portions so as to hold the plurality of the rolling elements in arranged condition such that they can roll, and further having both end portions, the plurality of rolling elements being further composed in the form of a single or plural end-present rolling element chains which are built into the full track.

Further according to the present invention, there is provided an end-present rolling element chain comprising a plurality of rolling elements and a resin connecting body having interposed portions which are interposed between the rolling elements and connecting portions for connecting the respective interposed portions so as to hold the plurality of rolling elements in arranged condition such that the rolling elements can roll, the resin connecting body having chamfered guiding portions for guiding both end portions of the resin connecting body.

According to the present invention, the track rail of the sliding guide apparatus has rolling paths for the rolling elements in its axial direction. The shape of this rolling path is not restricted to any particular one, but for example if the rolling element is a ball, this may be circular arc groove or gothic arc groove. Further, the number of the rolling grooves can be arbitrarily determined depending on the number of the full tracks formed on the moving body. For example, it is permissible to form one track on single side or two tracks on single side.

The moving body forming the sliding guide apparatus comprises a main unit having a loaded rolling path in which loaded rolling elements roll facing the rolling path of the track rail and an unloaded rolling path in which unloaded rolling elements roll, and a pair of lid portions which are mounted on front and rear ends in advancement direction and in which direction changing paths for the rolling elements for connecting the loaded rolling path and the unloaded rolling path are formed. The shape and structure thereof, the number of the incorporated full tracks, performance, function and the like are not restricted to any particular ones. For example, a type in which a single full track is provided on single side, a type in which two tracks are provided on single side, a type in which loads in four directions are supported, a type in which one side supports downward load while the other side supports upward load, a type in which a bearing lace having a loaded rolling path is provided, and the like are available.

Preferably, the main unit of this moving body is composed of a bearing race having at least a loaded rolling path and a resin forming portion which is formed on this bearing race in mold. Further preferably, it is permissible to form guiding grooves for guiding a resin connecting body of the end-present rolling element chain in an unloaded area (that is, an unloaded rolling path formed in the resin forming portion of the main unit and direction changing path formed by a pair of lid portions made of synthetic resin) of the full track formed in this moving body. Further, it is permissible to form a ball holding portion made of synthetic resin on both sides of the loaded rolling path of the bearing race as a part of the resin forming portion and a guiding groove for guiding the resin connecting portion of the end-present rolling element chain over an entire range of the full track including this ball holding portion.

Further according to the present invention, the end-present rolling element chain comprises a plurality of rolling elements and a resin connecting body having interposed portions which are interposed between the respective rolling elements and connecting portions for connecting the respective interposed portions so as to hold the plurality of the rolling elements in arranged condition such that they can roll. Preferably, chamfered guiding portions for guiding both end portions of the resin connecting body are formed at the both end portions of the resin connecting body. Consequently, when the end-present rolling element chain is moved in the full track, particularly when the both end portions of the end-present rolling element chain invade into the direction changing guiding hole or escapes from this direction changing guiding hole, the both end portions are guided so as to move the chain smoothly. As for the chamfered guiding portions formed on both ends of the resin connecting body, a radius of curvature, shape and the like thereof are determined and designed taking into account a radius of curvature and the like of the direction changing path in the full track of the sliding guide apparatus.

Although the length of the end-present rolling element chain is determined taking into account a length of the full track of the sliding guide apparatus in which the chain is used, if the sliding guide apparatus is so large that the length of the full track is very long, it is permissible to divide this full track to plural sections, that is, 2 or 3 sections, thereby making it possible to reduce the size of forming molds. In this case, it is recommended to form the chamfered guiding portions on both end portions of each resin connecting body of a divided end-present rolling element chain.

Here, as a rolling element for use in such an end-present rolling element chain, concretely balls or rollers are available. As a rolling element for use in a sliding guide apparatus requiring a smooth sliding property, the ball is preferred. As a rolling element for use in a sliding guide apparatus in which a relatively heavy load is applied, the roller is preferred.

Further, as a method for producing the end-present rolling element chain of the present invention, a method for forming a resin connecting body holding a plurality of the rolling elements by injection molding with the plurality of the rolling elements disposed as inner rings, is available. For the injection molding with the plurality of the rolling elements disposed as inner rings, so-called insert moldings disclosed in the aforementioned Japanese Examined Patent Publication No. Hei 6-56181, Japanese Unexamined Patent Application No. Hei 5-52217, Japanese Unexamined Patent Application No. Hei 5-126149, Japanese Unexamined Patent Application No. Hei 5-196036, Japanese Unexamined Patent Application No. Hei 5-196037, are applicable.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a partially sectional side view of a linear sliding guide apparatus according to an embodiment of the present invention;

FIG. **2** is a partially sectional front view of FIG. **1**;

FIG. **3** is a plan view of an end-present rolling element chain for use in the linear sliding guide apparatus of FIG. **1**;

FIG. **4** is a front view of FIG. **3**;

FIG. **5** is a sectional view taken along the lines V—V of FIG. **1**; and

FIG. **6** is a partially enlarged plan view showing an enlargement of an end portion of the end-present rolling element chain shown in FIG. **3**.

BEST MODE FOR CARRYING OUT THE INVENTION

Hereinafter, the embodiment of a linear sliding guide apparatus shown in the accompanying drawing will be described in detail.

FIGS. **1** and **2** show a linear sliding guide apparatus according to an embodiment of the present invention. This linear sliding guide apparatus basically is formed of end-present rolling element chain BC comprising a track rail **1**, a sliding base (moving body) **2** moving along this track rail **1** and a plurality of balls (rolling elements) **3** rolling between the sliding base **2** and track rail **1** while being loaded with a load.

According to this embodiment, the aforementioned track rail **1** has four rolling grooves (rolling paths) **1***a*, two grooves being provided on each side of right and left shoulders, such that the balls **3** roll in the rolling grooves **1***a*.

The aforementioned sliding base **2** comprises a main unit **5** having a loaded ball rolling groove (loaded rolling path) **4***a* in which load applied balls (loaded balls) **3***a* roll facing the rolling groove la of the track rail **1** and an unloaded ball guiding hole (unloaded rolling path) **4***b* in which no-load applied balls (unloaded balls) **3***b* roll, and a pair of lid portions **6** which are mounted on front and rear ends in advancement direction and in which direction changing holes (direction changing paths) **7** for the balls **3** for connecting the loaded ball rolling groove **4***a* and the unloaded ball guiding hole **4***b* are formed. Full track for the ball **3** is formed by the loaded ball rolling groove **4***a* and unloaded ball guiding hole **4***b* in the aforementioned sliding base **2**, direction changing hole **7** formed in the respective lid portions **6** and the rolling groove la of the track rail **1** facing the loaded ball rolling groove **4***a* in the sliding base **2**.

According to this embodiment, the main unit **5** of the aforementioned sliding base **2** comprises a metallic bearing race **8** having the loaded ball rolling groove **4***a* and through hole **10**, and a resin forming portion **9** which is insert-formed on the bearing race **8** in a mold and has a direction changing guide portion **9***a*, which forms the direction changing guide hole **7** together with the unloaded ball guiding hole **4***b* and the direction changing guiding groove **6***a* formed inside the respective lid portions **6**, and a ball holding portion **9***b* formed along the loaded ball rolling groove **4***a* of the bearing race **8**. A guiding groove **11** is formed in the unloaded ball guiding hole **4***b* and ball holding portion **9***b* of the resin forming portion **9** and direction changing guiding groove **6***a* of the respective lid portions **6** such that it extends endlessly along the formed full track, and guides the end-present rolling element chain BC incorporated in the full track so as to smooth a circulation of this end-present rolling element chain BC.

As shown in FIGS. **3** through **6**, the end-present rolling element chain BC is formed of flexible resin connecting body **12** which has a plurality of balls **3**, interposed portions **13** which are interposed between the balls **3** and connecting portions **14** for connecting the respective interposed portions **13** so as to hold the plurality of the balls **3** in arranged condition such that they can roll and has both end portions, and chamfered guiding portions **12***a* for guiding both end portions of this resin connecting body **12** are formed on the both portions of this resin connecting body **12**. Consequently, when the end-present rolling element chain BC is moved in the full track, particularly when the both end portions of the end-present rolling element chain BC invade into the direction changing guiding hole **7** or escapes from this direction changing guiding hole **7**, the both end portions are guided so as to move the chain BC smoothly.

When this end-present rolling element chain BC is incorporated in the full track of the sliding guide apparatus, the connection portions **14** composing the resin connecting body **12** of this end-present rolling element chain BC are engaged with the guiding grooves **11** formed in the aforementioned sliding base **2** so that the posture of the end-present rolling element chain BC is controlled during circulation thereof in the full track so as to secure a smooth rolling of the balls **3**. The chamfered guiding portions **12***a* formed on the both end portions of the resin connecting body **12** guide the front end portion of the end-present rolling element chain BC so as to achieve smooth circulation of the end-present rolling element chain BC.

INDUSTRIAL APPLICABILITY

As described above, according to the sliding guide apparatus and end-present rolling element chain of the present invention, the rolling elements are free of slip-out, easy to use and easy to be incorporated in the full track of the sliding guide apparatus. Further, automation of that work is possible. A ball selective engagement method for application of the pre-pressure and adjustment thereof can be applied without damaging its easy property thereof, and rather its operability thereof can be further improved.

What is claimed is:

1. A sliding guide apparatus containing a track rail, a moving body which moves along said track rail and a plurality of rolling elements which roll between said moving body and track rail while being loaded with a load, said track rail having a rolling path on which said rolling elements roll, said moving body comprising a main unit having a loaded rolling path in which loaded rolling elements roll facing the rolling path of said track rail and an unloaded rolling path in which unloaded rolling elements roll, and a pair of lid portions which are mounted on front and rear ends in advancement direction and in which direction changing paths for said rolling elements for connecting the loaded rolling path and the unloaded rolling path are formed, said loaded rolling path and unloaded rolling path of said moving body, direction changing path and rolling path of said track rail facing said loaded rolling path of said moving body forming full tracks for said rolling elements, said plurality of rolling elements being connected by flexible resin connecting body having interposed portions which are interposed between the respective rolling elements and connecting portions for connecting the respective interposed portions so as to hold said plurality of the rolling elements in arranged condition such that they can roll, and further having both end portions, said plurality of rolling elements being further composed in the form of a single or plural end-present rolling element chains which are built into said full track.

2. A sliding guide apparatus according to claim **1** wherein the main unit of said moving body comprises a bearing race having at least the loaded rolling path and a resin forming portion formed on said bearing race in mold.

3. A sliding guide apparatus according to claim **1** or **2** wherein said end-present rolling chain contains chamfered guiding portions which are provided on both ends of the resin connecting body and guide a circulation of said end-present rolling chain in said full-track.

4. An end-present rolling element chain comprising a plurality of rolling elements and a resin connecting body having interposed portions which are interposed between the rolling elements and connecting portions for connecting the respective interposed portions so as to hold said plurality of rolling elements in arranged condition such that said rolling elements can roll, said resin connecting body having chamfered guiding portions for guiding both end portions of said resin connecting body.

[57] **ABSTRACT**

The present invention relates to a linear movement device, for example, a linear guide device, a ball screw, a ball spline or the like in which a track shaft and a slide member is engaged movably relative to each other via a rolling element of a ball, a roller or the like, in details, to an improvement of a linear movement device having a lubricant supplying member coating a lubricant on a face of the track shaft. The linear movement device is constituted by a track shaft where a rolling face of a rolling element is formed, a slide member engaged with the track shaft via the rolling element and moved relative to the track shaft and a lubricant supplying member mounted to the slide member and coating a lubricant on a surface of the track shaft in accordance with the relative movement and further, the lubricant supplying member includes a lubricant coater brought into contact with the track shaft for coating the lubricant on the track shaft, a lubricant absorber installed contiguous to the lubricant coater for supplying the lubricant to the lubricant coater while absorbing the lubricant and holding the lubricant and oil amount controlling means for controlling an amount of the lubricant supplied from the lubricant absorber to the lubricant coater.

LINEAR MOVEMENT DEVICE AND LUBRICANT SUPPLYING DEVICE USED THEREFOR

TECHNICAL FIELD

The present invention relates to a linear movement device in which a track shaft and a slide member are engaged movably relative to each other via rolling elements of balls, rollers or the like as in, for example, a linear guide device, a ball screw, a ball spline or the like, in details, to an improvement of a linear movement device having a lubricant supplying device for coating a lubricant on a surface of the track shaft.

BACKGROUND ART

Conventionally, there has been known, as this kind of a linear movement device, a linear guide device used in a linear guide portion of a machine tool, a transferring device or the like for guiding a movable body of a table or the like on a fixed unit of a bed, a saddle or the like, a ball screw used along with the linear guide device for providing stroke of linear movement in accordance with a rotational amount of a motor to the movable body or the like.

The former linear guide device is constituted by a track rail (track shaft) arranged above the fixed unit and where a rolling groove of balls is formed in the longitudinal direction and a sliding base (slide member) having a load rolling groove opposed to the rolling groove of the track rail via a number of rolls and where an infinite circulation path of balls rolling on the load rolling groove is formed and is constituted such that the sliding base supporting the movable body is linearly moved continuously along the track rail in accordance with infinite circulation of the balls. Further, in contrast thereto, there is a case where it is constituted such that the track rail is moved relative to the fixed sliding base.

Meanwhile, the latter ball screw is constituted by a screw shaft (track shaft) where a ball rolling groove in a spiral shape is formed by a predetermined lead and a nut member (slide member) having a load rolling groove opposed to the ball rolling groove via a number of balls and where an infinite circulation path of the balls rolling on the load rolling groove is formed and is constituted such that the balls are circulated in the infinite circulation path in correspondence with relative rotational movement between the screw shaft and the nut member by which the nut member and the screw shaft are moved in the shaft direction relative to each other.

Meanwhile, in using such a linear movement device, the balls or the above-described rolling grooves and so on need to pertinently lubricate in accordance with conditions of use in view of restraining wear of the balls per se, wear of the rolling groove of the track rail or the screw shaft on which the balls roll or wear of the load rolling groove of the sliding base or the nut member and maintaining high precision movement of the slide member over a long period of time.

Conventionally, there has been known a linear guide device disclosed in Japanese Unexamined Utility Model Publication No. JP-A-7-23824 as a linear movement device having a device for supplying lubricant to balls, rolling grooves and so forth. According to the linear guide device, as shown in FIG. **19**, polymer members **120** impregnating a lubricant are provided on an inner face of a sliding base **122** opposed to a track rail **121**, the lubricant gradually oozing out from the polymer members **120** is coated on an upper face **123** and side faces **124** in accordance with reciprocating movement of the sliding base **122** by which the lubricant is supplied to rolling grooves **125** and balls **126**.

Further, there has been known other lubricant supplying device for lubricating a track shaft of a linear movement device disclosed in Japanese Unexamined Patent Publication No. JP-A-6-307442. According to the lubricant supplying device, as shown in FIG. **20**, pads **127** impregnating a lubricant are incorporated into cover frames **128** by which the pads **127** at inside thereof are brought into contact with a track rail **129** and the cover frames **128** are mounted at a front portion and a rear portion of a sliding base **130** in the movement direction such that the pads **127** are brought into sliding contact with the track rail **129** in accordance with the movement of the sliding base **130**. Accordingly, when the sliding base **130** is reciprocated along the track rail **129**, the lubricant oozed out from the pads **127** is coated on the surface of the track rail **129** and the lubricant is similarly supplied to rolling grooves or balls.

However, according to these lubricant supplying devices, the polymer member or the pad mounted to the sliding base is provided with both of a function as a coater for coating the lubricant on the track rail and a function as an absorber for holding the lubricant per se, a material which is optimum as the former of the coater is not necessarily a material which is optimum as the latter of the absorber and accordingly, it is difficult to stably supply the lubricant to the track rail over a long period of time.

That is, at an initial stage of start of use, the polymer member or the pad is sufficiently impregnated with the lubricant and accordingly, an amount of the lubricant excessive for lubricating the ball rolling grooves or the balls is coated on the track rail, whereas with an increase in an accumulated running distance of the sliding base in respect of the track rail, the amount of coating the lubricant to the track rail is significantly reduced and it is difficult to coat a necessary minimum amount of the lubricant for lubricating the ball rolling grooves and the balls stably on the track rail over a long period of time.

Meanwhile, although in order to coat a sufficient amount of the lubricant on the track rail over a long period of time, the polymer member or the pad may be magnified and a large amount of the lubricant may be held thereby, even when such a measure is adopted, the above-described problem in which the amount of supplying the lubricant is significantly changed in accordance with accumulation of the running distance of the sliding base cannot be resolved, or there also poses a problem in which the sliding base mounted with the polymer member or the pad is magnified and downsizing of a linear movement device cannot be achieved.

DISCLOSURE OF THE INVENTION

The present invention has been carried out in view of such a problem and it is an object of the present invention to provide a linear movement device capable of coating lubricant of an amount which is necessary minimum in lubricating a rolling groove of a rolling element or a rolling element stably over a long period of time and capable of achieving to downsize a slide member. Further, it is other object of the present invention to provide a lubricant supplying device preferable in a linear movement device such as a linear guide device, a ball screw device or the like.

In order to achieve the above-described object, there is provided a linear movement device including a track shaft where a rolling face of a rolling element is formed, a slide member engaged with the track shaft via the rolling element and moved relative to the track shaft and a lubricant supplying member mounted to the slide member and coating a lubricant on a surface of the track shaft in accordance with the relative movement as a premise wherein the lubricant supplying member includes a lubricant coater brought into contact with the track shaft for coating the lubricant on the track shaft, a lubricant absorber installed contiguous to the lubricant coater for supplying the lubricant to the lubricant coater while absorbing the lubricant and holding the lubricant and oil amount controlling means for controlling an amount of the lubricant supplied from the lubricant absorber to the lubricant coater.

According to such a technical means, coating of the lubricant on the track shaft is carried out by the lubricant supplying member mounted to the slide member, the lubricant supplying member includes the lubricant coater and the lubricant absorber and a function of coating the lubricant to the track shaft and a function of holding the lubricant are allotted to the lubricant coater and the lubricant absorber. Therefore, the lubricant of an amount in correspondence with an amount of supply from the lubricant absorber to the lubricant coater, is coated on the track shaft in this linear movement device.

Further, the lubricant supplying member is provided with the oil amount controlling means for controlling the amount of the lubricant supplied from the lubricant absorber to the lubricant coater and accordingly, the amount of supplying the lubricant from the former to the latter does not change significantly with elapse of time and a stable amount of the lubricant can always be impregnated to the lubricant coater.

In this way, according to the linear movement device of the present invention, even when an accumulated running distance of the slide member in respect of the track shaft is increased with elapse of time, the lubricant coater supplied with the lubricant from the lubricant absorber, impregnates always the stable amount of the lubricant and a constant amount of the lubricant can always be coated from the lubricant coater onto the track shaft.

In this case, while a material capable of coating the lubricant impregnated to the lubricant coater onto the track shaft with no stagnation, for example, felt made of polyester mixed with sheep wool, sintered resin or the like is preferable for the lubricant coater, a material capable of absorbing and holding a large amount of the lubricant, for example, felt made of polyester, sintered resin or the like is preferable for the lubricant absorber.

Further, in mounting the lubricant supplying member onto the slide member, the lubricant coater and the lubricant absorber may be directly mounted onto the slide member in an exposed state or the lubricant coater and the lubricant absorber may be incorporated in a casing and a casing may be mounted onto the slide member. For example, when the lubricant coater and the lubricant absorber are fabricated by sintered resin, they can be molded into desired shapes comparatively easily and can be fixed directly to the slide member by screwing.

Further, in incorporating the lubricant coater and the lubricant absorber in the casing, these may be incorporated separate casings respectively and two casings may be connected to constitute the lubricant supplying member.

Further, the oil amount controlling means may be of any constitution so far as the amount of supplying the lubricant from the lubricant absorber to the lubricant coater is restricted. For example, by using respectively different materials for forming the lubricant absorber and the lubricant coater, the movement of the lubricant from the former to the latter can be restricted to some degree and the lubricant which is held in the lubricant absorber in a large amount can be supplied to the lubricant coater by a constant amount.

As other oil amount controlling means, an oil amount adjusting film for permeating the lubricant may be installed between the lubricant absorber and the lubricant coater and only the lubricant which has permeated the oil amount adjusting film may be supplied from the lubricant absorber to the lubricant coater. As such an oil amount adjusting film, for example, paper through which the lubricant is permeable may be used and laminating operation may be performed by polyethylene or the like on the surface of the paper to adjust an area through which the lubricant permeate. According to such a constitution, by selecting material, thickness or the like of the oil amount adjusting film, an amount of the lubricant supplied from the lubricant absorber to the lubricant coater per unit time can be controlled and the amount of the lubricant coated from the lubricant coater onto the track shaft can be stabilized over a long period of time.

However, although in providing the oil amount adjusting film between the lubricant absorber and the lubricant coater, an intermediary between a peripheral edge of the oil amount adjusting film and the casing needs to hermetically seal completely by a caulking compound or the like to prevent the lubricant from leaking from the intermediary, the operation of hermetically sealing the surrounding is not easy since the oil amount adjusting film is as soft as paper or the like. Accordingly, from such a view point, it is preferable to constitute the oil amount controlling means by a thin stainless steel sheet or the like separating the lubricant absorber and the lubricant coater and open a supply hole for supplying the lubricant in the oil amount adjusting plate.

Further, according to the oil amount adjusting plate, by adjusting an inner diameter or a number of the supply holes opened in the plate, the amount of the lubricant supplied from the lubricant absorber to the lubricant coater per unit time can be controlled and the amount of the lubricant coated onto the track shaft by the lubricant coater can be adjusted.

Meanwhile, in view of the inherent object of lubricating the rolling face of the rolling element or the rolling element per se, the lubricant coater needs not to coat the lubricant on all the peripheral faces of the track shaft and the lubricant may be coated only on the rolling faces of the rolling elements.

Further, according to this kind of a linear movement device, it is general to hermetically seal a clearance between the track shaft and the slide member by mounting a seal member onto the slide member in order to prevent dust or the like adhered to the track shaft from entering the clearance between the track shaft and the slide member. According to the linear movement device of the present invention, although a seal member may be provided separately from the lubricant supplying member and the seal member may be mounted to the slide member or the lubricant supplying member, according to such a constitution, a number of parts mounted to the slide member is increased and assembling operation thereof is complicated. Hence, in order to construct a more simple constitution, it is preferable to install a seal grip portion which is brought into close contact with the surface of the track shaft at the casing of the lubricant supplying member such that the lubricant supplying member is provided with also a function as a seal member.

Further, when the seal grip portion is provided with the casing of the lubricant supplying member, it is preferable that the casing is formed by a soft elastic body of rubber of the like and the seal grip portion and the casing are integrally molded by injection molding or the like. In addition thereto, when the casing of the lubricant supplying member is formed by a soft elastic body, by piercing an injection needle into the casing, the lubricant can also be replenished easily to the lubricant absorber in the casing.

Incidentally, the linear movement device according to the present invention is a concept including not only the linear guide device mentioned above and the ball screw, but also a ball spline in which a nut member in a cylindrical shape is fitted to a spline shaft where ball rolling grooves are formed along the axial direction.

Meanwhile, according to another aspect of the present invention, there is provided a lubricant supplying device mounted to a slide member engaged with a track shaft via a rolling element for coating a lubricant to the track shaft in accordance with a relative movement between the slide member and the track shaft wherein the lubricant supplying device includes a lubricant coater brought into contact with the track shaft for coating the lubricant to the track shaft, a lubricant absorber installed contiguous to the lubricant coater for supplying the lubricant to the lubricant coater while absorbing the lubricant and holding the lubricant and oil amount controlling means for controlling an amount of the lubricant supplied from the lubricant absorber to the lubricant coater.

Further, also in the lubricant supplying device, the lubricant coater and the lubricant absorber may be mounted directly to the slide member in an exposed state, or the lubricant coater and the lubricant absorber may be incorporated in a casing and the casing may be mounted to the slide member.

BRIEF DESCRIPTION OF DRAWINGS

FIG. **1** is a disassembled perspective view showing a first embodiment in which the present invention is applied to a linear guide device.

FIGS. **2**(*a*) and **2**(*b*) are a front view and a side view showing a lubricant supplying member according to the first embodiment.

FIG. **3**(*a*) is a sectional view taken along a line A—A of FIG. 2 and FIG. **3**(*b*) is a sectional view taken along a line B—B of FIG. **2**.

FIG. **4** is a sectional view taken along a line C—C of FIG. **2**.

FIG. **5** is a sectional view showing an example in which the lubricant supplying member according to the first embodiment is modified such that a lubricant can be coated also on an upper face of a track rail.

FIGS. **6**(*a*) and **6**(*b*) illustrate a front view and a side view showing a second embodiment of a lubricant supplying member.

FIG. **7** is a sectional view taken along a line VII—VII of FIG. **6**.

FIG. **8** is a sectional view taken along a line VIII—VIII of FIG. **6**.

FIG. **9** is a plane view showing an outline of a tester for testing function of the lubricant supplying member according to the second embodiment.

FIGS. **10**(*a*)–**10**(*c*) are graphs showing a result of testing differences in delivery amounts of a lubricant coated on a track rail when a number of supply holes perforated in an oil amount adjusting plate is changed.

FIG. **11** illustrates graphs showing a result of testing a difference in delivery amounts of a lubricant coated on a track rail when an inner diameter of a supply hole perforated in an oil amount adjusting plate is changed.

FIG. **12** is a partially cut perspective view showing an embodiment in which the present invention is applied to a ball screw.

FIG. **13** is a sectional view showing a state of using the ball screw shown in FIG. **12**.

FIG. **14** is a view viewing the ball screw from a line XIV—XIV in FIG. **13**.

FIG. **15** is a longitudinal sectional view showing other embodiment in which the present invention is applied to a ball screw.

FIG. **16** is a partially cut perspective view showing an embodiment in which the present invention is applied to a ball spline.

FIG. **17** is a sectional view showing a state of using the ball spline shown in FIG. **16**.

FIG. **18** is a sectional view taken along a line XVIII—XVIII of FIG. **17**.

FIG. **19** is a partially cut sectional view showing an example of a conventional linear movement device.

FIGS. **20**(*a*) and **20**(*b*) are a disassembled perspective view and a sectional view showing other example of a conventional linear movement device.

Explanations of Notations

1—Track rail (track shaft), **2**—Sliding base (sliding member), **3**—Ball (rolling element), **4**—Lubricant supplying member, **41**—First casing (casing), **42**—Lubricant coater, **43**—Lubricant absorber, **44**—Second casing (casing), **45**—Oil amount adjusting plate (oil amount controlling means)

BEST MODE FOR CARRYING OUT THE INVENTION

A detailed explanation will be given of a linear movement device according to the present invention in reference to the attached drawings as follows.

FIG. **1** is a disassembled perspective view showing a first embodiment in which the present invention is applied to a linear guide device. The linear guide device according to the embodiment is constituted by a track rail (track shaft) **1** where rolling faces **11** for balls are formed along the longitudinal direction, a sliding base (sliding member) **2** fitted to the track rail via a number of balls **3** which are rolling elements and installed with infinite circulation paths of the balls at inside thereof and a pair of lubricant supplying members **4** for coating a lubricant on the surface of the track rail **1** in accordance with movement of the sliding base **2** which are mounted at both front and rear end faces in the direction of moving the sliding base **2** and is constituted such that the sliding base **2** is reciprocated on the track rail **1** in accordance with circulation of the balls **3**.

Further, the sliding base **2** is constituted by a block main body **23** substantially in a saddle-like shape having a face **21** for attaching a machine device of a table or the like and having ball return holes **22** for circulating the balls **3** and a pair of end plates **24** fixed to the both front and rear faces of the block main body **23**. The end plates **24** are formed with direction change paths (not illustrated) for scooping up the balls **3** from the ball rolling faces **11** of the track rail **1** and transferring the balls to the ball return holes **22** of the block main body **23** and on the other hand, transferring the balls **3** from the ball return holes **22** to the ball rolling faces **11** and by fixing the end plates **24** to the block main body **23** by using attaching bolts **25**, infinite circulation paths of the balls **3** are formed in the sliding base **2**.

Further, oil supply ports **26** for supplying a lubricant to the infinite circulation paths are installed to the block main body **23** and the oil supply ports are mounted with supply nipples **27** via the lubricant supplying members **4** and the end plates **24**.

Meanwhile, the lubricant supplying member **4** is constituted by a first casing **41** which is brought into contact with the end plate **24**, a lubricant coater **42** which is incorporated in the first casing **41** and is brought into contact with the track rail **1** for coating the lubricant to the track rail **1**, a lubricant absorber **43** which absorbs and holds the lubricant and supplies the lubricant to the lubricant coater **42**, a second casing **44** for incorporating the lubricant absorber **43**, and an oil amount adjusting plate (oil amount controlling means) **45** for separating the lubricant coater **42** and the lubricant absorber **43** when the first casing **41** and the second casing **44** are bonded with each other.

As shown in FIG. **2** through FIG. **4**, the first casing **41** is projected with a strip-like projection **47** along a contour of a steel plate for constituting a base plate **46** and a recess portion **48** surrounded by the strip-like projection **47** constitutes a space for incorporating the lubricant coater **42**. Further, openings **49** are formed in the strip-like projection **47** at positions opposed to the rolling faces **11** of the track rail **1** and portions of the lubricant coater **42** are projected from the openings **49**. Here, the strip-like projection **47** is molded by a rubber material which is a soft elastic body and is bonded to the base plate **46** by vulcanization bonding. The recess portion **48** is formed to evade through holes **28** and **29** for the attaching bolts **25** and the supply nipple **27** and a substantially H-like shape is constituted as a whole as shown in FIG. **4**.

Further, the second casing **43** is also projected with a strip-like projection **51** along the contour of a steel plate constituting a base plate **50** and a recess portion **52** surrounded by the strip-like projection **51** constitutes a space for incorporating the lubricant absorber **43**. The strip-like projection **51** is also molded by a rubber material which is a soft elastic body and is projected from a face of the substrate **50** on the side of the first casing **41** to be brought into contact with the strip-like projection **47** of the first casing **41**. Further, a face of the substrate **50** on the opposite side is covered with a protective layer **54** comprising a rubber member and the protective layer **54** is projected with a seal lip portion **55** that is brought into close contact with the side faces and the upper face of the track rail **1**. Further, the recess portion **52** of the second casing **43** is formed also to evade the through holes **28** and **29** for the attaching bolts **25** and the supply nipple **27** and a substantially H-like shape is constituted as a whole.

Further, the lubricant coater **42** is molded in a substantially H-like shape the same as that of the recess portion **48** of the first casing **41** and projection pieces **56** which are brought into contact with the rolling faces **11** of the track rail **1** are projected in conformity with positions of the openings **49** formed in the strip-like projection **47**. An entangled body of fiber having a material which is liable to cause movement of the lubricant by capillary phenomenon, that is, felt or the like having a low percentage of void, is suitable for the lubricant coater **42** such that the impregnated lubricant can be coated on the track rail **1** with no stagnation and in this embodiment, sheep wool felt having a percentage of void of 54% is used.

Further, the lubricant absorber **43** is molded in a substantially H-like shape the same as that of the recess portion **52** of the second casing **44** and an entangled body of fiber such as felt or the like having a high percentage of void is suitable therefor such that a large amount of the lubricant can be absorbed and held. In this embodiment, sheep wool felt mixed with rayon having a percentage of void of 81% is used.

Meanwhile, the oil amount adjusting plate **45** is constituted to be sandwiched between the lubricant coater **42** and the lubricant absorber **43** to separate them when the strip-like projection **47** of the first casing **41** and the strip-like projection **51** of the second casing **44** are bonded together and in this embodiment, a thin stainless steel sheet having a thickness of 0.1 through 0.2 mm is used. Further, the oil amount adjusting plate **45** is opened with a plurality of supply holes **57** and is constituted such that the lubricant impregnated in the lubricant absorber **43** is moved to the lubricant coater **42** via the supply holes **57**. Further, in order to prevent the lubricant from leaking from the lubricant absorber **43** to the lubricant coater **42** via the peripheral edge of the oil amount adjusting plate **45**, a stepped portion is formed in the strip-like projection **47** of the first casing **41** for fitting the peripheral edge of the oil amount adjusting plate **45** and when the strip-like projection **47** of the first casing **41** and the strip-like projection **51** of the second casing **44** are bonded together, the peripheral edge of the oil amount adjusting plate **45** is sealed by being sandwiched by the strip-like projections **47** and **51**.

Further, in order to smoothly supply the lubricant from the lubricant absorber **43** to the lubricant coater **42**, as shown in FIG. **2**, a vent hole **58** is opened in the strip-like projection **51** of the second casing **44** by which pressures in the first casing **41** and the second casing **44** are maintained always at the atmospheric pressure. Accordingly, the movement of the lubricant from the lubricant absorber **43** to the lubricant coater **42** is mainly dependent upon the capillary phenomenon of the lubricant at inside of the entangled bodies of fiber. However, the lubricant disposed upward from the supply holes **57** of the oil amount adjusting plate **45** in the lubricant impregnated in the lubricant absorber **43**, is moved to the side of the lubricant coater **42** also by gravity.

According to the lubricant supplying member **4** constituted as mentioned above, firstly, the lubricant is previously impregnated sufficiently to the lubricant coater **42** and the lubricant absorber **43**, thereafter, the lubricant coater **42** is incorporated into the first casing **41**, the lubricant absorber **43** is incorporated to the second casing **44** and the both casings **41** and **44** are bonded together by vulcanization bonding to sandwich the oil amount adjusting plate **45**. Thereby, integration of the lubricant supplying member **4** in which the lubricant absorber **43** and the lubricant coater **42** are incorporated is completed. Further, the lubricant supplying members **4** are mounted to both of the front and the rear end faces of the sliding base **2** by the attaching bolts **25**.

In a state where the lubricant supplying members **4** are attached to the sliding base **2**, the projection pieces **56** of the lubricant coater **42** projected from the first casing **41** are brought into press contact with the ball rolling faces **11** of the track rail **1** and when the sliding base **2** is moved on the track rail **1**, the lubricant is coated from the projection pieces **56** to the ball rolling faces **11**. Further, the seal lip portions **55** projected from the second casing **44** is brought into sliding contact with the upper face and the side faces of the track rail **1** and prevent dust adhered to the track rail **1** from invading a clearance between the track rail **1** and the sliding base **2**.

When the lubricant is coated from the projection pieces **56** of the lubricant coater **42** onto the track rail **1** in this way, the lubricant impregnated in the lubricant coater **42** is moved to the projection pieces **56** by the capillary phenomenon. Meanwhile, a large amount of the lubricant is held in the lubricant absorber **43** and therefore, when the lubricant impregnated to the lubricant coater **42** is gradually reduced, the lubricant impregnated in the lubricant absorber **43** is supplied to the lubricant coater **42** via the supply holes **57** of the oil amount adjusting plate **45** similarly by the capillary phenomenon.

In this way, a substantially constant amount of the lubricant is always impregnated in the lubricant coater **42** and stabilization of amount of the lubricant coated from the lubricant coater **42** onto the track rail **1** can be achieved. Further, the amount of the lubricant coated from the lubricant coater **42** onto the track rail **1** can arbitrarily be adjusted by changing a contact area between the projection pieces **56** and the ball rolling faces **11** of the track rail **1** or changing the percentage of void of the fiber entangled body constituting the lubricant coater **42**.

Meanwhile, according to the embodiment, the amount of the lubricant coated from the lubricant coater **42** onto the ball rolling faces **11** of the track rail **1** can be adjusted by changing the number or the inner diameter of the supply holes **57** opened in the oil amount adjusting plate **45**. The reason is that when the inner diameter or the number of the supply holes **57** opened in the oil amount adjusting plate **45** is changed, the contact area in respect with the lubricant absorber **43** and the lubricant coater **42** is changed and therefore, the amount of the lubricant supplied from the lubricant absorber **43** to the lubricant coater **42** per unit time is changed and the amount of the lubricant impregnated in the lubricant coater **42** is increased or decreased. Accordingly, in the linear movement device of the embodiment, an amount of the lubricant optimum to object of use can be coated onto the track rail **1** by adjusting the inner diameter and/or the number of the supply holes **57** opened in the oil amount adjusting plate **45** in accordance with different use or the like.

Further, in the case where a time period of use has elapsed to some degree and almost all of the lubricant impregnated in the lubricant absorber **43** has been consumed, the lubricant needs to replenish from outside to the lubricant absorber **43** and in such a case, the lubricant can be supplied to the lubricant absorber **43** in the second casing **44** via the vent hole **58** installed to the second casing **44**. Further, the strip-like projection **51** of the second casing **44** is molded by rubber material and therefore, by piercing an injection needle directly to the strip-like projection **51**, the lubricant can also be replenished easily to the lubricant absorber **43**.

Further, according to the lubricant supplying member **4** of the embodiment, the lubricant coater **42** is constituted to coat the lubricant only to ball rolling grooves **11** of the track rail **1**, however, in such a constitution, the lubricant is difficult to adhere onto the upper face of the track rail **1** and therefore, when the sliding base **2** is moved on the track rail **1** at high speed, there is a concern that the seal lip portions **55** which are brought into abrasive contact with the track rail **1** may be destructed. Therefore, from such a point of view, as shown in FIG. **5**, it is preferable to form the projection piece **56** of the lubricant coater **42** also at a position in correspondence with the upper face of the track rail **1** and to coat the lubricant from the projection piece **56** onto the upper face of the track rail **1**.

FIG. **6** through FIG. **8** show a second embodiment of a lubricant supplying member.

A lubricant supplying member **6** of the second embodiment is constituted by a casing **60** which is mounted to the end plate **24** of the sliding base **2**, a lubricant coater **61** and a lubricant absorber **62** both incorporated in the casing **60**, and an oil amount adjusting plate (oil amount controlling means) **63** which separates the lubricant coater **61** from the lubricant absorber **62**.

The casing **60** is constituted by a casing main body **65** having a recess portion **64** for constituting a space for accommodating the lubricant absorber **62** and the lubricant coater **61** and a lid base plate **66** for hermetically closing the recess portion **64** of the casing main body **65** and when the casing **60** is mounted to the end plate **24** of the sliding base **2**, the lid base plate **66** is brought into contact with the end plate **24**.

FIG. **8** shows the casing main body **65**. According to the casing main body **65**, a side wall **68** made of rubber is erected along the contour of a steel plate constituting a base plate **67** and the recess portion **64** surrounded by the side wall **68** constitutes a space for accommodating the lubricant coater **61** and the lubricant absorber **62**. The recess portion **64** is formed to evade through holes **69** and **70** for the attaching bolts **25** and the supply nipple **27** and two of the recess portions **64** in correspondence with both of the left and right side faces of the track rail **1** are installed independently from each other and the lubricant coater **61** and the lubricant absorber **62** for lubricating the left side face of the track rail **1** and those for lubricating the right side face are incorporated in the two recess portions **64** independently from each other. Further, a face of the base plate **67** on the side opposed to the side wall **68** is covered by a protective layer **71** comprising rubber material and as shown in FIG. **6**, the seal lip portion **72** which is brought into close contact with the side faces and the upper face of the track rail **1** is projected from the protective layer **71**.

Meanwhile, the side wall **68** is formed with recess grooves **73** at positions opposed to the rolling faces **11** of the track rail **1** and portions of the lubricant coater **61** incorporated in the recess portion **64** are projected from the recess grooves **73**. Further, a stepped portion **74** is formed at the side wall **68** along the inner peripheral edge of the recess portion **64** and the oil amount adjusting plate **63** is fitted to the stepped portion **74** by which the lubricant coater **61** and the lubricant absorber **62** are separated from each other. Further, a vent hole **75** is formed in the side wall **68** also in this embodiment and smooth movement of the lubricant from the lubricant absorber **62** to the lubricant coater **61** is achieved.

Similar to the first embodiment, the oil amount adjusting plate **63** is formed by a thin stainless steel sheet and only a single hole of a supply hole **76** for supplying the lubricant impregnated to the lubricant absorber **62** to the lubricant coater **61** is opened. Although the shape of the supply hole **76** is circular in this embodiment, other shape may be adopted. The positions of opening the supply holes **76** are disposed at positions designated by broken lines in FIG. **8** and positions constituting substantially even distances to two streaks of the ball rolling faces **11** to which the lubricant is supplied from the respective lubricant coaters **61**.

Further, according to the lubricant supplying member **6** constituted in this way, firstly, the side walls **68** and the protective layer **71** are bonded to the base plate **67** by vulcanization bonding to thereby fabricate the casing main body **65**, the lubricant absorber **62** impregnating with the lubricant is incorporated in the recess portion **64** of the casing main body **65** and thereafter, the oil amount adjusting plates **63** are fitted to the stepped portions **74** of the side walls **68** of the casing main body **65** to cover the lubricant absorbers **62**. Next, the lubricant coaters **61** are made to overlap the oil amount adjusting plates **63** and finally, the lid base plate **66** is bonded to the side walls **68** of the casing main body **65** by vulcanization bonding. In this way, the lubricant supplying member **6** incorporating the lubricant coater **61** and the lubricant absorber **62** at inside thereof is completed.

The lubricant supplying member **6** of the second embodiment constituted in this way is mounted to both of the front and rear end faces of the sliding base **2** of the linear guide device similar to the supplying member **4** of the first embodiment and the lubricant is coated from the lubricant coaters **61** onto the ball rolling faces **11** of the track rail **1** in accordance with movement of the sliding base **2**.

In order to confirm whether the lubricant can stably be coated on the ball rolling faces **11** of the track rail **1** by the lubricant supplying member **6** of the second embodiment, the inventors have measured an amount of the lubricant actually delivered from the lubricant supplying member **6** by using a tester **80** shown in FIG. **9**. According to the tester, a rotating circular disk **82** rotated by a motor **81** is assumed to represent the track rail **1**, three pieces of the lubricant supplying members **6** are arranged at the surrounding of the rotating circular disk **82** and the lubricant is coated from the lubricant coaters **61** of the lubricant supplying members **6** onto the rotating circular disk **82**. In this case, a speed of moving the rotating circular disk **82** relative to the lubricant supplying member **6** is set to 300 m/min. Further, in view of maintaining the viscosity of the lubricant constant, temperature of each of the lubricant supplying members **6** is monitored by a thermocouple and temperature of the lubricant occluded in the lubricant supplying member **6** is maintained at 25° C. Further, scrapers **83** are arranged among the lubricant supplying members **6** contiguous to each other such that coating condition of the lubricant on the rotating circular disk **82** is always made uniform and the lubricant coated from the lubricant supplying members **6** onto the rotating circular disk **82** is scraped off.

According to the test, the delivery amount of the lubricant from the lubricant supplying member **6** is calculated as follows. First, the weight of the lubricant supplying member **6** before supplying the lubricant is measured by an electronic balance, thereafter, the lubricant is injected into the lubricant absorber **62** incorporated in the lubricant supplying member **6** and the weight of the lubricant supplying member **6** is measured again by the electronic balance. Thereby, the weight of the supplied lubricant is grasped. Next, the lubricant supplying members **6** are set to the tester, the lubricant supplying members **6** are made to run by a predetermined distance by rotating the rotating circular disk **82** and thereafter, the weight of the lubricant supplying member **6** is measured by the electronic balance by which a total amount of the lubricant delivered during the rotation of the rotating circular disk **82** is calculated.

First, the applicant has carried out a test of confirming the delivery amount of the lubricant in respect of each of cases where the number of the supply hole having a diameter of 1 mm is 1, where it is 3 and where it is 6 in order to confirm whether the delivery amount of the lubricant in respect of the ball rolling face **11** of the track rail **1** differs in accordance with the number of the supply holes **76** opened in the oil amount adjusting plate **63**. Further, the test has been carried out by preparing 3 of test pieces in respect of each of the numbers of the supply holes **76**. FIG. **10**(*a*) shows a result when the number of supply hole is 1, FIG. **10**(*b*) shows that in the case of 2 of the supply holes and FIG. **10**(*c*) shows a case of 3 of the supply holes.

As is apparent from these graphs, it is confirmed that even in cases of different numbers of the supply holes **76** opened in the oil amount adjusting plate **63**, after running a certain degree of distance, the inclinations of the graphs are reduced, and an extremely small amount of the lubricant is stably supplied from the lubricant supplying member **6** to the rotating circular disk **82**. However, it has been found that although when the number of the supply hole **76** opened in the oil amount adjusting plate **63** is 1, substantially the same amount of the lubricant is delivered in each of the three test pieces, when the number of the supply holes **76** is plural, there is a tendency in which a dispersion in the delivery amount of the lubricant is significant in respect of the three test pieces and when the test piece is changed, the delivery amount of the lubricant differs significantly. Therefore, it is preferable in view of achieving stabilization of the amount of coating the lubricant onto the track rail **1** for each of the lubricant supplying members **6** to set the number of the supply hole **76** opened in the oil amount adjusting plate **63** to 1 for each of the lubricant coater **61**.

Next, the applicant has carried out a test of confirming the delivery amount of the lubricant in respect of 4 kinds of cases where the inner diameter of the supply hole **76** is 1 mm, where it is 2 mm, where it is 4 mm and further, where the oil amount adjusting plate **63** is not installed in order to confirm whether the delivery amount of the lubricant in respect of the ball rolling face **11** of the track rail **1** differs in accordance with a change in the inner diameter of the supply hole **76** opened in the oil amount adjusting plate **63**. Further, the test has been carried out by preparing three test pieces for each of the inner diameters of the supply hole **76**. A result thereof is shown in FIG. **11**.

As is apparent from these graphs, it has been found that the larger the inner diameter of the supply hole **76** opened in the oil amount adjusting plate **63**, the larger the inclination of the graph and the more increased is the lubricant coated from the lubricant supplying member **6** onto the rotating circular disk **82**. The reason seems to be that the larger the inner diameter of the supply hole **76**, the more increased is the contact area between the lubricant coater **61** and the lubricant absorber **62**, the amount of the lubricant moving from the lubricant absorber **62** to the lubricant coater **61** is increased and more lubricant is impregnated by the lubricant coater **61**.

Accordingly, it is preferable in view of stably coating a small amount of lubricant to the ball rolling face **11** of the track rail **1** over a long period of time to determine that the number of the supply hole **76** opened in the oil amount adjusting plate **63** is set to 1 for each of the lubricant coaters **61** and determine the inner diameter in accordance with the amount of lubricant which is necessitated in accordance with use of a bearing for linear sliding or the like.

Further, when the inventors has measured the delivery amount of lubricant by changing the attitude of the lubricant supplying member **6** in respect to the rotating circular disk **82**, even in the case where the number and the inner diameter of the supply hole opened in the oil amount adjusting plate **63** remains the same, the amount of lubricant delivered from the respective lubricant supplying member **6** onto the rotating circular disk **12** has differed. The reason seems to be that when the attitude of using the lubricant supplying member **6** is changed, the amount of lubricant disposed upward from the supply hole **76** of the oil amount adjusting plate **63** in the lubricant impregnated to the lubricant absorber **62** is changed and the amount of the lubricant moving from the lubricant absorber **62** to the lubricant coater **61** is changed by influence of gravity.

Accordingly, it is preferable that the supply hole **76** is opened in the oil amount adjusting plate **63** in coincidence with the gravity center of the lubricant absorber **62** and according to such a constitution, regardless of the attitude of using the lubricant supplying member **6**, the amount of lubricant moving from the lubricant absorber **62** to the lubricant coater **61** by influence of gravity can be made substantially constant.

FIG. **12** through FIG. **14** show an embodiment where the present invention is applied to a ball screw.

In the drawings, notation **90** designates a screw shaft (track shaft) on which a ball rolling groove **91** in a spiral shape is formed with a predetermined lead, notation **92** designates a nut member (slide member) having infinite tracks for circulating balls **93** and screwed to the screw shaft **90** via the balls **93**, and notation **94** designates lubricant supplying members mounted to both of front and rear end faces of the nut member **92**. Further, the lubricant coater **42**, the lubricant absorber **43** and the oil amount adjusting plate (oil amount controlling means) **45** provided to the lubricant supplying member **94** are the same as those in the first embodiment mentioned above and accordingly, the same reference notations are attached thereto in the drawings and an explanation thereof will be omitted.

Here, the nut member **92** is constituted by a nut main body **96** made of steel projected with a flange portion **95** for fixing the nut member **92** and a pair of lids **97** made of synthetic resin fixed on both of the front and rear end faces of the nut main body **96**.

While a load rolling groove **98** in a spiral shape opposed to the ball rolling groove **91** of the screw shaft **90** is formed on the inner diameter side, a ball return hole **99** in parallel with the screw shaft **90** is perforated. Further, the lid **97** is formed with direction change paths **100** for guiding the balls **93** which have finished rolling on the load rolling groove **98** of the nut main body **96** to ends on one side of the ball return holes **99** and on the other hand, guiding the balls **93** from ends on the other side of the ball return hole **99** to the load rolling groove **98** and the infinite tracks of the balls **93** are completed by fixing the lids **97** to the nut main body **96**.

Further, although the lubricant supplying member **94** is formed in a ring-like shape in compliance with the shape of the nut member **92**, the point where the lubricant coater, the oil amount adjusting plate and the lubricant absorber are incorporated in the casing is similar to that in the lubricant supplying members **4** and **6** mounted to the above-described linear guiding device and a detailed explanation thereof will be omitted here.

Further, according to the ball screw device of the embodiment constituted as mentioned above, when the screw shaft **90** and the nut member **92** are rotated relative to each other, the balls **93** roll on the load rolling groove **98** of the nut member **92** and the ball rolling groove **91** of the screw shaft **90** and the nut member **92** is moved in the axial direction of the screw shaft **90** while revoluting around the screw shaft **90**. In this case, the lubricant is coated from the lubricant supplying member **94** onto the ball rolling groove **91** of the screw shaft **90** in accordance with the movement of the nut member **92** and lubrication of the ball rolling groove **91** and the balls **93** rolling thereon is carried out similar to the above-described embodiments.

Further, the ball screw shown in FIG. **12** through FIG. **14** is of a type where the nut member **92** is fixed to a machine device of a table or the like by the flange portion **95** and which is used by rotating the screw shaft **90** by a motor, the ball screw to which the present invention is applicable is not limited thereto but, for example, as shown in FIG. **15**, it may be of a type in which the nut member **92** is supported rotatably by a fixed unit of a table of the like via a pair of angular contact bearings **101** and which is used by rotating it in respect of the nut member **92** by a motor (not illustrated).

Next, FIG. **16** through FIG. **18** show an embodiment in which the present invention is applied to a ball spline.

In the drawings, notation **110** designates a spline shaft (track shaft) where ball rolling grooves **111** are formed along the axial direction, notation **112** designates a nut member (slide member) having infinite tracks for circulating balls **113** and fitted to the spline shaft **110** via the balls **113** and notation **114** designates lubricant supplying members mounted to both of front and rear end faces of nut member **112**.

In this case, the nut member **112** is constituted by a nut main body **116** made of steel where a key groove **115** for fixing the nut member **112** is formed on the outer peripheral face and ball retainers **117** made of synthetic resin for forming the infinite circulation paths of the balls **113** by being fitted to the inner diameter of the nut main body **116**. Further, although the lubricant supplying member **114** is formed in a ring-like shape in compliance with the shape of the nut member **112**, the point where the lubricant coater, the oil amount adjusting plate and the lubricant absorber are incorporated in the casing is the same as that of the lubricant supplying members **4** and **6** mounted to a bearing for linear sliding and a detailed explanation thereof will be omitted here.

Further, according to the ball spline of the embodiment constituted as described above, when the nut member **112** is moved along the spline shaft **110**, the lubricant is coated from the lubricant supplying members **114** mounted to the nut member **112** onto the ball rolling grooves **111** of the spline shaft **110** and lubrication of the ball rolling grooves **111** and the balls **113** rolling thereon is carried out similar to the above-described embodiments.

INDUSTRIAL APPLICABILITY

As has been explained, according to the linear movement device of the present invention, the lubricant supplying member is provided with the lubricant coater for coating lubricant to the track shaft and the lubricant absorber for supplying the lubricant to the lubricant coater and is further provided with the oil amount controlling means for controlling the amount of the lubricant supplied from the lubricant absorber to the lubricant coater and accordingly, even when the accumulated running distance of the guide member in respect of the track shaft is increased in accordance with elapse of time, a stable amount of the lubricant is always impregnated to the lubricant coater supplied with the lubricant from the lubricant absorber, a constant amount of the lubricant is always coated from the lubricant coater onto the track shaft and accordingly, an amount of the lubricant which is a necessary minimum in lubricating the rolling face of the rolling element or the rolling element can be coated on the track shaft stably over a long period of time.

Further, the necessary minimum amount of the lubricant can stably be coated and therefore, the face of the track shaft for rolling the rolling element can be lubricated by a small amount of the lubricant over a long period of time and the lubricant absorber can be downsized by that amount and a compact linear movement device can be designed.

What is claimed is:

1. A linear movement device comprising a track shaft where a rolling face of a rolling element is formed, a slide member engaged with the track shaft via the rolling element and moved relative to the track shaft and a lubricant supplying member mounted to the slide member and coating a lubricant on a surface of the track shaft in accordance with the relative movement:

wherein the lubricant supplying member comprises a lubricant coater brought into contact with the track shaft for coating the lubricant on the track shaft, a lubricant absorber installed contiguous to the lubricant coater for supplying the lubricant to the lubricant coater while absorbing the lubricant and holding the lubricant and oil amount controlling means for controlling an amount of the lubricant supplied from the lubricant absorber to the lubricant coater.

2. The linear movement device according to claim **1**, wherein the lubricant supplying member comprises a casing mounted to the sliding member and the lubricant coater and the lubricant absorber are incorporated in the casing.

3. The linear movement device according to claim **2**, wherein the casing comprises a seal lip portion brought into close contact with the surface of the track shaft.

4. The linear movement device according to claim **2** or claim **3**, wherein the casing is formed by a soft elastic body.

5. The linear movement device according to claim **1** or **2**, wherein the oil amount controlling means is constituted by changing a material of the lubricant absorber from a material of the lubricant coater.

6. The linear movement device according to claim **1** or **2**, wherein the oil amount controlling means is an oil amount adjusting film which separates the lubricant absorber from the lubricant coater and permeates the lubricant from a side of the lubricant absorber to a side of the lubricant coater.

7. The linear movement device according to claim **1** or claim **2**, wherein the supply amount controlling means is an oil amount adjusting film which separates the lubricant absorber from the lubricant coater and in which a supply hole of the lubricant is opened.

8. The linear movement device according to claim **7**, wherein an inner diameter and/or a number of the supply holes opened in the oil amount adjusting plate is adjusted in accordance with an amount of lubricant to be coated on the track shaft.

9. A lubricant supplying device mounted to a slide member engaged with a track shaft via a rolling element for coating a lubricant to the track shaft in accordance with a relative movement between the slide member and the track shaft:

wherein the lubricant supplying device comprises a lubricant coater brought into contact with the track shaft for coating the lubricant to the track shaft, a lubricant absorber installed contiguous to the lubricant coater for supplying the lubricant to the lubricant coater while absorbing the lubricant and holding the lubricant and oil amount controlling means for controlling an amount of the lubricant supplied from the lubricant absorber to the lubricant coater.

10. The lubricant supplying device according to claim **9**, wherein the lubricant coater and the lubricant absorber are incorporated in a casing and mounted to the slide member via the casing.

[57] **ABSTRACT**

A guide apparatus for biaxial shifting motion and uniaxial turning motion comprises a biaxial shifting guide mechanism and a pivot supporting mechanism. The biaxial shifting motion guide mechanism supports a second member so as to be movable relative to a first member in a constant posture state along biaxial lines intersecting at right angles with each other. The pivot supporting mechanism is disposed on the biaxial shifting motion guide mechanism at an opposite side of the first member and pivotably supports the second member.

GUIDE APPARATUS FOR BIAXIAL SHIFTING MOTION AND UNIAXIAL TURNING MOTION

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a guide apparatus for biaxial shifting motion and uniaxial turning motion.

2. Description of the Related Art

There has already been known a guide apparatus for biaxial shifting motion and uniaxial turning motion disclosed for example in Japanese Patent Provisional Publication No. H8-99243.

In the above-mentioned guide apparatus, a linear motion guide apparatus composed of a guide rail and a movable block is combined with the other linear motion guide apparatus having the same structure so that the movable block of the former is pivotably connected through a pivot supporting mechanism to the movable block of the latter. The guide rail of the former linear motion guide apparatus is fixed to a base and the guide rail of the latter liner motion guide apparatus is fixed to a table. A plurality of guide apparatus each having such a structure are used to form a table for biaxial shifting motion and uniaxial turning motion.

The above-described conventional guide apparatus for biaxial shifting motion and uniaxial turning motion however has the following problems.

In the conventional guide apparatus, two guide rails defining biaxial directions respectively turn on the plane defined by the biaxial lines. As a result, there is difficulty in control of turning motion at a point other than the origin of the coordinate axes and of shifting motion in longitudinal and lateral directions (i.e., X and Y directions) after the turn by a prescribed turning angle. When a table **103** turns as shown in FIG. **11** at the origin of the coordinate axes with the use of three sets of guide apparatus for biaxial shifting motion and uniaxial turning motion **100**, **101**, **102**, movable guide rails **100**Y, **101**X, **102**X of the guide apparatus **100**, **101**, **102** incline relative to stationary guide rails **100**X, **101**Y, **102**Y. A translation operation of the table **103** from the above-mentioned condition requires a parallel movement of each of the movable guide rails **100**Y, **101**X, **102**X as well as a proper maintenance of the inclined angle of the movable guide rails **100**Y, **101**X, **102**X relative to the stationary guide rails **100**OX, **101**Y, **102**Y, thus leading to an extremely complex control.

It is actually difficult to dispose the pivot supporting mechanism between the movable blocks of the linear motion guide apparatus. More specifically, when the pivot supporting mechanism having outer and inner rings is disposed between the movable blocks, the outer ring is for example secured to one of the movable blocks and the inner ring is secured to the other of them. Accordingly, it is necessary to form a hole on the one movable block, into which the outer ring can be fitted, to form a projection on the other movable block, which can be fitted into the inner surface of the inner ring, and to provide a means for preventing the pivot supporting mechanism from coming out, thus requiring a complex structure.

There is also required a proper squareness of the bottom surface of each of the guide rails secured to the base and the table, respectively, relative to the pivot axis of each of the pivot supporting mechanisms. The squareness is determined for example by the fitting surfaces of the outer ring and the portion of the one movable block, which forms the hole as

well as the fitting surfaces of the inner ring and the projection formed on the other movable block, as described above. Combination of a working error in diametrical length of the hole formed on the one movable block with an improper squareness of the inner peripheral surface of the portion of the one movable block, which forms the hole, combination of a working error in diametrical length of the outer periphery of the projection formed on the other movable block with an improper squareness of the outer peripheral surface of the projection, and combination of working errors in an outer diametrical length of the outer ring and an inner diametrical length of the inner ring are complicated and there cannot be obtained a proper squareness of the bottom surface of the guide rail relative to the pivot axis of the pivot supporting mechanism.

An improper squareness causes a wavy movement of the table when the table turns, thus making it impossible to carry out a positional determination with high precision. A conceivable method of disposing a guide mechanism between the movable blocks in order to obtain a proper squareness leads to a complicated structure.

A plurality of holes for bolts for fixing the guide rails to the table are required to be formed thereon. In this case, it is necessary to apply a precise working to the table to form the hole with a prescribed proper pitch.

When force is applied to the table at a position apart from the pivot axis of the guide apparatus for biaxial shifting motion and uniaxial turning motion, a moment load having a function of inclining the pivot axis is applied to the pivot supporting mechanism. The moment load is applied through the guide rail to the pivot supporting mechanism so that the moment load is amplified by an amount corresponding to the length of the guide rail. Accordingly, a large displacement occurs at the pivot axis and the inclination angle of the table increases, thus leading to a poor positional determination.

SUMMARY OF THE INVENTION

An object of the present invention, which was made in order to solve the above-described problems, is therefore to provide a guide apparatus for biaxial shifting motion and uniaxial turning motion, which permits an easy operation control and an easy installation in a table and a proper guide and support of the table with high precision.

In order to attain the aforementioned object, a guide apparatus for biaxial shifting motion and uniaxial turning motion comprises a biaxial shifting motion guide mechanism for supporting a second member so as to be movable relative to a first member in a constant posture state along biaxial lines intersecting at right angles with each other; and a pivot supporting mechanism disposed on said biaxial shifting motion guide mechanism at an opposite side of said first member, for pivotably supporting said second member.

In the present invention, even when the second member is moved in parallel to a prescribed position and then is turned there, the biaxial lines in the biaxial shifting motion guide mechanism are invariable, thus making it possible to make an easy determination of an amount of displacement in each of the biaxial directions, which corresponds to the turning motion of the second member.

The biaxial lines in the biaxial shifting motion guide mechanism are invariable as mentioned above even after the turning motion of the second member, it is very easy to control of the parallel movement of the second member along the biaxial directions.

In the present invention, the pivot supporting mechanism may comprise a first ring and a second ring. The first ring is secured to the biaxial shifting motion guide mechanism and has a central axis, which is substantially identical with a line intersecting at right angles a plane defined by the biaxial lines. The second ring is coupled through a plurality of rolling members with the first ring so as to be rotatable relative thereto and is connected to the second member.

The biaxial shifting motion guide mechanism may comprise a first guide rail secured to the first member, a movable block connected through a plurality of rolling members to the first guide rail so as to be movable and a second guide rail connected through a plurality of rolling members to the movable block so as to be movable in a direction intersecting the first guide rail. The pivot supporting mechanism may comprise a first ring and a second ring. The first ring is secured to the second guide rail and the second ring is coupled through a plurality of rolling members with the first ring so as to be rotatable relative thereto and is secured to the second member.

In such an embodiment of the present invention, the first ring is secured to the second guide rail and the second ring is secured to the second member. Accordingly, the securing of the first ring to the second rail suffices, leading to an easy installation working.

The first guide rail and the second guide rail are connected to the single movable block, and parallelism between the bottom surfaces of the pair of guide rails can therefore be obtained by an easy machining process of the single movable block.

As a result, when there is obtained only a proper squareness of the pivot axis of the first ring relative to the second guide rail, a proper squareness of the bottom surface of the first guide rail relative to the pivot axis can automatically be obtained, and the parts of the guide apparatus can very easily be assembled under a precise positional determination condition.

Formation of only a hole, into which the second ring is to be fitted, on a table as the second member suffices, thus leading to an easy working process on the table. When force is applied to the table at a position apart from the pivot axis of the guide apparatus for biaxial shifting motion and uniaxial turning motion, a moment load having a function of inclining the pivot axis is applied to the pivot supporting mechanism. The moment load is however applied through the second ring to the pivot axis and a merely small displacement occurs at the pivot axis.

The apparatus of the present invention may further comprise a linear actuator secured to any one of the first member and the second member. The linear actuator is operatively connected to the movable block.

In such an embodiment of the present invention, pushing the movable block by means of the above-mentioned linear actuator permits relative movement of the movable block between the first member and the second member.

According to such an operative connection of the linear actuator with the movable block, it is unnecessary to form any specific connecting portions for the linear actuator on the first and second members.

It is preferable to use a screw feeding mechanism as the linear actuator. In this case, the movable block preferably has a nut portion, to which a feed screw of the above-mentioned screw feeding mechanism is screwed.

When the screw feeding mechanism is used, the non-turning condition of the feed screw permits to make a positional determination of the movable block in the axial direction of the feed screw.

It is preferable to provide the apparatus of the present invention with the following features:

(1) the first recess portion, into which the first guide rail is to be inserted slidably is formed on one side of the movable block;

(2) there are provided four roller running grooves so that the two roller running grooves of them are respectively formed on the upper and lower portions of each of the right and left-hand longitudinal side surfaces of the first guide rail, there are provided four roller running counter-grooves, which face the four roller running grooves, respectively, so that the two roller running counter-grooves of them are respectively formed on the upper and lower portions of each of the right and left-hand inner surfaces of the first recess portion, there are formed four rolling member returning passages on the movable block so as to be in parallel with the above-mentioned four roller running grooves, and there is provided on each of the longitudinal opposite ends of the movable block a side cover having direction changing passages for connecting the four roller running grooves with the four rolling member returning passages;

(3) in each of the right and left-hand longitudinal side surfaces of the first guide rail, a line connecting the contact points of the rolling member with the upper roller running groove and the upper roller running counter-groove facing thereon and the other line connecting the contact points of the rolling member with the lower roller running groove and the lower roller running counter-groove facing thereon symmetrically incline relative to a horizontal line locating between the upper two trains of rolling members and the lower two trains of rolling members;

(4) the second recess portion, into which the second guide rail is to be inserted slidably is formed on the other side of the movable block;

(5) there are provided four roller running grooves so that the two roller running grooves of them are respectively formed on the upper and lower portions of each of the right and left-hand longitudinal side surfaces of the second guide rail, and there are provided four roller running counter-grooves, which face the four roller running grooves, respectively, so that the two roller running counter-grooves of them are respectively formed on the upper and lower portions of each of the right and left-hand inner surfaces of the second recess portion, there are formed four rolling member returning passages on the movable block so as to be in parallel with the above-mentioned four roller running grooves, and there is provided on each of the longitudinal opposite ends of the movable block a side cover having direction changing passages for connecting the four roller running grooves with the four rolling member returning passages; and

(6) in each of the right and left-hand longitudinal side surfaces of the second guide rail, a line connecting the contact points of the rolling member with the upper roller running groove and the upper roller running counter-groove facing thereon and the other line connecting the contact points of the rolling member with the lower roller running groove and the lower roller running counter-groove facing thereon symmetrically incline relative to a horizontal line locating between the upper two trains of rolling members and the lower two trains of rolling members.

According to such a structure in which the four trains of rolling members are disposed between the first recess portion of the movable block and the first guide rail and the similar four trains of rolling members are also disposed between the second recess portion of the movable block and the second guide rail, and in each of the right and left-hand longitudinal side surfaces of each of the first and second guide rails, the line connecting the contact points of the rolling member with the upper roller running groove and the upper roller running counter-groove facing thereon and the other line connecting the contact points of the rolling member with the lower roller running groove and the lower roller running counter-groove facing thereon symmetrically incline relative to the horizontal line locating between the upper two trains of rolling members and the lower two trains of rolling members, there can be obtained a supporting structure having a high rigidity against loads applied from any direction, such as compressive load in the axial direction of the pivot axis, tensile load in the axial direction of the pivot axis, load acting in a direction perpendicular to the pivot axis, moment load having a function of inclining the pivot axis and the like.

In the present invention, the biaxial shifting motion guide mechanism may comprise a first guide rail secured to the first member, a first movable block connected through a plurality of rolling members to the first guide rail so as to be movable, a second guide rail secured to the first movable block so as to intersect the first guide rail and a second movable block movably connected through a plurality of rolling members to the second guide rail; and the pivot supporting mechanism may comprise a first ring and a second ring. The first ring is secured to the second movable block and the second ring is coupled through a plurality of rolling members with the first ring so as to be rotatable relative thereto and is secured to the second member.

Also in such an embodiment of the present invention, the first ring is secured to the second guide rail and the second ring is secured to the second member. Accordingly, the securing of the first ring to the second rail suffices, leading to an easy installation working.

In the above-mentioned embodiment, the second guide rail is secured to the first movable block and the second movable block is slidably connected to the second guide rail. As a result, when there is obtained only a proper squareness in the contact surfaces of the first movable block and the second guide rail, which are secured to each other, and in the contact surfaces of the second movable block and the first guide rail, a proper squareness of the bottom surface of the first guide rail relative to the pivot axis can automatically be obtained, and the parts of the guide apparatus can very easily be assembled under a precise positional determination condition.

Formation of only a hole, into which the second ring is to be fitted, on a table as the second member suffices, thus leading to an easy working process on the table. When force is applied to the table at a position apart from the pivot axis of the guide apparatus for biaxial shifting motion and uniaxial turning motion, a moment load having a function of inclining the pivot axis is applied to the pivot supporting mechanism. The moment load is however applied through the second ring to the pivot axis and a merely small displacement occurs at the pivot axis.

In the present invention, the first guide rail may have a pair of supporting walls, between which the first movable block is held through the rolling members.

According to such a structure in which the first movable block is held between the pair of supporting walls of the first guide rail, stability can be improved.

It is preferable to dispose a linear actuator for moving the first movable block relative to the first guide rail, between the first guide rail and the first movable block.

When the linear actuator is disposed between the first guide rail and the first movable block as mentioned above, and the linear actuator is located in the central portion of the first movable block, the distance between the portion of the first movable block, to which force for moving the first movable block is imparted, and each of the trains of the rolling members located between the first guide rail and the first movable block can be decreased, with the result that moment load caused by the rolling resistance of the trains of the rolling members and the driving force for moving the first movable block does not have any adverse effects.

The above-mentioned linear actuator is preferably composed of a screw shaft, which is disposed so as to be in parallel with the supporting walls of the first guide rail and is screwed into a screw hole formed on the first movable block; a bearing member for rotatably supporting the screw shaft; and a driving mechanism for rotating the screw shaft.

According to such a structure, it is unnecessary to provide any specific linear driving mechanism between the base and the table.

It is also preferable to provide the apparatus of the present invention with the following features:

(1) there are provided four roller running grooves so that the two roller running grooves of them are respectively formed on the upper and lower portions of each of the right and left-hand supporting walls of the first guide rail, there are provided four roller running counter-grooves, which face the four roller running grooves, respectively, so that the two roller running counter-grooves of them are respectively formed on the upper and lower portions of each of the right and left-hand side surfaces of the first guide rail, there are formed four rolling member returning passages on the first movable block so as to be in parallel with the above-mentioned four roller running grooves, and there is provided on each of the longitudinal opposite ends of the movable block a side cover having direction changing passages for connecting the four roller running grooves with the four rolling member returning passages;

(2) the second recess portion, into which the second guide rail is to be inserted slidably is formed on the second movable block; and

(3) there are provided four roller running grooves so that the two roller running grooves of them are respectively formed on the upper and lower portions of each of the right and left-hand longitudinal side surfaces of the second guide rail, and there are provided four roller running counter-grooves, which face the four roller running grooves, respectively, so that the two roller running counter-grooves of them are respectively formed on the upper and lower portions of each of the right and left-hand inner surfaces of the second recess portion of the second movable block, there are formed four rolling member returning passages on the second movable block so as to be in parallel with the above-mentioned four roller running grooves, and there is provided on each of the longitudinal opposite ends of the second movable block a side cover having direction changing passages for connecting the four roller running grooves with the four rolling member returning passages.

When the four trains of rolling members are disposed between the first movable block and the supporting walls of the first guide rail and the similar four trains of rolling members are also disposed between the second guide rail and the inner side surfaces of the recess portion of the second movable block, and a line connecting the contact points of the rolling member with the upper roller running groove and the upper roller running counter-groove facing thereon and the other line connecting the contact points of the rolling member with the lower roller running groove and the lower roller running counter-groove facing thereon symmetrically incline relative to a horizontal line locating between the upper two trains of rolling members and the lower two trains of rolling members, then there can be obtained a supporting structure having a high rigidity against loads applied from any direction, such as compressive load in the axial direction of the pivot axis, tensile load in the axial direction of the pivot axis, load acting in a direction perpendicular to the pivot axis, moment load having a function of inclining the pivot axis and the like.

In the present invention, the second ring may be coupled through rollers as the rolling members with an outer periphery of the first ring; the first ring may have on an outer peripheral surface thereof a first groove, which opens outward in a radius direction of the first ring, the first groove is composed of an upper roller-running surface and a lower roller-running surface intersecting the upper roller-running surface substantially at right angles; the second ring may have on an inner peripheral surface thereof a second groove, which opens inward in a radius direction of the second ring so as to face the first groove, the second groove is composed of an upper roller-running surface and a lower roller-running surface intersecting the upper roller-running surface substantially at right angles; and a part of the rollers disposed between the first groove and the second groove may be rollable between the upper roller-running surface of the first ring and the lower roller-running surface of the second ring, and a remaining part of the rollers may be rollable between the lower roller-running surface of the first ring and the upper roller-running surface of the second ring.

According to such a structure in which the rollers are disposed between the first ring and the second ring, there can be obtained a supporting structure, which is composed of a pair of rings, i.e., the first ring and the second ring, and has a high rigidity against loads applied from any direction, such as compressive load in the axial direction of the pivot axis, tensile load in the axial direction of the pivot axis, load acting in a direction perpendicular to the pivot axis, moment load having a function of inclining the pivot axis and the like. As a result, there can be obtained the supporting structure, which is lightweight and has a high rigidity. In addition, such a supporting structure can be provided in a large-size.

Each of the above-mentioned part of the rollers disposed so as to be rollable between the upper roller-running surface of the first groove and the lower roller-running surface of the second groove, and each of the remaining part of the rollers disposed so as to be rollable between the lower roller-running surface of the first groove and the upper roller-running surface of the second groove may be arranged alternately.

It is preferable to provide a pre-load imparting means for imparting pre-load to the rollers disposed between the first groove and the second groove. The supporting structure having a further high rigidity can be obtained by imparting such pre-load to the rollers.

An apparatus for biaxial shifting motion and uniaxial turning motion of the present invention comprise (1) a base, (2) a table, (3) a biaxial shifting motion guide mechanism for supporting the table so as to be movable relative to the base in a constant posture state along biaxial lines intersecting at right angles with each other and (4) a pivot supporting mechanism disposed on the biaxial shifting motion guide mechanism at an opposite side of the base, for pivotably supporting the table.

In an embodiment of the above-described apparatus of the present invention, the biaxial shifting motion guide mechanism may comprise a first guide rail secured to the base, a movable block connected through a plurality of rolling members to the first guide rail so as to be movable and a second guide rail connected through a plurality of rolling members to the movable block so as to be movable in a direction intersecting the first guide rail, and the pivot supporting mechanism may comprise a first ring and a second ring. The first ring is secured to the second guide rail and the second ring is coupled through a plurality of rolling members with the first ring so as to be rotatable relative thereto and is secured to the table.

In the other embodiment of the above-mentioned apparatus of the present invention, the biaxial shifting motion guide mechanism may comprise a first guide rail secured to the base, a first movable block connected through a plurality of rolling members to the first guide rail so as to be movable, a second guide rail secured to the first movable block so as to intersect the first guide rail and a second movable block movably connected through a plurality of rolling members to the second guide rail, and the pivot supporting mechanism may comprise a first ring and a second ring. The first ring is secured to the second movable block and the second ring is coupled through a plurality of rolling members with the first ring so as to be rotatable relative thereto and is secured to the table.

In the above described embodiments of the present invention, the first guide rail of the biaxial shifting motion guide mechanism is secured to the base and the second ring of the pivot supporting mechanism is secured to the table. However, the second ring of the pivot supporting mechanism may be secured to the base and the first guide rail of the biaxial shifting motion guide mechanism may be secured to the table.

As the biaxial shifting motion guide mechanism, there may be used a plurality of biaxial shifting motion guide mechanisms disposed between the base and the table.

The plurality of biaxial shifting motion guide mechanisms can be disposed in any place. In case that the table having a rectangular shape is supported, the biaxial shifting motion guide mechanisms respectively disposed at the four corners of the table permit to prevent the four corners of the table from being deformed. There is available a structure in which a large vacancy is formed at the central portion of the table, and as a result, a working process of passing something through the vacancy can be carried out. Such a structure leads to decrease in weight of the apparatus.

A braking mechanism for maintaining the stationary condition of the table relative to the base may be provided between the table and the base. The braking mechanism may comprise a brake pad provided so as to be capable of coming into contact with any one of the table and the base or separating therefrom, a linear guide mechanism secured to the other of the table and the base, for guiding and supporting the brake pad, and a pressure mechanism for moving the brake pad toward the above-mentioned one of the table and the base and pressing the same against the above-mentioned one of them.

According to such a structure in which the brake pad is guided and supported by the linear guide mechanism, load given to the brake pad through the table can be born by means of the linear guide mechanism and is not applied to the pressure mechanism. Even when the pressure mechanism has no sufficient rigidity in the transverse direction, there occurs no variation in shifting position of the table, which may be caused by the deformation of the pressure mechanism.

BRIEF DESCRIPTION OF THE DRAWINGS

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Now, embodiments of a guide apparatus for biaxial shifting motion and uniaxial turning motion of the present invention will be described in detail below with reference to the accompanying drawings.

FIGS. **1**(*a*) to **3**(*b*) illustrate a guide apparatus **1** for biaxial motion and uniaxial turning motion of the first embodiment of the present invention.

In the first embodiment, the guide apparatus **1** is composed of a biaxial shifting motion guide mechanism **70** designed as an integral body and of a pivot supporting mechanism **80** combined with the biaxial shifting motion guide mechanism **70**.

More specifically, the biaxial shifting motion guide mechanism **70** is composed of a first guide rail **2** secured to a base **34** designed as the first member, a movable block **4** connected through balls **3** designed as a plurality of rolling members to the first guide rail **2** so as to be movable and a second guide rail **6** connected through balls **5** designed as a plurality of rolling members to the movable block **4** so as to be movable in a direction intersecting the first guide rail **2**.

The pivot supporting mechanism **80** is composed of a first ring **7** and a second ring **9**. The first ring **7** is secured to the second guide rail **6**. The second ring **9** is coupled through rollers **8** designed as a plurality of rolling members with the first ring **7** so as to be rotatable relative thereto. A table **33** designed as the second member is secured to the above-mentioned second ring **9**.

The first ring **7** designed as an inner ring and the above-mentioned second guide rail **6** having a linear shape are connected with each other through a coupling portion **29**.

The coupling portion **29** is provided with a first coupling plate **30** having a rectangular shape and a second coupling plate **31** having a disc-shape. The second guide rail **6** is secured to the first coupling plate **30**. The first ring **7** is secured to the second coupling plate **31**. The first coupling plate **30** and the second coupling plate **31** are connected to each other by means of a fastening member **32** such as a bolt and the like. The second coupling plate **31** has on its periphery a projection portion **311**. The first ring **7** designed as the inner ring is fitted to the projection portion **311** from the upper side. A supporting member **71** is tightly secured to the upper surface of the projection portion **311** by means of the fastening member **32** such as a bolt and the like. The first ring **7** is designed to be held between the supporting member **71** and a shoulder portion **311***a*, which is located at the lower portion of the projection portion **311** so as to maintain the stationary condition of the first ring **7**.

The table **33** to which the second ring **9** is to be secured has an opening **72** having a circular shape. The above-mentioned supporting member **71** of the first ring **7** is designed to be able to be inserted in the opening **72** from the upper side. A recess portion **73** is formed on the lower peripheral surface of the opening **72** of the table **33**. The second ring **72** is fitted to the recess portion **73**. A supporting member **74** for holding the second ring **9** is tightly secured to the peripheral edge of the recess portion **73** by means of the fastening member **32** such as a bolt and the like. The second ring **9** is designed to be held between the supporting member **74** and the peripheral edge **73***a* of the recess portion **73** so as to maintain the stationary condition of the second ring **9**.

A detailed description of the biaxial shifting motion guide mechanism **70** will be given below. The first guide rail **2**, the movable block **4** and the second guide rail **6** compose, as shown in FIG. **2**(*a*), a biaxial linear guide mechanism in which guiding directions cross each other at right angles. The movable block **4** has on its lower surface a first recess portion **10** having an inverse U-shaped cross section, in which the first guide rail **2** is to be inserted slidably. The movable block **4** has on its upper surface, i.e., the opposite surface to the first recess portion **10**, a second recess portion **11** in which the second guide rail **6** is to be inserted slidably.

The first guide rail **2** is provided with four ball running grooves **12** so that the two ball running grooves **12** are formed on each of the right and left-hand surfaces of the first guide rail **2**. On the other hand, the movable block **4** is provided with four ball running counter-grooves **13** so that the two ball running counter-grooves **13** are formed on each of the right and left-hand inner surfaces defining the first recess portion **10** of the movable block **4**, which face the right and left-hand surfaces of the first guide rail **2**. Accordingly, the four ball running grooves **12** of the first guide rail **2** face the four ball running counter-grooves **13** of the movable block **4**, respectively.

The movable block **4** has four ball return passages **14**, which are formed in parallel with each other on the lower half portion of the movable block **4**. The four ball return passages **14** correspond to the four ball running counter-grooves **13** formed in the first recess portion **10** of the movable block **4**, respectively. A side plate **16** is secured to each of the opposite end portions of the lower half portion of the movable block **4**, which has the first recess portion **10**. Each of the side plates **16** has four direction changing passages **15** for connecting the four ball running grooves **13** and the four ball return passages **14** of the movable block **4**.

In each of the right and left-hand longitudinal side surfaces of the first guide rail **2**, a line connecting the contact points of the ball **3** with the upper roller running groove **12** and the upper roller running counter-groove **13** facing thereon and the other line connecting the contact: points of the ball **3** with the lower roller running groove **12** and the lower roller running counter-groove **13** facing thereon symmetrically incline at a prescribed angle a relative to a horizontal line locating between the upper two trains of balls **3** and the lower two trains of balls **3**. In this embodiment, there is adopted a structure in which the line connecting the contact points of the ball **3** with the upper roller running groove **12** and the upper roller running counter-groove **13** facing thereon and the other line connecting the contact points of the ball **3** with the lower roller running groove **12** and the lower roller running counter-groove **13** facing thereon are close to each other at the inside of the first recess portion **10**, on the one hand, and are apart from each other at the outside of the first: recess portion **10**, on the other hand. Pre-load is given to the balls **3**. In the modification, there may of course be adopted a structure in which the line connecting the contact points of the ball **3** with the upper roller running groove **12** and the upper roller running counter-groove **13** facing thereon and the other line connecting the contact points of the ball **3** with the lower roller running groove **12** and the lower roller running counter-groove **13** facing thereon are apart from each other at the inside of the first recess portion **10**.

The second guide rail **6** is also provided with four ball running grooves **17** so that the two ball running grooves **17** are formed on each of the right and left-hand surfaces of the second guide rail **6**. On the other hand, the movable block **4** is provided with four ball running counter-grooves **18** so that the two ball running counter-grooves **18** are formed on each of the right and left-hand inner surfaces defining the second recess portion **11** of the movable block **4**, which face the right and left-hand surfaces of the second guide rail **6**. Accordingly, the four ball running grooves **17** of the second guide rail **6** face the four ball running counter-grooves **18** of the movable block **4**, respectively.

Further, the movable block **4** has four ball return passages **19**, which are formed in parallel with each other on the upper half portion of the movable block **4**. The four ball return passages **19** correspond to the four ball running counter-grooves **18** formed in the second recess portion **11** of the movable block **4**, respectively. A side plate **21** is secured to each of the opposite end portions of the upper half portion of the movable block **4**, which has the second recess portion **11**. Each of the side plates **21** has four direction changing passages **20** for connecting the four ball running grooves **18** and the four ball return passages **19** of the movable block **4**.

In each of the right and left-hand longitudinal side surfaces of the second guide rail **6**, a line connecting the contact points of the ball **5** with the upper roller running groove **17** and the upper roller running counter-groove **18** facing thereon and the other line connecting the contact points of the ball **5** with the lower roller running groove **17** and the lower roller running counter-groove **18** facing thereon symmetrically incline at a prescribed angle a relative to a horizontal line locating between the upper two trains of balls **5** and the lower two trains of balls **5**. In this embodiment, there is adopted a structure in which the line connecting the contact points of the ball **5** with the upper roller running groove **17** and the upper roller running counter-groove **18** facing thereon and the other line connecting the contact points of the ball **5** with the lower roller running groove **17** and the lower roller running counter-groove **18** facing thereon are close to each other at the inside of the second recess portion **11**, on the one hand, and are apart from each other at the outside of the second recess portion **11**, on the other hand. In the modification, there may of course be adopted a structure in which the line connecting the contact points of the ball **5** with the upper roller running groove **17** and the upper roller running counter-groove **18** facing thereon and the other line connecting the contact points of the ball **5** with the lower roller running groove **17** and the lower roller running counter-groove **18** facing thereon are apart from each other at the inside of the second recess portion **11**. Pre-load is given to the balls **5**.

Then, a detailed description of the pivot supporting mechanism **80** will be given below. As shown in FIGS. **3**(*a*) and **3**(*b*), the first and second rings **7**, **9** are designed as inner and outer rings, which are arranged concentrically with each other, respectively. In this embodiment, the first ring **7** secured to the second guide rail **6** is used as the inner ring, and the second ring **9** is used as the outer ring. Rollers **8** are used as the rolling members in this embodiment.

The first ring **7** designed as the inner ring has on its outer peripheral surface a first groove **24**, which opens outward in a radius direction of the first ring **7**. The first groove **24** is composed of an upper roller-running surface **22** and a lower roller-running surface **23** intersecting the upper roller-running surface **22** substantially at right angles. The second ring **9** has on its inner peripheral surface a second groove **27**, which opens inward in a radius direction of the second ring **9** so as to face the first groove **24**. The second groove **27** is composed of an upper roller-running surface **25** and a lower roller-running surface **26** intersecting the upper roller-running surface **25** substantially at right angles.

A part of the rollers **8** disposed between the first groove **24** and the second groove **27** is rollable between the upper roller-running surface **22** of the first groove **24** and the lower roller-running surface **26** of the second groove **27**. A remaining part of the rollers **8** is rollable between the lower roller-running surface **23** of the first groove **24** and the upper roller-running surface **25** of the second groove **27**.

There is especially adopted a so-called "cross-roller type" structure in which each of the part of the rollers **8** disposed so as to be rollable between the upper roller-running surface **22** of the first groove **24** and the lower roller-running surface **26** of the second groove **27**, and each of the remaining part of the rollers **8** disposed so as to be rollable between the lower roller-running surface **23** of the first groove **24** and the upper roller-running surface **25** of the second groove **27** are arranged alternately. A spacing retainer **28** is disposed between the adjacent two rollers **8**.

In this embodiment, there is adopted a structure in which every other roller **8** has the same oriented central axis, which is perpendicular to an oriented axis of the other roller **8**. There may be adopted a modified structure in which every two or three roller **8** has the same oriented central axis, which is perpendicular to an oriented axis of the other roller **8**. Arrangement of the rollers **8** may optionally be modified in this manner.

Pre-load is given to the rollers **8** disposed between the first ring **7** and the second ring **9**.

In this embodiment, the first ring **7** is divided into upper and lower half portions. When a gap is formed between the upper and lower half portions of the first ring **7**, the rollers **8** can be brought into contact freely with the upper roller-running surface **22** and the lower roller-running surface **23** of the first groove **24**. When the upper half portion of the first ring **7** is pressed against the lower half portion thereof so as to form no gap between them, each of the rollers **8** is pressed under a prescribed pressure, thus imparting pre-load to the rollers **8**.

With respect to such a pre-load imparting mechanism, there may be used the second ring **9**, which has a slit so that the second ring **9** can change its shape from a C-shape under a released condition into a circular shape under a restricted condition. When the second ring **9** having such a structure is fitted to the recess portion **73** of the table **33**, the both ends of the second ring **9**, which define the slit are brought into contact with each other so as to decrease the diameter of the second ring **9**, thus imparting pre-load to the rollers **8**.

According to such a structure, in which the rollers **8** are disposed between the first ring **7** and the second ring **9**, there can be obtained a supporting structure, which is composed of the first ring **7** and the second ring **8**, and has a high rigidity against loads applied from any direction, such as compressive load in the axial direction of the pivot axis C, tensile load in the axial direction of the pivot axis C, load acting in a direction perpendicular to the pivot axis C, moment load having a function of inclining the pivot axis C and the like. As a result, there can be obtained the supporting structure, which is lightweight and has a high rigidity.

FIGS. **4**(*a*) and **4**(*b*) and FIG. **5** illustrate a table type working apparatus provided with the guide apparatus **1** for biaxial shifting motion and uniaxial turning motion of the first embodiment of the present invention.

In the above-mentioned table type working apparatus, a table **33** is supported through four guide apparatus **1A**, **1B**, **1C**, **1D** for biaxial shifting motion and uniaxial turning motion on a base **34** so as to be able to shift in biaxial directions intersecting at right angles with each other and to turn around a pivot axis Co located at the central portion of the table **33**. The table **33** has an opening **35** formed at the central portion thereof. The base **34** has an opening **36** formed at the central portion thereof. The four guide apparatus **1A**, **1B**, **1C**, **1D** for biaxial shifting motion and uniaxial turning motion are disposed on the four corners so as to surround the openings **35**, **36** and to maintain the condition that a first line connecting the centers of the guide apparatus **1A**, **1C** intersects a second line connecting the centers of the guide apparatus **1B**, **1D** at right angles. In case that the table **33** having a square shape is supported, arrangement of the four guide apparatus **1A**, **1B**, **1C**, **1D** at the four corners of the table **33** permits to prevent the four corners of the table **33** from being deformed. There is available a structure in which a large vacancy is formed at the central portion of the table **33**, and as a result, a working process of passing something through the vacancy can be carried out. Such a structure leads to decrease in weight of the apparatus.

Here, the pivot axis Co, which locates at the central portion of the table **33** does not always coincide with the central axis O of the base **34**. More specifically, the table **33** can be shifted in the biaxial directions relative to the base **34**. When the center of the t able **33** i s shifted to a place other than the central axis O of the base **34**, the pivot axis Co of the table **33** does not coincide with the central axis O of the base **34**. The table **33** can be turned around the pivot axis Co at any position to which the table **33** can be shifted.

The four guide apparatus **1A**, **1B**, **1C**, **1D** for biaxial shifting motion and uniaxial turning motion are arranged so that the first line connecting the centers of the guide apparatus **1A**, **1C** intersects the second line connecting the centers of the guide apparatus **1B**, **1D** at right angles at the central axis O of the base **34**. Accordingly, the guide apparatus **1A**, **1C** are located symmetrically relative to the second line and the guide apparatus **1B**, **1D** are also located symmetrically relative to the first line . Assumptions that one axis of the biaxial directions mentioned above is an X-axis in the lateral direction in FIG. **4**(*a*) and the other axis of them is a Y-axis in the longitudinal direction in the same figure, cause the description given below to be simplified. With respect to the two guide apparatus **1A**, **1B**, which are disposed at the left-hand side of the Y-axis so as to be symmetrical relative to the X-axis, each of the first guide rails **2A**, **2B** secured to the base **34** is arranged in parallel with the X-axis, and each of the second guide rails **6A**, **6B** is arranged in parallel with the Y-axis.

With respect to the two guide apparatus **1C**, **1D**, which are disposed at the right-hand side of the Y-axis so as to be symmetrical relative to the X-axis, each of the first guide rails **2C**, **2D** secured to the base **34** is arranged in parallel with the Y-axis, and each of the second guide rails **6C**, **6D** is arranged in parallel with the X-axis.

Linear drive mechanisms **37A**, **37B**, **37D**, which perform a linear expansion or contraction action, are operatively connected to three guide apparatus **1A**, **1B**, **1D** of the above-described four guide apparatus **1A**, **1B**, **1C**, **1D**.

More specifically, the linear drive mechanisms **37A**, **37B**, which perform the linear action along the X-axis are respectively connected to the two guide apparatus **1A**, **1B**, which are disposed at the left-hand side of the Y-axis. The linear drive mechanism **37D**, which performs the linear action along the Y-axis is connected to the guide apparatus **1D**, which is disposed at the right-hand side of the Y-axis and the upper side of the X-axis. The guide apparatus **1C**, which is disposed at the right-hand side of the Y-axis and the lower side of the X-axis, is designed to make a following motion.

The linear drive mechanisms **37A**, **37B**, **37D** cause the movable blocks **4A**, **4B**, **4D** of the guide apparatus **1A**, **1B**, 1D to move relative to the base **34**. The linear drive mechanisms **37**A, **37**B, **37**D have the respective first end portions secured to the base **34** and the respective second end portions operatively connected to the respective movable blocks **4**A, **4**B, **4**D of the guide apparatus **1**A, **1**B, **1**D. The movable blocks **4**A, **4**B, **4**D are movable relative to the base **34**, and the guide apparatus **1**A, **1**B, **1**D are movable in the directions of the X-axis and the Y-axis along the first guide rail **2**A, **2**B, **2**D secured to the base **34**.

There may of course be adopted a modified structure in which the respective first end portions of the linear drive mechanisms **37**A, **37**B, **37**D are secured to the table **33** so that the movable blocks **4**A, **4**B, **4**D are movable relative to the table **33**. In this case, the linear drive mechanisms **37**A, **37**B, **37**D are designed to be movable in the directions parallel with the second guide rails **6**A, **6**B, **6**D secured to the table **33**.

All the linear drive mechanisms **37**A, **37**B, **37**D have the same structure and are composed of a motor **38** and a screw feeding mechanism **39** for converting the rotational motion of the motor **38** into the linear motion. The screw feeding mechanism **39** is composed of a nut **41** connected through a bracket **40** to the movable block **4**A, **4**B, **4**D, a screw shaft **42** engaged in the nut **41**, a bearing **43** of the plural trains-angular contact type for rotatably supporting the screw shaft **42**, and a bearing support member **44** for supporting the bearing **43**. The motor **38** is secured through a bracket **45** on the base **34**. The motor shaft **46** is connected through a coupling member **47** to the end of the screw shaft **42**.

The above-mentioned linear drive mechanisms **37**A, **3713**, **37**D may be connected between the base **34** and the table **33** so as to have no relation to the guide apparatus **1**A, **1**B, **1**D.

Detecting mechanisms **48** for detecting a feeding amount are provided in the vicinity of the linear drive mechanisms **37**A, **37**B, **37**D.

The two linear drive mechanisms **37**A, **37**B, which perform a linear motion in the X direction, are caused to be driven in synchronization with each other by the same amount of operation in order to shift the table **33** for example in the X direction. As a result, the movable blocks **4**A, **4**B of the two guide apparatus **1**A, **1**B shift in the X direction relative to the first guide rail **2**A, **2**B. The second guide rails **6**C, **6**D of the two guide apparatus **1**C, **1**D disposed at the right-hand side of the Y-axis accordingly shift in the X direction relative to the movable blocks **4**C, **4**D.

Drive of the linear drive mechanism **37**D, which performs a liner motion in the Y direction, is carried out in order to shift the table **33** in the Y direction. As a result, the second guide rails **6**A, **6**B shift in the Y direction relative to the movable blocks **4**A, **4**B of the two guide apparatus **1**A, **1**B disposed at the left-hand side of the Y-axis. The movable blocks **4**C, **4**D of the two guide apparatus **1**C, **1**D disposed at the right-hand side of the Y-axis accordingly shift in the Y direction relative to the first guide rails **2**C, **2**D.

The combination of the synchronous drive of the two linear drive mechanisms **37**A, **37**B performing the linear motion in the X direction with the drive of the single linear drive mechanism **37**D performing the linear motion in the Y direction permits the table **33** to be shifted in a constant posture state in the X and Y directions. The pivot axis Co of the table **33** simultaneously shifts in the X and Y directions.

The linear drive mechanism **37**A performing the linear motion in the X direction is caused to be driven by a feeding amount of $+\Delta X$, the linear drive mechanism **37**B performing the linear motion in the X direction is caused to be driven in the opposite direction to the driving direction of the linear drive mechanism **37**A by a feeding amount of $-\Delta X$, and the linear drive mechanism **37**D performing the linear motion in the Y direction is caused to be driven by a feeding amount of ΔY, in order to turn the table **33** around the pivot axis Co as shown in FIG. **5**. As a result, the table **33** turns around the pivot axis Co by a prescribed angle of $\Delta\theta$. The relationship among ΔX, ΔY and $\Delta\theta$ can geometrically be obtained and expressed by a formula. When the formula is previously stored in a controlling apparatus, the designation of a turning angle of the table **33** causes values of ΔX and ΔY as well as a value of turning number of each of the motors **38** to be calculated automatically so that the linear drive mechanisms **37**A, **37**B, **37**D can be controlled on the basis of the thus calculated values.

Linear motors may be used to perform the direct drive in replacement of the screw feeding mechanism **39** as the linear drive mechanisms **37**A, **37**B, **37**D. There may be used fluid-pressure type actuators instead, which utilizes hydraulic pressure such as oil pressure, or gas pressure such as air pressure.

The braking mechanism **49** designed as a braking means for maintaining the stationary condition of the table **33** relative to the base **34** is provided on each of two places between the table **33** and the base **34**.

As shown in FIGS. **6**(*a*) to **6**(*d*), the braking mechanism **49** is provided with a cylinder **51**, which is designed as a pressure mechanism secured to the base **34** through a cylinder-bracket **50** and utilizes the fluid pressure such as hydraulic pressure, i.e., oil pressure, etc., gas pressure, i.e., air pressure, etc., or the like, and a brake plate **53** secured to the table **33** through brake-brackets **52**. The both ends of the brake plate **53** are fixed to the brake-brackets **52** through two fastening members such as bolts placed horizontally. As is clear from FIG. **6**(*d*), the cylinder **51** is arranged above the brake plate **53**.

The cylinder **51** is a gas-pressure type cylinder such as an air cylinder, which is fixed to the cylinder-bracket **50** by means of a fastening member such as a bolt. The cylinder-bracket **50** has a hole **55** in which a piston rod **54** extending downward from the cylinder **51** is to be inserted. A pad-bracket **56** is fixed to the forward end of the piston rod **54** passing through the above-mentioned hole **55**, by means of fastening members such as bolts. A brake pad **57** is secured to the lower surface of the pad-bracket **56** by means of fastening members such as bolts so as to press the brake plate **53**.

The cylinder-bracket **50** has a long hole **50***a* in which a portion of a rail-bracket **58** is inserted. The rail-bracket **58** is secured to the cylinder-bracket **50** by means of fastening members such as bolts placed vertically. A guide rail **60** of a linear motion guide mechanism **59** is secured to the rail-bracket **58** by means of two fastening members such as bolts placed horizontally. A block-bracket **62** is secured to a movable block **61** of the linear motion guide mechanism **59** by means of fastening members such as bolts. The linear motion guide mechanism **59** has a structure in which the movable block **61** is movably connected to the guide rail **60** through rolling members.

The block-bracket **62** is fixed to the pad-bracket **56** by means of two fastening members such as bolts placed horizontally, in a space covered with the cylinder-bracket **50**. Accordingly, the upward or downward movement of the piston rod **54** of the cylinder **51** causes the movable block **61** of the linear motion guide mechanism **59** to move in the same direction.

The above-described braking mechanism **49** operates as follows.

When the piston rod **54** of the cylinder **51** is moved downward, the brake plate **53** is pressed down by means of the brake pad **57** secured to the forward end of the piston rod **54**. The thus pressed brake plate **53**, which is extremely thin, is deformed so as to be pressed against the base **34**.

The brake plate **53** has a rectangular shape, whose long side is extremely longer than the short side thereof, and the brake-bracket **52** has a sufficient rigidity. There is almost no adverse influence on the upper surface of the table **33**.

The cylinder **51** has a low rigidity against load acting in the lateral direction. A high rigidity can be ensured by means of the block-bracket **62** secured to the linear motion guide mechanism **59** in the vicinity of the cylinder **51** and by means of the pad-bracket **56** secured to the forward end of the piston rod **54** of the cylinder **51**.

A linear actuator utilizing an electromagnetic force caused by a solenoid may be used in replacement of the above-described fluid-p-pressure type cylinder as the braking mechanism.

Any kind of mechanism having a function of bearing load in the lateral direction may be used as the linear motion guide mechanism **59**. As the linear motion guide mechanism **59**, there may be used a slide bearing as well as a linear bearing utilizing the guiding function of rolling members.

FIGS. **7**(*a*) and **7**(*b*) illustrate a guide apparatus **100** for biaxial motion and uniaxial turning motion of the second embodiment of the present invention.

The guide apparatus **100** for biaxial motion and uniaxial turning motion is composed of a first linear motion guide mechanism **170** acting in the single axial direction, a second linear motion guide mechanism **190**, which is disposed above the first linear motion guide mechanism **170** and connected thereto so that the guide direction of the second linear motion guide mechanism **190** intersects the guide direction of the first linear motion guide mechanism **170** at right angles, and a pivot supporting mechanism **180**, which is disposed above the second linear motion guide mechanism **190** and connected thereto.

More specifically, the first linear motion guide mechanism **170** is composed of a first guide rail **101** and a first movable block **103**, which is movably connected to the first guide rail **101** through balls **102** designed as a plurality of rolling members.

The second linear motion guide mechanism **190** is composed of a second guide rail **104** secured to the first movable block **103** of the first linear motion guide mechanism **170** so as to intersect the first guide rail **101**, and of a second movable block **106**, which is connected to the second guide rail **104** through balls **105** designed as a plurality of rolling members so as to be movable along the second guide rail **104**.

The pivot supporting mechanism **180** is composed of a first ring **107** secured to the second movable block **106** of the second linear motion guide mechanism **190**, and of a second ring **109** coupled with the first ring **107** through rollers **108** designed as a plurality of rolling members so as to be turnable relative to the first ring **107**.

The first ring **107** designed as the inner ring is connected to the above-mentioned second movable block **106** through a coupling portion **129**.

The coupling portion **129** is provided with a first coupling plate **130** having a rectangular shape and a second coupling plate **131** having a disc-shape. The second movable block **106** is secured to the first coupling plate **130**. The first ring **107** is secured to the second coupling plate **131**. The first coupling plate **130** and the second coupling plate **131** are connected to each other by means of a fastening member **132** such as a bolt and the like. The second coupling plate **131** has on its periphery a projection portion **1311**. The first ring **107** designed as the inner ring is fitted to the projection portion **1311** from the upper side. A supporting member **171** is tightly secured to the upper surface of the projection portion **1311** by means of the fastening member **132** such as a bolt and the like. The first ring **107** is designed to be held between the supporting member **171** and a shoulder portion **1311***a*, which is located at the lower portion of the projection portion **1311** so as to maintain the stationary condition of the first ring **107**.

The table **133** to which the second ring **109** is to be secured has an opening **172** having a circular shape. The above-mentioned supporting member **171** of the first ring **107** is designed to be able to be inserted in the opening **172** from the upper side. A recess portion **173** is formed on the lower peripheral surface of the opening **172** of the table **133**. The second ring **172** is fitted to the recess portion **173**. A supporting member **174** for holding the second ring **109** is tightly secured to the peripheral edge of the recess portion **173** by means of the fastening member **132** such as a bolt and the like. The second ring **109** is designed to be held between the supporting member **174** and the peripheral edge **173**a of the recess portion **173** so as to maintain the stationary condition of the second ring **L09**.

A detailed description of the first linear motion guide mechanism **170** will be given below.

As shown in FIGS. **8**(*a*) and **8**(*b*), the first guide rail **101** is designed as an integral formed body, which is composed of a pair of supporting wall portions **110, 110**, between which the first movable block **103** is held and supported, and of a bottom wall portion **110***a* for connecting the supporting wall portions **110, 110**. The first guide rail **101** is provided with four ball running grooves **112** so that the two ball running grooves **112** are formed on each of the inner surfaces of the supporting wall portions **110, 110**. On the other hand, the first movable block **103** is provided with four ball running counter-grooves **113** so that the two ball running counter-grooves **113** are formed on each of the right and left-hand outer surfaces of the first movable block **103**. Accordingly, the four ball running grooves **112** of the first guide rail **101** face the four ball running counter-grooves **113** of the first movable block **103**, respectively.

The first movable block **103** has four ball return passages **114**, which are formed in parallel with each other. The four ball return passages **114** correspond to the four ball running counter-grooves **113**, respectively. A side plate **116** is secured to each of the opposite end portions of the first movable block **103**. Each of the side plates **116** has four direction changing passages **115** for connecting the four ball running grooves **113** and the four ball return passages **114**.

In each of the inner surfaces of the supporting wall portions **110, 110** of the first guide rail **101**, a line connecting the contact points of the ball **102** with the upper roller running groove **112** and the upper roller running counter-groove **113** facing thereon and the other line connecting the contact points of the ball **102** with the lower roller running groove **112** and the lower roller running counter-groove **113** facing thereon symmetrically incline at a prescribed angle α relative to a horizontal line locating between the upper two trains of balls **102** and the lower two trains of balls **102**. In this embodiment, there is adopted a structure in which the line connecting the contact points of the ball **102** with the upper roller running groove **112** and the upper roller running counter-groove **113** facing thereon and the other line connecting the contact points of the ball **102** with the lower roller running groove **112** and the lower roller running counter-groove **113** facing thereon are close to each other at the inside of the supporting wall portions **110**, **110**, on the one hand, and are apart from each other at the outside of the supporting wall portions **110**, **110**, on the other hand.

When the first linear motion guide mechanism **170** is coupled with a linear motion drive mechanism **200**, there can be obtained a guide apparatus for biaxial shifting motion and uniaxial turning motion, provided with a driving mechanism.

More specifically, the first movable block **103** has in its central portion a screw hole **201**, which extends in parallel with the lower roller running counter-grooves **113**. A screw shaft **202** is engaged in the screw hole **201**. It is preferable to dispose balls between the screw hole **201** and the screw shaft **202** so as to be rollable, to form a ball screw mechanism.

The both end portions of the screw shaft **202** are rotatably supported through bearings **204** on bearing supports **203** fixed to the first guide rail **101**. The one end of the screw shaft **202** is connected through a coupling member **205** to an output shaft **207** of a motor **206** fixed to the first guide rail **101**.

A detailed description of the second linear motion guide mechanism **190** will be given below.

As shown in FIGS. **8**(*c*) and **8**(*d*), the second movable block **106** has on its lower surface a second recess portion **111** in which the second guide rail **104** secured on the first movable block **103** is movably inserted.

The second guide rail **104** is also provided with four ball running grooves **117** so that the two ball running grooves **117** are formed on each of the right and left-hand side surfaces of the second guide rail **104**. On the other hand, the second movable block **106** is provided with four ball running counter-grooves **118** so that the two ball running counter-grooves **118** are formed on each of the right and left-hand inner surfaces of the second recess portion **1 1 1** of the second movable block **106**. Accordingly, the four ball running grooves **117** of the second guide rail **104** face the four ball running counter-grooves **118** of the second movable block **106**, respectively.

The second movable block **106** has four ball return passages **119**, which are formed in parallel with each other. The four ball return passages **119** correspond to the four ball running counter-grooves **118** of the second recess portion **111**, respectively. A side plate **121** is secured to each of the opposite end portions of the second movable block **106**. Each of the side plates **121** has four direction changing passages **120** for connecting the four ball running counter-grooves **118** and the four ball return passages **119**.

In each of the right and left-hand longitudinal side surfaces of the second guide rail **104**, a line connecting the contact points of the ball **105** with the upper roller running groove **117** and the upper roller running counter-groove **118** facing thereon and the other line connecting the contact points of the ball **105** with the lower roller running groove **117** and the lower roller running counter-groove **118** facing thereon symmetrically incline at a prescribed angle α relative to a horizontal line locating between the upper two trains of balls **105** and the lower two trains of balls **105**. In this embodiment, there is adopted a structure in which the line connecting the contact points of the ball **105** with the upper roller running groove **117** and the upper roller running counter-groove **118** facing thereon and the other line connecting the contact points of the ball **105** with the lower roller running groove **117** and the lower roller running counter-groove **118** facing thereon are close to each other at the inside of the second recess portion **111**, on the one hand, and are apart from each other at the outside of the second recess portion **111**, on the other hand.

A detailed description of the pivot supporting mechanism **180** will be given below.

As shown in FIGS. **9**(*a*) and **9**(*b*), the first and second rings **107**, **109** are designed as inner and outer rings, which are arranged concentrically with each other, respectively. In this embodiment, the first ring **107** secured to the second guide rail **104** is used as the inner ring, and the second ring **109** is used as the outer ring. Rollers **108** are used as the rolling members in this embodiment.

The first ring **107** designed as the inner ring is connected to the above-mentioned second movable block **106** through a coupling portion **129**.

The first ring **107** designed as the inner ring has on its outer peripheral surface a first groove **124**, which opens outward in a radius direction of the first ring **107**. The first groove **124** is composed of an upper roller-running surface **122** and a lower roller-running surface **123** intersecting the upper roller-running surface **122** substantially at right angles. The second ring **109** has on its inner peripheral surface a second groove **127**, which opens inward in a radius direction of the second ring **109** so as to face the first groove **124**. The second groove **127** is composed of an upper roller-running surface **125** and a lower roller-running surface **126** intersecting the upper roller-running surface **125** substantially at right angles.

A part of the rollers **108** disposed between the first groove **124** and the second groove **127** is rollable between the upper roller-running surface **122** of the first groove **124** and the lower roller-running surface **126** of the second groove **127**. A remaining part of the rollers **108** is rollable between the lower roller-running surface **123** of the first groove **124** and the upper roller-running surface **125** of the second groove **127**.

There is especially adopted a so-called "cross-roller type" structure in which each of the part of the rollers **108** disposed so as to be rollable between the upper roller-running surface **122** of the first groove **124** and the lower roller-running surface **126** of the second groove **127**, and each of the remaining part of the rollers **108** disposed so as to be rollable between the lower roller-running surface **123** of the first groove **124** and the upper roller-running surface **125** of the second groove **127** are arranged alternately. A spacing retainer **128** is disposed between the adjacent two rollers **108**.

In this embodiment, there is adopted a structure in which every other roller **108** has the same oriented central axis, which is perpendicular to an oriented axis of the other roller **108**. There may be adopted a modified structure in which every two or three roller **108** has the same oriented central axis, which is perpendicular to an oriented axis of the other roller **108**. Arrangement of the rollers **8** may optionally be modified in this manner.

Pre-load is given to the rollers **8** disposed between the first ring **107** and the second ring **109**.

In this embodiment, the first ring **107** is divided into upper and lower half portions. When a gap is formed between the upper and lower half portions of the first ring **107**, the rollers **108** can be brought into contact freely with the upper roller-running surface **122** and the lower roller-running surface **123** of the first groove **124**. When the upper half portion of the first ring **107** is pressed against the lower half portion thereof so as to form no gap between them, each of the rollers **108** is pressed under a prescribed pressure, thus imparting pre-load to the rollers **108**.

With respect to such a pre-load imparting mechanism, there may be used the second ring **109**, which has a slit so that the second ring **109** can change its shape from a C-shape under a released condition into a circular shape under a restricted condition. When the second ring **109** having such a structure is fitted to the recess portion **173** of the table **133**, the both ends of the second ring **109**, which define the slit are brought into contact with each other so as to decrease the diameter of the second ring **109**, thus imparting pre-load to the rollers **108**.

According to such a structure, in which the rollers **108** are disposed between the first ring **107** and the second ring **109**, there can be obtained a supporting structure, which is composed of the first ring **107** and the second ring **108**, and has a high rigidity against loads applied from any direction, such as compressive load in the axial direction of the pivot axis C, tensile load in the axial direction of the pivot axis C, load acting in a direction perpendicular to the pivot axis C, moment load having a function of inclining the pivot axis C and the like. As a result, there can be obtained the supporting structure, which is lightweight and has a high rigidity.

FIGS. **10**(*a*) and **10**(*b*) illustrate a table type working apparatus provided with the guide apparatus **100** for biaxial shifting motion and uniaxial turning motion of the second embodiment of the present invention.

In the above-mentioned table type working apparatus, a table **133** is supported through four guide apparatus **100**A, **100**B, **100**C, **100**D for biaxial shifting motion and uniaxial turning motion on a base **134** so as to be able to shift in biaxial directions intersecting at right angles with each other and to turn around a pivot axis Co located at the central portion of the table **133**.

Here, the pivot axis Co, which locates at the central portion of the table **133** does not always coincide with the central axis O of the base **134**. More specifically, the table **133** can be shifted in the biaxial directions relative to the base **134**. When the center of the table **133** is shifted to a place other than the central axis O of the base **134**, the pivot axis Co of the table **133** does not coincide with the central axis O of the base **134**. The table **133** can be turned around the pivot axis Co at any position to which the table **133** can be shifted.

The four guide apparatus **100**A, **100**B, **100**C, **100**D for biaxial shifting motion and uniaxial turning motion are arranged so that the first line connecting the centers of the guide apparatus **100**A **100**C intersects the second line connecting the center s of the guide apparatus **100**B, **100**D at right angles at the central axis O of the base **134**. Accordingly, the guide apparatus 1A, 1C are located symmetrically relative to the central axis O of the base **134** and the guide apparatus 1B, 1D are e also located symmetrically relative to the above-mentioned central axis O.

Assumptions that one axis of the biaxial directions mentioned above is an X-axis in the lateral direction in FIG. **10**(*a*) and the other axis of them is a Y-axis in the longitudinal direction in the same figure, cause the description given below to be simplified. With respect to the guide apparatus **100**A, which is disposed at the left-hand side of the Y-axis as well as at the upper side of the X-axis and the guide apparatus **100**C, which is disposed at the right-hand side of the Y-axis as well as at the lower s side of the X-axis, each of the first guide rails **101**A, **101**C secured to the base **134** is a arranged in parallel with the X-axis , and each of the second guide rails **104**A, **104**B is arranged in parallel with the Y-axis.

With respect to the guide apparatus **100**B, which is disposed at the left-hand side of the Y-axis a s well as at the lower side of the X-axis and the guide apparatus **100**D, which is disposed at the right-hand side of the Y-axis as well as at the upper side of the X-axis, each of the first guide rails **110**B, **101**D secured to the base **134** is arranged in parallel with the Y-axis, and each of the second guide rails **104**B, **104**D is arranged in parallel with the X-axis.

Linear drive mechanisms **200**A, **200**B, **200**C, which perform a linear expansion or contraction action, are operatively connected to three guide apparatus **100**A, **100**B, **100**C of the above-described four guide apparatus **100**A, **100**B, **100**C, **100**D.

The two linear drive mechanisms **200**A, **200**C, which perform a linear motion in the X direction, are caused to be driven in synchronization with each other by the same amount of operation in order to shift the table **133** for example in the X direction. As a result, the second movable blocks **106**B, **106**D of the guide apparatus **100**B, **100**D shift in the X direction along the second guide rails **104**B, **104**D.

Drive of the linear drive mechanism **200**B, which performs a linear motion in the Y direction, is carried out in order to shift the table **133** in the Y direction. As a result, the second movable blocks **106**A, **106**C of the guide apparatus **100**A, **100**C shift in the Y direction along the second guide rails **104**A, **104**C.

The combination of the synchronous drive of the two linear drive mechanisms **200**A, **200**C performing the linear motion in the X direction with the drive of the single linear drive mechanism **200**B performing the linear motion in the Y direction permits the table **133** to be shifted in a constant posture state in the X and Y directions. The pivot axis Co of the table **133** simultaneously shifts in the X and Y directions.

The linear drive mechanism **200**A performing the linear motion in the X direction is caused to be driven by a feeding amount of $+\Delta X$, the linear drive mechanism **200**B performing the linear motion in the X direction is caused to be driven in the opposite direction to the driving direction of the linear drive mechanism **200**A by a feeding amount of $-\Delta X$, and the linear drive mechanism **200**B performing the linear motion in the Y direction is caused to be driven by a feeding amount of ΔY, in order to turn the table **133** around the pivot axis Co. As a result, the table **133** turns around the pivot axis Co by a prescribed angle of $\Delta\theta$. The relationship among ΔX, ΔY and $\Delta\theta$ can geometrically be obtained and expressed by a formula. When the formula is previously stored in a controlling apparatus, the designation of a turning angle of the table **33** causes values of ΔX and ΔY as well as a value of turning number of each of the motors to be calculated automatically so that the linear drive mechanisms **200**A, **200**B, **200**C can be controlled on the basis of the thus calculated values.

Linear motors may be used to perform the direct drive in replacement of the screw feeding mechanism **39** as the linear drive mechanisms **200**A, **200**B, **200**D. There may be used fluid-pressure type actuators instead, which utilizes hydraulic pressure such as oil pressure, or gas pressure such as air pressure.

Needless to say, there may be provided the same braking mechanism as in the first embodiment of the present invention, for maintaining the stationary condition of the table **133** relative to the base **134**. The description of the braking mechanism will be omitted.

In the biaxial shifting motion guide mechanism of the guide apparatus according to the first embodiment of the present invention, the movable block has on its opposite surfaces the first and second recess portions, respectively, extending directions of which intersect with each other at right angles, and the first and second guide rails are inserted through the rolling members in the first and second recess portions, respectively, so as to perform a linear motion. In the biaxial shifting motion guide mechanism of the guide apparatus according to the second embodiment of the present invention, the first movable block is supported through the rolling members between the right and left-hand supporting walls of the first guide rail so as to perform a linear motion, the second guide rail is secured to the above-mentioned first movable block so that the extending directions of the first and second guide rails intersect with each other at right angles, and the second movable block is connected through the rolling members to the second guide rail so as to perform a linear motion. The structure of the biaxial shifting motion guide mechanism is not limited only to that of these embodiments. More specifically, there may be adopted any kind of structure, which permits to support the second member so as to be movable relative to the first member in a constant posture state along the biaxial lines intersecting at right angles with each other.

According to the present invention as described in detail, the second member can be supported so as to be movable relative to the first member in the constant posture state along the biaxial directions intersecting at right angles with each other. Even when the second member is moved in parallel to a prescribed position and then is turned there, the biaxial lines in the biaxial shifting motion guide mechanism are invariable, thus making it possible to make an easy determination of an amount of displacement in each of the biaxial directions, which corresponds to the turning motion of the second member.

The biaxial lines in the biaxial shifting motion guide mechanism are invariable as mentioned above even after the turning motion of the second member, it is very easy to control of the parallel movement: of the second member along the biaxial directions.

When there is adopted a structure in which the first ring is secured to the second guide rail and the second ring is secured to the second member, the securing of the first ring to the second rail suffices, leading to an easy installation working.

When there is adopted a structure in which the first guide rail and the second guide rail are connected to the single movable block, parallelism between the bottom surfaces of the pair of guide rails can therefore be obtained by an easy machining process of the single movable block. As a result, when there is obtained only a proper squareness of the pivot axis of the first ring relative to the second guide rail, a proper squareness of the bottom surface of the first guide rail relative to the pivot axis can automatically be obtained, and the parts of the guide apparatus can very easily be assembled under a precise positional determination condition.

Formation of only a hole, into which the second ring is to be fitted, on a table as the second member suffices, thus leading to an easy working process on the table. When force is applied to the table at a position apart from the pivot axis of the guide apparatus for biaxial shifting motion and uniaxial turning motion, a moment load having a function of inclining the pivot axis is applied to the pivot supporting mechanism. The moment load is however applied through the second ring to the pivot axis and a merely small displacement occurs at the pivot axis.

When there is adopted a structure in which a linear actuator secured to any one of the first member and the second member is operatively connected to the movable block, relative movement of the movable block between the first member and the second member is permitted by pushing the movable block by means of the above-mentioned linear actuator and it is unnecessary to form any specific connecting portions for the linear actuator on the first and second members.

In case that there is adopted a structure in which the second guide rail is secured to the first movable block and the second movable block is slidably connected to the second guide rail, when there is obtained only a proper squareness in the contact surfaces of the first movable block and the second guide rail, which are secured to each other, and in the contact surfaces of the second movable block and the first guide rail, a proper squareness of the bottom surface of the first guide rail relative to the pivot axis can automatically be obtained, and the parts of the guide apparatus can very easily be assembled under a precise positional determination condition.

When there is adopted a structure in which the first guide rail has a pair of supporting walls, between which the first movable block is held through the rolling members, stability can be improved.

When the linear actuator is disposed between the first guide rail and the first movable block, and the linear actuator is located in the central portion of the first movable block, the distance between the portion of the first movable block, to which force for moving the first movable block is imparted, and each of the trains of the rolling members located between the first guide rail and the first movable block can be decreased, with the result that moment load caused by the rolling resistance of the trains of the rolling members and the driving force for moving the first movable block does not have any adverse effects.

When there is adopted a structure in which the rollers are disposed between the first ring and the second ring, there can be obtained a supporting structure, which is composed of a pair of rings, i.e., the first ring and the second ring, and has a high rigidity against loads applied from any direction, such as compressive load in the axial direction of the pivot axis, tensile load in the axial direction of the pivot axis, load acting in a direction perpendicular to the pivot axis, moment load having a function of inclining the pivot axis and the like. As a result, there can be obtained the supporting structure, which is lightweight and has a high rigidity. In addition, such a supporting structure can be provided in a large-size.

When there is adopted a structure in which the table is supported by means of a plurality of biaxial shifting motion guide mechanisms, the plurality of biaxial shifting motion guide mechanisms can be disposed in any place. In case that the table having a rectangular shape is supported, the biaxial shifting motion guide mechanisms respectively disposed at the four corners of the table permit to prevent the four corners of the table from being deformed. There is available a structure in which a large vacancy is formed at the central portion of the table, and as a result, a working process of passing something through the vacancy can be carried out. Such a structure leads to decrease in weight of the apparatus.

What is claimed is:

1. A guide apparatus for biaxial shifting motion and uniaxial turning motion, which comprises:

a biaxial shifting motion guide mechanism for supporting a second member so as to be movable relative to a first member in a constant posture state along biaxial lines intersecting at right angles with each other; and

a pivot supporting mechanism disposed on said biaxial shifting motion guide mechanism at an opposite side of said first member, for pivotably supporting said second member, wherein:

said biaxial shifting motion guide mechanism comprises a first guide rail secured to said first member, a movable block connected through a plurality of rolling members to said first guide rail so as to be movable and a second guide rail connected through a plurality of rolling members to said movable block so as to be movable in a direction intersecting said first guide rail; and

said pivot supporting mechanism comprises a first ring and a second ring, said first ring being secured to said second guide rail and said second ring being coupled through a plurality of rolling members with said first ring so as to be rotatable relative thereto and being secured to said second member.

2. The apparatus as claimed in claim **1**, further comprises:

a linear actuator secured to any one of said first member and said second member, said linear actuator being operatively connected to said movable block.

3. A guide apparatus for biaxial shifting motion and uniaxial turning motion, which comprises:

a biaxial shifting motion guide mechanism for supporting a second member so as to be movable relative to a first member in a constant posture state along biaxial lines intersecting at right angles with each other; and

a pivot supporting mechanism disposed on said biaxial shifting motion guide mechanism at an opposite side of said first member, for pivotably supporting said second member, wherein:

said biaxial shifting motion guide mechanism comprises a first guide rail secured to said first member, a first movable block connected through a plurality of rolling members to said first guide rail so as to be movable, a second guide rail secured to said first movable block so as to intersect said first guide rail and a second movable block movably connected through a plurality of rolling members to said second guide rail; and

said pivot supporting mechanism comprises a first ring and a second ring, said first ring being secured to said second movable block and said second ring being coupled through a plurality of rolling members with said first ring so as to be rotatable relative thereto and being secured to said second member.

4. The apparatus as claimed in claim **3**, wherein:

said first guide rail has a pair of supporting walls, between which said first movable block is held through said rolling members.

5. The apparatus as claimed in claim **3**, further comprises:

a linear actuator is disposed between said first guide rail arid said first movable block, for causing said first movable block to move.

6. The apparatus as claimed in claim **4**, further comprises:

a linear actuator is disposed between said first guide rail and said first movable block, for causing said first movable block to move.

7. An apparatus for biaxial shifting motion and unaxial turning motion, which comprises:

a base;

a table;

a biaxial shifting motion guide mechanism for supporting said table so as to be movable relative to said base in a constant posture state along biaxial lines intersecting at right angles with each other; and

a pivot supporting mechanism disposed on said biaxial shifting motion guide mechanism at an opposite side of said base, for pivotably supporting said table, wherein:

said biaxial shifting motion guide mechanism comprises a first guild rail secured to said base, a movable block connected through a plurality of rolling members to said first guide rail so as to be movable and a second guide rail connected through a plurality of rolling members to said movable block so as to be movable in a direction intersecting said first guide rail; and

said pivot supporting mechanism comprises a first ring and a second ring, said first ring being secured to said second guide rail and said second ring being coupled through a plurality of rolling members with said first ring so as to be rotatable relative thereto and being secured to said table.

8. An apparatus for biaxial shifting motion and uniaxial turning motion, which comprises:

a base;

a table;

a biaxial shifting motion guide mechanism for supporting said table so as to be movable relative to said base in a constant posture state along biaxial lines intersecting at right angles with each other; and

a pivot supporting mechanism disposed on said biaxial shifting motion guide mechanism at an opposite side of said base, for pivotably supporting said table, wherein:

said biaxial shifting motion guide mechanism comprises a first guide rail secured to said base, a first movable block connected through a plurality of rolling members to said first guide rail so as to be movable, a second guide rail secured to said first movable block so as to intersect said first guide rail and a second movable block movably connected through a plurality of rolling members to said second guide rail; and

said pivot supporting mechanism comprises a first ring and a second ring, said first ring being secured to said second movable block and said second ring being coupled through a plurality of rolling members with said first ring so as to be rotatable relative thereto and being secured to said table.

[57] **ABSTRACT**

An object of the present invention is to provide a ball spline unit enabling the balls to smoothly circulate without increasing a size of the ball spline unit, and enabling to be integrally molded by accurately setting a position of a resin portion to be formed to an outer cylinder. To achieve the object, the present invention is characterized in that at least one of the unloaded ball passage, retainer portions and ball direction changing passage inner peripheral portions is integrally molded with the outer cylinder in accordance with an insert molding method in which the outer cylinder is positioned within a molding die with reference to the loaded ball rolling grooves.

BALL SPLINE UNIT AND METHOD OF FORMING OUTER CYLINDER OF BALL SPLINE UNIT

TECHNICAL FIELD

The present invention relates to a ball spline unit in which balls are disposed between a spline shaft and an outer cylinder and relates to a method of molding the outer cylinder of the ball spline unit.

BACKGROUND ART

The conventional ball spline unit of this type has a structure comprising a cylindrical outer cylinder to which a plurality of loaded ball rolling grooves are formed at an inner periphery of the outer cylinder. This outer cylinder is provided with a plurality of unloaded ball passages corresponding to the loaded ball rolling grooves. Both ends portions of the outer cylinder are provided with side covers each having a direction changing passage for communicating the loaded ball rolling grooves with the unloaded ball passages. Further, in order to prevent balls disposed in the loaded ball rolling grooves from dropping off, retainer portions are provided with the inner periphery of the outer cylinder along the loaded ball rolling grooves.

A spline shaft is inserted into the outer cylinder so that the outer cylinder is reciprocally moved. At an outer periphery of the spline shaft, there are formed with loaded ball rolling grooves corresponding to the loaded ball rolling grooves formed to the outer cylinder, and a number of balls are disposed between the loaded ball rolling grooves.

However, in the conventional spline unit described above, since a radius of curvature of the direction changing passage is small, sticks of the ball are liable to occur. In order to prevent the sticking of the balls, it is effective to increase the radius of curvature of the direction changing passage. However, such structure will result in increase of a size of the spline unit.

On the other hand, it has been conventionally attempted to lower a noise level and manufacturing cost of the spline unit by forming ball supporting portions, side covers and the unloaded ball passages as resin molded members for which high rigidity is not required.

However, each of the conventional resin molded members was a separately molded member which is separately formed form the outer cylinder. Therefore, an assembling process for integrating the molded members was required after completion of molding the respective members.

In this regard, one may happen to think of integrally molding the ball supporting portions or the like with the outer cylinder for the purpose of reducing the assembling steps.

As an example of such integrally molding technique, for example, a method of forming a linear motion ball bearing shown in U.S. Pat. No. 4,128,279 is well known.

As shown in FIG. **9**, the aforementioned linear motion ball bearing is constructed so as to comprise an outer cylinder **101** a part of which is cut out so as to have an opened sectional shape, and a shaft **105** to be inserted into the outer cylinder **101**.

A number of balls **104** arranged in an axial direction are disposed between the inner circumference of the outer cylinder **101** and the outer circumference of the shaft **105**, so that the outer cylinder **101** can linearly move along the shaft **105**. The balls **104** are arranged in a circumferential direction of the outer cylinder **101** so as to form a plurality of ball rows. Each of the ball rows is arranged so as to circulate through the direction changing passages **108** formed to both ends of the outer cylinder **101** and through the plurality of unloaded ball passages **110** provided to the outer circumference of the outer cylinder **101**. The balls **104** disposed in the loaded region between the outer cylinder **101** and the shaft **105** are retained by retainer portions **106** provided at both sides of the ball row so as to extend along the axial direction.

Further, afore-mentioned retainer portions **106**, inner peripheral portion **108***a* of the direction changing passage **108** and the unloaded ball passages **110** were integrally molded with the outer cylinder **101** by using an insert-molding method.

However, in a case of the conventional linear motion ball bearing described above, when the insert molding is performed, as shown in FIG. **9**(*c*), for example, the outer periphery of the outer cylinder **101** is tightly contact to a first molding die **111** while the inner periphery of the outer cylinder **101** is tightly contact to a second molding die **112** thereby to form cavities **106***a* and **110***a* for molding the retaining portions **106** and the unloaded ball passages **110**. However, it was difficult for the inner and outer peripheries of the outer cylinder **101** to accurately and tightly contact to the first and second cavities **111** and **112**, so that there was arisen a problem that a gap was liable to occur between the contacting surfaces, generating burrs.

In particular, when the burrs are generated between the contacting surfaces of the inner periphery of the outer cylinder **101** and the second molding die **112**, thus resulting in generation of the burrs at loaded ball rolling surfaces, so that such burrs are required to be removed. However, it is very difficult and practically impossible to remove such burrs generated at inner portions between the retaining portions **106** and **106**.

When such burrs exist, the circulation of the balls **104** is obstructed, so that a feeding accuracy is deteriorated. In the worst case, the balls **104** are jammed or clogged up to stop a machine using the spline unit, thus resulting in serious influence on productivity.

The present invention has been conceived for solving the afore-mentioned problems encountered in the prior arts, and an object of the present invention is to provide a ball spline unit enabling the balls to smoothly circulate without increasing the size of the ball spline unit.

Further, another object is to provide a method of molding an outer cylinder of the ball spline unit which is capable of being integrally molded by accurately setting positions of resin portions to be formed to the outer cylinder.

DISCLOSURE OF THE INVENTION

The present invention provides a ball spline unit comprising a cylindrical outer cylinder of which inner periphery is formed with a plurality of loaded ball rolling grooves, a plurality of unloaded ball passages corresponding to the ball rolling grooves formed to the outer cylinder, side covers each having a direction changing passage for connecting the loaded ball rolling grooves to the unloaded ball passages, the side covers being provided at both end portions of the outer cylinder, retainer portions provided along the the loaded ball rolling grooves so as to prevent balls in the loaded ball rolling grooves from dropping off, a spline shaft inserted into the outer cylinder, an outer periphery of the spline shaft being formed with loaded ball rolling grooves corresponding to the loaded ball rolling grooves formed to the outer cylinder, and a number of balls disposed between the outer cylinder and the loaded ball rolling grooves formed to the spline shaft so as to endlessly circulate through the direction changing passages and the unloaded ball passages,

wherein a ball chain having a number of spacer portions disposed between the respective balls of the number of balls and having connecting portions for connecting the adjacent spacer portions is provided, and

wherein at least one of the unloaded ball passage, retainer portions and ball direction changing passage inner peripheral portions is integrally molded with the outer cylinder in accordance with an insert molding method in which the outer cylinder is positioned within a molding die with reference to the loaded ball rolling grooves.

According to the structure described above, the balls in the direction changing passage are drawn by the ball chain and moved, so that the balls are smoothly moved even if the curvature radius of the direction changing passage is relatively small. Therefore, the balls can be smoothly circulated and moved without increasing the size of the outer cylinder.

Further, the balls would not collide to each other at the time of rolling and transferring, so that the noise generation can be reduced. In addition, the balls would not collide to also the inner peripheral surface of the unloaded ball passage, the noise generation can be further reduced.

On the other hand, at least one of the unloaded ball passage, ball retaining portions and ball direction changing passage inner peripheral portions are integrally molded by the insert molding with reference to the loaded ball rolling grooves formed to the inner periphery of the outer cylinder. Owing to this structure, the assembling process can be simplified and reduced.

In addition, there is no fear of causing irregularities due to the assembling error at joint portions to be formed between the ball direction changing passage and the loaded ball rolling grooves and between the direction changing passage and the unloaded ball rolling grooves, so that the circulation of the balls can be performed smoothly and the noise generation can be also reduced.

Furthermore, the outer cylinder is positioned in the molding die with reference to the loaded ball rolling grooves, so that it becomes possible to prevent the burrs from generating at a portion between the loaded ball rolling grooves and the molding die. Once the burrs are generated at the loaded ball rolling grooves, it is impossible to remove the burrs. In order to remove the burrs, the outer cylinder is obliged to be broken. Therefore, it is greatly important to prevent the generation of the burrs.

In addition, when grooves for accommodating the connected portions of the ball chain are formed in an entire circumference of the unloaded ball rolling grooves, the retainer portions and the ball direction changing passage, run-out of the ball chain can be prevented.

On the other hand, when the ball chain is constructed so that each of the balls can be retained by the respective spacer portion, an operation of assembling the balls into the outer cylinder can be completed by only inserting the ball chain retaining the balls in a form of continuous chain.

Further, even if the outer cylinder is drawn or detached from the spline shaft, the balls are retained by the ball chain, so that the retainer portions may be omitted.

The ball chain has a function of circulating the ball while providing a predetermined gap between the respective balls and is not always required to have a retentive function of preventing the balls from dropping off. In a case where the ball chain having no such retentive function is used, the balls are required to be retained when the outer cylinder is detached from the spline shaft, so that it is preferable to provide the retainer portion to the outer cylinder. However, if the outer cylinder is not required to retain the balls, it goes without saying that the retainer portion can be omitted.

In addition, in the structure described above, even in a state where a guide portion for guiding the ball chain is provided to the unloaded ball passage, the retainer portion and the ball direction changing passage, it is possible to use the spline unit by assembling only the balls without using the ball chain. Namely, this structure of the outer cylinder can be applied to both the following two cases, i.e., a case where the balls are assembled into the ball chain, then the ball chain is attached to the outer cylinder and a case where only the balls are attached to the outer cylinder without using the ball chain.

On the other hand, it is preferable that the inner periphery of the outer cylinder is formed with a plural set of loaded ball rolling groove sets in a circumferential direction, wherein each of the loaded ball rolling groove set consists of a pair of loaded ball rolling grooves adjacently arranged to each other, and the outer periphery of the spline shaft is formed with a plurality of corner portions positioned between the paired loaded ball rolling grooves which constitutes the loaded ball rolling groove set, and both side surfaces of the corner portions are provided with a pair of loaded ball rolling grooves corresponding to the paired loaded ball rolling grooves formed to the outer cylinder, while the inner periphery of the outer cylinder is formed with a plurality of unloaded ball passages corresponding to the respective loaded ball rolling grooves, wherein the unloaded ball passages are provided at portions between the plurality of the loaded ball rolling groove sets.

According to the structure described above, an outer diameter of the outer cylinder can be further reduced.

Furthermore, it is also preferable that the inner periphery of the outer cylinder is formed with a plural set of loaded ball rolling groove sets in a circumferential direction, in which of the loaded ball rolling groove set consists of a pair of loaded ball rolling grooves adjacently arranged to each other, and the outer periphery of the spline shaft is formed with a pair of loaded ball rolling grooves corresponding to the paired loaded ball rolling grooves formed to the outer cylinder, wherein the paired loaded ball rolling grooves formed to the spline shaft are formed at both side surfaces of a plurality of corner portions positioned between the paired loaded ball rolling grooves which constitutes the loaded ball rolling groove set, while the outer periphery of the outer cylinder is formed with a plurality of unloaded ball passages corresponding to the plurality of the loaded ball rolling groove.

In particular, the ball spline unit is characterized in that the unloaded ball passages to be formed to the outer periphery of the outer cylinder are arranged in a direction along a contact angle line connecting contact portions of the balls with respect to the respective loaded ball rolling grooves between which the balls are disposed.

According to this structure, a direction of the direction changing passage coincides with the rolling direction of the balls, so that the balls are smoothly rolled and moved.

A method of molding an outer cylinder according to the present invention is characterized by comprising the steps of:

providing a plural set of loaded ball rolling groove sets to an inner periphery of the outer cylinder in a circumferential direction, in which each of the loaded ball rolling groove sets consists of a pair of loaded ball rolling grooves arranged adjacently to each other;

disposing the outer cylinder to a portion between a first molding die and a second molding die arranged coaxially to each other, and providing a plurality of supporting convex portions for supporting the outer cylinder to an outer periphery of the first molding die which is positioned at inner peripheral side of the outer cylinder, the supporting convex portion engaging with the paired loaded ball rolling grooves of the respective loaded ball rolling groove sets formed to the outer cylinder; and

positioning the outer cylinder to the portion between the first and second molding dies with reference to the loaded ball rolling grooves so that the outer cylinder is supported by the plurality of the supporting convex portions, forming at least one of cavities, for forming first resin portions constituting unloaded ball passages, for forming second resin portions constituting retainer portions and for forming ball direction changing passage inner peripheral portions, to portions between the first and second molding portions and the outer cylinder, then injecting molding material into the cavities thereby to integrally mold the respective portions with the outer cylinder.

According to the method described above, the supporting convex portion formed to the first molding die is supported so as to be clamped by the paired loaded ball rolling grooves of the respective loaded ball rolling groove set formed to the outer cylinder. Therefore, even if a molding pressure is applied to the outer cylinder, the outer cylinder can be supported without causing any backlash in a rotating direction or in a direction orthogonal to a center axis, so that the molding material would not invade into the ball rolling grooves, thus preventing the generation of burrs.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1**(*a*) is a longitudinal sectional view showing a first embodiment of a ball spline unit according to the present invention, and FIGS. **1**(*b*)–(*e*) are views showing structures of ball chain.

FIG. **2**(*a*) is a front vie w partially in section of the ball spline unit shown in FIG. **1**, and FIG. **2**(*b*) is a side view, half in section, of the ball spline unit shown in FIG. **2**(*a*).

FIG. **3**(*a*) is a cross sectional view showing an outer cylinder of the ball spline unit shown in FIG. **1**, FIG. **3**(*b*) is a view showing an end surface of the outer cylinder, FIG. **3**(*c*) i s a view partially i n section of a ball rolling groove in which ball chain is not used, and FIGS. **3**(*d*) and **3**(*e*) are partially sectional views of a ball rolling groove portions in which only a guide portion for preventing run-out of the ball chain is provided.

FIG. **4**(*a*) is a longitudinal sectional view of a side cover, FIG. **4**(*b*) is a rear end view of the side cover, and FIG. **4**(*c*) is a view showing a state where the outer cylinder and the side cover are engaged.

FIGS. **5**(*a*), (*b*) are views showing one embodiment of a method of molding an outer cylinder according to the present invention.

FIGS. **6**(*a*)–(*f*) are views showing modifications of the ball chain shown in FIG. **1**.

FIG. **7**(*a*) is a longitudinal sectional view showing a second embodiment of a ball spline unit according to the present invention, and FIGS. **7**(*b*)–(*d*) are views showing structures of ball chain.

FIG. **8**(*a*) is a sectional view showing a third embodiment of a ball spline unit according to the present invention, and FIGS. **8**(*b*)–(*d*) are views showing structures of ball chain.

FIG. **9** is a view showing a conventional linear motion bearing.

BEST MODE FOR EMBODYING THE INVENTION

In order to explain the present invention in more detail, the preferred embodiments of this invention will be described hereunder with reference to the accompanying drawings.

[Embodiment 1]

FIGS. **1** and **2** show an embodiment 1 of a ball spline unit according to the present invention.

In general, the ball spline unit **1** is constituted by comprising a cylindrical outer cylinder **3**, a pair of side covers **5** provided to both ends of the outer cylinder **3**, and a spline shaft **8** interfitted into an inner periphery of the outer cylinder **3** through a number of balls **9** so that the outer cylinder is relatively slidable with respect to the spline shaft **8**.

The outer cylinder **3** is a cylindrical body composed of metal having a high rigidity, and the inner periphery of the outer cylinder **3** is formed with a plurality of loaded ball rolling grooves **2**. The loaded ball rolling grooves **2** are constructed as a plural set of loaded ball rolling groove sets **2A** to be arranged in an circumferential direction, each of the loaded ball rolling groove sets **2A** consisting of a pair of loaded ball rolling grooves **2, 2** arranged adjacently to each other. In this embodiment, three sets of loaded ball rolling groove sets **2A** are provided at an equal interval in the circumferential direction.

On the other hand, the spline shaft **8** is inserted into the outer cylinder **3**, and an outer periphery of the spline shaft **8** is provided with three corner portions **8***a* at positions between the paired loaded ball rolling grooves **2, 2** which constitute the respective loaded ball rolling groove sets **2A**. Both side surfaces of the respective corner portions **8***a* are provided with a pair of loaded ball rolling grooves **7, 7** corresponding to the paired loaded ball rolling grooves **2, 2** formed to the outer cylinder **3**. Further, six rows of balls **9** are disposed between the six sets of loaded ball rolling grooves **2** and **7** arranged so as to oppose to each other, and the balls of the respective rows are applied with a predetermined preload.

A contact angle line L connecting contact points of each loaded ball **9** contacting to the loaded ball rolling grooves **2** and **7** is inclined with a predetermined angle α with respect to a radial line connecting a center of the ball to a center of the spline shaft **8**. The contact angle α is set so as to be linearly symmetric to each other with respect to a line connecting the center of the spline shaft **8** to the center of the corner portion **8***a*.

The six rows of balls **9** disposed between the respective loaded ball rolling grooves **2** and **7** are circulated and moved in such a manner that the balls **9** are moved from one end of the loaded ball rolling groove **2**, then moved into the unloaded ball passage **4**, which is formed in parallel with the loaded ball rolling groove **2**, through a direction changing passage **19** formed to one side cover **5**, then the balls **9** are moved through a direction changing passage **19** formed to the other side cover **5**, subsequently transferred again to the loaded ball rolling grooves **2** and **7**. The balls **9** are arranged over an entire circumference of a circulation passage consisting of a passage formed between the loaded ball rolling grooves **2** and **7**, the direction changing passages **19** and the unloaded ball passage **4**. The balls **9** are retained by a ball chain **60**.

The ball chain **60** comprises spacer portions **61** disposed between the respective balls **9** and connecting portions **62** for connecting the adjacent spacer portions **61**. Both ends of the ball chain **60** are not connected, and the ball chain **60** is attached in a state where a part of chain is cut off. In this regard, however, the ball chain **60** can be also formed in an endless shape by connecting both the end portions.

The spacer portion **61** comprises a flexible spacer plate **63** provided with a U-shaped structure having one side formed with a slit **65** and a pair of retention pieces **64** to which the adjacent balls **9** are seated respectively. The retention piece **64** is provided to right and left leg portions of the U-shaped spacer plate **63**, and each of the retention pieces **64** comprises a spherical crown-shaped concave portion **64***a* thereby to realize a structure enabling the balls **9** to be retained.

On the other hand, the connecting portion **62** is constituted by a belt-shaped member for connecting both sides of the spacer portion **61**. However, the connecting portion **62** may have a structure in which only one side of the respective spacer portion **61** is connected.

The ball chain **60** can be flexibly bent at a portion of the slit **65** formed to the spacer portion **61**. A bending direction of the ball chain **60** in the direction changing passage **19** is as follows. Namely, the ball chain **60** has a structure so that the ball chain **60** circulates by being bent in a direction so as to open the slit **65** while a bottom side of the U-shaped spacer plate **63** directs inward. As shown in FIGS. **1**(*b*) and (*d*), a width of the slit **65** can be appropriately selected in accordance with the curvature radius or the like of the direction changing passage **19**.

When the balls **9** are retained by the ball chain **60** as described above, the balls **9** in the direction changing passage **19** are drawn by the ball chain **60** and moved, so that the balls **9** are smoothly moved even if the curvature radius of the direction changing passage **19** is relatively small. Therefore, the balls **9** can be smoothly circulated and moved without increasing the size of the spline unit.

Particularly, in this embodiment, the respective spacer portions **61** is constituted by being provided with the slit **65** so as to be easily opened, the curvature radius of the direction changing passage **19** can be further decreased.

As shown in FIG. **3**(*a*), the loaded ball rolling grooves **2**, **2** constituting the respective loaded ball rolling groove set **2**A formed to the outer cylinder **3** are provided to both end portions of a first U-shaped groove **10** having a U-shape in cross section. However, the groove **10** is not limited to the U-shaped groove, and may be also constituted by a circular-arc-shaped groove.

In addition, a second U-shaped groove **11** to which the unloaded ball passage **4** is formed is provided to a portion between the aforementioned first U-shaped grooves **10** formed to the inner periphery of the outer cylinder **3**. A first resin portion **12** extending in an entire longitudinal direction of the outer cylinder **3** is integrally interfitted into the second U-shaped groove **11**. The first resin portion **12** has a circular-arc shape in section having a sufficient thickness, and a portion of the first resin portion **12** ranging from an outer end portion to a half thereof in a thickness direction is integrally interfitted into the second U-shaped groove **11**, while an inner end portion of the first resin portion **12** is inwardly projected from the inner periphery of the outer cylinder **3**.

Furthermore, the first resin portion **12** is formed with an unloaded ball passage **4**. The unloaded ball passage **4** is constituted by a circular through hole having a diameter slightly larger than that of the ball **9** and is formed so that a center position of the passage **4** coincides with an inner diameter line of the outer cylinder **3**.

In addition, side peripheries **6***a* in a circumferential direction of an inner end portion of the first resin portion **12** is projected toward a side of the adjacent first U-shaped groove **10**.

The outer circumference of the outer cylinder **3** is provided, at center portion thereof, with a lubricant guide groove **13** extending over an entire circumference of the outer cylinder **3** so as to supply the lubricant. The lubricant guide groove **13** is communicated with the second U-shaped groove **11** of the inner peripheral side through a first communication hole **14**. In addition, the first resin portion **12** is provided with a second communication hole **15** for communicating the aforementioned first communication hole **14** with the respective unloaded ball passage **4**. Further, the outer periphery of the outer cylinder **3** is provided with a key groove **3***a* extending in an axial direction.

The aforementioned first U-shaped groove **10** is provided with a second resin portion **16** for retaining the ball **9**. A side periphery in a circumferential direction of the second resin portion **16** and a side periphery in a circumferential direction of the first resin portion **12** are opposed to each other with a distance smaller than the diameter of the ball **9** thereby to constitute the retainer portions **6***a* and **6***b* for preventing the ball **9** from dropping-off.

As shown in FIG. **3**(*b*), the first resin portion **12** and the second resin portion **16** are integrally connected at a ring-shaped third resin portion **18** which is bonded to both end surfaces of the outer cylinder **3**. An end portion of the linearly extending loaded ball rolling groove **2** and an end portion of the unloaded ball passage **4** are opened to the end surface of the third resin portion **18**, and circular-arc-shaped direction changing passage inner peripheral portions **19***a* are provided between the loaded ball rolling groove **2** and the unloaded ball passage **4**.

On the other hand, as shown in FIG. **4**, the side cover **5** to be attached to the end surfaces of the outer cylinder **3** is a ring-shaped member, and has a ring-shaped end surface which abuts against the ring-shaped end surface of the third resin portion **18**. This end surface is formed with a circular-arc groove as concavity for constituting a direction changing outer periphery portion **19***b* so as to correspond to the direction changing passage inner peripheral portions **19***a* formed to six portions of the end surface of the third resin portion **18**.

In addition, the outer peripheral portion of the side cover **5** is provided with a ring-shaped wall **22** which engages with an outer peripheral surface of the third resin portion **18** formed to a side of the outer cylinder **3**. The inner periphery of the ring-shaped wall **22** is provided with an engaging projection **23** which engages with an engaging groove **21** formed to the outer periphery of the third resin portion **18**. An end surface of the ring-shaped wall **22** abuts against an end surface of the outer cylinder **5**.

The aforementioned unloaded ball passage **4**, the retainer portions **6***a* and **6***b*, and the inner periphery portion **19***a* and the outer periphery portion **19***b* of the ball direction changing passage **19** are provided with guide grooves **66** as guide portions for guiding the ball chain **60**. The guide grooves **66** are formed over an entire circumference so that one side peripheries of the connecting portion **62** and the retainer plate **63** of the ball chain **60** are accommodated into the guide grooves **66**, thereby to prevent the run-out of the ball chain **60** during the rolling of the balls.

That is, the guide grooves **66** are linearly formed to the inner peripheral surface of the unloaded ball passage **4** of the first resin portion **12**, side peripheral portions **12***a*, **16***a* opposing to each other in a circumferential direction of the first resin portion **12** and the second resin portion **16** constituting the retainer portions. In addition, a circular-arc-shaped guide grooves **66** are formed to the direction changing inner peripheral portion **19***a* and the direction changing outer peripheral portion **19***b* to be formed to the side cover **5**.

By the way, even if the outer cylinder **3** is detached from the spline shaft **8**, the balls are retained by the ball chain **60**, so that the aforementioned retainer portions **6***a,* **6***b* are not always necessary. However, when the retainer portions **6***a,* **6***b* are provided, as shown in FIG. **3**(*c*), the outer cylinder **3** can cope with a case where only the balls **9** are attached to the outer cylinder **3** without using the ball chain **60**. Namely, one outer cylinder **3** can be commonly applied to both the following two specifications, i.e., a specification of a type using ball chain and a specification of a type using only the balls, thus being advantageous.

In particular, in a case where only the balls are provided, the guide grooves **66** for the ball chain **60** can be utilized as lubricant supplying groove for supplying lubricants such as grease or the like.

In addition, even in a case where the retainer portions **6***a,* **6***b* are omitted, it is preferable to provide a guide portion for the ball chain for the purpose of preventing the run-out of the ball chain **60**. In this case, for example, as shown in FIG. **3**(*d*), the aforementioned guide portion can be constituted by a guide wall **66***a* for guiding one side surfaces of the connecting portion **62** and the spacer portion **63** of the ball chain **60**. Further, as shown in FIG. **3**(*e*), the guide portion can be also constituted by a guide wall **66***b* having a stepped-shape.

All of the first resin portion **12** for constituting the unloaded ball passage, the first and second resin portions **12**, **17** for constituting the retainer portions **6**, and the third resin portion **18** for constituting the rolling member direction changing passage inner peripheral portion **19***a* is integrally molded with the outer cylinder **3** in accordance with the insert molding method in which the outer cylinder **3** is disposed in the molding die.

FIG. **5** is a view showing an interfitting state of the outer cylinder **3** and the molding die at the time of the insert molding.

The insert molding of the outer cylinder **3** is carried out in accordance with the following steps. Namely, the outer cylinder **3** is disposed between a first molding die **40** and a second molding die **41** that are coaxially arranged to each other with reference to the loaded ball rolling grooves **2** thereby to form a cavity **12***a* for forming the first resin portion **12** for constituting the unloaded ball passage **4**, a cavity **16***a* for forming the second resin portion **16** for constituting the retainer portions, a cavity **19***c* for forming the ball direction changing passage inner peripheral portions **19***a,* and a cavity **18***a* for forming the third resin portion **18**. Then, a resin material is injected into the respective cavities **12***a,* **16***a,* **18***a* and **19***c* thereby to form the first resin portion **12**, the second resin portion **16**, the third resin portion **18** and the direction changing passage inner peripheral portion **19***a*.

That is, the first molding die **40** is provided with a supporting convex portion **42** for supporting the outer cylinder **3** by engaging with the respective loaded ball rolling grooves **2** formed to the outer cylinder **3**. The supporting convex portion **42** has a circular arc-shape in section corresponding to the circular arc-shape in section of the inner peripheral shape of the loaded ball rolling grooves **2**, and tightly interfits into the loaded ball rolling grooves **2**. Further, A core member **43** for forming the unloaded ball passage **4** is inserted into the cavity **12***a* for forming the first resin portion, the cavity **12***a* being formed between the first molding die **40** and the second molding die **41**.

Furthermore, the supporting convex portion **42** and the core member **43** are formed with convex projections **42***a* and **43***a* corresponding to the guide grooves **66** for accommodating the side peripheries of the connecting portions **62** and the retainer plates **63** of the ball chain **60**, whereby the guide grooves **66** are also integrally molded.

As described above, the outer cylinder **3** is positioned between the first and second molding dies **40** and **41** with reference to the loaded ball rolling grooves **2**, so that the generation of burrs can be prevented at a portion between the loaded ball rolling grooves **2** and the first molding die **40**. In particular, in this embodiment, the ball rolling groove sets are basically provided at three portions, and the outer cylinder **3** is positioned by the first molding die **40** at three points. In addition, there is provided an angular-contact structure, so that the positioning in a rotational direction can be also carried out, and the outer cylinder **3** can be accurately positioned with respect to the first molding die **40**.

In addition, when a grinding work of the outer periphery of the outer cylinder **3** to be insert-molded is performed with reference to the loaded ball rolling grooves **2**, a gap between the contact surfaces of the second molding die **41** and the outer periphery of the outer cylinder **3** inserted into the molding die can be set as small as possible, so that it becomes possible to prevent also the generation of burrs at outer circumferential side.

By the way, in order to prevent the generation of burrs, it is not always necessary for the contacting surfaces of the outer cylinder **3** and the supporting convex portion **42** of the molding die **40** to completely and tightly contact to each other. The gap may be allowed as far as the a size of the gap is sufficiently small to prevent the molding material from invading into the molding die.

As in the present invention, when the outer periphery of the outer cylinder **3** is finished by the grinding work and the outer cylinder **3** is disposed within the molding die with reference to the loaded ball rolling grooves **2**, a gap of the outer periphery can be set to a predetermined small size capable of preventing the molding material from invading thereinto.

In addition, not only the gap of the outer periphery of the outer cylinder **3** but also a gap between the loaded ball rolling grooves **2** of the inner periphery side and the first molding die **40** can be set to a predetermined small size capable of preventing the molding material from invading thereinto. Furthermore, also the loaded ball rolling grooves **2** is finished by grinding work, so that the molding die and the loaded ball rolling grooves **2** will contact to each other with a gap having a small extent.

As described above, when the small gaps are provided to portions between the outer and inner peripheries of the first and second molding dies **40**, **41** and the outer cylinder **3**, it becomes possible to easily attach the outer cylinder **3** and to effectively prevent the generation of the burrs.

As described above, since all of the unloaded ball passage **4**, ball retaining portions **6** and the direction changing passage inner peripheral portions **19***a* are integrally molded by the insert molding method with reference to the loaded ball rolling grooves **2** formed to the inner periphery of the outer cylinder **3**, the assembling process can be remarkably simplified and reduced.

In addition, there is no fear of causing irregularities due to the assembling error at joint portions to be formed between the direction changing passage **19** and the loaded ball rolling grooves **6** and between the direction changing passage **19** and the unloaded ball rolling grooves **4**, so that the circulation of the balls can be performed smoothly and the noise generation can be also reduced.

In this embodiment, although all of the unloaded ball passage **4**, ball retainer portions **6** and the direction changing passage inner peripheral portions **19***a* are integrally molded with the outer cylinder by the insert molding method, at least one of those members may also be formed by the insert molding method.

FIG. **6** are views showing modifications of the ball chains to be used in the above embodiments.

FIGS. **6**(*a*) and **6**(*b*) show a ball chain in which, among the connecting portions **62** provided both sides of the spacer portions **61**, slits **62** are provided to the connecting portions **62** of the same side as the slit of the spacer portions **62**. According to the structure described above, as shown in FIG. **6**(*c*), the slit **67** of the connecting portion **62** together with the slit **65** of the spacer portion **61** are opened in the direction changing passage, so that the curvature radius of the direction changing passage can be further reduced.

Of course, as shown in FIG. **6**(*d*), it is also possible to arrange the slits **65**, **67** so that sides of the slits are located at inside of the direction changing passage.

FIG. **6**(*e*) shows an example in which cut-outs **68** are formed to a side periphery opposed to the slit **65** of the spacer portion **61** of the ball chain **60** to be more easily deformable.

FIG. **6**(*f*) shows an example in which slits **69** are formed to one side connecting portions **62** among the connecting portions **62** provided at both sides of the ball for connecting the adjacent spacer portions **61** without forming slits **65** to the spacer portions **61** to be more fittably bent.

Next, other embodiments of the present invention will be explained hereunder.

In the explanation of the respective embodiments, the reference numerals are used to denote the same elements or members as those of the first embodiment (Embodiment 1), and the detailed explanations of the same elements or members are omitted.

[Embodiment 2]

FIG. **7** shows a second embodiment of the present invention. This embodiment 2 is an example in which the loaded ball passages are formed to the outer periphery of the outer cylinder.

This embodiment 2 is different from the embodiment 1 in a point that the loaded ball passages **4** are formed to the outer peripheral side of the outer cylinder **3**. Namely, the second U-shaped grooves **51** are formed to the outer peripheral side of the outer cylinder **3**, and the unloaded ball passages **4** are formed to the second resin portions **51** integrally molded so as to fill the second resin portions **52**.

In this case, the ball chain is constituted by comprising retainer pieces **71**, **71** as a pair of spacer portions disposed between the balls **9** and belt-shaped connecting portions **72** for connecting both sides of the respective retainer pieces **71**, in which the belt-shaped connecting portion **72** is formed in a belt shape as a whole. In the direction changing passage **19**, the ball chain changes its moving direction by bending a surface including both the sides of the belt-shaped connecting portions **72**.

In this embodiment, slits are not provided to the retainer piece **71** as the spacer portion. According to this structure, the ball chain can be more stably guided in comparison with the ball chain **60** of the embodiment 1 provided with slits **65**. In the embodiment 1, the unloaded ball passages are formed to the inner periphery of the outer cylinder, so that a difference in a length between the outer and inner circumferential lengths of a circulation track is increased. Therefore, in order to realize the smooth direction changing, the slit **65** is formed at outer side portion of the paired retainer pieces **64**.

In particular, in a case where the spline shaft **8** is rotated with a high speed, a centrifugal force to be applied to the ball increases. In the case of the embodiment 1, however, a circulating direction of the ball chain **60** is orthogonal to a direction to which the centrifugal force is applied, so that a friction force caused between the ball chain and the guide groove is disadvantageously increased when the ball chain **60** is deformed by the centrifugal force. As a result, there may be a fear that the smooth circulation of the ball chain will be obstructed.

In contrast, according to this embodiment 2, both sides of the ball are connected by the belt-shaped connecting portion **72**, the circulating direction of the ball chain **70** is close to the direction to which the centrifugal force is applied in comparison with that of the embodiment 1, so that the deformation of the ball chain **70** occurs along the circulating direction of the ball chain **70**. As a result, an influence of the centrifugal force can be lowered.

[Embodiment 3]

FIG. **8** shows a third embodiment of the present invention.

This embodiment 3 of a ball spline unit is formed by providing the unloaded ball passages **4** to the outer peripheral side of the outer cylinder **3** in the same manner as in the embodiment 2. In particular, the ball spline unit has a structure of that the unloaded ball passages **4** to be formed to the outer periphery of the outer cylinder **3** are arranged in a direction along a contact angle line L connecting contact portions of the balls **9** with respect to the respective loaded ball rolling grooves **2** and **7** between which the balls **9** are disposed.

According to this structure, a direction of the direction changing passage **19** coincides with the rolling direction of the balls, so that the balls **9** are smoothly rolled and moved.

The outer periphery of the outer cylinder **3** is formed with a second U-shaped grooves **51**, and the unloaded ball passages **4** are formed to the second resin portions **51** integrally molded so as to fill the second U-shaped grooves **52**. As described above, since the unloaded ball passages **4** are formed to the outer peripheral side of the outer cylinder **3**, the concave portions as formed in the embodiment 1 are not formed at portions of inner periphery of the outer cylinder **3** to which the first resin portions **12** are provided. As a result, the first resin portions **12** are molded in a form of circular-arc-shape having a uniform thickness.

In addition, in the same manner as in the embodiment 2, the ball chain **70** is constituted by comprising retainer pieces **71**, **71** as spacer portions disposed between the balls **9** and connecting portions **72** for connecting both sides of the respective retainer pieces **71**, in which each of the connecting portions **72** is formed in a belt shape as a whole. In the direction changing passage **19**, the ball chain **70** changes its moving direction by bending a surface including the both sides of the belt-shaped connecting portions **72**.

In this embodiment 3, the circulating direction of the ball chain **70** is further close to the direction to which the centrifugal force is applied in comparison with that of the embodiment 2, so that an influence of the centrifugal force can be further lowered than that of the embodiment 2, whereby the ball chain can be smoothly circulated.

According to the present invention as described above, since a number of balls are retained by the ball chain, the ball chain is smoothly moved even if the curvature radius of the direction changing passage is relatively small. Therefore, the balls can be smoothly circulated and moved without increasing an outer diameter of the outer cylinder.

Further, the balls would not collide with each other at the time of rolling and transferring and would also not collide with the inner peripheral surface of the unloaded ball passage, so that the noise generation can be reduced thereby to improve a low-noise property.

In addition, since at least one of the unloaded ball passage, ball retaining portions and ball direction changing passage inner peripheral portions are integrally molded by the insert molding with reference to the loaded ball rolling grooves formed to the inner periphery of the outer cylinder, the assembling process can be simplified and reduced. At the same time, there is no fear of causing irregularities due to the assembling error at joint portions to be formed between the ball direction changing passage and the loaded ball rolling grooves and between the direction changing passage and the unloaded ball rolling grooves, so that the circulation of the balls can be performed smoothly and it becomes possible for the balls to smoothly circulated and moved in co-operation with the guiding function of the ball chain.

Furthermore, since the outer cylinder is positioned in the molding die with reference to the loaded ball rolling grooves and molded, it becomes possible to prevent the burrs from generating at a portion between the loaded ball rolling grooves and the molding die.

In addition, when grooves for accommodating the connected portions of the ball chain are formed in an entire circumference of the unloaded ball rolling grooves, the retainer portions and the ball direction changing passage, run-out of the ball chain can be prevented.

Furthermore, when the ball chain has a function of retaining the balls, an operation of assembling the balls into the outer cylinder can be completed by only inserting the ball chain retaining a number of balls in a form of continuous chain.

On the other hand, when the inner periphery of the outer cylinder at portions between the plurality of the loaded ball rolling groove sets is formed with a plurality of unloaded ball passages corresponding to the respective loaded ball rolling grooves, it becomes possible to further reduce an outer diameter of the outer cylinder.

In addition, when the outer peripheral portion of the outer cylinder is formed with a plurality of unloaded ball passages corresponding to the respective loaded ball rolling grooves, and the unloaded ball passages are arranged along a contacting direction of the balls, a direction of the direction changing passage coincides with the rolling direction of the balls, so that the balls are smoothly rolled and moved.

Furthermore, according to the method of molding the outer cylinder of the present invention, the supporting convex portion formed to the first molding die is supported so as to be clamped by the paired loaded ball rolling grooves of the respective loaded ball rolling groove set by utilizing the ball contacting structure of the outer cylinder, so that even if a molding pressure is applied to the outer cylinder, the outer cylinder can be supported without causing any backlash in a rotating direction or in a direction orthogonal to a center axis. As a result, the molding material would not invade into the ball rolling grooves, thus securely preventing the generation of burrs.

INDUSTRIAL APPLICABILITY

The present invention can be widely applicable to ball spline units each comprising an outer cylinder and a circulation passages formed to the outer cylinder for endlessly circulating the balls. In particular, since the ball spline unit is constructed by using a ball chain so that the ball can be smoothly moved even if the curvature radius of the direction changing passage is relatively small, the ball spline unit can be formed in a small size. In addition, the assembling of the balls into the outer cylinder can be easily performed, and the assembling workability is excellent.

What is claimed is:

1. A ball spline unit comprising:

an outer cylinder of which inner periphery is formed with a plurality of loaded ball rolling grooves;

a plurality of unloaded ball passages corresponding to said ball rolling grooves formed to said outer cylinder;

side covers each having a direction changing passage for connecting said loaded ball rolling grooves to said unloaded ball passages, said side covers being provided at both end portions of said outer cylinder;

retainer portions provided along said loaded ball rolling grooves so as to prevent balls in the loaded ball rolling grooves from dropping off;

a spline shaft inserted into said outer cylinder, an outer periphery of said spline shaft being formed with loaded ball rolling grooves corresponding to said loaded ball rolling grooves formed to said outer cylinder; and

a number of balls disposed between said outer cylinder and said loaded ball rolling grooves formed to said spline shaft so as to endlessly circulate through said direction changing passages and said unloaded ball passages;

wherein a ball chain comprising a number of spacer portions disposed between the respective balls of a number of balls and connecting portions for connecting the adjacent spacer portions is provided, and

wherein at least one of said unloaded ball passage, retainer portions and ball direction changing passage inner peripheral portions is integrally molded with the outer cylinder in accordance with an insert molding method in which the outer cylinder is positioned within a molding die with reference to the loaded ball rolling grooves.

2. A ball spline unit according to claim **1**, wherein said unloaded ball passage, said retainer portions and said ball direction changing passage are provided with a guide portion for guiding said ball chain.

3. A ball spline unit comprising:

an outer cylinder of which inner periphery is formed with a plurality of loaded ball rolling grooves;

a plurality of unloaded ball passages corresponding to said ball rolling grooves formed to said outer cylinder;

side covers each having a direction changing passage for connecting said loaded ball rolling grooves to said unloaded ball passages, said side covers being provided at both end portions of said outer cylinder;

a spline shaft inserted into said outer cylinder, an outer periphery of said spline shaft being formed with loaded ball rolling grooves corresponding to said loaded ball rolling grooves formed to said outer cylinder; and

a number of balls disposed between said outer cylinder and said loaded ball rolling grooves formed to said spline shaft so as to endlessly circulate through said direction changing passages and said unloaded ball passages;

wherein a ball chain comprising a number of spacer portions disposed between the respective balls of a number of balls and connecting portions for connecting the adjacent spacer portions is provided, and

wherein at least one of the unloaded ball passage and ball direction changing passage inner peripheral portions is integrally molded with the outer cylinder in accordance with an insert molding method in which the outer cylinder is positioned within a molding die with reference to the loaded ball rolling grooves.

4. A ball spline unit according to claim **3**, wherein said unloaded ball passage and said ball direction changing passage are provided with a guide portion for guiding said ball chain.

5. A ball spline unit according to any one of claims **1**, **2**, **3** and **4**, wherein said ball chain is constructed so that each of the balls is retained by the respective spacer portions provided between the balls.

6. A ball spline unit comprising:

an outer cylinder of which inner periphery is formed with a plurality of loaded ball rolling grooves;

a plurality of unloaded ball passages corresponding to said ball rolling grooves formed to said outer cylinder;

side covers each having a direction changing passage for connecting said loaded ball rolling grooves to said unloaded ball passages, said side covers being provided at both end portions of said outer cylinder;

retainer portions provided along said loaded ball rolling grooves so as to prevent balls in the loaded ball rolling grooves from dropping off;

a spline shaft inserted into said outer cylinder, an outer periphery of said spline shaft being formed with loaded ball rolling grooves corresponding to said loaded ball rolling grooves formed to said outer cylinder; and

a number of balls disposed between said outer cylinder and said loaded ball rolling grooves formed to said spline shaft so as to endlessly circulate through said direction changing passages and said unloaded ball passages;

wherein at least one of said unloaded ball passage, retainer portions and ball direction changing passage inner peripheral portions is integrally molded with the outer cylinder in accordance with an insert molding method in which the outer cylinder is positioned within a molding die with reference to the loaded ball rolling grooves, and said unloaded ball passage, said retainer portions and said ball direction changing passage are provided with a guide portion for guiding said ball chain in which a number of balls are interlinked; and

wherein only a number of said balls are attached to said outer cylinder without using a ball chain.

[57] **ABSTRACT**

A linear rolling motion guide apparatus comprises a track member as a guide rail formed with a track extending in a longitudinal direction thereof, a movable member as a movable block formed with a rolling member circulation passage including a loaded rolling member rolling track corresponding, in position, to the track of the track member, a number of rolling members such as balls rolling in the rolling member circulation passage, the movable member being arranged to be movable relatively to the track member by a rolling motion of the rolling member and a rolling member connection assembly, as a retainer, mounted to the movable member, the rolling member connection assembly having a flexible belt-shaped member supporting the rolling members in series to be rotatable. The movable member is formed with a single material and the movable member is integrally formed with guide portions, for guiding the flexible belt-shaped member, to both sides of the loaded rolling member rolling track with the same material as that of the movable member through the same manufacturing process therefor.

LINEAR ROLLING MOTION GUIDE APPARATUS

BACKGROUND OF THE INVENTION

The present invention relates to a linear rolling motion guide apparatus particularly provided with a connection belt assembly for supporting rolling members continuously in series.

In a known linear rolling motion guide apparatus, a movable block (movable member) and a track rail (track member) are assembled to be relatively movable by a number of rolling members such as balls. The track rail is formed, along a longitudinal direction thereof, with a track along which the rolling members are rolled, and the movable block is formed with a rolling member circulation passage including a loaded track opposing (corresponding) to the track of the track rail when assembled. The rolling members are accommodated in an arranged state in the rolling member circulation passage and rolled on the track rail and circulated in the circulation passage, while being loaded load, in accordance with the relative motion between the track rail and the movable block.

With the known linear motion guide apparatus mentioned above, there is also provided a structure in which the rolling members are supported or held in series by a belt member having flexibility. According to such support structure, the generation of noises and abrasion which may be caused through the friction of adjacent rolling members can be prevented and the coming-off of the rolling members at a time of removing the movable block from the track rail can be also prevented.

The movable member is provided with linear guide portions along the loaded track for guiding side edge portions of the belt member projecting on both sides of the rolling members, and such guide portions are formed of a steel plate, for example, as a member independent from the movable block. Furthermore, a portion of the movable block to which the load is applied is formed of a metal material having a large mechanical strength and a portion to which any load is not applied is formed of a synthetic resin material. In such structure, the guide portion for guiding the belt member is formed of a synthetic resin (which may be called hereinlater merely resin) integrally with the movable block.

However, the fact that the guide portion is formed of the steel plate other than the material forming the movable block requires many parts or members and also requires another working for fastening the guide portions to the movable block by means of screws or the like after the formation of the movable block. Furthermore, it is troublesome and difficult to fasten the guide portions to the movable block by means of screws at a small space between the movable block and the track rail.

Incidentally, in the structure in which the resin guide portion is integrally formed with a resin portion of the movable block, there is required another working step for integrally molding the guide portions with the resin to a movable block body made of metal after the metal movable block body has been formed. Moreover, since the movable block is thus formed with the resin portion, it is inconvenient to use such movable block in a high temperature atmosphere or vacuum environment.

SUMMARY OF THE INVENTION

An object of the present invention is to substantially eliminate defects or drawbacks encountered in the prior art

mentioned above and to provide a linear rolling motion guide apparatus with reduced components or parts and reduced assembling workings at a time of forming a guide portion for guiding a flexible belt member to a movable block (movable member).

This and other objects can be achieved according to the present invention by providing a linear rolling motion guide apparatus comprising:

a track member formed with a track extending in a longitudinal direction thereof;

a movable member formed with a rolling member circulation passage including a loaded rolling member rolling track corresponding, in position, to the track of the track member;

a number of rolling members, such as balls or rollers, rolling in the rolling member circulation passage, the movable member being arranged to be movable relatively to the track member by a rolling motion of the rolling members; and

a rolling member connection assembly mounted to the movable member, the rolling member connection assembly having a flexible belt-shaped member supporting the rolling members in series to be rotatable,

the movable member being formed with a single material and the movable member being integrally formed with guide portions, for guiding the flexible belt-shaped member, to both sides of the loaded rolling member rolling track with the same material as that of the movable member through the same manufacturing process therefor.

In preferred embodiments of the above aspect, the movable member is formed by injection molding a mixture material of metal powder and synthetic material, removing the synthetic material thereafter through a heat treatment or chemical treatment and then sintering the material.

The rolling member circulation passage includes a rolling member return passage arranged substantially in parallel to the loaded rolling member rolling passage, the rolling member return passage being formed with a guide groove, for guiding the flexible belt-shaped member, integrally to the movable member through the same manufacturing process therefor.

The rolling member circulation passage includes a pair of rolling member rolling direction changing passages connecting the loaded rolling member rolling track and the rolling member return passage, each of the rolling member rolling direction changing passage includes an inner peripheral portion and an outer peripheral portion, the inner peripheral portion being formed of the same material as that of the movable member through the same manufacturing process therefor, the outer peripheral portion being formed with a body different from that of the movable member, and when the inner peripheral portions and the outer peripheral portions of a pair of rolling member rolling direction changing passage are mated with each other, a guide groove for guiding the belt-shaped member is formed to the rolling member return passage.

The linear rolling motion guide apparatus further comprises a pair of end plates disposed at both longitudinal end portions of the movable member and the end plates constitute the outer peripheral portions of the rolling member rolling direction changing passages. The outer peripheral portion is formed by injection molding a mixture material of metal powder and synthetic material, removing the synthetic material thereafter through a heat treatment or chemical treatment and then sintering the material.

The flexible belt-shaped member is formed of a metal such as thin sheet of stainless steel plate.

The loaded rolling member rolling track is ground by means of a grinder through a space between the guide portions formed to both the side portions of the loaded rolling member rolling track.

More in detail, the track member is a guide rail having substantially a rectangular cross section and the movable member is a movable block having two leg portions so as to provide substantially a ⊐-shaped cross section, the guide rail being arranged between the leg portions so that said track formed to the guide rail accords, in position, with the loaded rolling member rolling track formed to the movable block.

The flexible belt-shaped member is a retainer composed of a belt-shaped plate and a number of holes which are arranged with equal interval with each other and in which the rolling member is held to be rotatable and side edge portions of the belt-shaped plate are guided by the guide portions when the retainer is assembled with the movable member.

According to the characteristic features of the present invention mentioned above, since the movable member and the guide portions are formed of the same material such as metal and synthetic resin at the same time for carrying out an injection molding process or casting process, constructional parts or elements and assembling steps can be effectively reduced for manufacturing the linear rolling motion guide apparatus.

Furthermore, when the movable member is formed through a metal injection molding process, the movable member can be formed with fine and complicated structure, as well as the guide portions. In such case, the guide portions are also formed of the metal material, and accordingly, even if the guide portion is formed in thin shape between the movable member and the track member, the guide portions can provide sufficient strength. In addition, in a prior art including a case in which a resin part is formed integrally with a metal movable member, burr may be caused between the movable member and the resin part. However, according to the present invention in which the guide portions and the movable member are formed integrally through the injection molding process, such burr is not caused.

Still furthermore, according to the present invention, since the guide groove is formed integrally with the rolling member return passage, the number of parts or elements and assembling steps can be effectively reduced. Moreover, the side edge portions of the flexible belt-shaped member as retainer are guided by the guide groove of the rolling member return passage, so that the vibration of the flexible belt-shaped member can be effectively suppressed, thus the predetermined track being properly and stably maintained, and the rolling members such as balls can also be stably rolled on the predetermined track.

Still furthermore, since the inner peripheral portion of the rolling member rolling direction changing passage is integrally formed with the movable member, the number of parts or elements and assembling steps can be effectively reduced. Furthermore, in the rolling member rolling direction changing passage, the flexible belt-shaped member is guided by the guide groove, so that the vibration of the flexible belt-shaped member in this passage can be also effectively suppressed, thus the predetermined track being properly and stably maintained, and the rolling members such as balls supported by the flexible belt-shaped member can also be stably rolled on the predetermined track.

Still furthermore, according to the present invention, all the parts or members constituting the linear rolling motion guide apparatus can be formed of metal material, so that the apparatus can be used in a high temperature condition and a vacuum condition in which an apparatus formed of resin parts such as in the prior art is not used.

Still furthermore, the loaded rolling member rolling track can be ground between the guide portions by coinciding the contact angle direction of the rolling members with the cutting direction of the grinding member even in a case where the guide portions are integrally formed with the loaded rolling member rolling track, so that the surface thereof can be smoothly ground, resulting in the smooth circulation of the rolling members such as balls.

The nature and further characteristic features of the present invention will be made more clear from the following descriptions made with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

In the accompanying drawings:

FIG. **1** is a perspective view of a linear rolling motion guide apparatus according to one embodiment of the present invention;

FIG. **2** is a developed perspective view showing a movable block body and end plates of the linear rolling motion guide apparatus of FIG. **1**;

FIG. **3** is a sectional view taken along the line III—III of FIG. **1**;

FIG. **4** shows a retainer and a plurality of balls of the linear motion guide apparatus of FIG. **1** and includes FIG. **4**A of a side view, FIG. **4**B of a plan view and FIG. **4**C of a front view;

FIG. **5** is a bottom view including a half-sectional portion of the structure shown in FIG. **1**;

FIG. **6** is a partial view showing one example of a movable block forming mold;

FIG. **7** is a sectional view of FIG. **6**;

FIG. **8** is a partial view showing one example of an end plate forming mold; and

FIG. **9** is a schematic view showing a loaded rolling groove grinding working.

DESCRIPTION OF THE PREFERRED EMBODIMENT

With reference to FIG. **1** showing a perspective view of a linear rolling motion guide apparatus **1** of the present invention, a movable block **2** as movable member is supported by a guide rail **4** as track member by a number of rolling members **3**, **3**, - - - , **3**, i.e. balls in this embodiment so that the movable block **2** is linearly movable along the guide rail **4**. It is to be noted that, in a modified example, the movable block **2** may be formed as stationary side and the guide rail **4** may formed as movable side.

The guide rail **4** has an elongated structure and has substantially a rectangular cross section and has both lateral side surfaces to which a pair of ball rolling grooves **5**, as tracks for rolling the balls **3**, **3**, - - - , **3**, are formed along the entire longitudinal lengths thereof.

The movable block **2** is composed, as shown in FIG. **2**, of a movable block body **6** and end plates **7** and **8** mounted to both longitudinal ends of the movable block body **6**. The movable block body **6** has substantially a gate (⊐)-shaped cross section and provided with a horizontal portion **6***a* opposing to an upper surface of the guide rail **4** and a pair of leg portions **6***b*, **6***b* opposing to the lateral side surfaces

4*a*, 4*a* of the guide rail **4**, when the guide rail **4** is arranged in the ⊐-shaped space of the movable block body **6**. The paired leg portions **6***b*, **6***b* are formed, at inside surfaces thereof, with loaded ball rolling grooves **9**, **9** as loaded tracks corresponding to ball rolling grooves **5**, **5** formed to the side surfaces **4***a*, **4***a* of the guide rail **4**. Guide portions **10**, **10** are formed to both side portions of the loaded ball rolling groove **9** linearly along the groove **9**, and the guide portions **10**, **10** are formed of the same material as that of the movable block body through the same manufacturing process therefor at a same time of forming the movable block body. The guide portions **10**, **10** are formed with thin thickness, as shown in FIG. **3**, in spaces between the inside surfaces of the leg portions **6***a*, **6***a* and the side surfaces **4***a*, **4***a* of the guide rail **4**, respectively. According to the formation of these guide portions **10**, **10**, guide grooves for guiding the side edge portions of retainers **20**, formed as flexible belt members, for supporting the balls **3**, **3**, - - - , **3** in series to be rotatable, are formed to both the side portions of the loaded ball rolling grooves **9**, **9**, respectively. Such connected arrangement of the balls **3**, **3**, - - - , **3** and the retainer **20** will be called "rolling member connection belt assembly **26**" hereinlater.

Furthermore, each of the paired leg portions **6***b*, **6***b* is formed with a ball return passage **11** as a rolling member return passage to be substantially parallel to the loaded ball rolling groove **9** and adapted to return the balls from one end of the loaded ball rolling groove **9** to the other end thereof through the ball return passage **11**. The ball return passage **11** has an inner diameter slightly larger than a diameter of the ball **3**. The ball return passage **11** is also formed integrally with a guide groove **11***a* for guiding the side edge portion of the retainer **20** in the manner substantially the same as that mentioned with respect to the movable block body **6**.

With reference to FIG. **2**, each of the end plates **7** and **8** has a gate (⊐)-shaped cross section as like as the sectional shape of the movable block body **6**. The end plate **7** (**8**) is formed with an outer peripheral portion **12** of a ball rolling direction changing passage for scooping the balls **3** rolling in the loaded ball rolling groove **9** to guide the balls **3** to the ball return passage **11** and, reversely, for again guiding the balls **3** from the ball return passage **11** to the loaded ball rolling groove **9**. The movable block body **6** is formed, at both the longitudinal end portions, with rounded pieces (R-pieces) **13** formed as inner peripheral portions constituting the ball rolling direction changing passages. The end plate **7** (**8**) is formed with a body different from that of the movable block body **6**.

When the end plates **7** and **8** are mounted correctly in positions to the movable block body **6**, the rounded pieces **13** and the outer peripheral portions **12** constitute, in combination, the ball rolling direction changing passages at both the longitudinal end portions of the movable block **2** and guide grooves for guiding the side edge portions of the retainers **20** can be formed as like as the formation of the ball return passage **11**.

The ball rolling direction changing passages, the loaded ball rolling grooves **9** and the ball return passages **11** are called in combination "rolling member circulation passage".

The movable block body **6** and the end plates **7** and **8** are formed with single material or substance through a metal injection molding (MIM) process. This MIM process includes the steps of injection molding a mixture composed of metal powder and synthetic material (mainly in fine grain or particle form), removing the synthetic material component through a thermal treatment or chemical treatment and performing a sintering treatment.

That is, in the first step, a binder composed of fine synthetic material particles is added to the metal powder, kneading the mixture of the binder and the metal powder into pellet and then injection molding the pellet by using a known injection molding machine. In this step, there is utilized fine metal powder, as starting material, consisting of metal element of C, Si, Mn, Cr, Mo, W, V, Ti, Fe or the like having a powder (particle) diameter of about 10 μm. Further, the "single material" mentioned above means only one kind of these metal elements and also means an alloy of these metal elements, and a polyethylene or the like may be used as the binder.

In the next step, the injection molded product is heat treated in a furnace to vaporize the binder component and then remove the same through thermal treatment or chemical treatment. Thereafter, the metal body is preliminarily sintered thereby to obtain a molded part having a sufficient stability. In a subsequent sintering step, a molded product having a high relative density nearly of 100%.

According to the adoption of such metal injection molding (MIM) process, a product having fine and complicated composition or structure can be manufactured without performing any cutting working. Thus, according to such MIM process, the guide portions **10** having fine and complicated structure can be simultaneously formed integrally with the movable block body **6**. Therefore, it becomes not necessary to form the guide portions **10** separately from the movable block body **6**, and hence, the assembling working and the number of constituent components can be effectively reduced. Furthermore, an adequate mechanical strength of the product can be obtained by increasing the relative density of the metal injection mold product, so that the guide portion **10** can maintain adequate strength even if it be formed with thin thickness in a narrow space between the movable block body **6** and the guide rail **4**.

Furthermore, through the MIM process mentioned above, the fine guide grooves **11***a* can be formed to the ball return passages **11** of the movable block body **6**, and the end plates **7** and **8** having a complicated structure, with the outer peripheral portions **12** of the ball rolling direction changing passages being formed, can be also formed. Still furthermore, the guide grooves for guiding the side edge portions **20***a* of the retainer **20** can be also formed to the ball rolling direction changing passages constituted by the end plates **7** and **8** and the rounded pieces (R-pieces) **13**, **13**.

As can be seen from FIG. **2**, threaded portions for screw engagement are formed to the end surfaces of the movable block body **6** for fastening the end plates **7** and **8** to the movable block body **6**, and threaded portions for screw engagement are also formed to the upper surface of the movable block body **6** for securing a material mounted thereon. The end plates **7** and **8** are formed with holes into which fastening screws are engaged for securely mounting the end plates to the movable block body and holes into which fastening screws are engaged for fixing end face seals **14** (FIG. **1**) for preventing dust or dirt from entering into the end plates **7** and **8**. Furthermore, as shown in FIG. **1**, the end plate **7** is formed with a lubricant passage **15** extending towards the ball rolling direction changing passage, and a grease nipple **16** is fitted to the lubricant passage **15**.

A number of balls **3** are held continuously by a retainer **20** having a flexibility and formed in shape of belt as shown in FIG. **4**. The retainer **20** is formed with a number of ball holes **20***b* with equal interval from each other and the balls **3** are held in the ball holes **20***a*, respectively, to be rotatable. The retainer **20** is also formed with side edge portions **20***a* on both width sides thereof. Furthermore, the longitudinal ends of the retainer **20** is formed so as to provide round end portions so that the retainer **20** can be easily and smoothly inserted into the movable block **2**. The retainer **20** is preferably formed of a stainless steel plate in shape of belt having an elastic or flexible property.

FIG. **5** shows a state of the balls **3** rolling between the loaded ball rolling groove **5** and the ball rolling groove **5** as the loaded area and between the ball return passage **11** and the ball rolling direction changing passage as the non-loaded area. According to the arrangement in which a number of balls **3** are held continuously in series by the retainer **20**, noises and abrasion of the balls **3** caused by the mutual friction of the balls **3** can be prevented. Furthermore, in the absence of the retainer, resistance, which is applied to the balls **3** at the time when the balls **3** moves from the non-loaded area to the loaded area, is increased and, hence, the smooth ball rolling motion is obstructed by such resistance. However, according to the location of the retainer **20**, the balls **3** can be smoothly taken into the loaded area and, hence, smoothly moved from the non-loaded area to the loaded area. Still furthermore, the side edge portions **20***a* of the retainer **20** can be guided in the entire length thereof by the guide portion **10** formed along the loaded ball rolling groove of the movable block **6**, the guide groove formed to the ball rolling direction changing passage and the guide groove **11***a* formed to the ball return passage **11**, so that the vibration of the entire structure of the retainer **20** at the time of the ball circulation can be restricted. Therefore, the retainer **20** can be moved on a predetermined track throughout the entire periphery of the endless circulation passage, and hence, the balls **3** held by the retainer **20** can be also moved on the predetermined track.

As mentioned above, according to the present invention, parts or elements, including the retainer, constituting the linear rolling motion guide apparatus can be formed of metal materials, so that the linear rolling motion apparatus thus manufactured can be used in an environment of a temperature of more than 80° C. in which a conventional linear rolling motion guide apparatus formed of materials including resin can not be used. Furthermore, in a prior art, when the linear rolling motion guide apparatus is used in a vacuum environment, gas is generated from the resin material part and, hence, the vacuum condition cannot be kept. However, according to the metal structure of the present invention, the gas cannot be generated and, hence, it becomes possible to use the linear rolling motion guide apparatus in the vacuum condition. Further, it is preferred to use a solid lubricant in the use at a high temperature environment.

FIGS. **6** and **7** show schematic views of a mold for molding the movable block **6** according to the present invention.

With reference to FIG. **6**, the mold is composed of an upper mold half **21** and a lower mold half **22** between which cavities are defined for forming the movable block **6**. The cavities are formed on both the lateral sides of the lower mold half **22** and each of the cavities includes a cavity portion **23***a* for forming an outside portion of a leg portion **6***b* of the movable block **6**, a cavity portion **23***b* for forming an inside portion of the leg portion **6***b*, the loaded ball rolling groove **9** thereof and the guide portion **10**, and a cavity portion **23***c* for forming the round (R) piece portions **13** to the front end rear portions of the leg portion **6***b*. On the other hand, the upper mold half **21** is formed with a pin **24** for forming the ball return passage **11**. The lower mold half **22** is also formed with a gate **25** communicating with the cavity portion **23***a*. According to such structure, the pellet formed by kneading the metal powder and the synthetic materialrinjected into the cavities **23***a*, **23***b* and **23***c* through the gate **25**.

FIG. **8** shows a schematic view of a mold for molding the end plates **7** and **8**, and the mold is composed of an upper mold half **30** and a lower mold half **31** between which cavities **32***a* for molding leg portions of the end plates **7** and **8** are formed. The lower mold half **31** is formed with circular (arcuate) projections **31***a* for forming outer peripheral portions **12** of the ball rolling direction changing passages. The upper mold half **30** is formed with a gate **33** communicating with the cavity **32***a*, and the metal powder is injected into the cavity **32***a* through the gate **33**.

FIG. **9** is a view for showing a grinding operation for grinding the loaded ball rolling groove **9**, which is ground by an outer peripheral portion of a grinding wheel **41**, in shape of disc, fixed to the front end of a rotation shaft **40**. According to the present invention, the loaded ball rolling groove **9** can be ground through the guide portions **10** formed on both sides of the groove **9**.

In a circular arc structure in which the loaded ball rolling groove **9** is formed in a single arcuate shape, the grinding working is performed by making approximately coincide a cutting direction (direction A in FIG. **9**) of the grinding wheel **41** with the contact angle direction of the loaded ball rolling groove **9** (direction B in FIG. **9**), the contact angle direction being a direction of a line connecting the center point of the ball **3** and a contact point of the ball **3** to the circular arc groove. On the other hand, in a Gothic arc structure in which the loaded ball rolling groove **9** is formed by two arcuate portions, a grinding wheel having two arcuate portions having outer peripheries corresponding to the shape of the Gothic arc groove, i.e. so-called, formed grinding wheel, will be utilized.

Further, it is to be noted that the present invention is not limited to the described embodiments and many other changes and modifications may be made without departing from the scopes of the appended claims.

For example, in the above embodiment, although the single row of balls is arranged on each side surface of the guide rail **4**, the number of rows and arranging portions thereof can be optionally be changed in accordance with the magnitude or direction of load to be applied to the balls. Moreover, the guide rail **4** may have various shapes of cross section other than that mentioned hereinabove.

Furthermore, the track member **4** may be formed as a spline shaft and the movable member **2** may be formed as an outer cylinder which is movable with respect to the spline shaft through a number of rolling members such as balls or rollers.

What is claimed is:

1. A linear rolling motion guide apparatus comprising:

a track member formed with a track extending in a longitudinal direction thereof;

a movable member formed with a rolling member circulation passage including a loaded rolling member rolling track corresponding, in position, to said track;

a number of rolling members rolling in the rolling member circulation passage, said movable member being arranged to be movable relatively to said track member by a rolling motion of the rolling members; and

a rolling member connection assembly mounted to the movable member, said rolling member connection assembly having a flexible belt-shaped member supporting the rolling members in series to be rotatable, said movable member being integrally formed with guide portions, for guiding said flexible belt-shaped member, to both sides of the loaded rolling member rolling track with the same material as that of the movable member through the same manufacturing process therefor.

2. A linear rolling motion guide apparatus according to claim **1**, said movable member is formed with a single material.

3. A linear rolling motion guide apparatus according to claim **1**, wherein said movable member is formed by injection molding a mixture material of metal powder and synthetic material, removing the synthetic material thereafter through a heat treatment or chemical treatment and then sintering the material.

4. A linear rolling motion guide apparatus according to claim **1**, wherein said rolling member circulation passage includes a rolling member return passage arranged substantially in parallel to the loaded rolling member rolling passage, said rolling member return passage being formed with a guide groove, for guiding said flexible belt-shaped member, integrally to the movable member through the same manufacturing process therefor.

5. A linear rolling motion guide apparatus according to claim **1**, wherein said rolling member circulation passage includes a pair of rolling member rolling direction changing passages connecting said loaded rolling member rolling track and said rolling member return passage, each of said rolling member rolling direction changing passages includes an inner peripheral portion and an outer peripheral portion, said inner peripheral portion being formed of the same material as that of the movable member through the same manufacturing process therefor, said outer peripheral portion being formed with a body different from that of the movable member, and when the inner peripheral portions and the outer peripheral portions of a pair of rolling member rolling direction changing passage are mated with each other, a guide groove for guiding said belt-shaped member is formed to the rolling member return passage.

6. A linear rolling motion guide apparatus according to claim **5**, further comprising a pair of end plates disposed at both longitudinal end portions of the movable member and said end plates constitute said outer peripheral portions of the rolling member rolling direction changing passages.

7. A linear rolling motion guide apparatus according to claim **5**, wherein said outer peripheral portion is formed by injection molding a mixture material of metal powder and synthetic material, removing the synthetic material thereafter through a heat treatment or chemical treatment and then sintering the material.

8. A linear rolling motion guide apparatus according to claim **1**, wherein said flexible belt-shaped member is formed of a metal material.

9. A linear rolling motion guide apparatus according to claim **8**, wherein said flexible belt-shaped member is formed of a sheet of stainless steel plate.

10. A linear rolling motion guide apparatus according to claim **1**, wherein said loaded rolling member rolling track is ground by means of a grinder through a space between said guide portions formed to both the side portions of the loaded rolling member rolling track.

11. A linear rolling motion guide apparatus according to claim **1**, wherein said track member is a guide rail having substantially a rectangular cross section and said movable member is a movable block having two leg portions so as to provide substantially a gate (コ)-shaped cross section, said guide rail being arranged between said leg portions so that said track formed to the guide rail accords in position with said loaded rolling member rolling track formed to the movable block.

12. A linear rolling motion guide apparatus according to claim **1**, wherein said flexible belt-shaped member is a retainer composed of a belt-shaped plate and a number of holes which are arranged with equal interval with each other and in which the rolling member is held to be rotatable and side edge portions of said belt-shaped plate are guided by said guide portions when the retainer is assembled with the movable member.

13. A linear rolling motion guide apparatus according to claim **1**, wherein said rolling members are balls.

[57] **ABSTRACT**

A linear motion guiding apparatus comprises a guide rail provided with a ball running groove, and a movable block movably arranged along the guide rail through balls. The movable block is provided with a ball running counter-groove, a ball returning passage arranged away from the ball running counter-groove and direction changing passages for connecting these members. A resin-formed body for forming a ball circulation passage comprises a pair of ball passage forming portions, a returning passage forming portion and a pair of direction changing passage-inner guide forming portions. The resin-formed body is separately formed from a body of the movable block. At least two portions of (a) the ball passage forming portions, (b) the returning passage forming portion, (c) one of the direction changing passage-inner guide forming portions and (d) another of the of direction changing passage-inner guide forming portions are connected with each other through integral forming so that the resin-formed body can be built in the body of the movable block.

LINEAR MOTION GUIDING APPARATUS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a linear motion guiding apparatus in which a passage forming member formed of resin is built into a body of movable member.

2. Description of the Related Art

The applicant has already proposed a technical idea that, in a movable block of a linear motion guiding apparatus, a pair of ball passage forming portions extending along the opposite longitudinal sides of a loaded-ball running groove, a ball returning passage forming portion and a pair of direction changing passage-inner guide forming portions were integrally formed of resin with a body of the movable block (refer to Japanese Patent Provisional Publication No. H7-317,762).

More specifically, when a resin forming is carried out, the body of the movable block is inserted in a die, and the ball passage forming portions, the direction changing passage-inner guide forming portions or the ball returning passage forming portion is integrally formed with the block body.

In the conventional movable block obtained by the integral forming, the block body is inserted in the die, as mentioned above. When the block body has a large size, a large-scaled die is required to be used. It is not easy to prepare such a large-scaled die, and there is actual restriction in size. The ball passage forming portions located at the opposite longitudinal sides of the ball running groove extending along the longitudinal direction of the block body are thin and long, with the result that molten resin may not reach every part of the space for forming the ball passage forming portions during the resin forming treatment.

Increase in number of gates formed on the die may solve the above-mentioned problem of misrun of the molten resin. However, when the block body is inserted in the die, the block body may deteriorate the run of the molten resin.

When the movable block has a pair of wing portions, which face right and left-hand side portions of the guide rail so that the guide rail is held between the wing portions, and there are four trains of balls between the right and left-hand side portions of the guide rail and the right and left-hand wing portions of the moving block, and more specifically, the upper and lower trains of balls are arranged at each of a gap between the right-hand side portion of the guide rail and the corresponding right-hand wing portion of the moving block and another gap between the left-hand side portion of the guide rail and the corresponding left-hand wing portion of the moving block, the block body inserted in the die may deteriorate the run of the molten resin in the width direction of the moving block.

SUMMARY OF THE INVENTION

An object of the present invention is therefore to provide a linear motion guiding apparatus in which a resin-formed body for forming a rolling member circulation passage is formed separately from a body of a movable member so as to permit easy formation of the resin-formed body, and such a resin-formed body is able to be built in the body of the movable member, ensuring integral formability of the maximum number of unit parts for defining the rolling member circulation passage.

In order to attain the aforementioned object, a linear motion guiding apparatus comprises:

a guide member provided with a rolling member running track, and

a movable member arranged so as to be movable along the guide member through a large number of rolling members, said movable member being provided with (i) a rolling member running counter-track corresponding to the rolling member running track of said guide member, (ii) a rolling member returning passage arranged away from said rolling member running counter-track by a prescribed distance and in parallel therewith and (iii) a pair of direction changing passages for connecting the rolling member running counter-track and the rolling member returning passage to permit circulation of the rolling members,

characterized in that:

a resin-formed body for forming a rolling member circulation passage comprises a pair of rolling member passage forming portions extending along both longitudinal sides of said rolling member running counter-track, a returning passage forming portion for forming the rolling member returning passage and a pair of direction changing passage-inner guide forming portions for forming inner peripheral guide portions of said direction changing passages, said resin-formed body being separately formed from a body of said movable member; and

at least two portions of (a) said pair of rolling member passage forming portions, (b) said returning passage forming portion, (c) one of said pair of direction changing passage-inner guide forming portions and (d) another of said pair of direction changing passage-inner guide forming portions are connected with each other through integral forming so that said resin-formed body can be built in the body of said movable member.

Embodiments of the combination of these portions (a) to (d) for the resin-formed body for forming the rolling member circulation passage may include the following three examples:

the first example in which the resin-formed body comprises (i) an integral body of the pair of rolling member passage forming portions and the pair of direction changing passage-inner guide forming portions, and (ii) the returning passage forming portion separately formed from the integral body

the second example in which the resin-formed body comprises (i) an integral body of the pair of rolling member passage forming portions, the returning passage forming portion and one of the pair of direction changing passage-inner guide forming portions, and (ii) another of the pair of direction changing passage-inner guide forming portions separately formed from the integral body; and

the third example in which the resin-formed body is manufactured by preparing an integral body of the pair of rolling member passage forming portions, the returning passage forming portion and the pair of direction changing passage-inner guide forming portions, and then dividing the pair of rolling member passage forming portions and the returning passage forming portion in longitudinal intermediate portions thereof into respective two parts.

According to the present invention, the resin-formed body for forming the rolling member circulation passage is separately formed from the body of the movable member. Even if the movable member has a large size, the flow of molten resin is not therefore restricted by the body of the movable member unlike the conventional prior art in which the body of the movable member and the resin-formed body are integrally formed with each other, and it is possible to ensure proper run of molten resin through increase in a number of gates in the die, thus leading to an excellent formability. In general, it is hard to achieve proper run of molten resin especially at the rolling member passage forming portions extending along the longitudinal sides of the rolling member running counter-track, and it is therefore effective to separately form the resin-formed body from the body of the movable member in the same manner as the present invention.

The rolling member circulation passage is formed by the resin-formed body. Therefore, the direct positioning can be achieved in the relative positional relationship between the direction changing passage-inner guide forming portions and the rolling member passage forming portion, as well as the relative positional relationship between the direction changing passage-inner guide forming portions and the returning passage forming portion, and the continuity of the rolling member circulation passage is properly ensured, thus leading to smooth run of the rolling members.

Since the rolling member passage forming portions are located along the both longitudinal sides of the rolling member running counter-track, the direction changing passage-inner guide forming portions having a proper relative positional relationship with the rolling member passage forming portions are accurately set on the both ends of the rolling member running counter-track.

Maintenance of a proper relative positional relationship of the direction changing passage-inner guide forming portions with the rolling member returning passage causes the direction changing passage-inner guide forming portions to be accurately connected to the inner surface of the rolling member returning passage.

Especially, change in a running direction of the rolling members takes place in the connection area of the rolling member passage forming portions with the direction changing passage-inner guide forming portions as well as in the connection area of the direction changing passage-inner guide forming portions with returning passage forming portion. When two portions in such a connection area are connected with each other by integral forming, a step for assembling these two portions is not required, thus making it possible to ensure a smooth continuity of these two portions without being affected by accuracy of assembly.

The rolling member returning passage may be a through-hole formed in the body of the movable member, the resin formed-body may comprise the pair of direction changing passage-inner guide forming portions and the rolling member passage forming portions extending along the both longitudinal sides of the rolling member running counter-track, and the rolling member passage forming portions and at least one of the pair of direction changing passage-inner guide forming portions may be connected with each other through integral forming.

When the rolling member passage forming portions and the direction changing passage-inner guide forming portions are integrally formed with each other so as to provide the smooth connection area in this manner, it is possible to achieve the smooth run of the rolling members in the connection area of these portions, thus improving circulation property of the rolling member without providing any returning passage forming portion made of resin. Such a construction causes easy manufacture of the apparatus due to no existence of the returning passage forming portion.

The present invention may have additional features that a rolling member retainer is provided, the rolling member retainer being able to retain the rolling members in a train with a prescribed distance kept between adjacent two of the rolling members, and the rolling member retainer having side edge portions projecting from both sides of each of the rolling members; and guide grooves for guiding the side edge portions of the rolling member retainer are formed on an entire periphery of the rolling member circulation passage.

The present invention may have additional features that a retaining portion is provided on the rolling member passage forming portion, for preventing the rolling member retainer being out of place, when the movable member is removed from the guide member, and a guide portion is continuously formed on the entire periphery of the rolling member circulation passage, for guiding the side edge portions of the rolling member retainer.

Such provision of the rolling member retainer permits the smooth run of the rolling members by means of the rolling member retainer, due to proper maintenance of continuity of the guide portion for the rolling member retainer.

Since the guide portion for the rolling member retainer having a small thickness is not formed by inserting the body of the movable member in a die and then injecting molten resin into the die, but is separately formed from the body of the movable member, position of gates can freely be determined without being restricted by the body of the movable member, with the result that molten resin can reach, during formation of the guide portion, the entire space therefor, which is formed in the die.

The present invention may have additional features that each of the direction changing passage-inner guide forming portions has a thin sheet portion, which is to be brought into contact with the end face of the body of the movable member, and each of the direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions or the returning passage forming portion by means of the thin sheet portion.

When each of the direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions by means of the thin sheet portion, deformation of the thin sheet portion can absorb distortion, which occurs between the direction changing passage-inner guide forming portion and the rolling member passage forming portion, or between the direction changing passage-inner guide forming portion and the returning passage forming portion. Accordingly, it is possible to maintain an accurate positional relationship between the end of the direction changing passage-inner guide forming portion and the rolling member passage forming portion or between the direction changing passage-inner guide forming portion and the returning passage forming portion.

The thin sheet portion is urged against the flat end face of the body of the movable member by a clamping force, which is applied to the side cover plate. The position of the direction changing passage-inner guide forming portion can therefore be corrected through deformation of the thin sheet portion, even when the direction changing passage-inner guide forming portion is not correctly positioned relative to the end face of the body of the movable member. In addition, the thin sheet portion can firmly be secured between the side cover plate and the body of the movable member by the clamping force, which is applied to the side cover plate, thus preventing the direction changing passage-inner guide forming portion from being incorrectly placed.

The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member comprises a movable block, which is provided with a horizontal portion, which faces an upper surface of the guide rail and a pair of wing portions, between which the guide rail is held at right and left-hand side surfaces thereof; two trains of the rolling members are arranged in a gap between the upper surface of the guide rail and a lower surface of the movable block, and a single train of the rolling members is arranged in each of gaps between the right and left-hand side surfaces of the guide rail and both of the wing portions, so as to provide a total number of trains of four.

The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member comprises a movable block, which is provided with a pair of wing portions, between which the guide rail is held at right and left-hand side surfaces thereof; and two trains of the rolling members are arranged in each of gaps between the right and left-hand side surfaces of the guide rail and both of the wing portions, so as to provide a total number of trains of four.

In these cases, the respective four direction changing passage-inner guide forming portions may be formed into an integral body, or the respective two direction changing passage-inner guide forming portions at each of the right and left-hand sides of the movable block may be formed into an integral body.

The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member is provided with a horizontal portion, which faces an upper surface of the guide rail and a single wing portion, which faces one side surface of the guide rail; a single train of the rolling members is arranged in a gap between the one side surface of the guide rail and the single wing portion, and another single train of the rolling members is arranged in a gap between the upper surface of the guide rail and a lower surface of the horizontal portion in a vicinity of a corner of the guide rail.

The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member comprises a movable block, which is provided with a pair of wing portions, between which the guide rail is held at right and left-hand side surfaces thereof; and a single train of the rolling members is arranged in each of gaps between the right and left-hand side surfaces of the guide rail and both of the wing portions, so as to provide a total number of trains of two.

The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member comprises a movable block arranged along one side surface of the guide rail; and two trains of the rolling members are arranged in a gap between the one side surface of the guide rail and the movable block.

The apparatus of the present invention may have the construction that the guide member comprises a spline shaft; and the movable member comprises an outer tube, which is movably supported on the spline shaft through a plurality of trains of the rolling members.

In addition, according to the present invention, there is also provided a linear motion guiding apparatus comprising:

a guide rail provided with two rolling member running tracks on each of right and left-hand side surfaces of the guide rail, so as to provide a total number of the rolling member running tracks of four; and

a movable block provided with a pair of wing portions, between which the guide rail is held at the right and left-hand side surfaces thereof, each of said wing portions having on an inner surface thereof two rolling member running counter-tracks corresponding to said two rolling member running tracks of the guide rail, so as to provide a total number of the rolling member running counter-tracks of four, said movable block having four endless circulation passages, which are formed by four rolling member returning passages arranged in parallel with said four rolling member running counter-tracks, respectively, and rolling member returning passages for connecting both ends of each of said four rolling member running counter-tracks with both ends of each of said four rolling member returning passages, respectively

characterized in that:

a resin-formed body comprises, for each of said endless circulation passages, a pair of rolling member passage forming portions extending along both longitudinal sides of said rolling member running counter-track, a returning passage forming portion for forming the rolling member returning passage and a pair of direction changing passage-inner guide forming portions for forming inner peripheral guide portions of said direction changing passages, said resin-formed body being separately formed from a body of said movable block;

said resin-formed body is divided into two body-parts, which are arranged on the wing portions of the movable block, respectively, so as to form the two endless circulation passages at an inner side of each of the wing portions; and

in each of the two body-parts, the rolling member running counter-track and the pair of direction changing passage-inner guide forming portions are formed into an integral body, and the returning passage forming portion is separately formed from said integral body.

According to the present invention, the resin-formed body for forming the rolling member circulation passage is separately formed from the body of the movable block. Even if the movable block has a large size, the flow of molten resin is not therefore restricted by the body of the movable block unlike the conventional prior art in which the body of the movable block and the resin-formed body are integrally formed with each other, and it is possible to ensure proper run of molten resin through increase in a number of gates in the die, thus leading to an excellent formability. In general, it is hard to achieve proper run of molten resin especially at the rolling member passage forming portions extending along the longitudinal sides of the rolling member running counter-track, and it is therefore effective to separately form the resin-formed body from the body of the movable block in the same manner as the present invention.

Especially, since the resin-formed body is divided into the two body-parts, each of which forms two endless circulation passages, a proper run of molten resin can be ensured, even when the block of the movable block has a larger width.

The rolling member circulation passage is formed by the resin-formed body. Therefore, the direct positioning can be achieved in the relative positional relationship between the direction changing passage-inner guide forming portions and the rolling member passage forming portion, as well as the relative positional relationship between the direction changing passage-inner guide forming portions and the returning passage forming portion, and the continuity of the rolling member circulation passage is properly ensured, thus leading to smooth run of the rolling members.

Since the rolling member passage forming portions are located along the both longitudinal sides of the rolling member running counter-track, the direction changing passage-inner guide forming portions having a proper relative positional relationship with the rolling member passage forming portions are accurately set on the both ends of the rolling member running counter-track.

Maintenance of a proper relative positional relationship of the direction changing passage-inner guide forming portions with the rolling member returning passage causes the direction changing passage-inner guide forming portions to be accurately connected to the inner surface of the rolling member returning passage.

Especially, change in a running direction of the rolling members takes place in the connection area of the rolling member passage forming portions with the direction changing passage-inner guide forming portions. When these two portions in such a connection area are connected with each other by integral forming, a step for assembling these two portions is not required, thus making it possible to ensure a smooth continuity of these two portions without being affected by accuracy of assembly.

The present invention may have additional features that a rolling member retainer is provided, the rolling member retainer being able to retain the rolling members in a train with a prescribed distance kept between adjacent two of the rolling members, and the rolling member retainer having side edge portions projecting from both sides of each of the rolling members; and guide grooves for guiding the side edge portions of the rolling member retainer are formed on an entire periphery of the rolling member circulation passage.

Such provision of the rolling member retainer permits the smooth run of the rolling members by means of the rolling member retainer, due to proper maintenance of continuity of the guide portion for the rolling member retainer.

Since the guide portion for the rolling member retainer having a small thickness is not formed by inserting the body of the movable block in a die and then injecting molten resin into the die, but is separately formed from the body of the movable block, position of gates can freely be determined without being restricted by the body of the movable block, with the result that molten resin can reach, during formation of the guide portion, the entire space therefor, which is formed in the die.

The present invention may have additional features that each of the direction changing passage-inner guide forming portions has a thin sheet portion, which is to be brought into contact with the end face of the body of the movable block, and each of the direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions or the returning passage forming portion by means of the thin sheet portion.

When each of the direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions by means of the thin sheet portion, deformation of the thin sheet portion can absorb distortion, which occurs between the direction changing passage-inner guide forming portion and the rolling member passage forming portion, or between the direction changing passage-inner guide forming portion and the returning passage forming portion. Accordingly, it is possible to maintain an accurate positional relationship between the end of the direction changing passage-inner guide forming portion and the rolling member passage forming portion or between the direction changing passage-inner guide forming portion and the returning passage forming portion.

The thin sheet portion is urged against the flat end face of the body of the movable member by a clamping force, which is applied to the side cover plate. The position of the direction changing passage-inner guide forming portion can therefore be corrected through deformation of the thin sheet portion, even when the direction changing passage-inner guide forming portion is not correctly positioned relative to the end face of the body of the movable block. In addition, the thin sheet portion can firmly be secured between the side cover plate and the body of the movable block by the clamping force, which is applied to the side cover plate, thus preventing the direction changing passage-inner guide forming portion from being incorrectly placed.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic disassembling perspective view illustrating a movable block of a linear motion guiding apparatus of the first embodiment of the present invention;

FIG. **2** shows a resin frame member as shown in FIG. **1**, as one of resin-formed bodies for forming a ball circulation passage, and more specifically,

FIG. **2**(*a*) is a front view of the resin frame member,

FIG. **2**(*b*) is a side view thereof,

FIG. **2**(*c*) is a cross-sectional view cut along the line C—C as indicated in FIG. **2**(*a*),

FIG. **2**(*d*) is a cross-sectional view cut along the line D—D as indicated in FIG. **2**(*b*),

FIG. **2**(*e*) is an enlarged cross-sectional view cut along the line E—E as indicated in FIG. **2**(*a*) and

FIG. **2**(*f*) is an enlarged cross-sectional view cut along the line F—F as indicated in FIG. **2**(*a*);

FIG. **3**(*a*) is a front view having a cross-section, illustrating the linear motion guiding apparatus of the first embodiment of the present invention as shown in FIG. **1**,

FIG. **3**(*b*) is a front view of the apparatus as shown in FIG. **3**(*a*), in which a half portion of a side cover plate is omitted, and

FIGS. **3**(*c*) to (*f*) are partially cross-sectional views illustrating embodiments of the structure of a ball passage forming portion and the vicinity thereof, as shown in FIG. **3**(*a*);

FIG. **4**(*a*) is a side view having a partial cross section, of the linear motion guiding apparatus of the first embodiment of the present invention,

FIG. **4**(*b*) is a cross-sectional view of a ball circulation passage of the movable block as shown in FIG. **4**(A), from which a ball retainer is removed,

FIG. **4**(*c*) is a partial side view of the ball retainer,

FIG. **4**(*d*) is a plan view of the ball retainer as shown in FIG. **4**(*c*) and

FIG. **4**(*e*) is a view of the ball retainer, with sight being placed in a direction of an arrow of "a" as indicated in FIG. **4**(*d*);

FIG. **5** shows a side cover plate of the movable block, and more specifically,

FIG. **5**(*a*) is a front view of the side cover plate,

FIG. **5**(*b*) is a back view thereof and

FIG. **5**(*c*) is a transverse sectional view thereof at its central portion;

FIGS. **6**(*a*) to **6**(*i*) are descriptive views illustrating steps for assembling the movable block as shown in FIG. **1**;

FIG. **7**(*a*) is an enlarged partial view of the direction changing passage as shown in FIG. **4**(*b*),

FIG. **7**(*b*) is a partial side view of the direction changing passage as shown in FIG. **4**(*b*), in which the side cover plate is removed,

FIG. **7**(*c*) is a partial side view illustrating a recess portion, which forms the direction changing passage in the side cover plate as shown in FIG. **7**(*a*),

FIG. 7(*d*) is a partial cross-sectional view of an outer peripheral side-half pipe member for forming a part of a resin pipe as shown in FIG. **7**(*a*),

FIG. 7(*e*) is a side view of the outer peripheral side-half pipe member as shown in FIG. **7**(*d*),

FIG. 7(*f*) is a partial cross-sectional view of an inner peripheral side-half pipe member for forming another part of the resin pipe as shown in FIG. **7**(*a*),

FIG. 7(*g*) is a side view of the inner peripheral side-half pipe member as shown in FIG. **7**(*f*);

FIG. **8** is a schematic disassembling perspective view illustrating the first modification of the resin-formed body for forming the ball circulation passage in the first embodiment of the present invention;

FIG. **9**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in FIG. **8**,

FIG. **9**(*b*) is a view illustrating the first resin frame of the resin-formed body,

FIG. **9**(*c*) is a view illustrating the second resin frame thereof,

FIG. **9**(*d*) is a back view of the first resin frame and

FIG. **9**(*e*) is a back view of the second resin frame;

FIG. **10** is a schematic disassembling perspective view illustrating the second modification of the resin-formed body for forming the ball circulation passage in the first embodiment of the present invention;

FIG. **11**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in FIG. **10**,

FIG. **11**(*b*) is a side view illustrating the connecting end of one of divided resin frames, as shown in FIG. **11**(*a*) and

FIG. **11**(*c*) is an enlarged cross-sectional view illustrating the connecting portion of the resin frames;

FIG. **12** is a schematic disassembling perspective view illustrating the third modification of the resin-formed body for forming the ball circulation passage in the first embodiment of the present invention;

FIG. **13**(*a*) is a side view having a partial cross section, illustrating the linear motion guiding apparatus, in which the movable block as shown in FIG. **12** is used, and

FIG. **13**(*b*) is a cross-sectional view of the resin-formed body for forming the ball circulation passage as shown in FIG. **13**(*a*);

FIG. **14**(*a*) is an enlarged partial cross-sectional view of the direction changing passage as shown in FIG. **13**(*b*), which is formed in the side cover plate removed from the ball passage forming portion,

FIG. **14**(*b*) is a partial cross-sectional view illustrating the side cover as shown in FIG. **14**(*a*), which is secured to the ball passage forming portion,

FIG. **14**(*c*) is a partial side view illustrating the ball passage forming portion, in which the side cover plate as shown in FIG. **14**(*a*) is removed, and

FIG. **14**(*d*) is a partial side view illustrating a recess portion, which forms the direction changing passage in the side cover plate as shown in FIG. **14**(*a*);

FIG. **15** is a schematic disassembling perspective view illustrating the fourth modification of the resin-formed body for forming the ball circulation passage in the first embodiment of the present invention;

FIGS. **16**(*a*) to **16**(*h*) are descriptive views illustrating the other embodiments of arrangement of the trains of balls in the linear motion guiding apparatus of the first embodiment of the present invention;

FIG. **17** is a perspective view illustrating the constructional elements other than the resin-formed body for forming the ball circulation passage of the linear motion guiding apparatus as shown in FIG. **16**(*a*), which is provided with two trains of balls at each of the both sides;

FIG. **18** is a schematic disassembling perspective view illustrating a movable block of a linear motion guiding apparatus of the second embodiment of the present invention;

FIG. **19**(*a*) is a front view illustrating the linear motion guiding apparatus of the second embodiment of the present invention as shown in FIG. **18**,

FIG. **19**(*b*) is a partial cross-sectional view illustrating one ball circulation passage of the apparatus as shown in FIG. **19**(*a*),

FIG. **19**(*c*) is a partial plan view of a roller retainer as shown in FIG. **19**(*b*) and

FIG. **19**(*d*) is a view of the roller retainer, with sight being placed in a direction of an arrow of "d" as indicated in FIG. **19**(*c*);

FIG. **20** shows the resin-formed body for forming the ball circulation passage as shown in FIG. **18**, and more specifically,

FIG. **20**(*a*) is a cross-sectional view cut along the line a—a as indicated in FIG. **20**(*b*),

FIG. **20**(*b*) is a front view of the resin-formed body for forming the ball circulation passage as shown in FIG. **20**(*a*),

FIG. **20**(*c*) is a partial side view of the resin-formed body for forming the ball circulation passage, in which the resin pipe as shown in FIG. **20**(*a*) is removed,

FIG. **20**(*d*) is a cross-sectional view of an outer peripheral side-half pipe member for forming a part of a resin pipe as shown in FIG. **20**(*a*),

FIG. **20**(*e*) is a side view of the outer peripheral side-half pipe member as shown in FIG. **20**(*d*),

FIG. **20**(*f*) is a cross-sectional view of an inner peripheral side-half pipe member for forming another part of the resin pipe as shown in FIG. **20**(*a*),

FIG. **20**(*g*) is a side view of the inner peripheral side-half pipe member as shown in FIG. **20**(*f*) and

FIG. **20**(*h*) is a partial cross-sectional view illustrating the constructional example of the roller passage forming portion, in which the roller retainer is not used;

FIG. **21** is a schematic disassembling perspective view illustrating the first modification of the resin-formed body for forming the ball circulation passage in the second embodiment of the present invention;

FIG. **22**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in FIG. **21**,

FIG. **22**(*b*) is a view illustrating the first resin frame as shown in FIG. **22**(*a*), with sight being placed on the divided end side thereof and

FIG. **22**(*c*) is a view illustrating the second resin frame as shown in FIG. **22**(*a*), with sight being placed on the divided end side thereof;

FIG. **23** is a schematic disassembling perspective view illustrating the second modification of the resin-formed body for forming the ball circulation passage in the second embodiment of the present invention;

FIG. **24**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in FIG. **23**, FIG. **24**(*b*) is a view illustrating one resin frame as shown in FIG. **24**(*a*), with sight being placed on the divided end side thereof and

FIG. **24**(*c*) is a view illustrating the other resin frame as shown in FIG. **24**(*a*), with sight being placed on the divided end side thereof;

FIG. **25** is a schematic disassembling perspective view illustrating the third modification of the resin-formed body for forming the ball circulation passage in the second embodiment of the present invention;

FIG. **26** is a schematic disassembling perspective view illustrating the fourth modification of the resin-formed body for forming the ball circulation passage in the second embodiment of the present invention;

FIG. **27** is a front view having a cross-sectional half portion, illustrating the other embodiment of arrangement of the trains of balls in the linear motion guiding apparatus of the second embodiment of the present invention;

FIG. **28** is a schematic disassembling perspective view of an outer tube of a ball-spline as a linear motion guiding apparatus of the third embodiment of the present invention;

FIG. **29**(*a*) is a front view having a cross-section, illustrating the ball spline of the third embodiment of the present invention, in which the outer tube as shown in FIG. **28** is used,

FIG. **29**(*b*) is a partial cross-sectional view illustrating one ball circulation passage of the apparatus as shown in FIG. **29**(*a*) and

FIG. **29**(*c*) is a disassembling cross-sectional view illustrating the construction of the ball circulation passage, in which the roller retainer as shown in FIG. **29**(*b*) is removed;

FIG. **30** shows the resin-formed body for forming the ball circulation passage as shown in FIG. **29**, and more specifically,

FIG. **30**(*a*) is a cross-sectional view cut along the line a—a as indicated in FIG. **30**(*b*),

FIG. **30**(*b*) is a front view of the resin-formed body for forming the ball circulation passage as shown in FIG. **30**(*a*),

FIG. **30**(*c*) is a partial side view of the resin-formed body for forming the ball circulation passage, in which the resin pipe as shown in FIG. **30**(*a*) is removed,

FIG. **30**(*d*) is a cross-sectional view of an outer peripheral side-half pipe member for forming a part of a resin pipe as shown in FIG. **30**(*a*),

FIG. **30**(*e*) is a side view of the outer peripheral side-half pipe member as shown in FIG. **30**(*d*),

FIG. **30**(*f*) is a cross-sectional view of an inner peripheral side-half pipe member for forming another part of the resin pipe as shown in FIG. **30**(*a*) and

FIG. **30**(*g*) is a side view of the inner peripheral side-half pipe member as shown in FIG. **30**(*f*);

FIG. **31** is a schematic disassembling perspective view illustrating the first modification of the resin-formed body for forming the ball circulation passage in the third embodiment of the present invention;

FIG. **32**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in FIG. **31**,

FIG. **32**(*b*) is a view illustrating the first resin frame as shown in FIG. **32**(*a*), with sight being placed on the divided end side thereof and

FIG. **32**(*c*) is a view illustrating the second resin frame as shown in FIG. **32**(*a*), with sight being placed on the divided end side thereof;

FIG. **33** is a schematic disassembling perspective view illustrating the second modification of the resin-formed body for forming the ball circulation passage in the third embodiment of the present invention;

FIG. **34**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in FIG. **33**,

FIG. **34**(*b*) is a view illustrating one resin frame as shown in FIG. **34**(*a*), with sight being placed on the divided end side thereof and

FIG. **34**(*c*) is a view illustrating the other resin frame as shown in FIG. **34**(*a*), with sight being placed on the divided end side thereof;

FIG. **35** is a schematic disassembling perspective view illustrating the third modification of the resin-formed body for forming the ball circulation passage in the third embodiment of the present invention;

FIG. **36** is a schematic disassembling perspective view illustrating the fourth modification of the resin-formed body for forming the ball circulation passage in the third embodiment of the present invention;

FIG. **37** is a front view having a partial cross-section, illustrating the another embodiment of arrangement of the trains of balls in the ball spline as the linear motion guiding apparatus of the third embodiment of the present invention;

FIG. **38**(*a*) is a front view having a partial cross-section, illustrating a roller-spline as the linear motion guiding apparatus of the fourth embodiment of the present invention, in which a side cover plate is removed, and

FIG. **38**(*b*) is a longitudinal partial cross-sectional view of one roller circulation passage as shown in FIG. **38**(*b*);

FIG. **39**(*a*) is a partial cross-sectional view illustrating the constructional example of the resin-formed body for forming the roller circulation passage of the roller spline as shown in FIG. **38**, and

FIGS. **39**(*b*) to **39**(*e*) are views illustrating the first to fourth modifications of the resin-formed body for forming the roller circulation passage;

FIG. **40**(*a*) is a front view of the movable block of the linear motion guiding apparatus of the fourth embodiment of the present invention, in which the side cover plate is removed, and

FIG. **40**(*b*) is a perspective view of the movable block as shown in FIG. **40**(*a*);

FIG. **41** is a schematic disassembling perspective view of the resin-formed bodies for forming the ball circulation passage as shown in FIG. **40**;

FIG. **42**(*a*) is a front view of the resin frame composing the resin-formed body for forming the ball circulation passage, as shown in FIG. **41**,

FIG. **42**(*b*) is a left-hand side view of the resin-formed body as shown in FIG. **42**(*a*) and

FIG. **42**(*c*) is a right-hand side view of the resin-formed body as shown in FIG. **42**(*a*);

FIG. **43** shows a resin pipe for forming a part of the resin-formed body for forming the ball circulation passage, as shown in FIG. **41**, and more specifically,

FIG. **43**(*a*) is a front view of an outer peripheral side-half pipe member,

FIG. **43**(*b*) is a side view of the outer peripheral side-half pipe member as shown in FIG. **43**(*a*),

FIG. **43**(*c*) is a front view of an inner peripheral side-half pipe member,

FIG. 43(*d*) is a side view of the inner peripheral side-half pipe member as shown in FIG. **43**(*c*); and

FIG. **44**(*a*) is a cross-sectional view of one ball circulation passage, in which the ball retainer is removed from the movable block as shown in FIG. **40**(*a*),

FIG. **44**(*b*) is an enlarged partial view of the direction changing passage as shown in FIG. **44**(*a*),

FIG. **44**(*c*) is a partial side view of the ball retainer,

FIG. **44**(*d*) is a plan view of the ball retainer as shown in FIG. **44**(*c*),

FIG. **44**(*e*) is a view of the ball retainer, with sight being placed in a direction of an arrow of "a" as indicated in FIG. **44**(*d*),

FIG. **44**(*f*) is a partial side view of the direction changing passage as shown in FIG. **44**(*b*), in which the side cover plate is removed, and

FIG. **44**(*g*) is a partial side view illustrating a recess portion, which forms the direction changing passage in the side cover plate as shown in FIG. **44**(*b*).

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Now, embodiments of a linear motion guiding apparatus the present invention will be described in detail below with reference to the accompanying drawings.

First Embodiment

FIGS. **1** to **7** show a linear motion guiding apparatus of the first embodiment of the present invention.

The linear motion guiding apparatus **1** is provided with a guide rail **2** as a guide member, which extends linearly, and a movable block **4** as a movable member, which is arranged so as to be movable along the guide rail **2** through a large number of balls **3** as rolling members.

The guide rail **2** is formed into a long bar shape having a rectangular cross-section. Two ball running grooves **5, 5** as a rolling member running track are formed on the horizontal upper surface of the guide rail **2**, and a single ball running groove **5** as the rolling member running track is formed on each of the right and left-hand vertical surfaces of the guide rail **2**, so as to provide a total number of grooves **5** of four.

The movable block **4** is formed as a block body having an inverse U-shaped cross-section, with its opening end being directed downwardly. The block body is provided with a horizontal portion **6**, which faces the upper surface of the guide rail **2** and with a pair of wing portions **7, 7**, which extend downwardly from the right and left ends of the horizontal portion **6** and face the right and left-hand side surfaces of the guide rail **2**, respectively. The horizontal portion **6** has on its lower surface two ball running counter-grooves **8, 8** as a rolling member running counter-track, which correspond to the ball running grooves **5, 5** formed on the upper surface of the guide rail **2**. Each of the wing portions **7, 7** has on its inner surface a single ball running counter-groove **8** as the rolling member running counter-track, which corresponds to the respective ball running grooves **5, 5** formed on the right and left-hand side surfaces of the guide rail **2**.

In addition, in the movable block **4**, there are formed four ball returning passages **9, 9, 9, 9** as a rolling member returning passage, which are provided in parallel with the four ball running counter-grooves **8, 8, 8, 8**, respectively, as well as four pairs of direction changing passages **10, 10, 10, 10** each having a U-shape, for connecting the respective both ends of the ball running counter-grooves **8, 8, 8, 8** with the respective both ends of the ball returning passages **9, 9, 9, 9**, so as to form four endless circulation passages. The ball returning passages **9, 9** respectively corresponding to the ball running grooves **5, 5** formed on the upper side of the guide rail **2** are formed in the horizontal portion **6**. The other ball returning passages **9, 9** respectively corresponding to the ball running grooves **5, 5** formed on the right and left-hand vertical surfaces of the guide rail **2** are formed in the wing portions **7, 7** of the movable block **4**, respectively.

In each of the four endless circulation passages in this embodiment, the balls **3** are retained in the form of train by means a ball retainer **12** as a rolling member retainer, as shown in FIG. **4** so that the balls **3** can be circulated while being guided by the ball retainer **12**.

The ball retainer **12** comprises a flexible belt portion **12*b***, which is provided with ball holes **12*a*** for respectively receiving the balls **3**, and spacing portions **12*c*** provided between the adjacent two balls **3, 3**. The belt portion **12*b*** has a width longer than the diameter of the ball **3** so that the both side edges of the belt portion **12*b*** extend outwardly from the ball **3**.

The spacing portion **12*c*** is provided with a ball supporting spherical recess **12*d*** corresponding to the spherical surface of the ball **3**. The ball **3** is supported on its both sides by a pair of supporting spherical recesses **12*d*** so as to prevent the ball **3** from coming off the belt portion **12*b***. In this embodiment, the one end of the belt portion **12*b*** is not connected to the other end thereof, thus forming a strip-shaped belt having the both ends. The one end of the belt portion **12*b*** may be connected to the other end thereof so as to form an endless belt.

The movable block **4** is composed of a block body **13** having ball running counter-grooves **8, 8, 8, 8**, a resin-formed body **20** for forming ball circulation passages, which is inserted in the block body **13**, and a pair of side cover plates **40, 40** secured to the both end surfaces of the block body **13**, in which the resin-formed body **20** is inserted.

Each of the ball circulation passages of the resin-formed body **20** comprises a pair of ball passage forming portions **21, 21** extending along both longitudinal sides of the ball running counter-groove **8**, a pair of direction changing passage-inner guide forming portions **22, 22** provided on the both side surfaces of the block body **13**, and a resin pipe **23** as a returning passage forming portion, which is inserted into a through-hole formed in the block body **13**. In this embodiment, the ball passage forming portions **21, 21** and the pair of direction changing passage-inner guide forming portions **22, 22** are integrally formed with each other into an integral body, and the resin pipe **23** is separately formed from the above-mentioned integral body. More specifically, there is used a construction that the ball passage forming portions **21, 21** and the pair of direction changing passage-inner guide forming portions **22, 22** are integrally connected with each other through integral forming to form an integral resin frame **24**, and the four resin pipes **23** can respectively be inserted into the block body **13**.

The ball passage forming portions **21, 21** are provided with guide grooves for guiding the both side edges of the belt portion **12*b*** of the ball retainer **12** in a loaded area. The guide grooves can prevent the ball retainer **12** not only from being swung during run of the ball, but also from being sagged by engaging the side edges of the belt portion **12*b*** with the guide groove **21*a***, when the movable block **4** is removed from the guide rail **2**. The balls **3** are supported by the ball retainer **12**. More specifically, the ball retainer **12** is supported by a jaw portion of the guide groove **21*a***, with the result that the balls **3** are kept in its proper position so as not to come off the movable block **4**.

In this embodiment, a distance between the pair of ball passage forming portions **21, 21** arranged in parallel with each other on the both longitudinal sides of the ball running counter-groove **8** is slightly larger than the diameter of the ball **3**. The balls **3** come off the ball running counter-groove **8**, if the ball retainer **12** is not used. When an amount of projection of the jaw portion **21***b* is predetermined so that a distance between the pair of ball passage forming portions **21, 21** is slightly smaller than the diameter of the ball **3** as shown in FIG. **3**(*d*), it is however possible to prevent the balls **3** from coming off the ball running counter-groove **8** even without the ball retainer **12**. Such a construction can apply not only to the case where the balls **3** are inserted into the ball circulation passage with the use of the ball retainer **12**, but also to the case where the balls are inserted therein without the ball retainer **12**. The distance between the pair of ball passage forming portions **21, 21** may be slightly smaller than the diameter of the ball **3** so that the ball passage forming portions **21, 21** directly hold the ball **3** without the use of the ball retainer **12** as shown in FIG. **3**(*e*).

Guide grooves **9***c*, **10***c* are also formed in the ball returning passage **9** and the direction changing passage **10** as non-loaded areas, in order to guide the side edges of the belt portion **12***b*. The guide grooves **9***c*, **10***c* are connected to the above-mentioned guide groove **21***a* in the loaded area so as to form an endless groove on the entire periphery.

When the ball retainer **12** is not used as shown in FIG. **3**(*f*), the distance between the pair of ball passage forming portions **21, 21** arranged on the both longitudinal sides of the ball running counter-groove **8**, which portions do not have any jaw portions **21**, may be slightly smaller than the diameter of the ball **3**, thus preventing the balls **3** from coming off the ball running counter-groove **8**.

The four sets of ball passage forming portions **21, 21** are composed of the first thin connecting plate portion **25** extending longitudinally along the under surface of the horizontal portion **6** of the block body **13**, a pair of second connecting plate portions **26, 26**, which have an L-shaped cross section and extend in the longitudinal direction of the block body **13** along the corner portions between the horizontal portion **6** and the wing portions **7, 7** of the block body **13**, and a pair of third connecting plate portions **27, 27**, which extend in the longitudinal direction of the block body **13** along the lower surfaces of the wing portions **7, 7** of the block body **13**.

More specifically, the right and left-hand side edges of the first connecting plate portion **25** and the upper edges of the pair of right and left-hand second connecting plate portions **26, 26** are located at the both sides of the respective ball running counter-grooves **8, 8** provided on the under surface of the horizontal portion **6**, so as to form the ball passage forming portions **21, 21; 21, 21**. The lower edges of the second connecting plate portions **26, 26** and the inner edges of the third connecting plate portions **27, 27** are located at the both sides of the respective ball running counter-grooves **8, 8** provided on the respective inner surface of the wing portions **7, 7**, so as to form the other ball passage forming portions **21, 21; 21, 21**.

The direction changing passage-inner guide forming portion **22** has a thin sheet portion **29**, which is to be connected to the end surface of the block body **13**. The ball passage forming portions **21, 21** and the resin pipe **23** are connected through the above-mentioned thin sheet portion **29**. In this embodiment, the direction changing passage-inner guide forming portions **22, 22** and the ball passage forming portions **21, 21** are connected by means of the thin sheet portion **29** through integral forming. The resin pipe **23** is inserted in a hole **34** formed on the thin sheet portion **29** so as to make a faucet joint, and fixed to the thin sheet portion **29**.

The thin sheet portion **29** has the first end plate portion **30** corresponding to the end surface of the horizontal portion **6** of the block body **13**, a pair of third end plate portions **32, 32** corresponding to the end surfaces of the wing portions **7, 7** and the second end plate portions **31, 31** for connecting the first end plate portion **30** and the respective third end plate portions **32, 32**. The first end plate portion **30** has the direction changing passage-inner guide forming portions **22, 22**, which are formed so as to project corresponding to the two trains of balls **3, 3** on the upper surface side of the guide rail **2**. Each of the third end plate portions **32, 32** has the direction changing passage-inner guide forming portion **22**, which is formed so as to project corresponding to the single train of balls **3** on the side surface of the guide rail **2**.

The first end plate portions **30, 30**, which are to be placed respectively on the both ends of the block body **13** are connected at its lower portion with the both ends of the first connecting plate portion **25** extending longitudinally between the first end plate portions **30, 30**. The second end plate portions **31, 31**, which are to be placed respectively on the both ends of the block body **13** are connected at its inner edge portion with the both ends of the second connecting plate portion **26** extending longitudinally between the second end plate portions **31, 31**. The other second end plate portions **31, 31** have the same connecting structure. The third end plate portions **32, 32**, which are to be placed respectively on the both ends of the block body **13** are connected at its inner edge portion with the both ends of the third connecting plate portion **27** extending longitudinally between the third end plate portions **32, 32**. The other third end plate portions **32, 32** have the same connecting structure. A single resin frame **24** is formed in this way.

Each of the direction changing passage-inner guide forming portions **22** has a semi-cylindrical shape. On the outer periphery of the direction changing passage-inner guide forming portion **22**, there is formed an inner guide groove **10***a* having a semi-circular cross section so as to form the inner guide portion for the direction changing passage **10**. The one end of the inner guide groove **10***a* is connected to the end of the ball running counter-groove **8**. Accordingly, the one end of the inner guide groove **10***a* has the same cross-sectional shape as the ball running counter-groove **8** so as to make an alignment of the one end of the inner guide groove **10***a* with the end of the ball running counter-groove **8**. The other end of the inner guide groove **10***a* of the direction changing passage **10** is connected to the end of the ball returning passage **9**. Accordingly, the other end of the inner guide groove **10***a* has the same cross-sectional shape as the ball returning passage **9** so as to make an alignment of the other end of the inner guide groove **10***a* with the end of the ball returning passage **9**.

Cylindrical flange portions **33, 33** are formed on the both ends of the inner guide groove **10***a*. The distance between the respective outer surfaces of the cylindrical flange portions **33, 33** is larger than the width of the belt portion **12***b*. The cylindrical flange portions **33, 33** form a retainer-guide groove **10***c* for the ball retainer **12** in cooperation with a semi-circular recess portion having cutouts, which is formed on the inner periphery of the recess of the side cover plate **40** described later.

The both ends of the inner guide groove **10***a* for the direction changing passage **10** extend to the contacting surface of the first and third end plate portions **30, 32** with the end surface of the block body **13** so as to be connected to the respective ends of the ball running counter-groove **8** and the ball returning passage **9**. Pipe inserting holes **34, 34, 34, 34** having a semi-circular shape, in which the ends of the resin pipes **23** are to be inserted are formed on the first and third end plate portions **30, 32**.

As shown in FIG. **7**, the resin pipe **23** is composed of an inner peripheral side-half pipe member **23***a* located in the inner peripheral side of the ball circulation passage, which is continuously connected to the inner guide groove **10***a* for the direction changing passage, and an outer peripheral side-half pipe member **23***b* located in the outer peripheral side of the ball circulation passage, which is continuously connected to an outer guide groove **10***b* for the direction changing passage **10**, which is formed on the side cover plate **40**. The inner peripheral side-half pipe member **23***a* has a groove portion **9***a* having a semi-circular cross section, and side edge portions **23***c* extending longitudinally along the groove portion **9***a*.

The outer peripheral side-half pipe member **23***b* is formed into a linear member having the same circular cross section as the outer guide groove **10***b* for the direction changing passage, which is formed on the side cover plate **40**. The outer peripheral side-half pipe member **23***b* has a groove portion **9***b*, which is continuously connected to the outer guide groove **10***b*, and side edge portions **23***d* extending longitudinally along the groove portion **9***b*. The side edge portions **23***d* is provided on its outer edges with projections **23***e*, which are to be brought into contact with the outer edges of the side edge portions **23***c* of the inner peripheral side-half pipe member **23***a* to form the retainer-guide groove **9***c* for the ball retainer **12**.

The inner peripheral side-half pipe member **23***a* of the resin pipe **23** has the same length of the block body **13**. The inner peripheral side-half pipe member **23***a* is positioned so as to be brought into contact with the back surface of the direction changing passage-inner guide forming portion **22**.

The outer peripheral side-half pipe member **23***b* of the resin pipe **23** has on the other hand a longer length than the block body **13** by a length corresponding to the thickness of the thin sheet portion **29**. The outer peripheral side-half pipe members **23***b* are inserted in the inserting holes **34** of the first and third end plate portions **30, 32**. Longitudinal positional determination of the outer peripheral side-half pipe member **23***b* is made by bringing the both ends of the outer peripheral side-half pipe member **23***b* inserted in the inserting holes **34** into contact with the peripheral edge of the end portion of the outer guide grooves **10***b* for the direction changing passage, which are formed on the side cover plate **40**. The projections **23***e* formed on the both side edges of the outer peripheral side-half pipe member **23***b* come into contact with the outer edges of the cylindrical flange portions **33** formed on the direction changing passage-inner guide forming portion **22** to form a part of the guide groove **10***c*, and the outer peripheral side-half pipe member **23***b* and the inner peripheral side-half pipe member **23***a* are restricted to be turned in the inserting hole **14**.

The resin pipes **23** and the direction changing passage-inner guide forming portions **22** are accurately positioned through the inserting holes **34** formed on the first and third end plate portions **30, 32** of the thin sheet portion **29** and a proper assembling is carried out in this manner.

As shown in FIG. **5**, the side cover plate **40** is provided with an inserting recess portion **40**a, in which the thin sheet portion **29** is inserted, four recess portions **41** having the outer guide grooves **10***b* for the direction changing passage, into which portions the direction changing passage-inner guide forming portions **22** are fitted, and screw-fixing portions for securing the side cover plate **40** to the block body **13**. In the screw-fixing portions, the side cover plate **40** is fixed to the block body **13** by inserting bolts **44** into holes **43** formed on the side cover plate **40** and engaging the bolts with screwed holes **45** formed on the end surface of the block body **13**. The holes **43** are located between the first and third end plate portions **30, 32** of the thin sheet portion **29**.

As shown in FIG. **7**, the outer guide groove **10***b* for the direction changing passage in the recess portion **41** has on its side edges larger-diameter arcuate recesses **46**, which form the retainer-guide groove **10***c* in cooperation with the cylindrical flange portions **33** of the direction changing passage-inner guide forming portions **22**, and a smaller-diameter arcuate recesses **47**, in which the cylindrical flange portions **33** are inserted. The direction changing passage-inner guide forming portion **22** provided with the inner guide groove **10***a* for the direction changing passage is fitted into the recess portion **41** of the side cover plate **40**, and the thin sheet portion **29** is received in the inserting recess portion **40**a of the side cover plate **40**. The thin sheet portion **29** is held between the side cover plate **40** and the end surface of the block body **13** through a clamping force so as to be firmly fixed therebetween.

The direction changing passage-inner guide forming portions **22** and the ball passage forming portion **21** are connected through the thin sheet portion **29**, thus making it possible to maintain an accurate positional relationship of the end of the inner guide groove **10***a* for the direction changing passage formed in the direction changing passage-inner guide forming portion **22** relative to the ball passage forming portions **21, 21**, as well as an accurate positional relationship of the inner guide groove **10***a* for the direction changing passage relative to the ball returning passage **9**.

The thin sheet portion **29** located in the vicinity of the direction changing passage-inner guide forming portion **22** is uniformly urged against the flat end surface of the block body **13** through a clamping force applied to the side cover plate **40** (see FIG. **7**). Even when the direction changing passage-inner guide forming portion **22** is not located in a correct position, the thin sheet portion **29** changes its shape on the end surface of the block body **13**, thus permitting the correct positioning of the direction changing passage-inner guide forming portion **22**. The thin sheet portion **29** is firmly clamped and fixed through a clamping force, which is applied to the side cover plate **40**, and frictional force caused by such a clamping step may prevent an unfavorable movement of the inner guide groove **10***a* for the direction changing passage.

The side cover plate **40** is secured to the block body **13** so that the direction changing passage-inner guide forming portion **22** assembled to the block body **13** is fitted into the recess portion **41** of the side cover plate **40**. Such a fitting step permits to make an accurate positioning of the side cover plate **40** relative to the block body **13**.

FIG. **6** shows assembling steps for the above-described resin-formed body for forming the ball circulation passage.

First, the inner peripheral side-half pipe member **23***a* of the resin pipe **23** is inserted in the through-hole **14** of the block body **13** (see FIGS. **6**(*a*) and **6**(*b*)).

Then, the resin frame **24** obtained by integral forming is inserted in the recess of the block body **13**, while causing the thin sheet portions **29** at the both ends of the resin frame **24** to slide on the respective end surfaces of the block body **13** (see FIGS. **6**(*c*) and **6**(*d*)). The first connecting plate portion **25** of the resin frame **24** comes into contact with the under surface of the horizontal portion **6**, thus making positional determination in the vertical direction of the resin frame **24**. The second connecting plate portion **26** and the third connecting plate portion **27** of the resin frame **24** come into contact with the respective inner surfaces of the wing portions **7**, **7** of the block body **13**, thus making positional determination of the ball passage forming portions **21**, **21** and the direction changing passage-inner guide forming portion **22** (see FIGS. **6**(*e*) and **6**(*f*)). At this time, the inserting hole **34** of the thin sheet portion **29** is aligned with the through-hole **14** of the block body **13**.

Then, the outer peripheral side-half pipe member **23***b* is inserted in the through-hole **14** from the inserting hole **34**, thus completing the assembling step of the resin-formed body **20** for forming the ball circulation passage (see FIGS. **6**(*g*) and **6**(*h*)).

Then, the one side cover plate **40** is secured to the one end surface of the block body **13** by a clamping step, the ball retainer **12** holding the balls is inserted, and the other side cover plate **40** is secured to the other end surface of the block body **13** by the same clamping step, thus completing the assembling step of the movable block **4**.

According to the present invention, the resin-formed body **20** for forming the ball circulation passage is separately formed from the block body **13**. Even when the movable block **4** has a larger size, there is no restriction of flow of molten resin by the block body **13**, unlike the case where the block body **13** is integrally formed with the resin-formed body **20**. Increase in number of gates formed on a die may ensure proper run of the molten resin, thus improving the formability. Especially, the ball passage forming portions **21**, **21** located at the opposite longitudinal sides of the ball running groove **8** are thin, with the result that molten resin may not reach every part of the space for forming the ball passage forming portions **21**, **21**. It is therefore effective to form the resin-formed body **20** separately from the block body **13** in accordance with the embodiment of the present invention.

The continuous circulation passage is formed by the resin-formed body **20**, and it is therefore possible to make positional determination of the inner guide groove **10***a* for the direction changing passage relative to the ball passage forming portions **21**, **21**, as well as positional determination of the inner guide groove **10***a* for the direction changing passage relative to the ball returning passage **9**, thus ensuring continuity of the circulation passage so as to make smooth circulation of the balls **3**.

When the proper positional relationship of the inner guide groove **10***a* for the direction changing passage relative to the ball passage forming portions **21**, **21**, is maintained, the ball passage forming portions **21**, **21** are located at the longitudinal both sides of the ball running groove **8** so as to be aligned with the ends of the inner guide groove **10***a* for the direction changing passage.

When the proper positional relationship of the inner guide groove **10***a* for the direction changing passage relative to the ball returning passage **9** is maintained, the inner guide groove **10***a* for the direction changing passage can be aligned with the inner groove **23***a* of the ball returning passage **9**.

The connecting portion of the ball passage forming portions **21**, **21** and the direction changing passage-inner guide forming portion **22** is obtained by integral forming, thus permitting omission of an assembling step of the connecting portion. Although the running direction of the balls **3** is changed in such a connecting portion, the above-mentioned integral structure may ensure continuity of the circulation passage, without being affected by assembling accuracy. It is therefore possible to make smooth run of the balls **3** from the ball running passage between the ball running groove **5** and the ball running counter-groove **8** to the direction changing passage **10**, as well as from the direction changing passage **10** to the ball returning passage **9**.

Description will be given of modifications of the resin-formed body **20** for forming the ball circulation passage, which is divided into parts. In the description of the modifications, modified features will only be explained in comparison with the first embodiment of the present invention. The same reference numerals will be given to the same components as those in the first embodiment of the present invention, and description thereof will be omitted.

First Modification

FIGS. **8** and **9** show the first modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the first embodiment.

In the first modification, the resin-formed body **20** for forming the ball circulation passage is composed of the first resin-formed frame **20**A, which is obtained by integrally connecting both of the ball passage forming portions **21**, **21** and the resin pipes **23** at their ends with the direction changing passage-inner guide forming portions **22**A for one side, and the second resin-formed frame **20**B, which is provided with the direction changing passage-inner guide forming portions **22**B for the other side and separately formed from the first resin-formed frame **20**A.

In this case, the ball passage forming portions **21**, **21** are integrally connected with the direction changing passage-inner guide forming portions **22**A through the thin sheet portion **29**A as in the first embodiment.

The direction changing passage-inner guide forming portions **22**A are also integrally connected with the resin pipes **23** through the thin sheet portion **29**A. In this case, the resin pipe **23** is formed into a tubular integral body, although the half pipe members are used in the first embodiment. Accordingly, there exists no inserting hole **34** in the thin sheet portion **29**A, and the ball returning passage **9** is exposed on the thin sheet portion **29**A.

The first resin-formed frame **20**A and the second resin-formed frame **20**B are connected, as shown in FIG. **9**, by means of a joint method using the combination of a recess and a projection to be inserted therein, such as a faucet joint method. In the illustrated example, a recess portion **36** of a dove-tail groove is formed in the second resin-formed frame **20**B, and an engaging projection **35** to be engaged with the recess portion **36** is formed, on the other hand, in the ball passage forming portions **21**, **21**.

In this case, the resin pipe **23** of the first resin-formed frame **20**A is inserted in the through-hole **14** of the block body **13**, and the first, second and third connecting plate portions **25**, **26**, **27** are inserted along the under surface of the horizontal portion **6** of the block body **13** and the inner surfaces of the wing portions **7**,**7**.

Then, the engaging projections **35** formed at the respective free end portions of the first, second and third connecting plate portions **25**, **26**, **27** are engaged with the recess portions **36** formed on the thin sheet portion **29**B of the second resin-formed frame **24**B, which is arranged on the other end surface of the block body **13**.

The recess portions **36** may be formed on the first resin-formed frame **20**A and the engaging projections **35** may be formed on the second resin-formed frame **20**B. The connecting method is not limited to the method described above, and there may be used any conventional connecting method, in which the ends of the divided parts can be maintained in a proper connecting position and connected.

Second Modification

FIGS. **10** and **11** show the second modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the first embodiment.

In the second modification, the resin-formed body **20** for forming the ball circulation passage, which has been obtained by integrally forming both of the ball passage forming portions **21, 21** and the resin pipes **23** as a returning passage forming portion with a pair of direction changing passage-inner guide forming portions **22, 22**, is divided at the middle portion of each of the ball passage forming portions **21, 21** and the resin pipes **23** into two parts. More specifically, the ball passage forming portions **21, 21** and the resin pipes **23** are divided at their middle portion into the respective two half parts, and each of the thus divided two half parts is integrally formed with the direction changing passage-inner guide forming portions **22, 22**, thus forming two resin-formed frames **20**C, **20**D having substantially the same shape.

Four sets of the ball passage forming portions **21, 21** are formed on the first, second and third connecting plate portions **25, 26, 27**. Recess portions **38** and engaging projections **37** to be inserted therein are formed on the divided ends of the first, second and third connecting plate portions **25, 26, 27** and the divided ends of the resin pipes **23**.

Third Modification

FIGS. **12** to **14** show the third modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the first embodiment.

In the third modification, there is not used the resin pipe **23** as a returning passage forming portion described in the first embodiment, and a resin-formed frame **20**E is obtained by integrally forming the first, second and third connecting plate portions **25, 26, 27** having the ball passage forming portions **21, 21** with the thin sheet portions **29, 29** each having the pair of direction changing passage-inner guide forming portions **22, 22**. The ball returning passage **9** is composed as a through-hole formed in the block body **13**.

In this case, an engaging projection **39***a*, which is engageable with a tapered portion **15** formed in the opening end of the ball returning passage **9** may be formed in the opening end of the ball hole **39** of the thin sheet portion **29**. Such a construction permits to make a proper connection of the end of the ball returning passage **9** and the direction changing passage-inner guide forming portion **22**.

In the illustrated example, an arcuate engaging projection **48** is additionally formed on the connection portion of the outer guide groove **10***b* for the direction changing passage with the ball returning passage **9**. The engaging projection **48** can be fitted into the ball hole **39** of the thin sheet portion **29** and engaged with the tapered portion **15** of the opening end of the ball returning passage **9**.

Fourth Modification

FIG. **15** shows the fourth modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the first embodiment.

In the fourth modification, there is not used the resin pipe **23** described in the third modification, a resin-formed frame **24**B is obtained by integrally forming the ball passage forming portions **21** with the direction changing passage-inner guide forming portions **22** for the one side, the other resin-formed frame **24**C provided with the direction changing passage-inner guide forming portions **22** for the other side is separately formed from the above-mentioned resin-formed frame **24**B, and the resin-formed frames **24**B, **24**C are connected with each other by engagement of the engaging projection **35** with the recess **36**. The structure other than the above-mentioned construction is the same as that of the third modification.

Modifications of the Ball Train

In the first embodiment and the first to fourth modifications, there is described that two trains of the balls are provided on the upper surface of the guide rail **2** and the single train of the balls is provided on each of the side surfaces of the guide rail **2**, so as to provide the total number of trains of four. In the present invention, the other type of ball trains can however be applied as shown in FIG. **16**. With respect to the division of the resin-formed body **20** for forming the ball circulation passage, all the modifications as shown in FIG. **16** are based on the divisional pattern of the first embodiment. All the divisional patterns of the first to fourth modifications may however be applied to the modifications of the ball train as shown in FIG. **16**.

In the example as shown in FIGS. **16**(*a*) and **16**(*b*), two lower and upper trains of the balls as rolling members are provided on each of the gaps between the right and left-hand side surfaces of the guide rail **2** and the inner surfaces of the right and left-hand wing portions **7, 7** of the movable block **13**, so as to provide the total number of trains of four.

FIG. **16**(*b*) shows the resin-formed body **20** in which all the ball passage forming portions for the four trains of the balls are integrally formed with each other. The resin-formed body **20** may however be divided into two resin-formed bodies **20, 20**, which correspond to two trains of the balls for each of the right and left-hand sides of the guide rail **2**, as shown in FIG. **18**.

In the example as shown in FIGS. **16**(*c*) and **16**(*d*), the movable block **4** is provided with the horizontal portion **6** facing the upper surface of the guide rail **2** and a single wing portion **7** facing the one side surface of the guide rail **2**. The single train of the balls **3** as rolling members is provided between the one side surface of the guide rail **2** and the single wing portion **7** of the movable block **4**, and the other single train of the balls **3** is provided between the upper surface of the guide rail **2** and the lower surface of the horizontal portion in the vicinity of the corner of the guide rail **2**, so as to provide the total number of trains of two.

In the example as shown in FIGS. **16**(*e*) and **16**(*f*), the movable block **4** is provided with a pair of wing portions **7, 7** between which the guide rail **2** is held at its right and left-hand surfaces. The single train of the balls **3** is provided in each of the gaps between the right and left-hand surfaces of the guide rail **2** and the inner surfaces of the right and left-hand wing portions **7, 7** of the movable block **4**, so as to provide the total number of trains of two.

In the example as shown in FIGS. **16**(*g*) and **16**(*h*), the movable block **4** is arranged along the one side surface of the guide rail **2**. Two upper and lower trains of the balls **3** are provided between the one side surface of the guide rail **2** and the movable block **4**.

Second Embodiment

FIGS. **18** to **20** show a linear motion guiding apparatus of the second embodiment of the present invention.

In the second embodiment, rollers are used as rolling members. More specifically, the linear motion guiding apparatus comprises a guide rail **202** as a guide member, extending linearly, and a movable block **204** arranged so as to be movable along the guide rail **202** through a large number of rollers **203** as rolling members.

The guide rail **202** is formed into a long bar shape having a rectangular cross-section. Two roller running surfaces **205, 205** as a rolling member running track are formed on the horizontal upper surface of the guide rail **2**, and a single roller running surface **205** as the rolling member running track is formed on each of the right and left-hand vertical surfaces of the guide rail **2**, so as to provide a total number of surfaces **5** of four.

The movable block **204** is formed as a block body having an inverse U-shaped cross-section, with its opening end being directed downwardly. The block body is provided with a horizontal portion **206**, which faces the upper surface of the guide rail **202** and with a pair of wing portions **207, 207**, which extend downwardly from the right and left ends of the horizontal portion **206** and face the right and left-hand side surfaces of the guide rail **202**, respectively. The horizontal portion **206** has on its lower surface two roller running counter-surfaces **208, 208** as a rolling member running counter-track, which correspond to the roller running surfaces **205, 205** formed on the upper surface of the guide rail **202**. Each of the wing portions **207, 207** has on its inner surface a single roller running counter-surface **208** as the rolling member running counter-track, which corresponds to the respective roller running surfaces **205, 205** formed on the right and left-hand side surfaces of the guide rail **202**.

In addition, in the movable block **204**, there are formed four roller returning passages **209, 209, 209, 209** as a rolling member returning passage, which are provided in parallel with the four roller running counter-surfaces **208, 208, 208, 208**, respectively, as well as four pairs of direction changing passages **210, 210, 210, 210** each having a U-shape, for connecting the respective both ends of the roller running counter-surfaces **208, 208, 208, 208** with the respective both ends of the roller returning passages **209, 209, 209, 209**, so as to form four endless circulation passages.

The roller returning passages **209, 209** respectively corresponding to the roller running surfaces **205, 205** formed on the upper side of the guide rail **202** are formed in the horizontal portion **206**. The other roller returning passages **209, 209** respectively corresponding to the roller running surfaces **205, 205** formed on the right and left-hand vertical surfaces of the guide rail **202** are formed in the wing portions **207, 207** of the movable block **204**, respectively.

In each of the endless circulation passages in this embodiment, the rollers **3** are retained in the form of train by means a roller retainer **212** as a rolling member retainer so that the rollers **203** can be circulated while being guided by the roller retainer **212**.

As shown in FIGS. **19**(*b*) to **19**(*d*), the roller retainer **212** comprises a flexible belt portion **212***b*, which is provided with roller holes **212***a* for respectively receiving the rollers **203**, and spacing portions **212***c* provided between the adjacent two rollers **203, 203**. The belt portion **212***b* has a width longer than the diameter of the roller **203** so that the both side edges of the belt portion **212***b* extend outwardly from the roller **203**.

The spacing portion **212***c* is provided with a roller supporting recess **212***d* corresponding to the cylindrical surface of the roller **203**. The roller **203** is supported on its both sides by a pair of supporting recesses **212***d* so as to prevent the roller **203** from coming off the belt portion **212***b*. In this embodiment, the one end of the belt portion **212***b* is not connected to the other end thereof, thus forming a strip-shaped belt having the both ends. The one end of the belt portion **212***b* may be connected to the other end thereof so as to form an endless belt.

As shown in FIGS. **18** and **20**, the movable block **204** is composed of a metallic block body **213** having roller running counter-surfaces **208, 208, 208, 208**, a resin-formed body **220** for forming roller circulation passages, which is inserted in the block body **213**, and a pair of side cover plates **214, 214** secured to the both end surfaces of the block body **213**, in which the resin-formed body **220** is inserted.

In the second embodiment, four circulation passages are formed by two resin-formed bodies **220, 220** for forming the roller circulation passage, which are arranged at the right and left-hand sides.

Each of the roller circulation passages of the resin-formed bodies **220** comprises a pair of roller passage forming portions **221, 221** extending along both longitudinal sides of the roller running counter-surface **208**, a pair of direction changing passage-inner guide forming portions **222, 222** provided on the both side surfaces of the block body **213**, and a resin pipe **223** as a returning passage forming portion, which is inserted into a through-hole formed in the block body **213**.

The roller passage forming portions **221, 221** are provided with guide surfaces for guiding the both side edges of the belt portion **212***b* of the roller retainer **212** in a loaded area as illustrated in detain in FIG. **20**. The guide grooves can prevent the roller retainer **212** not only from being swung during run of the roller, but also from being sagged by engaging the side edges of the belt portion **212***b* with the guide groove **221***a*. The rollers **203** are supported by the roller retainer **212**. More specifically, the roller retainer **212** is supported by a jaw portion of the guide groove **221***a*, with the result that the rollers **203** are kept-in its proper position so as not to come off the movable block **204**.

In this embodiment, the one end of the belt portion **212***b* is not connected to the other end thereof, thus forming a strip-shaped belt having the both ends. The one end of the belt portion **212***b* may be connected to the other end thereof so as to form an endless belt.

Guide grooves **209***c*, **210***c* are also formed in the roller returning passage **209** and the direction changing passage **210** as non-loaded areas, in order to guide the side edges of the belt portion **212***b*. The guide grooves **209***c*, **210***c* are connected to the above-mentioned guide groove **221***a* in the loaded area so as to form an endless groove on the entire periphery.

In each of the resin-formed bodies **220, 220** for forming the roller circulation passage, the roller passage forming portions **221, 221** and the pair of the direction changing passage-inner guide forming portions **222, 222** are integrally formed with each other. The resin pipe **223** for forming the roller returning passage **209** is separately formed from the resin-formed bodies **220, 220**. More specifically, the one ends of the two pairs of the roller passage forming portions **221, 221** are integrally connected with the ends of the pair of direction changing passage-inner guide forming portions **222, 222** to form a single resin frame **220**A so that the thus formed resin frame **220**A can be inserted into the block body **213**. The other resin frame **220**A has the same construction.

The roller passage forming portions **221, 221** to be arranged on the upper surface of the guide rail **202** are integrally connected with the other roller passage forming portions **221, 221** to be arranged on the side surface of the guide rail **202** by means of a thin connecting plate portion **226**.

The direction changing passage-inner guide forming portion **222** is integrally formed with a thin sheet portion **229**, which is to be brought into contact with the end surface of the block body **213**.

The thin sheet portion **229** has the first end plate portion **230**, which is to be brought into contact with the end surface of the horizontal portion **206** of the block body **213**, the third end plate portion **232**, which is to be brought into contact with the end surface of the wing portion **207**, and the second end plate portion **231**, which is arranged at the corner between the horizontal portion **206** and the wing portion **207** on the end surface of the block body **213**, and connects the first end plate portion **230** with the third end plate portion **232**.

The pair of roller passage forming portions **221, 221**, which are arranged on the both longitudinal sides of the roller running surface **208** are integrally formed on the inside edge of the first end plate portion **230** and the inside edge of the third end plate portion **232**, respectively. The both ends of the connecting plate portion **226** are integrally connected with the inside edges of the second plate portions **231, 231**.

Each of the direction changing passage-inner guide forming portions **222** has a semi-cylindrical shape. On the outer periphery of the direction changing passage-inner guide forming portion **222**, there is formed an inner guide groove **210***a* having a rectangular cross section so as to form the inner guide portion for the direction changing passage **210**. The one end of the bottom of the inner guide groove **210***a* is connected to the end of the roller running counter-surface **208**. Accordingly, the one end of the inner guide groove **210***a* has the same cross-sectional shape as the roller running counter-surface **208** so as to make an alignment of the one end of the inner guide groove **210***a* with the end of the roller running counter-surface **208**. The other end of the inner guide groove **210***a* of the direction changing passage **210** is connected to the end of the roller returning passage **229**. Accordingly, the other end of the inner guide groove **210***a* has the same cross-sectional shape as the roller returning passage **209** so as to make an alignment of the other end of the inner guide groove **210***a* with the end of the roller returning passage **209**.

Cylindrical flange portions **233, 233** are formed on the both ends of the inner guide groove **210***a*. The distance between the respective outer surfaces of the cylindrical flange portions **233, 233** is larger than the width of the belt portion **212***b*. The cylindrical flange portions **233, 233** form a guide groove **210***c* for the roller retainer **212** in cooperation with the side cover plate **240** described later.

The one end of the inner guide groove **210***a* for the direction changing passage **210** extends to the contacting surface of the first and third end plate portions **230, 232** with the end surface of the block body **213** so as to be connected to the end of the roller running counter-surface **208**. The other end of the inner guide groove **210***a* for the direction changing passage **210** extends to the end surface of the thin sheet portion **229**, which is apart from the block body **213**. A step portion **222***a* having a depth identical to the thickness of the thin sheet portion **229** is formed at the other end of the inner guide groove **210***a*. The inner peripheral side-half pipe member for the resin pipe **223** projects from the end surface of the block body **13** by a length identical to the thickness of the thin sheet portion **229**. The projected end of the half pipe member **223***a* is fitted into the step portion **222***a* of the thin sheet portion **229**.

Pipe inserting holes **234, 234** having a semi-circular shape, in which the ends of for the outer peripheral side-half pipe member **223***a* for the resin pipes **223** for forming the roller returning passage **209** are to be inserted are formed on the first and third end plate portions **230, 232** of the thin sheet portion **229**. The resin pipe **223** is inserted into the circular through-hole **214** formed in the block body **213** so that the inner peripheral surface of the resin pipe **223** form the roller returning passage **209**.

As shown in FIG. **20**, the resin pipe **223** is composed of the inner peripheral side-half pipe member **223***a*, which is continuously connected to the inner guide groove **210***a* for the direction changing passage, and the outer peripheral side-half pipe member **223***b*, which is continuously connected to the outer guide groove **210***b* for the direction changing passage **210**, which is formed on the side cover plate **240**. The inner peripheral side-half pipe member **223***a* has an inner groove portion **209***a* having a rectangular cross section, and side edge portions **223***b* extending longitudinally along the inner groove portion **209***a*. The longitudinal edge portions **223***c* of the inner peripheral side-half pipe member **223***a* has the same width as the flange portion **233** of the portion **228**.

The outer peripheral side-half pipe member **223***b* is formed into a linear member having the same rectangular cross section as the outer guide groove **210***b* for the direction changing passage, which is formed on the side cover plate **240**. The outer peripheral side-half pipe member **223***b* has a outer groove portion **209***b*, which is continuously connected to the outer guide groove **210***b*, and side edge portions **223***d* extending longitudinally along the outer groove portion **209***b*. The side edge portions **223***d* is provided on its outer edges with projections **223***e*, which are to be brought into contact with the side edge portions **223***c* of the inner peripheral side-half pipe member **223***a* to form the guide groove for the belt portion **212** of the roller retainer **212**.

The inner peripheral side-half pipe member **223***a* of the resin pipe **223** has the same length of the block body **213**. The inner peripheral side-half pipe member **223***a* is positioned so as to be brought into contact with the end surface of the direction changing passage-inner guide forming portion **222**, which is arranged on the side of the block body **213**.

The outer peripheral side-half pipe member **223***b* of the resin pipe **223** has on the other hand a longer length than the block body **213** by a length corresponding to the thickness of the first and third end plate portions of the thin sheet portion **229**, which are arranged on the both ends of the block body **213**. The outer peripheral side-half pipe members **223***b* are inserted in the inserting holes **234** of the first and third end plate portions **230, 232**. Longitudinal positional determination of the outer peripheral side-half pipe member **223***b* is made by bringing the both ends of the outer peripheral side-half pipe member **223***b* inserted in the inserting holes **234** into contact with the peripheral edge of the end portion of the outer guide grooves **210***b* for the direction changing passage, which are formed on the side cover plate **240**. The projections **223***e* formed on the both longitudinal side edges **223** of the outer peripheral side-half pipe member **223***b* come into contact with the cylindrical flange portions **233** at the side edges of the inner guide groove **210***a* of the direction changing passage-inner guide forming portion **222**, and the outer peripheral side-half pipe member **223***b* and the inner peripheral side-half pipe member **223***a* are restricted to be turned in the inserting hole **214**.

The resin pipes **223** and the direction changing passage-inner guide forming portions **222** are accurately positioned through the inserting holes **234** formed on the first and third end plate portions **230, 232** of the thin sheet portion **229** and a proper assembling is carried out in this manner.

The side cover plate **240** is provided with four recess portions **241** having the outer guide grooves **210***b* for the direction changing passage, into which the portions **228** of the direction changing passage-inner guide forming portions **222** are fitted, and screw-fixing portions for securing the side cover plate **240** to the block body **213**. In the screw-fixing portions, the side cover plate **240** is fixed to the block body **213** by inserting bolts **244** into holes **243** formed on the side cover plate **240** and engaging the bolts **244** with screwed holes **245** formed on the end surface of the block body **213**. The holes **243** are located between the first and third end plate portions **230, 232** of the thin sheet portion **229**.

The direction changing passage-inner guide forming portion **222** provided with the inner guide groove **210***a* for the direction changing passage is fitted into the recess portion **241** of the side cover plate **240**. The thin sheet portion **229** is held between the side cover plate **240** and the end surface of the block body **213** through a clamping force so as to be firmly fixed therebetween.

The direction changing passage-inner guide forming portions **222** and the roller passage forming portion **221** are connected through the thin sheet portion **229**, thus making it possible to maintain an accurate positional relationship of the end of the inner guide groove **210***a* for the direction changing passage relative to the roller passage forming portions **221**, as well as an accurate positional relationship of the inner guide groove **210***a* for the direction changing passage relative to the roller returning passage **209**.

The thin sheet portion **229** is uniformly urged against the flat end surface of the block body **213** through a clamping force applied to the side cover plate **240**. Even when the direction changing passage-inner guide forming portion **222** is not located in a correct position, the thin sheet portion **229** changes its shape, thus permitting the correct positioning of the direction changing passage-inner guide forming portion **222**. The thin sheet portion **229** is firmly clamped and fixed through a clamping force, which is applied to the side cover plate **240**, and frictional force caused by such a clamping step may prevent an unfavorable movement of the inner guide groove **210***a* for the direction changing passage.

Description will be given of modifications of the resin-formed body **220** for forming the roller circulation passage, which is divided into parts. In the description of the modifications, modified features will only be explained in comparison with the second embodiment of the present invention. The same reference numerals will be given to the same components as those in the second embodiment of the present invention, and description thereof will be omitted.

First Modification

FIGS. **21** and **22** show the first modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the second embodiment.

In the first modification, the resin-formed body **220** for forming the ball circulation passage is composed of the first resin-formed frame **220**A, which is obtained by integrally connecting both of the roller passage forming portions **221**, **221** and the resin pipes **223** at their ends with the direction changing passage-inner guide forming portions **222**A for one side, and the second resin-formed frame **220**B, which is provided with the direction changing passage-inner guide forming portions **222**B for the other side and separately formed from the first resin-formed frame **220**A.

In this case, the roller passage forming portions **221**, **221** are integrally connected with the direction changing passage-inner guide forming portions **222**A through the thin sheet portion **229**A as in the second embodiment.

The direction changing passage-inner guide forming portions **222** are also integrally connected with the resin pipes **223** through the thin sheet portion **229**A. In this case, the resin pipe **223** is formed into a tubular integral body, although the half pipe members are used in the second embodiment. Accordingly, there exists no inserting hole **234** in the thin sheet portion **229**A, and the roller returning passage **209** is exposed on the thin sheet portion **229**A.

The first resin-formed frame **220**A and the second resin-formed frame **220**B are connected, as shown in FIG. **22**, by means of a joint method using the combination of a recess and a projection to be inserted therein, such as a faucet joint method. In the illustrated example, a recess portion **236** of a dove-tail groove is formed in the second resin-formed frame **220**B, and an engaging projection **235** to be engaged with the recess portion **236** is formed, on the other hand, in the roller passage forming portions **221**, **221**.

In this case, the resin pipe **223** of the first resin-formed frame **220**A is inserted in the through-hole **214** of the block body **213**, and the roller passage forming portions **221**, **221** and the connecting plate portion **226** are inserted along the under surface of the horizontal portion **206** of the block body **213** and the inner surfaces of the wing portions **207**,**207**.

Then, the engaging projections **235** formed at the roller passage forming portions **221**, **221** and the connecting plate portion **226** are engaged with the recess portions **236** formed on the thin sheet portion **229**B of the second resin-formed frame **224**B, which is arranged on the other end surface of the block body **213**.

The recess portions **236** may be formed on the first resin-formed frame **220**A and the engaging projections **235** may be formed on the second resin-formed frame **220**B. The connecting method is not limited to the method described above, and there may be used any conventional connecting method in which the ends of the divided parts can be maintained in a proper connecting position and connected.

Second Modification

FIGS. **23** and **24** show the second modification of the resin-formed body **220** for forming the ball circulation passage, which is described in the second embodiment.

In the second modification, the resin-formed body **220** for forming the roller circulation passage, which has been obtained by integrally forming both of the roller passage forming portions **221**, **221** and the resin pipes **223** as a returning passage forming portion with a pair of direction changing passage-inner guide forming portions **222**, **222**, is divided at the middle portion of each of the roller passage forming portions **221**, **221** and the resin pipes **223** into two parts. More specifically, the roller passage forming portions **221**, **221** and the resin pipes **223** are divided at their middle portion into the respective two half parts, and each of the thus divided two half parts is integrally formed with the direction changing passage-inner guide forming portions **222**, **222**, thus forming two resin-formed frames **220**C, **220**D having substantially the same shape.

Recess portions **238** and engaging projections **237** to be inserted therein are formed on the divided ends of the roller passage forming portions **221**, **221** and the divided ends of the connecting plate portion **226** and the divided ends of the resin pipes **223**.

Third Modification

FIGS. **25** to **26** show the third modification of the resin-formed body **220** for forming the roller circulation passage, which is described in the second embodiment.

In the third modification, there is not used the resin pipe **223** as a returning passage forming portion described in the second embodiment, and a resin-formed frame **220**E is obtained by integrally forming the both of the roller passage forming portions and the connecting plate portion **226** with the thin sheet portions **229**, **229** each having the pair of direction changing passage-inner guide forming portions **222**, **222**. The roller returning passage **209** is composed as a through-hole formed in the block body **213**.

In this case, an engaging projection **239***a*, which is engageable with a tapered portion **215** formed in the opening end of the roller returning passage **209** may be formed in the opening end of the roller hole **239** of the thin sheet portion **229**. Such a construction permits to make a proper connection of the end of the roller returning passage **209** and the direction changing passage-inner guide forming portion **222**.

In the illustrated example, an arcuate engaging projection **248** is additionally formed on the connection portion of the outer guide groove **210***b* for the direction changing passage with the roller returning passage **209**. The engaging projection **248** can be fitted into the roller hole **239** of the thin sheet portion **229** and engaged with the tapered portion **215** of the opening end of the roller returning passage **209**.

Fourth Modification

FIG. **26** shows the fourth modification of the resin-formed body **220** for forming the roller circulation passage, which is described in the second embodiment.

In the fourth modification, there is not used the resin pipe **223** described in the third modification, a resin-formed frame **220**F is obtained by integrally forming the roller passage forming portions **221** with the direction changing passage-inner guide forming portions **222** for the one side, the other resin-formed frame **220**F provided with the direction changing passage-inner guide forming portions **222** for the other side is separately formed from the above-mentioned resin-formed frame **220**F, and the resin-formed frames **220**F, **220**F are connected with each other by engagement of the engaging projection **235** with the recess **236**. The structure other than the above-mentioned construction is the same as that of the third modification.

Modifications of the Roller Train

In the second embodiment and the first to fourth modifications, there is described that two trains of the rollers are provided on the upper surface of the guide rail **2** and the single train of the rollers is provided on each of the side surfaces of the guide rail **2**, so as to provide the total number of trains of four. In the present invention, the other type of roller trains can however be applied as shown in the figures. With respect to the division of the resin-formed body **220** for forming the roller circulation passage, all the modifications are based on the divisional pattern of the first embodiment. All the divisional patterns of the first to fourth modifications may however be applied to the modifications of the roller train.

In the example as shown in FIG. **27**, two lower and upper trains of the rollers as rolling members are provided on each of the gaps between the right and left-hand side surfaces of the guide rail **202** and the inner surfaces of the right and left-hand wing portions **207**, **207** of the movable block **204**, so as to provide the total number of trains of four.

In this case, four inner guide portions **210***a* corresponding to the four trains of the rollers **203** are integrally formed with each other in the direction changing passage-inner guide forming portions **222**.

In the above description, the present invention is applied to the linear motion guiding apparatus, in which the movable block is arranged on the guide rail as a track shaft through the rolling members. The present invention may however be applied to a so-called ball-spline, in which an outer tube as a movable member is fitted on a spline shaft as a track shaft, as described below.

Third Embodiment

A ball spline **301** as shown in FIGS. **28** to **30** is of a so-called "angular contact" ball spline, and has a spline shaft **302** as a guide member extending linearly and an outer tube **304** arranged so as to be movable along the spline shaft **302** through balls **303** as a large number of rolling members.

The spline shaft **304** is formed into a long bar shape having a circular cross-section. The spline shaft **304** has on its outer periphery three projections **306**. Two ball running grooves **305**, **305** are formed on the both sides of each of the projections **306**, so as to provide the total number of groove of six.

The outer tube **304** has on its inner periphery three recesses **307** corresponding to the projections **306** of the spline shaft **302**, respectively. Ball running counter-grooves **308**, **308** are formed at the both corners of each of the recesses **307**, so as to correspond to the above-mentioned ball running grooves **305**, **305**.

In addition, the outer tube **304** has six ball returning passage **309**, **309**; **309**, **309**; **309**, **309**, which are in parallel with the six ball running counter-grooves **308**, **308**; **308**, **308**; **308**, **308**, and six direction changing passages **310**, **310**; **310**, **310**; **310**, **310** formed into a U-shaped tube, which connect the ends of the above-mentioned ball running counter-grooves **308**, **308**; **308**, **308**; **308**, **308** with the ends of the above-mentioned ball returning passage **309**, **309**; **309**, **309**; **309**, **309**. The outer tube **304** has six circulation passages in this manner.

The ball arranged at each of the both side surfaces of the projection **306** of the spline shaft **302** comes in contact, at its opposite points, with the ball running groove **305** and the ball running counter-groove **308**, respectively. A line connecting the above-mentioned contact points is referred to as the "contact angle line". A contact angle α, i.e., an angle between the contact angle line and the radius line, which connects the center of the spline shaft **302** and the central portion of the projection **306** is relatively large. The ball returning passage **309** is located on the contact angle line.

In this third embodiment, the balls **303** inserted in each of the circulation passages are connected with each other by means of a ball retainer **312** so as to form the train of the balls **303**. The balls **303** are guided by means of the ball retainer **312** and circulated in each of the circulation passages. The ball retainer **312** has the same structure as shown in FIG. **14** and the description thereof is therefore omitted.

The outer tube **304** is composed of a tubular main body **313** having the ball running counter-grooves **308**, **308**; **308**, **308**; **308**, **308**, three resin-formed bodies **320**, **320**, **320** for forming the ball circulation passage, which are to be inserted in the main body **313**, and a pair of side cover plates **314**, **314** secured on the both ends of the main body **313** after the insertion of the resin-formed bodies **320**, **320**, **320** in the main body **313**.

In the third embodiment, the six circulation passages are formed by the three resin-formed bodies **320**, **320**, **320**.

Each of the circulation passages **311** of the resin-formed bodies **320** for forming the ball circulation passage has a pair of the ball passage forming portions **321**, **321** extending along the longitudinal side edges of the ball running counter-groove **308**, a pair of direction changing passage-inner guide forming portions **322**, **322** provided on the both ends of the main body **313**, and resin pipes **323** as a returning passage forming portion, which are inserted in through-holes formed in the main body **313**.

The ball passage forming portions **321**, **321** are provided with guide grooves for guiding the both side edges of the belt portion **312***b* of the ball retainer **312** in a loaded area. The guide grooves can prevent the ball retainer **312** not only from being swung during run of the ball, but also from being sagged by engaging the side edges of the belt portion **312***b* with the guide groove **321***a*, when the outer tube **304** is removed from the spline shaft **302**. The balls **303** are supported by the ball retainer **312**. More specifically, the ball retainer **312** is supported by a jaw portion of the guide groove **321***a*, with the result that the balls **303** are kept in its proper position so as not to come off the outer tube **304**.

Guide grooves **309***c*, **310***c* are also formed in the ball returning passage **309** and the direction changing passage **310** as non-loaded areas, in order to guide the side edges of the belt portion **312***b*. The guide grooves **309***c*, **310***c* are connected to the above-mentioned guide groove **321***a* in the loaded area so as to form an endless groove on the entire periphery.

In each of the resin-formed bodies **320** for forming the ball circulation passage, the ball passage forming portions **321, 321** and the pair of the direction changing passage-inner guide forming portions **322, 322** are integrally connected with each other. The resin-formed body **320** is divided at the other portions into separate parts so as to be able to be inserted in the main body **313**. In the third embodiment, a single resin frame **324** is obtained by integrally connecting the ends of the four sets of ball passage forming portions **321, 321** with the end of the pair of direction changing passage-inner guide forming portions **322, 322**, and the thus obtained resin frame **324** is divided at the connecting portion of the returning passage forming portion **323** with the direction changing passage-inner guide forming portions **322, 322** into the separate parts so as to be able to be inserted in the main body **313**.

The adjacent two of the roller passage forming portions **321, 321, 321, 321** are integrally connected with each other by means of a thin connecting sheet portion **326**. The direction changing passage-inner guide forming portion **322** is integrally formed with the thin sheet portion **329**, which is to be brought into contact with the end surface of the main body **313**.

The thin sheet portion **329** is provided with the first end plate portions **330, 330** and the second end plate portion **231** for connecting the first end plate portions **330, 330** with each other. Each of the pair of ball passage forming portions **321, 321** is integrally connected with the inner edge of the first end plate portion **230**. The both ends of the connecting plate portion **326** are integrally connected with the inner edge of the second end plate portion **331**.

Each of the direction changing passage-inner guide forming portions **322** has a semi-cylindrical shape. On the outer periphery of the direction changing passage-inner guide forming portion **322**, there is formed an inner guide groove **310***a* having a semi-circular cross section so as to form the inner guide portion for the direction changing passage **310**. The one end of the inner guide groove **310***a* is connected to the end of the ball running counter-groove **308**. Accordingly, the one end of the inner guide groove **310***a* has the same cross-sectional shape as the ball running counter-groove **308** so as to make an alignment of the one end of the inner guide groove **310***a* with the end of the ball running counter-groove **308**. The other end of the inner guide groove **310***a* of the direction changing passage **310** is connected to the end of the ball returning passage **309**. Accordingly, the other end of the inner guide groove **310***a* has the same cross-sectional shape as the ball returning passage **309** so as to make an alignment of the other end of the inner guide groove **310***a* with the end of the ball returning passage **309**.

Cylindrical flange portions **333, 333** are formed on the both ends of the inner guide groove **310***a*. The distance between the respective outer surfaces of the cylindrical flange portions **333, 333** is larger than the width of the belt portion **312***b*. The cylindrical flange portions **333, 333** form a retainer-guide groove **310***c* for the ball retainer **312** in cooperation with the side cover plate **340** described later.

The both ends of the inner guide groove **310***a* for the direction changing passage **310** extend to the contacting surface of the first end plate portion **330** with the end surface of the main body **313** so as to be connected to the respective ends of the ball running counter-groove **308** and the ball returning passage **309**.

Pipe inserting holes **334, 334** having a semi-circular shape, in which the ends of for the outer peripheral side-half pipe member **323***a* for the resin pipes **323** for forming the roller returning passage **309** are to be inserted are formed on the first and third end plate portions **330, 332** of the thin sheet portion **329**. The resin pipe **323** is inserted into the circular through-hole **314** formed in the main body **313** so that the inner peripheral surface of the resin pipe **323** form the ball returning passage **309**.

The resin pipe **323** is composed of the inner peripheral side-half pipe member **323***a*, which is continuously connected to the inner guide groove **310***a* for the direction changing passage, and the outer peripheral side-half pipe member **323***b*, which is continuously connected to the outer guide groove **310***b* for the direction changing passage **310**, which is formed on the side cover plate **340**. The inner peripheral side-half pipe member **323***a* has an inner groove portion **309***a* having a rectangular cross section, and side edge portions **323***b* extending longitudinally along the inner groove portion **309***a*. The longitudinal edge portions **323***c* of the inner peripheral side-half pipe member **323***a* has the same width as the flange portion **333** of the direction changing passage-inner guide forming portion **322**.

The outer peripheral side-half pipe member **323***b* is formed into a linear member having the same rectangular cross section as the outer guide groove **310***b* for the direction changing passage, which is formed on the side cover plate **340**. The outer peripheral side-half pipe member **323***b* has a outer groove portion **309***b*, which is continuously connected to the outer guide groove **310***b*, and side edge portions **323***d* extending longitudinally along the outer groove portion **309***b*. The side edge portions **323***d* is provided on its outer edges with projections **323***e*, which are to be brought into contact with the side edge portions **323***c* of the inner peripheral side-half pipe member **323***a* to form the guide groove for the belt portion **312** of the ball retainer **312**.

The inner peripheral side-half pipe member **323***a* of the resin pipe **323** has the same length of the main body **313**. The inner peripheral side-half pipe member **323***a* is positioned so as to be brought into contact with the end surface of the direction changing passage-inner guide forming portion **322**, which is arranged on the side of the main body **313**.

The outer peripheral side-half pipe member **323***b* of the resin pipe **323** has on the other hand a longer length than the main body **313** by a length corresponding to the thickness of the first end plate portions **330, 330** of the thin sheet portion **329**, which are arranged on the both ends of the main body **313**. The outer peripheral side-half pipe members **323***b* are inserted in the inserting holes **334** of the first end plate portions **330, 332**. Longitudinal positional determination of the outer peripheral side-half pipe member **323***b* is made by bringing the both ends of the outer peripheral side-half pipe member **323***b* inserted in the inserting holes **334** into contact with the peripheral edge of the end portion of the outer guide grooves **310***b* for the direction changing passage, which are formed on the side cover plate **340**. The projections **323***e* formed on the both longitudinal side edges **323** of the outer peripheral side-half pipe member **323***b* come into contact with the outer edges of the cylindrical flange portions of the direction changing passage-inner guide forming portion **322** to form a guide groove, and the outer peripheral side-half pipe member **323***b* and the inner peripheral side-half pipe member **323***a* are restricted to be turned in the inserting hole **314**.

The resin pipes **323** and the direction changing passage-inner guide forming portions **322** as the ball returning passage forming portions are accurately positioned through the inserting holes **334** formed on the first end plate portion **330, 330** of the thin sheet portion **329** and a proper assembling is carried out in this manner.

The side cover plate **340** is provided with four recess portions **341** having the outer guide grooves **310***b* for the direction changing passage, into which the direction changing passage-inner guide forming portions **322** are fitted, and screw-fixing portions for securing the side cover plate **340** to the main body **313**. In the screw-fixing portions, the side cover plate **340** is fixed to the main body **313** by inserting bolts **344** into holes **343** formed on the side cover plate **340** and engaging the bolts **344** with screwed holes **345** formed on the end surface of the main body **313**. The holes **343** are located between the first end plate portions **330**, **330** of the thin sheet portion **329**.

The direction changing passage-inner guide forming portion **322** is fitted into the recess portion **341** of the side cover plate **340**. The thin sheet portion **329** is held between the side cover plate **340** and the end surface of the main body **313** through a clamping force so as to be firmly fixed therebetween.

The direction changing passage-inner guide forming portions **322** and the ball passage forming portion **321** are connected through the thin sheet portion **329**, thus making it possible to maintain an accurate positional relationship of the end of the inner guide groove **310***a* for the direction changing passage relative to the ball passage forming portions **321**, as well as an accurate positional relationship of the inner guide groove **310***a* for the direction changing passage relative to the ball returning passage **309**.

The thin sheet portion **329** is uniformly urged against the flat end surface of the main body **313** through a clamping force applied to the side cover plate **340**. Even when the direction changing passage-inner guide forming portion **322** is not located in a correct position, the thin sheet portion **329** changes its shape, thus permitting the correct positioning of the direction changing passage-inner guide forming portion **322**. The thin sheet portion **329** is firmly clamped and fixed through a clamping force, which is applied to the side cover plate **340**, and frictional force caused by such a clamping step may prevent an unfavorable movement of the inner guide groove **310***a* for the direction changing passage.

According to the present invention, only the ball running counter-groove **308** for the circulation passage **311** is formed of the main body **313** having high rigidity, and the other portions are formed of the resin-formed bodies **320** for forming the ball circulation passage. Precision working of the ball running counter-groove **308** of the main body **313** suffices, thus permitting reduction in steps for working and decrease in the production cost.

The resin-formed body **320** for forming the ball circulation passage is separately formed from the main body **313**. Even when the outer tube **304** has a larger size, there is no restriction of flow of molten resin by the main body **313**, unlike the case where the main body **313** is integrally formed with the resin-formed body **320**. Increase in number of gates formed on a die may ensure proper run of the molten resin, thus improving the formability. Especially, the ball passage forming portions **321**, **321** located at the opposite longitudinal sides of the ball running groove **308** are thin, with the result that molten resin may not reach every part of the space for forming the ball passage forming portions **321**, **321**. It is therefore effective to form the resin-formed body **320** separately from the main body **313** in accordance with the embodiment of the present invention.

The ball passage forming portions **321**, **321** are continuously and integrally connected with the direction changing passage-inner guide forming portions **322**, and the divided parts are jointed so as to make alignment of them to make a faucet joint. It is therefore possible to ensure a proper continuity of the connecting portion of the circulation passage and to make smooth run of the balls **303** from the ball running passage between the ball running groove **305** and the ball running counter-groove **308** to the direction changing passage **310**, as well as from the direction changing passage **310** to the ball returning passage **309**.

Description will be given of modifications of the resin-formed body **320** for forming the ball circulation passage, which is divided into parts. In the description of the modifications, modified features will only be explained in comparison with the third embodiment of the present invention. The same reference numerals will be given to the same components as those in the third embodiment of the present invention, and description thereof will be omitted.

First Modification

FIGS. **31** and **32** show the first modification of the resin-formed body **320** for forming the ball circulation passage, which is described in the third embodiment.

In the first modification, the resin-formed body **320** for forming the ball circulation passage is composed of the first resin-formed frame **320**A, which is obtained by integrally connecting both of the ball passage forming portions **321**, **321** and the resin pipes **323** at their ends with the direction changing passage-inner guide forming portions **322**A for one side, and the second resin-formed frame **320**B, which is provided with the direction changing passage-inner guide forming portions **322**B for the other side and separately formed from the first resin-formed frame **320**A.

In this case, the ball passage forming portion s **321**, **321** are integrally connected with the direction changing passage-inner guide forming portions **322**A through the thin sheet portion **329**A as in the first embodiment.

The direction changing passage-inner guide forming portions **322**A are also integrally connected with the resin pipes **323** through the thin sheet portion **329**A. In this case, the resin pipe **323** is formed into a tubular integral body, although the half pipe members are used in the third embodiment. Accordingly, there exists no inserting hole s**34** in the thin sheet portion **329**A, and the ball returning passage **309** is exposed on the thin sheet portion **329**A.

The first resin-formed frame **320**A and the second resin-formed frame **320**B are connected, as shown in FIG. **32**, by means of a joint method using the combination of a recess and a projection to be inserted therein, such as a faucet joint method. In the illustrated example, a recess portion **336** of a dove-tail groove is formed in the second resin-formed frame **320**B, and an engaging projection **335** to be engaged with the recess portion **336** is formed, on the other hand, in the ball passage forming portions **321**, **321**.

In this case, the resin pipe **323** of the first resin-formed frame **320**A is inserted in the through-hole **314** of the main body **313**, and the ball passage forming portions **321**, **321** and the connecting plate portion **236** are inserted along the inner surface of the recess **307** of the main body **313**.

Then, the engaging projections **335** formed at the respective free end portions of the ball passage forming portions **321**, **321** and the connecting plate portion **326** are engaged with the recess portions **336** formed on the thin sheet portion **329**B of the second resin-formed frame **324**B, which is arranged on the other end surface of the main body **313**.

The recess portions **336** may be formed on the first resin-formed frame **320**A and the engaging projections **335** may be formed on the second resin-formed frame **320**B. The connecting method is not limited to the method described above, and there may be used any conventional connecting method, in which the ends of the divided parts can be maintained in a proper connecting position and connected.

Second Modification

FIGS. **33** and **34** show the second modification of the resin-formed body **320** for forming the ball circulation passage, which is described in the third embodiment.

In the second modification, the resin-formed body **320** for forming the ball circulation passage, which has been obtained by integrally forming both of the ball passage forming portions **321, 321** and the resin pipes **323** as a returning passage forming portion with a pair of direction changing passage-inner guide forming portions **322, 322**, is divided at the middle portion of each of the ball passage forming portions **321, 321** and the ball returning passage forming portions **323** into two parts. More specifically, the ball passage forming portions **321, 321** and the ball returning passage forming portions **323** are divided at their middle portion into the respective two half parts, and each of the thus divided two half parts is integrally formed with the direction changing passage-inner guide forming portions **322, 322**, thus forming two resin-formed frames **320**C, **320**D having substantially the same shape.

Recess portions **338** and engaging projections **337** to be inserted therein are formed on the divided ends of the ball passage forming portions **321, 321**, the divided ends of the central connecting plate portion **326** and the divided ends of the resin pipes **323**.

Third Modification

FIG. **35** shows the third modification of the resin-formed body **320** for forming the ball circulation passage, which is described in the third embodiment.

In the third modification, there is not used the resin pipe **323** as a returning passage forming portion described in the first embodiment, and a resin-formed frame **320**E is obtained by integrally forming the ball passage forming portions, the connecting plate portions **326** with the thin sheet portions **329, 329** each having the pair of direction changing passage-inner guide forming portions **322, 322**. The ball returning passage **309** is composed as a through-hole formed in the main body **313**.

In this case, an engaging projection **339***a*, which is engageable with a tapered portion **315** formed in the opening end of the ball returning passage **309** may be formed in the opening end of the ball hole **339** of the thin sheet portion **329**. Such a construction permits to make a proper connection of the end of the ball returning passage **309** and the direction changing passage-inner guide forming portion **322**.

In the illustrated example, an arcuate engaging projection **348** is additionally formed on the connection portion of the outer guide groove **310***b* formed on the side cover plate **340** with the ball returning passage **309**. The engaging projection **48** can be engaged with the thin sheet portion **329**.

Fourth Modification

FIG. **36** shows the fourth modification of the resin-formed body **320** for forming the ball circulation passage, which is described in the third embodiment.

In the fourth modification, there is not used the resin pipe **323** described in the third modification, a resin-formed frame **320**F is obtained by integrally forming the ball passage forming portions **321** with the direction changing passage-inner guide forming portions **322** for the one side, the other resin-formed frame **320**G provided with the direction changing passage-inner guide forming portions **322** for the other side is separately formed from the above-mentioned resin-formed frame **320**F, and the resin-formed frames **320**F, **320**G are connected with each other by engagement of the engaging projection **335** with the recess **336**. The structure other than the above-mentioned construction is the same as that of the third modification.

In the third embodiment described above, there are used three sets of resin-formed bodies for forming the ball circulation passage, each of which is divided into two parts. Six sets of resin-formed bodies may however be used for the respective circulation passages. The single set of resin-formed body may also be used. In this case, the divisional method of the resin-formed body should be based on the first, second and fourth modifications described above, taking into consideration the difficulty of insertion of the resin-formed body into the main body of the outer tube.

Modifications of the Ball Train

In the third embodiment and the first to fourth modifications thereof, the ball spline has the angular contact type ball train. The present invention may also be applied to the ball spline having the radial contact type ball train as shown in FIG. **37**. In such a radial contact type ball train, the spline shaft has no projections on the outer periphery so as to reveal the circular cross-section, and the outer tube has no recesses on the inner periphery so as to reveal the hollow cylindrical shape. The radial contact type ball train has the smaller contact angle α than that of the angular contact type ball train. With respect to the divisional method of the resin-formed body **320** for forming the ball circulation passage, all the patterns described in the third embodiment and the first to fourth modifications thereof may be used.

In the example illustrated in FIG. **37**, six resin-formed bodies **320** for forming the ball circulation passage are separately provided from each other for the respective six ball trains. The two sets of resin-formed bodies **320** mentioned above may be integrally formed with each other so as to prepare three sets of resin-formed bodies **320** having the six ball circulation passages. The single resin-formed body having the six ball circulation passages may also be used.

Fourth Embodiment

FIGS. **38** and **39** illustrate the forth embodiment of the present invention. In the fourth embodiment, the present invention is applied to a roller spline, in which rollers are used as the rolling members.

The roller spline **401** as shown in FIG. **38** is composed of a spline shaft **402** as a guide member extending linearly, and an outer tube **404** arranged so as to be movable along the spline shaft **402** through the rollers **403** as the rolling members.

The spline shaft **402** is formed into a long bar shape having a modified cross-section. The spline shaft **402** has on its outer periphery three projections **406**. Two roller running surfaces **405, 405** are formed on the both sides of each of the projections **406**, so as to provide the total number of running surfaces of six.

The outer tube **404** has on its inner periphery three recesses **407** corresponding to the projections **406** of the spline shaft **402**, respectively. Roller running counter-surfaces **408, 408** are formed at the both corners of each of the recesses **407**, so as to correspond to the above-mentioned roller running surfaces **405, 405**.

In addition, the outer tube **404** has six roller returning passage **409, 409; 409, 409; 409, 409**, which are in parallel with the six roller running counter-surfaces **408, 408; 408, 408; 408, 408**, and six direction changing passages **410, 410; 410, 410; 410, 410** formed into a U-shaped tube, which connect the ends of the above-mentioned roller running counter-surfaces **408, 408; 408, 408; 408, 408** with the ends of the above-mentioned roller returning passage **409, 409; 409, 409; 409, 409**. The outer tube **404** has six circulation passages in this manner.

The rollers **403** inserted in each of the circulation passages are connected with each other by means of the same roller retainer **412** as the roller retainer **212** shown in FIG. **19**, so as to form the train of the rollers **403**. The rollers **403** are guided by means of the roller retainer **412** and circulated in each of the circulation passages.

The outer tube **404** is composed of a tubular main body **413** having the roller running counter-grooves **408, 408; 408, 408; 408, 408**, three resin-formed bodies **420, 420, 420** for forming the ball circulation passage, which are to be inserted in the main body **413**, and a pair of side cover plates **440, 440** secured on the both ends of the main body **413** after the insertion of the resin-formed bodies **420, 420, 420** in the main body **413**.

In the fourth embodiment, the six circulation passages are formed by the three resin-formed bodies **420, 420, 420** as in the third embodiment.

Each of the resin-formed bodies **420** for forming the ball circulation passage has a pair of the roller passage forming portions **421, 421** extending along the longitudinal side edges of the roller running counter-groove **408**, a pair of direction changing passage-inner guide forming portions **422, 422** provided on the both ends of the main body **413**, and resin pipes **423** as a returning passage forming portion, which are inserted in through-holes formed in the main body **413**.

The roller passage forming portions **421, 421** are provided with guide grooves for guiding the both side edges of the belt portion **412***b* of the roller retainer **412** in a loaded area. The guide grooves can prevent the roller retainer **412** not only from being swung during run of the roller, but also from being sagged by engaging the side edges of the belt portion **412***b* with the guide groove **421***a*, when the outer tube **404** is removed from the spline shaft **402**. The rollers **403** are supported by the roller retainer **412**. More specifically, the roller retainer **412** is supported by a jaw portion of the guide groove **421***a*, with the result that the rollers **403** are kept in its proper position so as not to come off the outer tube **404**.

Guide grooves **409***c*, **410***c* are also formed in the roller returning passage **409** and the direction changing passage **410** as non-loaded areas, in order to guide the side edges of the belt portion **412***b*. The guide grooves **409***c*, **410***c* are connected to the above-mentioned guide groove **421***a* in the loaded area so as to form an endless groove on the entire periphery.

When the roller retainer **412** is not used, the guide grooves **421***a*, **410***a*, **409***a* are not needed, and the jaw portions as shown in FIG. **20**(*h*) for supporting the ends of the roller are formed on the roller passage forming portions **421**.

In each of the resin-formed bodies **420** for forming the roller circulation passage, at least one of four connecting portions of the roller passage forming portions **421, 421** with the pair of the direction changing passage-inner guide forming portions **422, 422** are integrally connected with each other. The resin-formed body **420** is divided at the other portions into separate parts so as to be able to be inserted in the main body **413**.

The fundamental embodiment of the resin-formed body for forming the roller circulation passage, which is to be used for the spline unit is described in detail in the third embodiment. The structure of the resin-formed body for forming the roller circulation passage is described in detail in the second embodiment. Here, only the fundamental divisional pattern of the resin-formed body **420** for forming the roller circulation passage will be briefly described below with reference to FIG. **39**.

In FIG. **39**(*a*), the both ends of the four sets of roller passage forming portions **421, 421** are integrally connected with the respective one end of the pair of direction changing passage-inner guide forming portions **422, 422** to form a single resin frame **424**, and the both ends of each of the returning passage forming portions **423** are not connected with the other end of the direction changing passage-inner guide forming portion **422** so that these parts can be assembled into the main body **413**.

In FIG. **39**(*b*), the resin-formed body **420** for forming the roller circulation passage is composed of the first resin-formed frame **420**A, which is obtained by integrally connecting both of the roller passage forming portions **421, 421** and the resin pipes **423** as a returning passage forming portion at their ends with the direction changing passage-inner guide forming portions **422**A for one side, and the second resin-formed frame **420**B, which is provided with the direction changing passage-inner guide forming portions **422**B for the other side and separately formed from the first resin-formed frame **420**A.

In FIG. **39**(*c*), the resin-formed body **420** for forming the roller circulation passage, which has been obtained by integrally forming both of the roller passage forming portions **421, 421** and the resin pipes **423** as a returning passage forming portion with a pair of direction changing passage-inner guide forming portions **422, 422**, is divided at the middle portion of each of the roller passage forming portions **421, 421** and the returning passage forming portions **423** into two parts. More specifically, the roller passage forming portions **421, 421** and the resin pipes **423** are divided at their middle portion into the respective two half parts, and each of the thus divided two half parts is integrally formed with the direction changing passage-inner guide forming portions **422, 422**, thus forming two resin-formed frames **420**C, **420**D having substantially the same shape.

In FIG. **39**(*d*), there is not used the resin pipe **423** as shown in FIG. **39**(*a*), and a resin-formed frame **420**E is obtained by integrally forming both of the roller passage forming portions and the connecting plate portion **326** with the thin sheet portions **429, 429** each having the pair of direction changing passage-inner guide forming portions **422, 422**. The roller returning passage **409** is composed as a through-hole formed in the main body **413**.

In FIG. **39**(*e*), there is not used the resin pipe **423** as shown in FIG. **39**(*b*), and a resin-formed frame **420**F is obtained by integrally forming the roller passage forming portions **421** with the direction changing passage-inner guide forming portions **422** for the one side, the other resin-formed frame **420**G provided with the direction changing passage-inner guide forming portions **422** for the other side is separately formed from the above-mentioned resin-formed frame **420**F.

In FIGS. **39**(*a*) to **29**(*e*), the resin-formed frames are connected with each other by means of the conventional joint method such as a faucet joint, which uses engagement of the engaging projection with the recess.

Fifth Embodiment

FIGS. **40** to **44** show a linear motion guiding apparatus of the fifth embodiment of the present invention.

The linear motion guiding apparatus **501** is provided with a guide rail **502** as a guide member, which extends linearly, and a movable block **504** as a movable member, which is arranged so as to be movable along the guide rail **502** through a large number of balls **503** as rolling members.

The guide rail **502** is formed into a long bar shape having a rectangular cross-section. Two ball running grooves **505, 505** as a rolling member running track are formed on each of the right and left-hand side surfaces of the guide rail **502**, so as to provide a total number of grooves **505** of four. The guide rail **502** has on each of its side surfaces a projection **502***a*, on the upper and lower positions of which the ball running grooves **505, 505** are arranged.

The movable block **504** is formed as a block body having an inverse U-shaped cross-section, with its opening end being directed downwardly. The block body is provided with a horizontal portion **506**, which faces the upper surface of the guide rail **502** and with a pair of wing portions **507, 507**, which extend downwardly from the right and left ends of the horizontal portion **506** and face the right and left-hand side surfaces of the guide rail **502**, respectively. Each of the wing portions **507, 507** has on its inner surface two ball running counter-grooves **508, 508** as a rolling member running counter-track, which correspond to the ball running grooves **505, 505** formed on the right and left-hand side surfaces of the guide rail **502**.

Each of the right and left-hand wing portions **507, 507** of the movable block **504** has two ball returning passage forming portions **509, 509** formed therein, which extend in parallel with the ball running counter-grooves **508, 508**. At both the longitudinal ends of each of the wing portions **507, 507**, there are arranged direction changing passages **510, 510; 510, 510** for connecting the ends of the ball running counter-grooves **508, 508; 508, 508** with the ends of the ball returning passage **509, 509; 509, 509**. In summary, each of the wing portions **507, 507** of the movable block **504** has two endless circulation passages, in which the balls **503** are circulated, so as to provide the total number of passage of four.

In each of the four endless circulation passages in this embodiment, the balls **503** are retained in the form of train by means a ball retainer **512** as a rolling member retainer so that the balls **503** can be circulated while being guided by the ball retainer **512**.

As shown in FIGS. **44**(*c*) to **44**(*e*), the ball retainer **512** comprises a flexible belt portion **512***b*, which is provided with ball holes **512***a* for respectively receiving the balls **503**, and spacing portions **512***c* provided between the adjacent two balls **503, 503**. The belt portion **512***b* has a width longer than the diameter of the ball **503** so that the both side edges of the belt portion **512***b* extend outwardly from the ball **503**.

The spacing portion **512***c* is provided with a ball supporting spherical recess **512***d* corresponding to the spherical surface of the ball **503**. The ball **503** is supported on its both sides by a pair of supporting spherical recesses **512***d* so as to prevent the ball **503** from coming off the belt portion **512***b*. In this embodiment, the one end of the belt portion **512***b* is not connected to the other end thereof, thus forming a strip-shaped belt having the both ends. The one end of the belt portion **512***b* may be connected to the other end thereof so as to form an endless belt.

As shown in FIG. **41**, the movable block **504** is composed of a block body **513** having ball running counter-grooves **508, 508, 508, 508**, a pair of right and left-hand resin-formed bodies **520, 520** for forming ball circulation passages, which is inserted in the block body **513**, and a pair of side cover plates **540** (only one cover plate **540** is illustrated) secured to the both end surfaces of the block body **13**, in which the resin-formed bodied **520, 520** are inserted.

Each of the right and left-hand resin-formed bodies **520, 520** for forming the ball circulation passage forms two endless circulation passages. The right and left-hand resin-formed bodies **520, 520** have the symmetrical shape. One of them will be described below and the description of other thereof will be omitted.

More specifically, the resin-formed body **520** for forming the ball circulation passage is composed of a resin frame **524** obtained by integrally forming the ball passage forming portions **521, 521** extending along both longitudinal sides of the ball running counter-groove **508** with the pair of direction changing passage-inner guide forming portions **522, 522** (see FIG. **42**); and a pair of resin pipes **523, 523** as a returning passage forming portion, which are to be inserted in through-holes **514, 514** formed in the block body **513** (see FIG. **43**). The ball passage forming portions **521, 521** are integrally formed with the pair of direction changing passage-inner guide forming portions **522, 522** to form the resin frame **524** as an integral body, and the pair of resin pipes **523, 523** are separately formed from such an integral body, so that these parts can be assembled into the block body **513**.

As shown in FIG. **42**, the ball passage forming portions **521, 521** are provided with guide grooves for guiding the both side edges of the belt portion **512***b* of the ball retainer **512** in a loaded area. The guide grooves can prevent the ball retainer **512** not only from being swung during run of the ball, but also from being sagged by engaging the side edges of the belt portion **512***b* with the guide groove **521***a*, when the movable block **504** is removed from the guide rail **502**. The balls **503** are supported by the ball retainer **512**. More specifically, the ball retainer **512** is supported by a jaw portion of the guide groove **521***a*, with the result that the balls **503** are kept in its proper position so as not to come off the movable block **504**.

The distance between the pair of ball passage forming portions **521, 521** arranged in parallel with each other on the both longitudinal sides of the ball running counter-groove **508** is slightly smaller than the diameter of the ball **503**. In such a construction, it is possible to prevent the balls **503** from coming off the ball passage forming portions **521, 521** even when the ball retainer **512** is not used.

Guide grooves **509***c*, **510***c* are also formed, as shown in FIGS. **44**(*a*) and **44**(*b*), in the ball returning passage **509, 509** and the direction changing passage **510, 510** as non-loaded areas, in order to guide the side edges of the belt portion **512***b*. The guide grooves **509***c*, **510***c* are connected to the above-mentioned guide groove **521***a* in the loaded area so as to form an endless groove on the entire periphery.

The ball passage forming portions **521, 521; 521, 521** are composed, as shown in FIG. **42**(*a*), of the first connecting plate portion **525** extending longitudinally along the corner between the horizontal portion **506** and the wing portion **507** of the block body **513** in the longitudinal direction of the block body **513**; the second connecting plate portion **526** extending longitudinally between the ball running counter-grooves **508, 508** on the inner surface of each of the wing portions **507** of the block body **513**; and a pair of third connecting plate portions **527** extending along the under surface of the wing portion **507** of the block body **513** in the longitudinal direction thereof.

The upper edge of the first connecting plate portion **525** and the lower edge of the second connecting plate portion **526**, which face to each other, are placed on the opposite longitudinal sides of the upper ball running counter-groove **508** provided in the wing portion **507**, so as to form the ball passage forming portions **521, 521**. The lower edge of the second connecting plate portion **526** and the upper edge of the third connecting plate portion **527**, which face to each other, are placed on the opposite longitudinal sides of the lower ball running counter-groove **508** provided in the wing portion **507**, so as to form the ball passage forming portions **521, 521**.

As shown in FIGS. **44**(*a*), **44**(*b*) and **44**(*c*), the direction changing passage-inner guide forming portions **522** and the ball passage forming portions **521, 521** are connected by means of the thin sheet portion **529** through integral forming. The resin pipe **523** is inserted in a hole **534** formed on the thin sheet portion **529** so as to make a faucet joint, and fixed to the thin sheet portion **529**.

The thin sheet portion **529** has the direction changing passage-inner guide forming portions **522**, **522**, which are formed so as to project corresponding to the two trains of balls **503**, **503** on the side surface of the guide rail **502**. The both ends of the first, second and third connecting plate portions **525**–**527** are connected to the thin sheet portion **529** to be arranged on the end of the block body **513** so as to form the single resin frame **524**.

Each of the direction changing passage-inner guide forming portions **522** has a semi-cylindrical shape. On the outer periphery of the direction changing passage-inner guide forming portion **522**, there is formed an inner guide groove **510***a* having a semi-circular cross section so as to form the inner guide portion for the direction changing passage **510**. The one end of the inner guide groove **510***a* is connected to the end of the ball running counter-groove **508**. Accordingly, the one end of the inner guide groove **510***a* has the same cross-sectional shape as the ball running counter-groove **508** so as to make an alignment of the one end of the inner guide groove **510***a* with the end of the ball running counter-groove **508**. The other end of the inner guide groove **510***a* of the direction changing passage **510** is connected to the end of the ball returning passage **509**. Accordingly, the other end of the inner guide groove **510***a* has the same cross-sectional shape as the ball returning passage **509** so as to make an alignment of the other end of the inner guide groove **510***a* with the end of the ball returning passage **509**.

Cylindrical flange portions **533**, **533** are formed on the both ends of the inner guide groove **510***a*. The distance between the respective outer surfaces of the cylindrical flange portions **533**, **533** is larger than the width of the belt portion **512***b*. The cylindrical flange portions **533**, **533** form a retainer-guide groove **510***c* for the ball retainer **512** in cooperation with a semi-circular recess portion having cutouts, which is formed on the inner periphery of the recess of the side cover plate **5040** described later.

The both ends of the inner guide groove **510***a* for the direction changing passage **510** extend to the contacting surface of the thin sheet portion **529** with the end surface of the block body **513** so as to be connected to the respective ends of the ball running counter-groove **508** and the ball returning passage **509**. Pipe inserting holes **534**, **534** having a semi-circular shape, in which the ends of the resin pipes **523** are to be inserted are formed on the thin sheet portion **529**.

As shown in FIG. **43**, the resin pipe **523** is composed of an outer peripheral side-half pipe member **523***b* located in the outer peripheral side of the ball circulation passage, which is continuously connected to the outer guide groove **510***b* for the direction changing passage **510** of the side cover plate **540**, and an inner peripheral side-half pipe member **523***a* located in the inner peripheral side of the ball circulation passage, which is continuously connected to an inner guide groove **510***a* for the direction changing passage **510** of the side cover plate **540**.

The inner peripheral side-half pipe member **523***a* has a groove portion **509***a* having a semi-circular cross section, and side edge portions **523***c* extending longitudinally along the groove portion **509***a*, as shown in FIGS. **43**(*c*) and **43**(*d*). The outer peripheral side-half pipe member **523***b* is formed into a linear member having the same circular cross section as the outer guide groove **510***b* for the direction changing passage, which is formed on the side cover plate **540**. The outer peripheral side-half pipe member **523***b* has a groove portion **509***b*, which is continuously connected to the outer guide groove **510***b*, and side edge portions **523***d* extending longitudinally along the groove portion **509***b*. The side edge portions **523***d* is provided on its outer edges with projections **523***e*, which are to be brought into contact with the outer edges of the side edge portions **523***c* of the inner peripheral side-half pipe member **523***a* to form the retainer-guide groove **509***c* for the ball retainer **512**.

The inner peripheral side-half pipe member **523***a* of the resin pipe **523** has the same length of the block body **513**. The inner peripheral side-half pipe member **523***a* is positioned so as to be brought into contact with the back surface of the direction changing passage-inner guide forming portion **522**.

The outer peripheral side-half pipe member **523***b* of the resin pipe **523** has on the other hand a longer length than the block body **513** by a length corresponding to the thickness of the thin sheet portion **529**. The outer peripheral side-half pipe members **523***b* are inserted in the inserting holes **534**. Longitudinal positional determination of the outer peripheral side-half pipe member **523***b* is made by bringing the both ends of the outer peripheral side-half pipe member **523***b* inserted in the inserting holes **534** into contact with the peripheral edge of the end portion of the outer guide grooves **510***b* for the direction changing passage, which are formed on the side cover plate **540**. The projections **523***e* formed on the both side edges of the outer peripheral side-half pipe member **523***b* come into contact with the outer edges of the cylindrical flange portions **533** formed on the direction changing passage-inner guide forming portion **522** to form a part of the guide groove **510***c*, and the outer peripheral side-half pipe member **523***b* and the inner peripheral side-half pipe member **523***a* are restricted to be turned in the inserting hole **514**.

The resin pipes **523** and the direction changing passage-inner guide forming portions **522** are accurately positioned through the inserting holes **534** formed on the thin sheet portion **529** and a proper assembling is carried out in this manner.

As shown in FIGS. **44**(*f*) and **44**(*g*), the side cover plate **540** is provided with an inserting recess portion **540**a, in which the thin sheet portion **529** is inserted, recess portions **541** having the outer guide grooves **510***b* for the direction changing passage, into which portions the direction changing passage-inner guide forming portions **522** are fitted, and screw-fixing portions for securing the side cover plate **540** to the block body **513**. In the screw-fixing portions, the side cover plate **540** is fixed to the block body **513** by inserting bolts (not shown) into holes **543** formed on the side cover plate **540** and engaging the bolts with screwed holes **545** formed on the end surface of the block body **513**. The holes **543** are located at four positions, i.e., the position corresponding to the thin sheet portion **529** between the direction changing passage-inner guide forming portions **522**, **522** of each of the resin-formed bodies **520**, **520**, and the positions in the vicinity of the thin sheet portions **529**, **529** on the horizontal portion **506**.

As shown in FIG. **44**(*g*), the outer guide groove **510***b* for the direction changing passage in the recess portion **541** has on its side edges larger-diameter arcuate recesses **546**, which form the retainer-guide groove **510***c* in cooperation with the cylindrical flange portions **533** of the direction changing passage-inner guide forming portions **522** as shown in FIG. **44**(*f*), and a smaller-diameter arcuate recesses **547**, in which the cylindrical flange portions **533** are inserted. The direction changing passage-inner guide forming portion **522** provided with the inner guide groove **510***a* for the direction changing passage is fitted into the recess portion **541** of the side cover plate **540**, and the thin sheet portion **529** is received in the inserting recess portion **540***a* of the side cover plate **540**. The thin sheet portion **529** is held between the side cover plate **540** and the end surface of the block body **513** through a clamping force so as to be firmly fixed therebetween.

The direction changing passage-inner guide forming portions **522** and the ball passage forming portion **521** are connected through the thin sheet portion **529**, thus making it possible to maintain an accurate positional relationship of the end of the inner guide groove **510***a* for the direction changing passage formed in the direction changing passage-inner guide forming portion **522** relative to the ball passage forming portions **521**, **521**, as well as an accurate positional relationship of the inner guide groove **510***a* for the direction changing passage relative to the ball returning passage **509**.

The thin sheet portion **529** located in the vicinity of the direction changing passage-inner guide forming portion **522** is uniformly urged against the flat end surface of the block body **513** through a clamping force applied to the side cover plate **540** (see FIG. **44**). Even when the direction changing passage-inner guide forming portion **522** is not located in a correct position, the thin sheet portion **529** changes its shape on the end surface of the block body **513**, thus permitting the correct positioning of the direction changing passage-inner guide forming portion **522**. The thin sheet portion **529** is firmly clamped and fixed through a clamping force, which is applied to the side cover plate **540**, and frictional force caused by such a clamping step may prevent an unfavorable movement of the inner guide groove **510***a* for the direction changing passage.

The side cover plate **540** is secured to the block body **513** so that the direction changing passage-inner guide forming portion **522** assembled to the block body **513** is fitted into the recess portion **541** of the side cover plate **40**. Such a fitting step permits to make an accurate positioning of the side cover plate **540** relative to the block body **513**.

Now, description will be given of assembling steps for the above-mentioned resin-formed bodies **520** for forming the ball circulation passage.

First, the inner peripheral side-half pipe member **523***a* of the resin pipe **523** is inserted in the through-hole **514** of the wing portion **507** of the block body **513**.

Then, the resin frame **524** obtained by integral forming is inserted in the recess of the block body **513**, while causing the thin sheet portions **529** at the both ends of the resin frame **524** to slide on the respective end surfaces of the wing portion **507** of the block body **513**. The first connecting plate portion **525** of the resin frame **524** comes into contact with the corner portion between the horizontal portion **506** and the wing portion **507**, thus making positional determination in the vertical direction of the resin frame **524**. The second connecting plate portion **526** and the third connecting plate portion **527** of the resin frame **524** come into contact with the respective inner surfaces of the wing portions **507** of the block body **513**, thus making positional determination of the ball passage forming portions **521**, **521** and the direction changing passage-inner guide forming portions **522**, **522**. At this time, the inserting holes **534**, **534** of the thin sheet portion **529** are aligned with the through-holes **514**, **514** of the block body **513**.

Then, the outer peripheral side-half pipe members **523***b*, **523***b* are inserted in the through-holes **514**, **514** from the inserting holes **534**, **534**, thus completing the assembling step of one of the resin-formed bodies **520**, **520** for forming the ball circulation passage.

The assembling step of the other of the resin-formed bodies **520**, **520** is carried out in the same manner.

Then, the one side cover plate **540** is secured to the one end surface of the block body **513** by a clamping step, the ball retainer **512** holding the balls is inserted, and the other side cover plate **540** is secured to the other end surface of the block body **513** by the same clamping step, thus completing the assembling step of the movable block **504**.

According to the present invention, the resin-formed bodies **520**, **520** for forming the ball circulation passage are separately formed from the block body **513**. Even when the movable block **504** has a larger size, there is no restriction of flow of molten resin by the block body **513**, unlike the case where the block body **513** is integrally formed with the resin-formed bodies **520**, **520**. Increase in number of gates formed on a die may ensure proper run of the molten resin, thus improving the formability. Especially, the ball passage forming portions **521**, **521** located at the opposite longitudinal sides of the ball running groove **508** are thin, with the result that molten resin may not reach every part of the space for forming the ball passage forming portions **521**, **521**. It is therefore effective to form the resin-formed bodies **520**, **520** separately from the block body **513** in accordance with the embodiment of the present invention.

In addition, since there are formed the right and left-hand resin-formed bodies **520**, **520** for forming the ball circulation passage, each of which has two endless circulation passages, a proper run of molten resin is ensured even when the movable block **513** has a larger width.

The continuous circulation passage is formed by the resin-formed body **520**, and it is therefore possible to make positional determination of the inner guide groove **510***a* for the direction changing passage relative to the ball passage forming portions **521**, **521**, as well as positional determination of the inner guide groove **510***a* for the direction changing passage relative to the ball returning passage **509**, thus ensuring continuity of the circulation passage so as to make smooth circulation of the balls **503**.

When the proper positional relationship of the inner guide groove **510***a* for the direction changing passage relative to the ball passage forming portions **521**, **521**, is maintained, the ball passage forming portions **521**, **521** are located at the longitudinal both sides of the ball running groove **508** so as to be aligned with the ends of the inner guide groove **510***a* for the direction changing passage.

When the proper positional relationship of the inner guide groove **510***a* for the direction changing passage relative to the ball returning passage **509** is maintained, the inner guide groove **510***a* for the direction changing passage can be aligned with the inner groove **523***a* of the ball returning passage **509**.

The connecting portion of the ball passage forming portions **521**, **521** and the direction changing passage-inner guide forming portion **522** is obtained by integral forming, thus permitting omission of an assembling step of the connecting portion. Although the running direction of the balls **503** is changed in such a connecting portion, the above-mentioned integral structure may ensure continuity of the circulation passage, without being affected by assembling accuracy. It is therefore possible to make smooth run of the balls **503** from the ball running passage between the ball running groove **505** and the ball running counter-groove **508** to the direction changing passage **510**, as well as from the direction changing passage **510** to the ball returning passage **509**.

According to the present invention as described in detail, since the resin-formed body for forming the rolling member circulation passage is separately formed from the block body, even when the movable block has a larger size, increase in number of gates formed on a die may ensure proper run of the molten resin, thus improving the formability. It is therefore effective to form the resin-formed body separately from the block body in accordance with the present invention, taking into consideration the fact that the rolling member passage forming portions located at the opposite longitudinal sides of the rolling member running track are thin, with the result that molten resin may not reach every part of the space for forming the rolling member passage forming portions.

The continuous circulation passage is formed by the resin-formed body, and it is therefore possible to make positional determination of the inner guide groove for the direction changing passage relative to the rolling member passage forming portions, as well as positional determination of the inner guide groove for the direction changing passage relative to the rolling member returning passage, thus ensuring continuity of the circulation passage so as to make smooth circulation of the rolling members.

When the connecting portion of the rolling member passage forming portions and the direction changing passage-inner guide forming portion or the connecting portion of the direction changing passage-inner guide forming portion and the returning passage forming portion, in which portion the running direction of the rolling members is changed is obtained by integral forming, it is possible to omit an assembling step of the connecting portion and to ensure continuity of the circulation passage, without being affected by assembling accuracy.

The integral formation of the connecting portion of the rolling member passage forming portion with the direction changing passage-inner guide forming portion may cause the smooth running of the rolling members between the rolling member running track in the loaded area and the direction changing passage-inner guide forming portion, even when the returning passage forming portion formed of resin is not used.

When the rolling member retainer is used, it is possible to maintain a proper continuity on the entire periphery of the circulation passage in the retainer guide portion for guiding the rolling member retainer.

The thin retainer guide portion is formed without insertion of the body of the movable member in a die, and position of gates in the die can freely be determined without being restricted by the body of the movable member, with the result that molten resin can reach, during formation of the guide portion, the entire space therefor, which is formed in the die.

In addition, the formation of the right and left-hand resin-formed bodies for forming the rolling member circulation passage, each of which has two endless circulation passages may ensure a proper run of molten resin even when the body of the movable member has a larger width.

The connection of the direction changing passage-inner guide forming portion with the rolling member passage forming portion through the thin sheet portion makes it possible to maintain, through deformation of the thin sheet portion, a proper positional relationship between the direction changing passage-inner guide forming portion and the rolling member passage forming portion or a proper positional relationship between the direction changing passage-inner guide forming portion and the rolling member returning passage forming portion, thus making an accurate positional determination of the end of the direction changing passage-inner guide forming portion relative to the rolling member returning passage forming portion as well as an accurate positional determination of the direction changing passage-inner guide forming portion relative to the rolling member returning passage forming portion.

The thin sheet portion is urged against the flat end face of the body of the movable member by a clamping force, which is applied to the side cover plate. It is therefore possible to correct the position of the direction changing passage-inner guide forming portion through deformation of the thin sheet portion, even when the direction changing passage-inner guide forming portion is not correctly positioned relative to the end face of the body of the movable member.

In addition, the thin sheet portion can firmly be secured between the side cover plate and the body of the movable member by the clamping force, which is applied to the side cover plate, and it is therefore possible to prevent the direction changing passage-inner guide forming portion from being incorrectly placed.

What is claimed is:

1. A linear motion guiding apparatus comprising:

a guide member provided with at least one rolling member running track, and

a movable member arranged so as to be movable along the guide member, said movable member being provided with (i) a rolling member running counter-track corresponding to each of the at least one rolling member running track of said guide member, (ii) a rolling member returning passage arranged in parallel with each said rolling member running counter-track and (iii) a direction changing passage for connecting each said rolling member running counter-track and the corresponding rolling member returning passage to permit circulation of a plurality of rolling members,

wherein:

said movable member comprises a movable main body and a separate resin-formed body for providing a rolling member circulation passage;

said resin-formed body comprises a pair of rolling member passage forming portions extending along both longitudinal sides of said rolling member running counter-track and a pair of direction changing passage-inner guide forming portions for providing inner peripheral guide portions of said direction changing passage; and

said resin-formed body is divided into a plurality of parts so that at least two of said pair of rolling member passage forming portions and said pair of direction changing passage-inner guide forming portions are integrally formed, and a remainder of said pair of rolling member passage forming portions and said pair of direction changing passage-inner guide forming portions is separated independently from said at least two, whereby said resin-formed body can be built in said movable main body;

said guide member comprises a guide rail provided with two said rolling member running tracks on each of right and left-hand side surfaces of the guide rail, so as to provide a total of four said rolling member running tracks;

said movable member comprises a movable block, said movable block comprising:

a pair of wing portions, between which the guide rail is held at the right and left-hand side surfaces thereof, each of said wing portions having on an inner surface thereof two said rolling member running counter-tracks corresponding to said two rolling member running tracks on each said side of the guide rail, so as to provide a total of four said rolling member running counter-tracks in the movable block;

four rolling member returning passages arranged in parallel with said four rolling member running counter-tracks, respectively; and direction changing passages for connecting both ends of each of said four rolling member running counter-tracks with ends of a respective one of said four rolling member returning passages;

said four rolling member running counter-tracks, said four rolling member returning passages and said direction changing passages providing four endless circulation passages;

said resin-formed body comprising, for each of said four endless circulation passages, the pair of rolling member passage forming portions, a returning passage forming portion for providing the rolling member returning passage and the pair of direction changing passage-inner guide forming portions;

said resin-formed body being divided into two body-parts, which are arranged on the wing portions of the movable block, respectively, so as to form the two endless circulation passages at an inner side of each of the wing portions; and

in each of the two body-parts, the pair of rolling member passage forming portions and the pair of direction changing passage-inner guide forming portions are provided as an integral body, and the returning passage forming portion is provided separate from said integral body.

2. An apparatus as claimed in claim **1**, wherein:

a rolling member retainer is provided, said rolling member retainer being able to retain the rolling members in a train with a prescribed distance kept between adjacent two of the rolling members, and said rolling member retainer having side edge portions projecting from both sides of each of the rolling members; and

guide grooves for guiding the side edge portions of the rolling member retainer are formed on an entire periphery of the rolling member circulation passage.

3. An apparatus as claimed in claim **1**, wherein:

each of said direction changing passage-inner guide forming portions has a thin sheet portion, which is to be brought into contact with an end face of the body of said movable member, and said each of said direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions or the returning passage forming portion by means of said thin sheet portion.

[57] **ABSTRACT**

The present invention relates to a ball chain used by being integrated to, for example, a ball endless track of a linear guide device for endless sliding in which a number of balls are arranged in one row and rollably held, particularly to a ball chain which is most pertinent to a linear guide device having a ball rolling groove in a shape of a Gothic arch. According to the ball chain, the number of balls are arranged in one row and the balls are held rollably, each of the balls is pinched by a pair of spherical seats and the spherical seats are connected to each other by flange portions to thereby constitute a ball holding unit and a plurality of the ball holding units are connected in a shape of a rosary by a flexible connecting portion. Further, the spherical seats and the flange portions are molded by a resin material whereas the connecting portion is formed by a material having a tensile strength larger than that of the resin material.

BALL CHAIN

TECHNICAL FIELD

The present invention relates to a ball chain used by being integrated, for example, to a ball endless track of a linear guide device for endless sliding in which a number of balls are arranged in one row and are held rollably, particularly to a ball chain which is most pertinent in a linear guide device having a ball rolling groove in a shape of a Gothic arch.

BACKGROUND ART

There has conventionally been known a linear guide device for guiding a movable body of a table or the like along a fixed unit of a bed or the like, which is constituted by a track rail having a ball rolling groove, a slider having a load rolling groove opposed to the ball rolling groove, having a no load rolling path for circulating balls from one end to other end of the load rolling groove and moved along the track rail and a number of the balls rolling between the slider and the track rail while carrying a load and circulating an endless track constituted by the load rolling groove of the slider and the no load rolling path.

According to the conventional linear guide device constituted in this way, the endless track of the slider is filled with the balls and accordingly, when the slider is moved along the track rail, the balls contiguous to each other are circulated in the endless track while colliding or sliding with each other by which there poses a problem in which the balls are worn at an early stage and the life of the device is shortened.

Hence, in order to resolve such a problem, there has been proposed a linear guide device in which a ball chain aligning and holding a number of balls is integrated to the endless track (Japanese Unexamined Patent Publication No. JP-A-5-52217). As shown by FIG. **16** and FIG. **17**, according to such a ball chain **100**, spacers **102** are interposed among respective balls **101** contiguous to each other, the balls **101** are connected in a shape of a rosary (i.e., string of beads) by connecting the respective spacers **102** by connecting portions **103** in a strip-like shape and the balls **101** are fabricated by injection molding of flexible resin where balls **101** are arranged in a mold as cores.

The conventional ball chain **100** constituted in this way, is integrated in an endless track **105** of a slider **104** and circulated in the endless track as shown by FIG. **18**, in this case, the spacers **102** are interposed among the balls **101** contiguous to each other and therefore, mutual friction or collision among the balls is prevented and wear of the balls **101** can be minimized.

However, according to such a conventional ball chain **100**, one of the spacers **102** supports two of the balls **101** disposed on both sides thereof and therefore, when an angle of contact of the spacer **102** with respect to the ball **101** is changed by bending or twisting the ball chain **100**, there poses a problem in which the balls **101** drop off among the spacers **102**.

Accordingly, although the conventional ball chain sufficiently achieves a function as a ball retainer for preventing mutual contact of balls, a function thereof as a so-called ball case for preventing detachment of balls is not sufficient. Therefore, according to a conventional linear guide device integrated with such a ball chain, in order to completely prevent accident of detachment of balls when a slider is removed from a track rail, as shown by FIG. **19**, ball retainers **107** are installed on both sides of a load rolling groove **106** of a slider **104**.

However, when a ball rolling groove **109** of a track rail **108** and the load rolling groove **106** of the slider **104** are formed in the shape of a so-called circular arc comprising a single ball rolling face, the depths of the rolling grooves **106** and **109** are comparatively small relative to the radius of the ball **101** and therefore, although as shown by FIG. **19**, the ball retainers **107** can be formed on the both sides of the load rolling groove **106** of the slider **104**, when the ball rolling groove **109** and the load rolling groove **106** are formed in a shape of a Gothic arch, that is, in a shape where a pair of ball rolling faces are intersected with each other, as shown by FIG. **20**, the depths of the rolling grooves **106** and **109** are near to the radius of the ball **101** and accordingly, it is almost impossible to install the ball retainers **107** on the both sides of the load rolling groove **106**.

Therefore, in integrating a ball chain to a linear guide device having ball rolling grooves in the shape of a Gothic arch, it is necessary to ensure sufficiently the function of the ball chain for retaining the balls and it is problematic to integrate a conventional ball chain having such a weak function as it is.

Meanwhile, such a ball chain **100** is used by being circulated in an endless track and accordingly, it is preferable to make the connecting portion **103** for connecting the respective spacers **102** as thin as possible and make a sectional area thereof as small as possible to flexibly bend the ball chain **100** in the endless track.

Meanwhile, considering that the respective spacers **102** are brought into sliding contact with the balls **101**, the resin material used in molding the ball chain **100** needs to be provided with lubrication performance, wear resistance and the like with respect to rolling of the balls **101** and therefore, there is a constant restriction in selecting resin for molding the ball chain **100** and mechanical strength of the mold resin per se is difficult to provide.

Therefore, according to the conventional ball chain **100**, the tensile strength of the connecting portion **103** is lower and there results a problem in which the connecting portion **103** is broken between the respective spacers **102** when the ball chain is being used in an endless circulating path.

DISCLOSURE OF THE INVENTION

The present invention has been carried out in view of such a problem and it is a first object thereof to provide a ball chain capable of firmly holding balls even when the ball chain is bent or twisted or the like and which is most pertinent to a linear guide device having a ball rolling groove in a shape of a Gothic arch.

Further, it is a second object of the present invention to provide a ball chain in which lubrication performance and wear resistance with respect to rolling of balls are excellent, arranged balls are rolled excellently and which is provided with sufficient tensile strength and capable of preventing breaking of the ball chain while it is being used.

According to an aspect of the present invention achieving the first object, there is provided a ball chain arranged with a number of balls in one row and rollably holding the balls wherein each of the bails are pinched by a pair of spherical seats and the spherical seats are connected to each other by flange portions to thereby constitute a ball holding unit and a plurality of the ball holding units are connected in the shape of a string of beads by a flexible connecting portion.

According to such a technical means, each of the balls is pinched by the pair of spherical seats connected by the flange portions, the ball holding unit is constituted for each of the balls and the ball chain is constituted by connecting the ball holding units in a shape of a string of beads by the flexible connecting portion and accordingly, even when the ball chain is bent or twisted or the like, the angle of contact of the spherical seat with respect to the ball remains unchanged and the ball can be held at each of the ball holding unit with certainty.

In this case, the ball chain according to the present invention can be fabricated by injection molding of synthetic resin in which the balls are inserted into a mold as cores and in view of reducing the minimum radius in bending the ball chain in a shape of a circular arc, it is preferable that the connecting portion is softer and the sectional area is preferably small.

Further, according to another aspect of the present invention achieving the second object mentioned above, there is provided a ball chain comprising a number of balls arranged in one row, a plurality of ball holding members arranged among the balls contiguous to each other for rotatably holding the balls and a connecting portion for connecting the ball holding members wherein the tensile strength of the connecting portions is larger than a tensile strength of the ball holding members.

According to such a technical means, the ball holding members for rotatably holding the balls are interposed among the balls contiguous to each other, the ball holding members are connected to each other by the connecting portion having a tensile strength larger than a tensile strength of the ball holding member and accordingly, even when a material for molding the ball holding member which is provided with a low mechanical strength is used, a sufficient tensile strength can be ensured for the ball chain as a whole. Further, the mechanical strength of the material per se for molding the ball holding member does not pose any problem and the tensile strength of the ball chain as a whole can be ensured and accordingly, such a molding material can be selected only in view of lubrication performance, wear resistance or the like with respect to rolling of the balls and excellent rolling of the arranged balls can be expected.

In this case, although the ball chain according to the present invention can be integrated by penetrating the connecting portion such as wire or the like through the ball holding members molded by resin, the integrating operation is troublesome when the ball holding members are penetrated one by one by the connecting portion and in view of reducing time and labor of integration, it is preferable to pad the ball holding members to the connecting portion by injection molding of synthetic resin.

Further, in molding the ball holding members by such an injection molding, it is preferable to form recesses and protrusions at the connecting portion in correspondence with portions for molding the ball holding members such that the ball holding members do not drop off the connecting portion after molding.

BRIEF DESCRIPTION OF DRAWINGS

FIG. **1** is a perspective view showing a first embodiment of a linear guide device using a ball chain according to the present invention;

FIG. **2** illustrates a front view and a sectional view showing the first embodiment of the linear guide device according to the present invention;

FIG. **3** is a sectional view showing an endless track of balls provided to a slider according to the first embodiment;

FIG. **4** is a view disassembling a moving block and a lid constituting the endless track of balls;

FIG. **5** illustrates a plane view and a front view showing the first embodiment of the ball chain according to the present invention;

FIG. **6** is an enlarged view showing a section of the endless track of balls according to the first embodiment of a linear guide device;

FIG. **7** is a plane view showing a second embodiment of a ball chain according to the present invention;

FIG. **8** is a plane view showing a third embodiment of a ball chain according to the present invention;

FIG. **9** is a plane view showing a fourth embodiment of a ball chain according to the present invention;

FIG. **10** illustrates a front view and a sectional view showing a fifth embodiment of a ball chain according to the present invention;

FIGS. **11***a* and *b* are front views showing connecting portions according to the fifth embodiment;

FIG. **12** illustrates a front view and a sectional view showing a sixth embodiment of a ball chain according to the present invention;

FIG. **13** is a front view showing connecting portions according to the sixth embodiment;

FIG. **14** illustrates a front view and a sectional view showing a seventh embodiment of a ball chain according to the present invention;

FIG. **15** illustrates a front view and a sectional view showing an eighth embodiment of a ball chain according to the present invention;

FIG. **16** is a front view showing a conventional ball chain;

FIG. **17** is a side view showing the conventional ball chain;

FIG. **18** is a sectional view showing a state in which the ball chain is integrated to an endless track of a slider of a linear guide device;

FIG. **19** is a sectional view showing a state of rolling balls in the case where a load rolling groove of a slider and a ball rolling groove of a track rail are formed in a shape of a circular arc; and

FIG. **20** is a sectional view showing a state of rolling balls in the case where a load rolling groove of the slider and a ball rolling groove of the track rail are formed in a shape of a Gothic arch.

BEST MODE FOR CARRYING OUT THE INVENTION

A detailed explanation will be given of a ball chain according to the present invention in reference to attached drawings as follows.

First Embodiment

FIG. **1** and FIG. **2** show an embodiment of a linear guide device integrated with a ball chain according to the present invention.

In the drawings, notation **1** designates a track rail arranged at a fixed unit of a bed of a machine tool or the like, notation **2** designates a slider for guiding a movable body of a table or the like along the track rail **1**, notation **3** designates a ball rolling between the track rail **1** and the slider **2** while carrying a load and is endlessly circulated in the slider **2**.

First, a section of the track rail **1** is formed substantially in a rectangular shape and a total of two streaks of ball rolling grooves **11** where the balls **3** roll are formed on both side faces thereof along a longitudinal direction (direction orthogonal to paper face of FIG. **2**). The track rail **1** is formed with bolt attaching holes **12** at pertinent intervals in the longitudinal direction and the track rail **1** is fixed to the fixed unit by fixing bolts, not illustrated, which are inserted into the bolt attaching holes **12**.

Further, the slider **2** is constituted by a moving block **4** having attaching faces **41** for a movable body of a table or the like and tap holes **42** into which fixing bolts of the movable body are screwed and a pair of lids **5** which are fixed to both front and rear end faces of the moving block **4** and endless tracks of the balls **3** are provided in the slider by fixing the lids **5** to the moving block **4**.

A section of the moving block **4** is formed substantially in the shape of a saddle having a horizontal portion **4***a* formed with the attaching faces **41** and a pair of skirt portions **4***b* hung from the horizontal portion **4***a* and a load rolling groove **43** opposed to the ball rolling groove **11** of the track rail **1** is formed on an inner face side of each of the skirt portions **4***b*. Further, a ball return hole **44** in correspondence with each of the load rolling grooves **43** is formed at each of the skirt portions **4***b* in which the balls **3** finished with rolling on the load rolling groove **43** and relieved of the load are rolled in the reverse direction to the direction of rolling on the load rolling groove **43**.

The moving block **4** is fabricated by utilizing injection molding of synthetic resin. That is, the moving block **4** is formed by padding synthetic resin by injection molding to a block main body **40** made of metal and formed by machining, portions requiring mechanical strength such as the movable body attaching face **41**, the load rolling face **43** of the ball **3** and the like mentioned above, are formed in the block main body **40** and in the meantime, portions where mechanical strength is not important, such as the ball return hole **44** and the like, are formed of synthetic resin and light weight formation of the moving block **4** is achieved as light as possible.

FIG. **3** is a sectional view showing an endless track of the balls **3** provided to the slider **2** and as shown by FIG. **4**, the endless track is completed by fixing the lids **5** to end faces of the moving block **4**. That is, when the lid **5** is fixed to the moving block **4**, a ball guide portion **46** on the side of the moving block **4** is fitted into a U-shape groove **51** on the side of the lid **5** by which a direction change path **54** in a U-like shape is completed and the load rolling face **43** of the moving block **4** is connected to the ball return hole **44** by the direction change path **54**.

Thereby, when the balls **3** carrying a load between the ball rolling groove **11** of the track rail **1** and a load rolling groove **43** of the moving block **4**, finishes rolling on the load rolling groove **43** in accordance with movement of the slider **2**, the balls are relieved of the load, enter the direction change path **54** of one of the lids **5** and are rolled in the ball return hole **44** of the moving block **4** in a no load state as they are in the reverse direction to the direction of rolling on the load rolling groove **43**. Further, the balls **3** which have finished rolling in the ball return hole **44**, enter again between the track rail **1** and the moving block **4** via the direction change path **54** of other of the lids **5** and roll on the load rolling groove **43** while carrying the load.

Meanwhile, the balls **3** are integrated to the endless track of the slider **2** in a state where they are held in one row by the ball chain **6** and the ball chain **6** is circulated in the endless track in accordance with rolling of the balls **3**. As shown by FIG. **5**, the ball chain **6** is formed by connecting a plurality of ball holding units **61** each holding a single ball **3** in a shape of a string of beads by a flexible connecting portion **62** and each of the ball holding units **61** is constituted by a pair of spherical seats **63** pinching the ball **3** from left and from right and flange portions **64** connecting the spherical seats **63** to each other.

The connecting portion **62** connects only side ends on one side of the ball holding units **61** arranged in one row to each other and when the connecting portion **62** is flexed as shown by FIG. **3**, slit-like spaces among the ball holding units **61** contiguous to each other are expanded and the ball chain **6** per se can be bent in a ring-like shape in a state where the flange portions **64** are disposed on an inner peripheral side or an outer peripheral side.

Further, the ball chain **6** is formed by injection molding of synthetic resin inserted with the balls **3** as cores in a mold and the connecting portions **62**, the spherical seats **63** and the flange portions **64** are integrally molded by such an injection molding and the balls **3** are incorporated by the spherical seats **63**.

FIG. **6** is an enlarged sectional view showing a state of rolling the balls **3** in the endless track.

The load rolling groove **43** of the slider **2** and the ball rolling groove **11** of the track rail **1** are formed in a shape of a Gothic arch formed by intersecting two of ball rolling faces **10** to each other and each of the balls **3** is brought into contact with two points of each of the load rolling groove **43** and the ball rolling groove **11**. Further, escape grooves **31** are respectively formed at deepest portions of the ball rolling groove **11** and the load rolling groove **43** which are formed in a shape of a Gothic arch, that is, positions in each of which the two ball rolling faces **10** are intersected with each other and the flange portions **64** of the ball chain **6** are contained in the escape grooves **31** while the balls **3** are rolling in the rolling grooves **43** and **11**.

Further, guide grooves **32** are formed in the ball return hole **44** of the slider **2** along the longitudinal direction, the flange portions **64** of the ball chain **6** under a no load state are guided by the guide grooves **32** and the ball chain **6** is prevented from meandering in the ball return hole **44**.

Further, according to the linear guide device of the embodiment constituted as described above, when the slider **2** is moved on the track rail **1**, the balls **3** roll on the load rolling groove **43** of the slider **2** and the ball rolling groove **11** of the track rail **1** and the ball chain **6** is circulated inside of the endless track formed in the slider **2**. In this case, according to the respective ball holding units **61** constituting the ball chain **6**, regardless of a state of flexing or extending the ball chain **6**, pairs of the spherical seats **63** always pinch the balls **3** with certainty and therefore, the balls **3** can be prevented from dropping off the ball chain **6** as less as possible.

Further, the ball chain **6** in the endless track is circulated while disposing the flange portions **64** on the outer peripheral side or the inner peripheral side and accordingly, for example, even when the slider **2** is drawn from the track rail **1** (state where track rail **1** is removed in FIG. **6**), the balls **3** are brought into a state where they are pinched from three directions by the load rolling groove **43** of the slider **2** and the flange portions **64** of the ball chain **6** and the balls **3** can be prevented from dropping off the endless track of the slider **2** with certainty.

Second Embodiment

FIG. **7** shows a second embodiment of a ball chain according to the present invention. Although the ball chain

7 is provided with a constitution substantially similar to that of the ball chain **6** of the first embodiment shown by FIG. **5**, the constitution is different therefrom only in that the flange portions **64** connecting pairs of the spherical seats **63** are arranged to divide in four the surroundings of the balls **3**. Therefore, according to the ball chain **7** of the second embodiment, the balls **3** are completely constrained at insides of the ball holding units **61** and the balls **3** can be completely prevented from dropping off the ball chain **7**.

Third Embodiment

FIG. **8** shows a third embodiment of a ball chain according to the present invention.

According to the ball chain **6** of the first embodiment, the connecting portion **62** for connecting the respective ball holding units **61** are also molded by resin and therefore, when the ball chain **6** is circulated in the endless track and flexing and extending thereof are repeated, there is a concern that the ball chain **6** is cut at the connecting portion **62**.

Hence, according to a ball chain **8** of the embodiment, a wire **80** penetrating the respective ball holding units **61** is installed and the connecting portion **62** is constituted by the wire **80**. Although a method of fabricating such a ball chain **8** is substantially the same as that of the ball chain **6** according to the first embodiment, a single piece of the wire **80** is inserted in a mold along with the balls **3** and the respective ball holding units **61** are molded to the wire **80** at an equal interval by injection molding of synthetic resin.

Further, according to the ball chain **8** of the embodiment where the connecting portion **62** is reinforced by the wire **80**, the connecting portion **62** is not broken even by repeated flexing and extending and trouble of breaking the ball chain **8** in the midst of use can be avoided.

Fourth Embodiment

FIG. **9** shows a fourth embodiment of a ball chain according to the present invention.

A ball chain **9** of the embodiment of constituted such that the connecting portion **62** for coupling the respective ball holding units **61** is formed at centers of the spherical seats **63** and a contiguous pair of the ball holding units **61** can be flexed in any direction centering on the connecting portion **62**. Therefore, different from the ball chains described above, there is no specific flexing direction in the ball chain **9** and the ball chain **9** can be integrated to the endless track without taking any special consideration in the flexing direction in the endless track of the slider **2**.

Further, although according to the linear guide devices mentioned above, the slider is provided with a total of two streaks of the ball endless tracks in which respective streaks are in correspondence with both left and right side faces of the track rail, the linear guide device according to the present invention is not limited thereto but the slider **2** may be provided with a total of four streaks of the ball endless tracks in which respective two streaks are in correspondence with each of both left and right side faces of the track rail **1**.

Fifth Embodiment

FIG. **10** shows a fifth embodiment of a ball chain according to the present invention.

According to a ball chain **71**, the plurality of balls **3** are arranged in a connector belt **72** in one row at a predetermined interval and the balls **3** are rotatable in a state where they are held by the connector belt **72**.

The connector belt **72** is constituted by a plurality of ball holding members **74** interposed among the respective balls **3** and a strip-like connecting portion **75** for connecting contiguous ball holding members **74** to each other and spherical seats **74***a* for embracing the spherical face of the ball **3** are formed at each of the ball holding members **74**. Thereby, the respective balls **3** are brought into a state where they are embraced from left and from right by the contiguous ball holding members **74** and are held by such a connector belt **72**.

As shown by FIGS. **11**(*a*) and **11**(*b*), according to the connecting portion **75**, through holes **75***a* each having a diameter slightly larger than the diameter of the ball, are formed in a stainless steel sheet (SUS 304 or the like) having a thickness of 0.05 through 0.2 mm which is formed in a strip-like shape and the balls **3** are contained in such through holes **75***a*. Meanwhile, the ball holding member **74** is molded by synthetic resin of polyamide-base elastomer, polyester-base elastomer or the like and is molded to the connecting portion **75** by injection molding. That is, as shown by FIG. **11**(*a*), ball dies **91** each having a diameter larger than the diameter of the ball **3** are projected at a predetermined interval in a forming mold **90** and as shown by FIG. **11**(*b*), the ball dies **91** are contained in the through holes **75***a* of the connecting portion **75** and under the state, the ball holding members **74** are molded to the connecting portion **75** by injection molding. Thereafter, the ball dies **91** are forcibly detached from among the ball holding members **74** and the balls **3** are pushed in portions detached from the ball dies **91** by which the ball chain **71** in which the balls **3** are contained in the through holes **75***a* of the connecting portion **75** by the ball holding members **74** is completed.

Further, the ball chain **71** of the embodiment constituted as described above, is used by being integrated to an endless track of a slider constituting a linear guide device or the like, the tensile strength of the connecting portion **75** formed by a stainless steel sheet is considerably larger than that of the ball holding member **74** made of synthetic resin and accordingly, even when large tensile force is exerted on the ball chain **71** during circulation in the endless track, the ball chain **71** is not broken between the ball holding members **74** contiguous to each other and smooth circulation of the ball chain **71** can always be expected.

Further, the tensile strength of the ball chain **71** per se is dependent on that of the connecting portion **75** and accordingly, it is not necessary to expect mechanical strength such as tensile strength or the like in resin material molding the ball holding members **74** and resin material used in injection molding can be selected only in view of lubrication performance, wear resistance or the like in respect of rolling of the balls **3**. Accordingly, smooth rolling of the balls **3** can also be expected.

Sixth Embodiment

FIG. **12** shows a sixth embodiment of a ball chain according to the present invention.

Although according to the above-described fifth embodiment, the connecting portion **75** is installed along both sides of a row of the balls which are arranged in one row, according to the embodiment, a connecting portion **76** is installed only on one side of the ball row. The other points as well as the constitution and the method of fabrication are the same as those in the fifth embodiment.

Accordingly, as shown in FIG. **13**, according to the connecting portion **76** of the embodiment, notched portions **76***a* each in a shape of an arch are arranged in the longitudinal direction at a predetermined interval and the balls **3** are contained in the notched portions **76***a*.

Seventh Embodiment

FIG. **14** shows a seventh embodiment of a ball chain according to the present invention.

Although according to the above-described fifth and sixth embodiments, a stainless steel sheet in a strip-like shape is used as the connecting portion, according to the embodiment, wires **77** each having a slender wire diameter are used as a connecting portion and ball holding members **78** are molded to the wires **77** by using injection molding of synthetic resin.

Each of the ball holding members **78** is arranged to be brought into contact with a single one of the ball and an independent ball holding unit is constituted by a pair of the ball holding members disposed on both sides of the ball. Therefore, even in the case where such a ball chain is used by being flexed extremely, according to each of the ball holding units, a pair of the ball holding members **78** hold the balls **3** with certainly and prevention of detachment of the ball **3** is achieved.

Eighth Embodiment

FIG. **15** shows an eighth embodiment of a ball chain according to the present invention.

Although according to the above-described ball chains of the respective embodiments, the ball holding members **74** interposed among the respective balls **3** are integrated with the connecting portion **75** (or **76**) in a strip-like shape by utilizing injection molding of synthetic resin, according to the embodiment, the connecting portion is constituted by a wire **79** having a slender wire diameter and ball holding members **80** previously formed by injection molding of synthetic resin which are penetrated by the wire **79** at a later stage.

That is, the ball holding members **80** are formed with through holes for inserting the wire **79** and by passing the wire **79** through the through holes, the respective ball holding members **80** are connected to each other. Such a wire **79** is folded back by a ball holding member **80***a* disposed at an end portion of the ball chain and is inserted through the respective ball holding members **80** at both sides of the ball row. Further, a stopper plate for fixedly engaging both end portions of the wire **79** is installed at an end portion of the ball chain, not illustrated, and a detachment preventive processing is carried out on the both end portions of the wire **79** which has passed through all of the ball holding members **80** after they are passed through the stopper plate.

Further, also in the ball chain of the eighth embodiment, the ball holding members **80** made of synthetic resin are connected by the wire **79** having large tensile strength by which the balls **3** are rotatably held and accordingly, even when large tensile force is exerted on the ball chain, the ball chain is not broken between the ball holding members **80** contiguous to each other and by using a resin material excellent in lubrication of the balls **3** for the ball holding members **80**, smooth formation of rolling of the balls **3** can be expected.

INDUSTRIAL APPLICABILITY

As has been explained, according to a ball chain of the present invention, a ball holding unit pinching a ball is formed by a pair of spherical seats, the ball chain is constituted by connecting a plurality of the ball holding units and accordingly, even when the ball chain is bent or twisted while it is being used, the balls do not drop off among the spherical seats and the balls can be held by the ball chain with certainty.

Further, according to a ball chain of the present invention, ball holding members interposed among balls contiguous to each other are connected to each other by a connecting portion having a tensile strength higher than that of the ball holding member and accordingly, even when a material for molding the ball holding member which is provided with a low mechanical strength is used, a sufficient tensile strength can be ensured for the ball chain as a whole and accordingly, occurrence of accident of breaking the ball chain while it is being used can be prevented beforehand.

Further, even in the case where the material for molding the ball holding member which is provided with low mechanical strength is used, the tensile strength of the ball chain can be ensured and occurrence of breaking the ball chain can be prevented and accordingly, in selecting a material for molding the ball holding member, consideration is given only in view of lubrication performance, wear resistance or the like in respect of rolling of the balls by which excellent rolling of the balls arranged thereby can be expected.

We claim:

1. A ball chain arranged with a number of balls in one row and rollably holding the balls:

wherein each of the balls are pinched by a pair of spherical seats and the spherical seats of each pair are connected to each other by flange portions to thereby constitute a ball holding unit and a plurality of the ball holding units are connected in series in the shape of a string of beads by a flexible connecting portion.

2. The ball chain according to claim **1**:

wherein the spherical seats and the flange portions are molded by a resin material and the connecting portion is formed by a material having a tensile strength larger than the tensile strength of the resin material.

3. A linear guide device comprising a track rail having ball rolling grooves each in a shape of a Gothic arch formed by intersecting a pair of ball rolling faces with each other, a slider having load rolling grooves each in a similar shape of a Gothic arch opposed to the ball rolling grooves and no load rolling paths for circulating the balls from one end to other end of each of the load rolling grooves for moving along the track rail and a number of balls rolling between the slider and the track rail while carrying a load and circulating endless tracks constituted by the load rolling grooves and the no load rolling paths of the slider:

wherein the ball chain according to claim **1** are integrated to each of the endless tracks of the slider such that the flange portions of the ball chain are disposed on an inner peripheral side or an outer peripheral side thereof and escape grooves by which the flange portions of the ball chains are contained and guided are formed at deepest portions of the ball rolling grooves of the track rail and the load rolling grooves of the slider both formed in the shape of the Gothic arch.

[57] **ABSTRACT**

A rolling motion guide apparatus comprises a track member having a rolling member rolling groove along a longitudinal direction of the track member, a plurality of rolling members rolling along the rolling member rolling groove of the track member, a movable member having a loaded rolling member rolling groove which constitutes a loaded rolling member rolling passage in association with the rolling member rolling groove of the track member. The movable member is movable along the track member through the rolling members rolling in the loaded rolling member rolling passage. A seal member is provided on a surface of the movable member facing the track member. The seal member is composed of a base plate portion disposed along the surface of the movable member facing the track member and sealing portions disposed to longitudinal side edge portions of the base plate portion so as to be contacted to the track member. The base plate portion is formed of resin material different from resin material of which the sealing portions are formed. The base plate portion and the sealing portions is integrally molded with each other through an extrusion process.

ROLLING MOTION GUIDE APPARATUS

BACKGROUND OF THE INVENTION

The present invention relates to a rolling motion guide apparatus having a seal member which is formed by integrally molding different parts or members with each other through an extrusion molding process and also relates to a rolling motion guide apparatus having such a seal member which is mounted on the apparatus by a new engaging or mounting method.

A rolling motion guide apparatus is well known as a means for conveying various machines or machinery. Such a rolling motion guide apparatus is provided with a track member and a movable member mounted on the track member in a straddle manner so as to be movable through a plurality of rolling members. When the movable member is moved along the track member, the machine or machinery mounted on the movable member is also moved. In such a rolling motion guide apparatus, the rolling members roll and circulate in an endless circulation passage formed by the combination of the rolling member rolling grooves formed on the movable member and the track member in accordance with the movement of the movable member.

In the known art, to such a rolling motion guide apparatus, a seal member is attached for protecting the rolling member and the endless circulation passage to prevent invasion of an external foreign material as well as leakage of a lubricant with which the endless circulation passage is filled. Particularly, in a case where it is desired to seal a gap formed between an upper surface of the track member and a surface of the movable member facing the upper surface of the track member, a plate-like seal member having sealing portions at its side edges is provided on the surface of the movable member facing the track member so as to seal the gap, as disclosed for example in Japanese Patent Laid-open (KOKAI) Publication No. HEI 7-286617.

A seal member utilized in the prior art is obtained by forming sealing portions of resin material, rubber material or the like and then joining the thus formed sealing portions on the peripheral edge portion of a base plate portion formed of a flat iron plate or the like, by a bonding method such as a thermal bonding method. Such a seal member is mounted on the movable member by fastening means such as screws prepared independently.

In the conventional method mentioned above, however, the seal member is formed by joining the base plate portion and the sealing portions after independently forming these portions, and accordingly, the number of parts or members to be used is increased and the manufacturing processes are also increased, which will require complicated manufacturing workings, in addition to a problem that the sealing portions may easily come off the base plate portion. In the above-mentioned prior art document of Japanese Patent Laid-open (KOKAI) Publication No. HEI 7-286617, there has been proposed one example for solving the problem. In that document, the base plate portion is formed so as to provide a stepped side edge portion for increasing a portion or area to be joined to the sealing portion. The formation of the base plate portion having such a stepped portion will make the manufacturing working further complicated.

Furthermore, in the conventional structure in which the base plate portion of the seal member has a flat shape, the seal member has a low rigidity and is easily plastically deformable. When the base plate portion is plastically deformed, the sealing portion is also deformed, and a gap will be hence caused between the front end of the sealing portion of the seal member and the track member, leading to reduction of the sealing function of the seal member.

On the other hand, in the conventional method in which the seal member is attached to the movable member by using the screw, parts to be used are increased and the manufacturing working and time are also increased and complicated, requiring much time, resulting in an increased production cost. Furthermore, in the method mentioned in the above Japanese Patent Publication in which the base plate portion and the sealing portion are joined without using any specific fastening means, it is required for the base plate portion to be formed into a specific shape.

SUMMARY OF THE INVENTION

An object of the present invention is to substantially eliminate defects or drawbacks encountered in the prior art mentioned above and to provide a rolling motion guide apparatus provided with a seal member capable of preventing a sealing portion from being detached or peeled off from a base plate portion so as to provide an improved rigidity and dimensional accuracy and also capable of having a mounting member for easily and surely mounting the seal member.

This and other objects can be achieved according to the present invention by providing, in one aspect, a rolling motion guide apparatus comprising:

a track member provided with a rolling member rolling groove along a longitudinal direction of the track member;

a plurality of rolling members rolling along the rolling member rolling groove formed on the track member;

a movable member provided with a loaded rolling member rolling groove which constitutes a loaded rolling member rolling passage in association with the rolling member rolling groove formed on the track member, the movable member being movable along the track member through the rolling members rolling in the loaded rolling member rolling passage; and

a seal member provided on a surface of the movable member facing the track member,

wherein the seal member comprises a base plate portion disposed along the surface of the movable member facing the track member and sealing portions disposed to longitudinal side edge portions of the base plate portion so as to be contacted to the track member, the base plate portion being formed of resin material different from resin material of which the sealing portions are formed, and the base plate portion and the sealing portions being integrally molded with each other through an extrusion process.

In a preferred embodiment in this aspect, the base plate portion is provided with an abutting portion having a surface which is perpendicular to the moving direction of the movable member and which has substantially a trapezoidal shape in section. The base plate portion may have a central portion in its sectional view which has a thickened portion and the side edge portions on which the sealing portions are disposed and which have thin thickness portions with respect to the thickened portion. The base plate portion and the sealing portions may be formed of different kinds of thermoplastic materials respectively.

According to this aspect of the present invention, the seal member is formed by integrally molding the base plate portion and the sealing portions with each other, and the formation and attachment of these portions can be carried out through a single extrusion molding process, which can reduce much time and labor for the manufacture thereof. The integral extrusion molding of the base plate portion with the sealing portions causes these portions to be formed into a single formed body. It is therefore possible to prevent the sealing portions from being separated from the base plate portion.

Furthermore, since the base plate portion can be held on the movable member by abutting the abutting portion against the movable member, the seal member can surely attached. The rigidity of the base plate portion can extremely be improved in comparison with a case in which the seal member is formed of a single plate member, and the deformation thereof can be also prevented, resulting in the realization of the improved sealing function.

Still furthermore, the formation of the thickened portion of the base plate portion can improve the strength and rigidity thereof and can prevent the deformation of the seal member at a time when the seal member is fitted to the engaging portion of the side cover.

In another aspect of the present invention, the above object can be achieved by providing a rolling motion guide apparatus comprising:

a track member provided with a rolling member rolling groove along a longitudinal direction of the track member;

a plurality of rolling members rolling along the rolling member rolling groove formed on the track member;

a movable member provided with a loaded rolling member rolling groove which constitutes a loaded rolling member rolling passage in association with the rolling member rolling groove formed on the track member, the movable member being movable along the track member through the rolling members rolling in the loaded rolling member rolling passage;

side covers fixed on both end surfaces of the movable member in the moving direction thereof; and

a seal member provided on a surface of the movable member facing the track member,

wherein the seal member comprises a base plate portion disposed along the surface of the movable member facing the track member and sealing portions disposed to longitudinal side edge portions of the base plate portion so as to be contacted to the track member, the side covers and the base plate portion are formed with engaging portions respectively, which are engaged with each other so as to hold the base plate portion of the seal member on the surface of the movable member facing the track member, and the base plate portion of the seal member is mountable on the end portions of the movable member through the engaging portions, with the side covers being fixed thereto.

In a preferred embodiment of this aspect, the base plate portion is provided with an abutting portion having a surface which is perpendicular to the moving direction of the movable member and which has substantially a trapezoidal shape in section.

In this aspect, also as mentioned in the above aspect, the base plate portion has a central portion in its sectional view which has a thickened portion and the side edge portions on which the sealing portions are disposed and which have thin thickness portions with respect to the thickened portion. The base plate portion may be formed of resin material different from resin material of which the sealing portions are formed, and the base plate portion and the sealing portions may integrally be molded with each other through an extrusion process. The base plate portion and the sealing portions may be formed of different kinds of thermoplastic materials respectively.

Furthermore, the engaging portion formed on each of the side covers at a portion facing a surface of the track member comprises a recessed fit portion having a size allowing the base plate portion to be fitted and engaging claw pieces engaged with engaging groove formed on the base plate portion, and each of the engaging claw pieces may have an inclined surface portion along which the base plate portion slides when fitted.

According to this aspect, in addition to the above one aspect, the seal member can be mounted on the movable member without using any other means, which results in the reduction of parts to be used and the manufacturing cost down, as well as the working time and labor. Furthermore, the seal member can easily be mounted without forming the base plate portion thereof so as to provide a specific shape. Since the seal member can be mounted merely by press-fitting the end portion of the seal member, it can be mounted on the movable member with the side covers being attached, improving the assembling working.

The nature and further characteristic features of the present invention can be made more clear from the following descriptions with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

In the accompanying drawings:

FIG. **1** is a perspective view of a rolling motion guide apparatus, partially cut away, according to one embodiment of the present invention;

FIG. **2** is a view, partially in section, viewed from a direction perpendicular to a guiding direction of the rolling motion guide apparatus shown in FIG. **1**;

FIG. **3** is a sectional side view showing an endless circulation passage for rolling members of the apparatus shown in FIG. **1**;

FIG. **4** is a back side view of a seal member to be mounted on the rolling motion guide apparatus of FIG. **1**;

FIG. **5** is an end view of the seal member;

FIG. **6** is an end view of another seal member to be utilized for the rolling motion guide apparatus of the present invention;

FIG. **7** is a sectional side view, partially cut away, of an apparatus for molding the seal member used for the rolling motion guide apparatus of the present invention;

FIG. **8** is an end view of a seal member formed by the molding apparatus of FIG. **7**;

FIG. **9** is a view showing a surface of a side cover facing a body of a movable member of the rolling motion guide apparatus;

FIG. **10** is an enlarged front view of an engaging portion shown in FIG. **9**;

FIG. **11** is an enlarged back side view of the engaging portion shown in FIG. **9**;

FIGS. **12**A and **12**B are views showing a process for mounting the seal member on the side cover; and

FIG. **13** a back side view showing a state of the seal member mounted on the side cover.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

One preferred embodiment of a rolling motion guide apparatus of the present invention will be described hereunder with reference to FIGS. **1** to **3**.

The rolling motion guide apparatus **1** of this embodiment is provided with a track member **2** and a movable member

4 which is mounted on the track member in a straddle manner through a plurality of spherical rolling members **3**—**3** such as balls so as to be freely movable on and along the track member **2**.

The track member **2** is a member having a surface, rectangular in cross section, perpendicular to the longitudinal direction thereof and formed with two rows of rolling member rolling grooves **5**, **5** on each side surface, totally four grooves, so as to extend throughout the entire longitudinal direction of the track member **2**. Each row of rolling member rolling grooves shows substantially a semi-circular shape. In the embodiment of FIG. **1**, although the track member **2** has a linear shape, it may be formed so as to provide a curved structure. Furthermore, the number of the rolling member rolling grooves is not limited to the described embodiment and other arrangements may be taken, for example, one row in each side, totally two rows. There may be taken further another arrangement having the total number of rows of three.

On the other hand, the movable member **4** has a cross sectional surface having an inverse U-shape, perpendicular to the moving direction of the movable member **4**. The movable member **4** is mounted on the track member **2** so as to straddle the same through a plurality of spherical rolling members **3**—**3** rolling in the passage composed of the groove formed on the inner surface of the movable member **4** and the groove formed on the outer surface of the track member **2**. The movable member **4** is composed of a movable member body **40**, side covers or lids **41**, **41** fixed on both the side ends in the longitudinal direction of the movable member body **40** and end plates **42**, **42** fixed on both the longitudinal ends thereof by means of screws **43**—**43**.

The inverse U-shaped movable member **4** has an inner space into which the track member **2** is located and has inner surfaces facing the outer surfaces of the track member, and two rows of loaded rolling member rolling grooves **6**, **6** are formed on each of the inner surface of the movable member **4** so as to correspond to or face on the rolling member rolling grooves **5**, **5** formed on the track member **2**, respectively. Each pair of these rolling member rolling grooves **5** and **6** form a loaded rolling member rolling passage **7** as a portion of a circulation passage of the rolling members **3**—**3**. The movable member body **40** is formed with return passages **8** each having a circular shape in cross section and extending along the entire longitudinal direction, i.e. moving direction thereof. The side covers **41**, **41** are formed with direction changing passages **9**, **9**, each connecting the loaded rolling member rolling passage **7** with the return passage **8**. In this manner, endless circulation passages **10** are formed by the continuous connection of the loaded rolling member rolling passages **7**, the return passages **8** and the direction changing passages **9** on both the sides of the track member **2** along the longitudinal moving direction thereof.

The rolling members **3**—**3** form a connection member **30** in association with spacers **31**—**31** disposed between adjacent rolling members **3**, **3** and belts, each in thin plate structure, supporting the rolling members **3**—**3** so as to be movable on both the sides thereof, and that is, in the connection member **30**, the rolling members **3**—**3** are connected by the spacers **31** and the belts in shape of a string of beads. The rolling members **3**—**3** circulate in the endless circulation passage **10** in the manner that when the movable member **4** is moved, the rolling members **3**—**3** are also moved in the loaded rolling member passage **7** and guided to one end side of the return passage **8** through the direction changing passage **9** on one end side, then moved along the return passage **8** toward the other one end side thereof, and then guided again to the loaded rolling member passage **7** through the other direction changing passage **9** on the other end side.

Seal members **11** and **12** are disposed on a horizontal surface **46** and both side surfaces **47**, **47** of the movable member **4** facing the track member **2** as shown in FIG. **2**. More specifically, the seal member **11** is disposed on the horizontal surface **46** of the movable member **4** facing the upper surface **21** of the track member **2** so as to extend in the movable member moving direction, i.e. the perpendicular direction to the drawing paper surface of FIG. **2**. On the other hand, the seal members **12**, **12** are disposed on the lower sides of the loaded rolling member passages **7**, **7** so as to seal the same.

FIGS. **4** to **6** show the detailed structure of the seal member **11**. The seal member **11** is composed of a base plate portion **111** and sealing portions **112**, **112** formed on both side edges **113**, **113** of the base plate portion **111** so as to entirely extend therealong.

The base plate portion **111** is formed so as to have a trapezoidal shape in an entire structure and has a contact portion **115** abutting against the movable member **4**. The base plate portion **111** includes a central thick portion having a large thickness sufficient for maintaining a proper rigidity of the base plate portion **111** and thin portions b, b having a small thickness on the sides of the side edge portions **113**, **113**. The back side surfaces, i.e., the lower side surfaces as viewed, of the thin portions b, b are formed with engaging grooves c, c to be engaged with engaging claws **402**, **402** of engaging portions (FIG. **9**) of the side covers **41**, **41**, respectively. The engaging groove c extends along the entire longitudinal direction of the base plate portion **111** and provides an inverse U-shaped cross section. However, this cross sectional shape is not limited to that shown in FIG. **5**, and the base plate portion **111** may be formed so as to provide a cross sectional shape shown in FIG. **6**, in which the contact portion **115** is partially formed. The base plate portion **111** may be formed of a resin material, preferably, a thermoplastic resin such as polyvinyl chloride, polyethylene, polystyrene, polypropylene, ABS resin, or the like.

The sealing portions **112**, **112** arranged on the both side edge portions **113**, **113** of the base plate portion **111** are formed of a resin material and have front end portions, each in shape of fork in section, so as to provide lip portions **114**, **114** (each being formed of lip portions **114***a*, **114***b*) having round distal end portions as shown in FIG. **5** or **6**. In a preferred embodiment, it is desired to make shorter the length of the lip portion **114***a* near the loaded rolling member rolling passage (FIG. **2**) than that of the other lip portion **114***b* positioned apart from the lip portion **114***a* with respect to the loaded rolling member passage **7** when assembled. Further, it may be preferred to form the sealing portions of a thermoplastic resin such as polyvinyl chloride, polyethylene or the like, but it is not limited to such resin material in the present invention and a rubber material may be utilized.

The base plate portion **111** and the sealing portions **112**, **112** are integrally formed with each other by an extrusion molding process so as to provide the seal member **11**. FIG. **7** shows one example of a molding apparatus D for molding the seal member **11**.

With reference to FIG. **7**, the molding apparatus D is provided with a first extrusion section S1 for forming the base plate portion **111** and a second extrusion section S2 for forming the sealing portions **112**, **112**. Each of these extrusion sections S1 and S2 is provided with a horn-shaped hopper **91** through which a raw material is fed, a barrel **93** into which the raw material is fed through the hopper **91**, a screw **92** disposed in the barrel **93** at substantially the central portion of the extrusion section for extruding the raw material, and a heater **94** disposed at the outer peripheral portion of the barrel **93** to heat the raw material in the barrel to a predetermined temperature. Both the extrusion sections S1 and S2 are connected to each other by means of a die **95** at the axial feed end portions of the screws **92**, **92**. The die **95** is a mold for molding the raw material so as to provide a desired shape and is provided with a material guide section **98** having a first supply passage **96** for supplying a raw material for the base plate portion **111** from the extrusion section S1 and a second supply passage **97** for supplying a raw material for the sealing portions **112** from the extrusion section S2 and a mixing section **99** for mixing these materials together.

The raw material for the base plate portion **111** is fed into a material feeding portion **98** of the die **95** through the first feeding passage **96** by the extrusion section S1. The raw material passes the material feeding portion **98** while being gradually formed into a shape of the base plate portion **111**. On the other hand, the raw material for the sealing portion **112** is extruded by the extrusion section S2, fed into the material feeding portion **98** of the die **95** through the second feeding passage **97** and, then, passes the material feeding portion **98** while being gradually formed into a shape of the sealing portion **112**. As shown in FIG. **7**, the second feeding passage **97** is positioned at each side of the first feeding passage **96** at the central portion of the material feeding portion **98**.

Thereafter, both the raw materials for the base plate portion **111** and the sealing portions **112** are supplied to the mixing portion **99**, and during the time when the raw materials pass through the mixing portion, both the raw materials are formed integrally into the seal member **11** of the rolling motion guide apparatus according to the embodiment of the present invention mentioned above.

FIGS. **9** to **12** show the various states of the side cover **41** to which the seal member **11** is attached. As shown in these figures, the side cover is formed with an engaging portion **400**, which is positioned at a portion of the side cover corresponding (opposing, when assembled,) to the upper surface **21** of the track member (see FIG. **2**). The engaging portion **400** is composed of a recessed fit portion **401** and engaging claws **402**, **402**. The base plate portion **111** is fitted into this recessed fit portion **401**, which has a cross sectional shape substantially equal to that of the base plate portion **112**. The engaging claws **402**, **402** can be engaged with the engaging grooves c, c formed on the base plate portion **111** as mentioned before. The engaging claw **402** projects toward the movable member body **40** (see FIG. **1**) and has an inclining surface **403**.

The seal member **11** is attached to the side cover **41** in the following manner. First, as shown in FIG. **12**, the base plate portion **111** is arranged so that the end surface in the longitudinal direction of the base plate portion **111** is positioned so that the upper side surface, as viewed in FIG. **5**, of the base plate portion **111** abuts against the inclining surface **403** of the engaging claw **402** (see FIG. **12**B) and then the end surface portion of the base plate portion **111** is pushed into the recessed fit portion **401** so as to establish the engaging state. FIG. **12**A shows a state that the base plate portion **111** of the seal member **11** is fitted into the engaging portion **400**. In this engagement, since the engaging claw **402** is formed with the inclining surface **403**, the base plate portion **111** can smoothly be fitted into the recessed fit portion **401** by sliding the end surface portion of the base plate portion along the inclining surface **403**. Further, the engaging grooves c, c, mentioned before with reference to FIGS. **4** and **5**, are arranged at portions at which they are engaged with the engaging claws **402**, **402** of the engaging portion **400**, whereby the seal member **11** can be prevented more surely from being disengaged from the side covers **41**, **41**.

FIG. **13** shows a seal member attaching state, in which the end surface of the sealing portion **112** is attached in an abutting state to the side surface of the sealing portion **412** of the end plate **42**. According to the construction of the seal member **11** in the manner mentioned above, the gap between the upper surface **21** of the track member **2** and the movable member **4** can be substantially completely sealed, and the invasion of the foreign material into the loaded rolling member rolling passage **7** from the central side of the guide apparatus **1** can be effectively prevented. Furthermore, though not shown, the sealing portions of the seal member **12** which seals the loaded rolling member rolling passage **7** from the lower side may also be constructed by abutting the longitudinal end portion thereof against the sealing portion **412** of the end plate **42**. According to the location of the sealing portions **112** and **412** of the respective seal members, the loaded rolling member rolling passage **7** can be sealed at its both the moving direction and the direction normal thereto of the movable member **4**, thus improving the dust proof effect. Furthermore, in order to ensure the smooth rolling of the rolling members **3**—**3** in the endless circulation passage **10**, lubricant such as grease may be applied to the endless circulation passage **10**. The lubricant is fed through the filling port **44** (FIG. **1**) and then supplied to the direction changing passage **9** through a lubricant guiding passage **45** formed on the side cover **41** as shown in FIG. **9**. In this viewpoint, the lubricant can also be prevented from leaking by locating the sealing portions **112** and **412** of the respective seal members in the manner mentioned above.

It is finally to be noted that the present invention is not limited to the described embodiment and many other changes or modifications may be made without departing from the scopes of the appended claims.

For example, in the described embodiment, although the rolling motion guide apparatus **1** provided with the endless circulation passage **10** is referred to, the present invention will be applicable to a rolling motion guide apparatus provided with a circulation passage having its ends.

What is claimed is:

1. A rolling motion guide apparatus comprising:

a track member provided with a rolling member rolling groove along a longitudinal direction of the track member;

a plurality of rolling members rolling along the rolling member rolling groove formed on the track member;

a movable member provided with a loaded rolling member rolling groove which constitutes a loaded rolling member rolling passage in association with the rolling member rolling groove formed on the track member, said movable member being movable along the track member through the rolling members rolling in the loaded rolling member rolling passage; and

a seal member provided on a surface of the movable member facing the track member,

wherein said seal member comprises a base plate portion disposed along the surface of the movable member facing the track member and sealing portions disposed to longitudinal side edge portions of the base plate portion so as to be contacted to the track member, said base plate portion being formed of resin material different from resin material of which said sealing portions are formed, and said base plate portion and said sealing portions being integrally molded with each other through an extrusion process.

2. The rolling motion guide apparatus according to claim **1**, wherein said base plate portion is provided with an abutting portion having a surface which is perpendicular to a moving direction of the movable member and which has substantially a trapezoidal shape in section.

3. The rolling motion guide apparatus according to claim **1**, wherein said base plate portion has a central portion in its sectional view which has a thickened portion and the side edge portions on which the sealing portions are disposed and which have thin thickness portions with respect to the thickened central portion.

4. The rolling motion guide apparatus according to claim **1**, wherein said base plate portion and said sealing portions are formed of different kinds of thermoplastic materials respectively.

5. A rolling motion guide apparatus comprising:

a track member provided with a rolling member rolling groove along a longitudinal direction of the track member;

a plurality of rolling members rolling along the rolling member rolling groove formed on the track member;

a movable member provided with a loaded rolling member rolling groove which constitutes a loaded rolling member rolling passage in association with the rolling member rolling groove formed on the track member, said movable member being movable along the track member through the rolling members rolling in the loaded rolling member rolling passage;

side covers fixed on both end surfaces of the movable member in the moving direction thereof; and

a seal member provided on a surface of the movable member facing the track member,

wherein said seal member comprises a base plate portion disposed along the surface of the movable member facing the track member and sealing portions disposed to longitudinal side edge portions of the base plate portion so as to be contacted to the track member, said side covers and said base plate portion are formed with engaging portions respectively, which are engaged with each other so as to hold the base plate portion of the seal member on the surface of the movable member facing the track member, and said base plate portion of the seal member is mountable on the end portions of the movable member through said engaging portions, with said side covers being fixed thereto.

6. The rolling motion guide apparatus according to claim **5**, wherein said base plate portion is provided with an abutting portion having a surface which is perpendicular to a moving direction of the movable member and which has substantially a trapezoidal shape in section.

7. The rolling motion guide apparatus according to claim **5**, wherein said base plate portion has a central portion in its sectional view which has a thickened portion and the side edge portions on which the sealing portions are disposed and which have thin thickness portions with respect to the thickened central portion.

8. The rolling motion guide apparatus according to claim **5**, wherein said base plate portion is formed of resin material different from resin material of which said sealing portions are formed, and said base plate portion and said sealing portions are integrally molded with each other through an extrusion process.

9. The rolling motion guide apparatus according to claim **8**, wherein said base plate portion and said sealing portions are formed of different kinds of thermoplastic materials respectively.

10. The rolling motion guide apparatus according to claim **5**, wherein said engaging portion formed on each of said side covers at a portion facing a surface of the track member comprises a recessed fit portion having a size allowing the base plate portion to be fitted and engaging claw pieces engaged with engaging grooves formed on the base plate portion.

11. The rolling motion guide apparatus according to claim **10**, wherein each of said engaging claw pieces has an inclined surface portion along which the base plate portion slides when fitted.

[57] **ABSTRACT**

The present invention relates to a method of manufacture of a slider of a rectilinear guide unit for guiding a movable body such as a work table of a machine tool, an industrial robot or the like by moving along an orbital rail arranged on a stationary section such as a bed, column or the like as it bears a load thereon. This method comprises a first step in which a metallic block main body as a core of the slider is machined to a predetermined shape and to form ball load rolling contact surfaces in the block main body and a second step in which the block main body machined in the previous step is inserted into a mold so as to allow a die-molding material to be padded thereon to thereby form an endless ball circulation path wherein in the first step, chamfered sections are formed on the corners of the block main body corresponding to a portion where the above-mentioned endless ball circulation path is formed.

METHOD FOR MANUFACTURE OF RECTILINEAR GUIDE UNIT

TECHNICAL FIELD

The present invention relates to a method of manufacture of a slider for a rectilinear guide unit for guiding a movable body such as a work table of a machine tool, an industrial robot and etc. while moving along an orbital rail arranged on a bed, column or the like, and more particularly to an improvement in a method in which a slider is formed by padding a die-molding material such as a synthetic resin to a metallic block main body.

BACKGROUND TECHNOLOGY

Conventionally, as a linear guide unit of the above type, there is known the one that has a structure comprising a orbital rail arranged on a stationary portion such as a bed and having ball rolling contact surfaces and a slider fastened to the orbital rail through a number of balls and movable along the rail which supports a movable body such as a table.

Further, the slider comprises a mobile block having ball load rolling contact surfaces opposing to the ball rolling contact surface of the orbital rail through the balls and ball return holes parallel to the ball load rolling contact surfaces and capable of moving along the orbital rail following the rolling of the balls, a pair of covers having change-direction paths for establishing communication between the ball load rolling contact surfaces and the ball return holes and ball retainers attached to the mobile block so as to prevent the falling of the balls from the ball load rolling contact surfaces and the end portions of the ball return holes are connected by the change-direction path when the covers are fixed to the front and rear end surfaces of the mobile block, respectively, thereby completing an endless circulation path for the balls in the slider.

In the case of the slider of the conventional rectilinear guide unit of the above-described structure, the process of drilling the ball return holes and the fixing of the ball retainers to the mobile block becomes necessary resulting in taking much time and labor for its manufacture so that the present applicant proposed a method of manufacture of the slider by making use of extrusion molding of a synthetic resin (refer to Japanese Unexamined Patent Publication No. 317762/1995).

More concretely, the above-proposed method is such that a synthetic resin is padded onto the metallic block main body having the above-mentioned load rolling contact surfaces subjected to cutting so that the ball return holes and the ball retainers are molded integral with the block main body and the ball guide sections on the side of the inner peripheral surface of each of the change-direction paths which have hitherto been formed in the covers are also molded on the end surfaces of the block main body to thereby manufacture the movable block. Besides the advantage of being able to manufacture a mobile block of a complicated shape in a simple manner, this proposed method has also such advantage that an endless ball circulation path provided with ball return holes, inner peripheral side ball guide sections and ball retainers formed continuous with one another can be formed with a synthetic resin thereby smoothing the circulation of the balls.

Now, where such endless ball circulation path is continuously formed with the synthetic resin, it is usual that the molten resin immediately after injection-molding solidifies as it contracts toward a direction parallel to the ball return holes but since such endless circulation path itself is so

formed as to surround the block main body, in the case of the mobile block which has been subjected to molding, the synthetic resin forming the endless ball circulation path binds the block main body tightly and a tensile stress remains in the molded synthetic resin. Consequently, there has arisen the problem that when the block main body has front and rear corners near the boundary of the ball return holes and the inner peripheral side ball guide sections formed of the synthetic resin, the tensile stress concentrates on the corners causing the synthetic resin to crack thereby hindering the smooth rolling of the balls in the endless ball circulation path.

Further, there has also been the problem that when the block main body has corners formed of synthetic resin, the flow of the molten resin is hindered at the time of injection-molding and the fluidity of such molten synthetic resin becomes insufficient so that a weld line is generated in the synthetic resin forming the endless ball circulation path and the smooth rolling of the balls is hindered because of the presence of such weld line.

In addition, due to the fact that when the block main body has corners formed of synthetic resin, the flow of the molten resin is hindered due to the presence of these corners, the thickness of the synthetic resin at the ball return holes and the ball retaining sections tends to become non-uniform and it has not been able to avoid the generation of deformation of the ball return holes and the ball retaining sections in the cooling process after molding. Accordingly, there has been the problem that the smooth rolling of the balls is hindered because of this point, too.

Now, in order to allow the balls rolling in the endless ball circulation path to circulate smoothly along a predetermined track, it is necessary to prevent each of the balls rolling within the endless ball circulation path from unsteadily moving right and left by reducing the gap between the ball and the inner wall of the endless circulation path to a minimum. Accordingly, in order to secure the smooth movement of the slider with respect to the orbital rail, it is necessary to mold the endless ball circulation path to a predetermined dimensional accuracy without fail so that a special consideration has been required for padding a synthetic resin to the metallic block main body by injection-molding.

DISCLOSURE OF THE INVENTION

The present invention has been made to solve the above-described problems and an object of the invention is to provide a method of manufacture of a slider of a rectilinear guide unit in which when the slider of the rectilinear guide unit provided with ball return holes and ball retaining sections formed by padding a synthetic resin on a metallic block main body, no cracking generates in the synthetic resin forming an endless ball circulation path and ball return holes and ball retaining sections can be accurately formed.

In order to achieve the above-described object, a method of manufacture of a slider of a rectilinear guide unit according to the present invention comprises a first step in which a metallic block main body as a core of the slider is machined to a predetermined shape and ball load rolling contact surfaces are formed in the block main body and a second step in which the block main body formed in the first step is inserted into a mold to thereby mold a die-molding material to form an endless ball circulation path and characterized in that the first step includes forming chamfered sections at corners of the block main body at positions corresponding to the portion where the endless ball circulation path is formed.

According to the method of the present invention comprising the above-mentioned steps, since the first step includes the formation of the chamfered sections on the corners of the block main body at positions corresponding to the portion where the endless ball circulation path is formed, even when the die-molding material is padded to the block main body so as to surround the latter, the die-molding material forming the endless ball circulation path does not crack due to a tensile stress applied on the die-molding material after completion of molding to thereby secure the smoothness of rolling of the balls in the endless ball circulation path.

Further, by the formation of the chamfered sections on the corners of the block main body at a position corresponding to the endless ball circulation path, the molten die-molding material injected into the mold quickly spreads in the longitudinal direction of the block main body so that the thickness of the ball return holes and the ball retaining sections forming parts of the endless ball circulation path can be equalized with ease, the generation of deformation or distortion of these portions after the completion of molding can be controlled and the formation of a welding line of the die-molding material such as a synthetic resin in the endless ball circulation path can be prevented. Accordingly, it is possible to secure the smooth rolling of the balls within the endless ball circulation path from this point, too.

In the above case, the chamfered sections to be formed at the corners of the block main body may be planar or curved.

Further, according to the method of the present invention, when the molten die-molding material is injected into the mold in the second step, it is preferable that the molten die-molding material be injected from a direction parallel to the load rolling contact surface of the block main body because by so doing, the flow velocity of the molten die-molding material in the longitudinal direction of the block main body is improved to form the ball return holes and the ball retaining sections more accurately thereby smoothing the rolling of the balls.

It should be noted that in the inventions described in claims **1** through **3**, whether or not the die-molding material is padded to the block main body to form ball retainers along both edges of the load rolling contact surface is a matter of design. In other word, the endless ball circulation path according to the present invention does not always include the ball retainers.

Further, the die-molding material referred to in the present invention also includes die-casting alloys and the like besides a synthetic resin material.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a front view (partly in section) of one embodiment of a rectilinear guide unit to be manufactured by a method of the present invention;

FIG. **2** is a side view (partly in section) of one embodiment of the linear guide shown in FIG. **1**;

FIG. **3** is an exploded perspective view of a slider according to one embodiment of the present invention;

FIG. **4** is a sectional view of a mobile block forming a slider shown in FIG. **3**;

FIG. **5** is a perspective view of a block main body as a core of the mobile block according to one embodiment of the present invention;

FIG. **6** is a front view of the block main body shown in FIG. **5**;

FIG. **7** is a sectional view of the block main body when the block main body is inserted into a mold; and

FIG. **8** is a sectional view of the mobile block according to one embodiment of the present invention especially when a synthetic resin material is padded onto the block wherein FIG. **8**(*a*) is a sectional view taken along the A—A line of FIG. **4** and FIG. **8**(*b*) is a sectional view taken along the B—B line of FIG. **4**.

DESCRIPTION OF REFERENCE SYMBOLS

Reference numeral **1** designates an orbital rail, reference numeral **2** designates a slider; reference numeral **3** designates a ball, reference numeral **8** designates a block main body, reference numerals **43***a* and **43***b* designate ball load rolling surfaces, reference numerals **44***a* and **44***b* designate ball return holes, reference numeral **45** designates a ball retaining section; reference numerals **50***a*, **50***b* designate chamfered sections and reference numerals **61** and **62** designate dies.

BEST MODE FOR CARRYING OUT THE INVENTION

The method of manufacture of a slider of a rectilinear guide unit according to the present invention will now be described by referring to the accompanying drawings.

FIGS. **1** and **2** show one embodiment of the rectilinear guide unit in which the slider manufactured by the method of the present invention is combined with an orbital rail. In these figures, reference numeral **1** designates an orbital rail arranged on a stationary portion such as a bed of a rectilinear guide unit, reference numeral **2** designates the slider for guiding a movable body such as a table and reference numeral **3** designates balls endlessly circulating within the slider **2** while rolling between the orbital rail **1** and the slider **2** as it bears a load thereon.

First, the orbital rail **1** is substantially rectangular in section and a total of four (4) lines of ball rolling contact surfaces **11***a* and **11***b* on which the balls **3** roll are formed along the longitudinal direction. These ball rolling contact surfaces **11***a* and **11***b* are formed on both side surfaces and both edges of the upper surface of the orbital rail **1**, respectively, such that the ball rolling contact surface **11***a* is formed downward at an angle of 30° with respect to the horizontal direction in FIG. **1** and the ball rolling contact surface **11***b* is formed upright. Further, the orbital rail **1** is provided with a plurality of bolt fitting holes **12** at suitable intervals in the longitudinal direction thereof so that the orbital rail **1** is fixed to the stationary portion of the machine tool or the like by means of fixing bolts (not shown) to be inserted into these holes **12**, respectively.

On the other hand, the above-mentioned slider **2** comprises a mobile block **4** having a fitting surface **41** for a movable body such as a table and a plurality of tap holes **42** into which movable body fixing bolts are inserted and a pair of covers **5** which are fixed to front and rear end surfaces of the mobile block **4** whereby when the covers **5** are fixed to the mobile block **4**, the slider can be provided therein with an endless circulation path for the balls **3**. Further, to each of the covers **5**, there is attached a seal member **6** coming into sliding contact with the orbital rail **1** so that dust and the like adhered to the orbital rail **1** are prevented from entering into the slider **2** following the movement of the slider **2**.

As shown in FIGS. **3** and **4**, the mobile block **4** is substantially in the shape of a saddle having a horizontal section **4***a* on which the fitting surface **41** is formed and a pair of skirts **4***b* drooping from the horizontal section **4***a* and on the lower surface of the horizontal section **4***a* and the inner surface of each of the skirts **4***b* there are formed a total of four load rolling contact surfaces **43***a* and **43***b*, respectively. Further, on the horizontal section **4***a* and each of the skirts **4***b*, there are provided ball return holes **44***a* and **44***b*, respectively, in correspondence to the load rolling contact surfaces **43***a* and **43***b* so that the load rolling contact surfaces **43***a* and **43***b* and the ball return holes **44***a* and **44***b* corresponding thereto are connected by ball change-direction paths **51** formed in each of the covers **5** resulting in the formation of an endless circulation path for the balls **3**.

With the above structure, each of the balls **3** which have borne a load between the ball rolling contact surfaces **11***a* and **11***b* of the orbital rail **1** and the load rolling contact surfaces **43***a* and **43***b* of the mobile block **4** is released from the load when it has rolled on the load rolling contact surfaces **43***a* and **43***b* following the movement of the slider **2**, so that the ball **3** enters the change-direction path **51** of one of the pair of the covers **5** and moves toward a direction reverse to the direction of rolling of the ball on the load rolling contact surfaces **43***a* and **43***b* in a no-load condition so as to roll through the ball return holes **44***a* and **44***b* of the mobile block **4**. Further, each of the balls **3** which has rolled through the ball return holes **44***a* and **44***b* enters again between the orbital rail **1** and the mobile block **4** through the change-direction path **51** of the other cover **5** and rolls on the load rolling contact surfaces **43***a* and **43***b* while it bears a load.

Further, on both sides of each of the load rolling contact surfaces **43***a* and **43***b* there are formed ball retaining sections **45** so as to hang over the load rolling contact surfaces **43***a* and **43***b* and when the slider **2** is removed from the orbital rail **1**, the balls **3** on the load rolling contact surfaces **43***a* and **43***b* are prevented from falling down from the slider **2**.

Further, in the instant embodiment, from the point of view of preventing as much as possible the abrasion of the balls by keeping the balls out of contact with one another within the endless ball circulation path, the balls **3** are fitted into a belt-like cage **7** made of a synthetic resin to thereby form a ball chain and such ball chain is assembled into the endless ball circulation path. For this purpose, each of the ball return holes **44***a* and **44***b* and each of the ball retaining sections **45** are provided with grooves for supporting both edges of the above-mentioned belt-like cage **7** which circulates through the endless ball circulating path together with the balls **3**.

In addition, as shown in FIG. **3**, on the front and rear end surfaces of the mobile block **4** there are provided semicircular ball guides **46**, respectively, so as to guide each of the balls **3** coming into, and getting away from, the ball return holes **44***a* and **44***b*, side by side with the change-direction paths **51** of the pair of covers **5**.

The mobile block **4** is formed by padding a synthetic resin to the metallic block main body **8** by an injection-molding process such that the portions such as the movable body fitting surface **41** and the load rolling contact surfaces **43***a* and **43***b* for the balls **3** where a mechanical strength is required are formed in the block main body **8** while the portions such as the ball return holes **44***a*, **44***b*, the ball retaining sections **45** and the ball guide sections **46** where the mechanical strength is not deemed important are made of a synthetic resin so as to make the weight of the mobile block **4** as small as possible.

FIG. **5** is a front view of the block main body **8** before it is padded with a synthetic resin. Such block main body **8** is finished in such a manner that the horizontal section **4***a* and the skirts **4***b* are roughly formed by drawing, then the movable body fitting surfaces **41**, reference side surfaces **47** and the load rolling contact surfaces **43***a* and **43***b* are formed

to have a predetermined degree of accuracy and through holes **48** as prepared holes for the ball return holes **44***b* are formed by drilling. Further, in the above-mentioned drawing process, in order to improve the adhesion of the synthetic resin to be padded to the block main body **8**, concave portions **49** serving as resin reservoirs are formed on the outer sides of the skirts **4***b*, respectively.

In the above case, in view of the fact that the synthetic resin is padded around the skirts **4***b* of the block main body **8** at the time of injection molding to be performed later, substantially curved chamfered sections **50***a* are formed at the corners of the front and rear end surfaces of each of the skirts **4***b* with the exception of the portions where the load rolling contact surfaces **43***a* and **43***b* are formed so that the molten synthetic resin at the time of injection molding is made to flow smoothly.

Next, the process of padding a synthetic resin, by injection-molding, to the block main body **8** finished to a predetermined shape as described above will be explained.

This injection molding is performed by the so called insert molding in which the finished block main body **8** is arranged within a mold so as to act as a core whereby the synthetic resin is padded only to a predetermined portion of the block main body **8** to thereby form the above-mentioned ball return holes **44***a* and **44***b*, the ball retaining sections **45**, the ball guide sections **46** and etc.

FIG. **7** is a sectional view of the block main body **8** inserted into a mold comprising dies **61** and **62**. The die **61** has a support **63** erected thereon so as to fix the block main body **8** thereto and when the block main body **8** is caused to fit about the support **63** from the direction of axis of the block main body **8** (i.e., the vertical direction in FIG. **7**), the block main body **8** is positioned between the dies **61** and **62** so that cavities **64** and **65** corresponding to the ball retaining sections **45** of the mobile body **4** are formed between the block main body **8** and the support **63** and at the same time, cavities **66** for forming the ball return holes **44***a* are formed between the skirts **4***b* and the die **61**. Further, into the through holes **48** of the block main body **8** and into the cavities **66** there are inserted rod-shaped die members **67** each having a sectional configuration coinciding with the shape of the ball return holes **44***a* and **44***b* so that when the molten synthetic resin is filled into these through holes **48** and the cavities **66**, the ball return holes **44***a* and **44***b* are formed.

Further, the die **61** is in contact with the lower edges of the reference side surfaces **47** of the block main body **8** whereby the molten synthetic resin to be filled into the cavities **66** is cut well to thereby prevent the synthetic resin from covering the reference side surfaces **47**.

In the instant embodiment, the filling of the molten synthetic resin into the cavities **64**, **65** and **66** is performed from a direction parallel to the load rolling contact surfaces **43***a* and **43***b* formed in the block main body **8** so that the molten synthetic resin flows quickly up to the innermost portions of the cavities **64**, **65** and **66** which extend long toward that direction.

Thus, after the block main body **8** has been inserted between the dies **61** and **62**, when the molten synthetic resin is filled into the cavities **64**, **65** and **66** so as to be padded on the block main body **8**, the mobile block **4** shown in FIG. **3** is completed.

FIG. **8** is a sectional view of the mobile block **4** finished by the above-described process especially in a state in which the mobile block **4** is padded with a synthetic resin wherein FIG. **8**(*a*) is a sectional view of the skirt **4***b* when taken along the A—A line of FIG. **4** and FIG. **8**(*b*) is a sectional view of the horizontal section **4***a* when taken along the B—B line of FIG. **4**. As will be clear from these figures, chamfered sections **50***a* are formed on the front and rear end surfaces of the skirt **4***b* of the block main body **8** and chamfered sections **50***b* are formed also at the opening edges of the through holes **48** formed in the horizontal section **4***a* so that when the molten synthetic resin is filled into the mold in the above-described insert-molding process, the molten synthetic resin spreads quickly around the skirts **4***b* and flows inside the through holes **48**.

Consequently, the equalization of thickness of the synthetic resin forming the ball return holes **44***a*, **44***b* and the ball retaining sections **45** is promoted so that it is possible to prevent as much as possible the deformation or distortion of the ball return holes **44***a* and **44***b* and the ball retaining sections **45** at the time of solidification of the contracted synthetic resin thereby increasing the dimensional accuracy of the endless ball circulation path formed by these elements. Further, it is also possible to prevent the generation of a weld line of the synthetic resin within such endless circulation path. As a result, the slider **2** assembled by using the mobile block **4** manufactured by the above-described process allows the balls **3** to smoothly roll within the endless ball circulation path and the slider **2** itself can smoothly move on the orbital rail **1**.

Further, since the chamfered sections **50***a* are formed on the front and rear end surfaces of the skirts **4***b* of the block main body **8**, respectively, even when the synthetic resin which forms the endless ball circulation path by being padded around each of the skirts **4***b* contracts after the completion of the injection-molding process, there is no possibility of the synthetic resin getting cracked and also due to this advantage, the rolling of the balls **3** in the endless ball circulation path can be made smooth.

INDUSTRIAL APPLICABILITY

As described above, according to the method of manufacture of the slider of the rectilinear guide unit of the present invention, even when the endless circulation path for the balls is formed by padding a die-molding material around the block main body, since the corners of the block main body corresponding to the endless ball circulation path are substantially curved, the endless ball circulation path made of the die-molding material does not crack so that it is possible to secure the smooth endless circulation of the balls and hence the smooth movement of the slider.

Further, by making the corners of the block main body substantially curved, the molten die-molding material flows quickly around the block main body at the time of molding and the equalization of thickness of the ball return holes and the ball retaining sections forming the endless ball circulation path is promoted. Consequently, the deformation or distortion of the ball return holes or the ball retaining sections is prevented to thereby increase the dimensional accuracy of the endless ball circulation path so that it is possible to secure the smooth circulation of the balls and hence the smooth movement of the slider with respect to this point, too.

What is claimed is:

1. A method of manufacture of a slider of a rectilinear guide unit, which method comprising:

machining a metallic block main body as a core of the slider to a predetermined shape having ball load rolling contact surfaces in the block main body:

positioning the block main body into a mold; and

molding a body portion onto the block main body for forming an endless ball circulation path using a die-molding material;

further comprising during said machining, forming chamfered sections on front and rear edge corners of the block main body corresponding to a portion where the endless ball circulation path is formed during the molding, said chamfered sections being covered by the die-molding material following the molding, whereby smooth flow of the die-molding material occurs during the molding.

2. The method according to claim **1**, wherein, in said molding, a molten die-molding material is injected from a direction parallel to the ball load rolling contact surfaces of the block main body inserted into a mold.

3. In a slider for a rectilinear guide unit including a metallic block main body having ball load rolling contact surfaces and a molded body portion on the block main body for endlessly circulating balls so that an endless ball circulation path is formed by said molding, the improvement wherein molding-flow-smoothing chamfered sections are formed on front and rear corners of the block main body corresponding to a portion where the endless ball circulation path is formed and are covered by said molded body portion.

METHOD OF MAKING A SLIDER OF A LINEAR GUIDE DEVICE

FIELD OF THE INVENTION AND RELATED ART STATEMENT

The present invention relates to a method of making a slider of a linear guide device for guiding a movable body such as a work table of a machine tool or an industrial robot or the like moving along a track rail arranged at a fixed portion such as a bed, a column or the like while applying load on the track rail, particularly to a method of forming a slider by building up a synthetic resin onto a block main body mace of a metal.

There has been known a conventional linear guide device of such a kind constituted by a track rail that is arranged at a fixed portion such as a bed or the like and on which rolling faces of balls are formed and a slider integrated to the track rail via a number of balls for moving along the track rail while supporting a movable body such as a table or the like.

Further, the above-described slider is constituted by a movable block having load rolling faces opposed to the rolling faces of the track rail via balls and ball return holes in parallel to the load rolling faces, which is movable along the track rail by rolling the balls, a pair of end caps respectively fixed to forward and backward end faces of the moving block and having direction change paths of the balls for communicating and connecting the load rolling faces with the ball return holes and ball retainers attached to the moving block for preventing the balls from coming off from the load rolling faces when the slider is removed from the track rail. Also, end portions of the load rolling faces and the ball return holes are connected by the direction change paths by fixing the end caps to the forward and rearward end faces of the moving block whereby infinite circulation paths of balls are completed in the slider.

Meanwhile, according to the conventional slider for the linear guide device constituted as described above, boring of the ball return hole, attaching operation of the ball retainers and the like are needed with respect to the moving block and considerable time and labor is required in manufacturing the slider. Therefore, the applicants have proposed to manufacture the slider by utilizing an injection molding process of a synthetic resin (Japanese Unexamined Patent Publication No. JP-7-317762).

Specifically, a synthetic resin is built up by injection molding onto a block main body made of a metal where the above-described load rolling faces have been ground and the ball return holes and the ball retainers are integrally formed with the block main body in the injection molding by which the moving block is manufactured, which is provided with an advantage whereby a moving block having a complicated shape can easily he manufactured.

Meanwhile, in building up a synthetic resin onto the block main body made of a metal, the ball retaining portions are formed on the both sides of the load rolling faces of the block main body as described above, where it is necessary to expose the load rolling faces per se on which the balls run without putting the synthetic resin on the load rolling faces. Therefore, it is necessary to cover the load rolling faces against the molten synthetic resin in the injection molding.

Accordingly, conventionally, in fixing the block main body in the mold of the injection molding, a projected support portion provided on the side of the mold is brought into contact with the load rolling faces of the block main body and the load rolling faces are covered against the molten synthetic resin by the projected support portion.

However, when the load rolling faces are covered by bringing the projected support portion of the mold into direct contact with the load rolling faces, since the load rolling faces are formed in a curved face corresponding to the curvature of the ball, it is necessary to form the projected support portion in contact with the load rolling faces also in a curved face in compliance with the curvature of the load rolling faces and if the curved faces of both are not brought into accurate alignment, the molten synthetic resin forming the retainers invades a clearance therebetween.

Furthermore, when the molten synthetic resin invades the clearance between the load rolling faces and the projected support portion of the mold, the molten synthetic resin constitutes burrs of the synthetic resin covering the load rolling faces and the smooth running of the balls is significantly hampered under such a state. Also, once the ball retainers are formed on the both sides of the load rolling faces, the load rolling faces cannot be polished since the ball retainer becomes a hazard for the polishing operation and therefore, the constituted burrs cannot be removed. Accordingly, in the method of manufacturing the moving block utilizing the injection molding, a countermeasure for preventing the occurrence per se of burrs covering the load rolling face is indispensable.

Meanwhile, it is preferable to set the block main body to the mold with the load rolling faces which have been formed, as positioning references in fixing the block main body in injection molding, since the ball retaining portions are needed to form accurately in the positional relationship thereof with the load rolling faces.

However, it is difficult to position the block main body by bringing the load rolling faces in contact with the projected support portion on the side of the mold, which is also formed in a curved face since the load rolling faces are formed in a curved face as described above. Especially, when the load rolling faces face in different four directions, it is extremely difficult to accurately position the block main body in the mold.

Also, when the projected support portion of the mold is brought into contact with the load rolling faces, the load rolling faces which have been grounded in the finishing operation may be damaged with high probability and the grinding operation of the block main body prior to the injection molding operation may completely be spoilt.

OBJECT AND SUMMARY OF INVENTION

The present invention has been carried out in view of such a problem and it is an object of the present invention to provide a method of making a slider of a linear guide device in which in forming the slider of the linear guide device installed with ball return holes and ball retaining portions by building up a synthetic resin onto a block main body made of a metal, the synthetic resin does not bring about burrs on load rolling faces of the block main body and the ball return holes and the retainers can be formed accurately.

In order to achieve the above-described object, a method of making a slider according to the present invention is comprising a first step of forming a block main body made of a metal which becomes a core part of the slider in a predetermined shape by machining and forming load rolling faces of balls on the block main body, and a second step of inserting the block main body formed in the first step into a mold and executing an injection molding of a synthetic resin whereby ball retaining portions are built on both sides of the load rolling faces of the block main body, wherein according to the first step pairs of smooth faces for shielding the molten synthetic resin are formed on both edges in the longitudinal direction of the load rolling faces formed on the block main body, whereas according to the second step the block main body is fixed at a predetermined position in the mold by bringing a projected support portion erected on the mold into contact with the smooth faces for shielding the molten synthetic resin.

As describe above, in forming the ball retaining portions on the both sides of the load rolling faces by utilizing the injection molding of a synthetic resin, it is necessary to prevent the molten synthetic resin from invading the load rolling faces. According to the invented method having the above-described steps, with respect to the main body fixed in the mold the pairs of faces for shielding the synthetic resin formed along the both edges of the load rolling faces are brought into contact with the projected support portion erected on the mold and therefore, the molten synthetic resin for forming the ball retaining portions can be prevented from flowing to the load rolling faces by the smooth faces for shielding the molten synthetic resin. Moreover, the smooth faces for shielding a molten synthetic resin are not formed in a curved face as in the load rolling faces but in a smooth face and therefore, no clearance is formed between the smooth faces for shielding the molten synthetic resin and the projected support portion of the mold which are brought into contact with each other and the molten synthetic resin can firmly be prevented from invading the load rolling faces. Therefore, according to the invented method formation of burr of the synthetic resin on the load rolling faces can firmly be prevented.

Meanwhile, when the slider made by this method is observed, it is recognized that the pairs of smooth faces for shielding the molten synthetic resin mold which become positioning references for fixing the main body in the injection molding and which are disposed between the load rolling faces and the ball retaining portions on the both sides of the load rolling faces, are exposed without being covered by the ball retaining portions. Accordingly, whether a slider is made by the invented method, can be determined by whether the pairs of faces for shielding the molten synthetic resin, which has been finished smoothly to a degree whereby they can be utilized as positioning references, are exposed on the both edges along the longitudinal direction of the load rolling faces. That is, according to another aspect of the present invention, there is provided a slider of a linear guide device wherein pairs of faces for shielding a molten synthetic resin which become references for fixing a block main body in injection molding, are exposed on both edges along the longitudinal direction of load rolling faces.

Also, according to the invented method, in the second step the block main body is positioned and fixed in the mold by bringing the projected support portion of the mold into contact with the smooth faces for shielding the synthetic resin and therefore, the positioning accuracy of the block main body in the mold is promoted in comparison with the conventional case in which the positioning is carried out by using the load rolling faces in a curved face whereby the positioning relationship between the ball retaining portions built up on the block main body by injection molding and the load rolling faces can be made accurate. Thereby, it can be prevented that noise is caused due to contact of the balls running on the load rolling faces with the ball retaining portions or the circulation of the balls becomes unstable in using the linear guide device.

Further, according to the invented method the block main body is fixed in the mold by bringing the projected support portion of the mold into contact with the faces for shielding the synthetic resin. It is preferable in this procedure that the projected support portion is brought into contact with the faces for shielding the molten synthetic resin which are formed on the both edges to span across the load rolling faces whereby spaces are formed between the projected support portion and the load rolling faces. The reason is that according to the invented method the machining of the load rolling faces are completed in the first step prior to the injection molding and therefore, if the projected support portion in the mold is brought into contact with the load rolling faces in the second step, the load rolling faces which have been finished with a predetermined face accuracy will be roughened.

As described above, according to the invented method the both edges of load rolling faces of the block main body which becomes a core part of a slider, are formed with the pairs of smooth faces for shielding the molten synthetic resin and in the step of the insert molding for building the synthetic resin on the block main body the faces for shielding the molten synthetic resin and the projected support portion erected on the mold are brought into contact. Therefore, the formation of burrs of the synthetic resin on the load rolling faces through the process of the insert molding can be prevented and the ball retaining portions can be formed accurately on the block main body whereby the slider of a linear guide device on which the balls run smoothly and in which generation of noise accompanied by the circulation of the balls is restrained as less as possible, can be manufactured.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a partially cut front view showing an embodiment of a linear guide device manufactured by the invented method;

FIG. **2** is a partially cut side view showing the embodiment of the linear guide device manufactured by the invented method;

FIG. **3** is an exploded perspective view of a slider in accordance with the embodiment;

FIG. **4** is a sectional view taken along a line IV—IV of FIG. **3**;

FIG. **5** is a perspective view showing a block main body constituting a core part of a moving block according to the embodiment;

FIG. **6** is a sectional view taken along a line VI—VI of FIG. **5**;

FIG. **7** is a front view showing a behavior of grinding operation on load rolling faces and smooth faces with respect to the block main body;

FIG. **8** is an enlarged view showing details of a region encircled by a circle A described by a broken line in FIG. **6**;

FIG. **9** is a sectional view showing the block main body inserted into a mold; and

FIG. **10** is an enlarged view showing details of a region encircled by a circle B drawn by a broken line in FIG. **9**.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

A detailed explanation will be given of a method of making a slider of a linear guide device according to the present invention in reference to the attached drawings as follows.

FIG. **1** and FIG. **2** illustrate an embodiment of a linear guide device in which a slider manufactured by the invented method is integrated with a track rail. In FIGS. **1** and **2**, numeral **1** designates a track rail arranged to a fixed portion such as a bed or the like of a machine tool, numeral **2** designates a slider for guiding a movable body such as a table or the like along the track rail **1** and numeral **3** designates a ball rolling under load between the track rail **1** and the slider **2** and infinitely circulated in the slider **2**.

Firstly, the section of the track rail **1** is formed in substantially a square shape in which a total of four tracks of ball rolling face **11***a* and **11***b* on which the balls **3** run, are formed along the longitudinal direction (orthogonal to the paper face of FIG. **1**). These ball rolling faces **11***a* and **11***b* are formed on the both side faces and the both edge portions of the upper face of the track rail **1** in which the ball rolling faces **11***a* on the both side faces are formed **30** downwardly from the left and right direction of the paper face whereas the ball rolling faces **11***b* on the upper face are formed upwardly in the vertical direction. Further, bolt attaching holes **12** are formed in the track rail **1** at pertinent intervals in the longitudinal direction and the track rail **1** is fixed to a fixed portion by fixing bolts, not illustrated, which are inserted into the bolt attaching holes **12**.

Meanwhile, the slider **2** is constituted by a moving block **4** having an attaching face **41** for attaching a movable body such as a table or the like and tap holes **42** for screwing fixing bolts of the movable body and a pair of end caps **5** fixed to the foreword and rearward end faces of the moving block **4** and infinite circulation paths of the balls **3** are provided in the slider by fixing the end caps **5** to the moving block **4**. Further, seal members **6** which are brought into abrasive contact with the track rail **1** are attached to the end caps **5** for preventing dust or dirt attached onto the track rail **1** from invading the inside of the slider **2** accompanied by the movement of the slider **2**.

As illustrated in FIG. **3** and FIG. **4**, the moving block **4** is provided with a horizontal portion **4***a* where the attaching face **41** is formed and a pair of skirt portions **4***b* hanging down from the horizontal portion **4***a* and the section thereof is formed in substantially a saddle form and four tracks of load rolling faces **43***a* and **43***b* are formed on the lower face of the horizontal portion **4***a* and on the inner faces of the respective skirt portions **4***b* opposingly to the ball rolling faces **11***a* and **11***b* of the track rail **1**. Also, ball return holes **44***a* and **44***b* respectively corresponding to the load rolling faces **43***a* and **43***b* are formed at the horizontal portion **4***a* and the skirt portions **4***b* and the respective load rolling faces **43***a* and **43***b* and the corresponding ball return holes **44***a* and **44***b* are connected by direction change paths **51** of the balls **3** formed in the end caps **5** thereby forming the infinite circulation paths of the balls.

Thereby, when the balls **3** which have been under load between the rolling faces **11***a* and **11***b* of the track rail **1** and the load rolling faces **43***a* and **43***b* of the moving block **4**, finish running on the load rolling faces **43***a* and **43***b* with the movement of slider **2**, they are relieved from the load and enter the direction change paths **51** of one of the end caps **5**, and run under no load in the ball return holes **44***a* and **44***b* of the moving block **4** toward a direction reverse to the running direction at the load rolling faces **43***a* and **43***b*. Further, the balls **3** which have finished running in the ball return holes **44***a* and **44***b*, enter again between the track rail **1** and the moving block **4** via the direction change paths **51** of the other one of the end caps **5** and run on the load rolling faces **43***a* and **43***b* under load.

Further, ball retaining portions **45** are formed on the both sides of the respective load rolling faces **43***a* and **43***b* as if covering the load rolling faces **43***a* and **43***b* thereby preventing the balls **3** which are disposed on the load rolling faces **43***a* and **43***b* from rolling down from the slider **2** when the slider **2** is removed from the track rail **1**.

Further, according to the embodiment, in view of avoiding contact among balls in the infinite circulation paths and preventing as less as possible the wear of the balls **3**, ball chains are constituted by rotatably fitting the balls **3** in belt-like cages **7** made of a synthetic resin and the ball chains are integrated to the infinite circulation paths. Therefore, recessed grooves for supporting the both edge portions of the belt-like cages **7** circulating in the infinite circulation paths along with the balls **3**, are formed in the hall return holes **44***a* and **44***b* and the ball retaining portions **45**.

Furthermore, as illustrated in FIG. **3**, ball guide portions **46** in a semicircular shape are projected at the foreword and rearward end faces of the moving block **4** for guiding the balls **3** entering and leaving the ball return holes **44***a* and **44***b* in cooperation with the direction change paths **51** of the end caps **5**.

The moving block **4** is formed by building by injection molding a synthetic resin onto the block main body **8** made of a metal which is formed by mechanical working. Portions requiring mechanical strength such as the movable body attaching face **41**, the load rolling faces **43***a* and **43***b* of the balls **3** and the like, are formed in the block main body **8**, whereas portions with no significance in mechanical strength such as the ball return holes **44***a* and **44***b*, the ball retaining portions **45** and the hall guide portions **46** and the like, are formed by a synthetic resin whereby light weight formation of the moving block **4** is achieved as light as possible. FIG. **5** and FIG. **6** show the block main body **8** before building a synthetic resin thereon. According to the block main body **8**, after the outline shape of the horizontal portion **4***a* and the skirt portions **4***b* has been formed by drawing, the movable body attaching face **41** and reference side faces **47** are formed with a predetermined accuracy by polishing and through holes **48** which become base holes for the ball return holes **44***b*, are formed by boring. Further, in the drawing process, recessed portions **49** which become resin storages are formed on the outer side of the skirt portions **4***b* with a purpose of promoting adherence of a synthetic resin which is to be built in later steps with respect to the block main body **8**.

The load rolling faces **43***a* and **43***b* are needed to form on the block main body **8** and the load rolling faces **43***a* and **43***b* are formed as illustrated in FIG. **7** after forming the movable body attaching face **41** and the reference side faces **47**. That is, the movable body attaching face **41** and the reference side faces **47** which have already been formed, are brought into contact with attaching reference faces of a polishing stage **9** thereby fixing the block main body **8**, under which the grindstone **10** is brought into contact with the block main body **8** whereby the load rolling faces **43***a* and **43***b* are polished. At this occasion the load rolling faces **43***a* and **43***b* are polished in one machining operation by using the same grindstone **10** in order to render accurate the positional relationship among the load rolling faces **43***a* formed at the skirt portions and the load rolling faces **43***b* formed at the horizontal portion.

FIG. **8** is an enlarged view showing the surroundings of the load rolling faces **43***a* and **43***b* which have been polished. According to the polishing operation using the grindstone **10** not only the load rolling faces **43***a* and **43***b* are formed but pairs of smooth faces **50** are formed along both edges in the longitudinal direction of the respective load rolling faces.

That is, the grindstone **10** is a formed polishing grindstone having a shape reverse to the shape of the load rolling faces **43***a* and **43***b* and the smooth faces **50** and the smooth faces **50** are formed with a constant positional accuracy in respect of the load rolling faces **43***a* and **43***b* which are disposed contiguously to the smooth faces **50**.

In steps of injection molding of a synthetic resin, mentioned later, the smooth faces **50** function as positioning reference faces of the block main body **8** in the mold and are used as measuring reference faces in measuring whether the load rolling face **43***a* and **43***b* are formed with a predetermined dimensional accuracy.

Next, an explanation will be given of a step of building a synthetic resin by injection molding onto the block main body **8** which has been finished in a predetermined shape in this way.

The injection molding is executed by a process in which the block main body **8** all the machining of which has been finished, is arranged in a mold as a core, which is referred to as insert molding, whereby a synthetic resin is built only at predetermined positions of the block main body **8** by which the ball return holes **44***a* and **44***b*, the ball retaining portions **45** and the like, are formed.

FIG. **9** is a sectional view showing the block main body **8** which is inserted into molds **61** and **62**. A projected support portion **63** for fixing the block main body **8** is erected on the mold **61** and positioning of the block main body **8** in the molds **61** and **62** is carried out by fitting the block main body **8** in respect of the projected support portion **63** from the axial direction (orthogonal to paper face) and cavities **64** and **65** corresponding to the ball retaining portion **45** of the moving block **4** are formed between the block main body **8** and the projected support portion **63** whereas cavities **66** for forming the ball return holes **44***a* are formed between the skirt portions **4***b* of the block main body **8** and the mold **61**. Further, rod-like mold bodies **67** having a sectional shape in agreement with the shape of the ball return holes **44***a* and **44***b*, are inserted into the through holes **48** of the block main body **8** and the cavities **66** by which the ball return holes **44***a* and **44***b* are formed when the molten synthetic resin is filled in the through holes **48** and the cavities **66**.

Also, the mold **61** is brought into contact with the lower end edges of the reference side faces **47** of the block main body **8** by which the shielding of the molten synthetic resin filled in the cavities **66** is carried out and the synthetic resin is prevented from covering the reference side faces **47**.

Meanwhile, FIG. **10** is an enlarged view showing details of a state of contact between the projected support portion **63** and block main body **8**. When the synthetic resin is put on the load rolling faces **43***a* and **43***b* formed on the block main body **8**, it becomes a hazard against the running of the balls **3** and therefore, it is required in such an insert molding that shielding of the molten synthetic resin is firmly carried out between the load rolling faces **43***a* and **43***b* and the contiguous cavities **64, 65** and **66**. Accordingly, in fitting the block main body **8** to the projected support portion **63**, the projected support portion **63** is brought into contact with the smooth faces **50** which are formed on the both edges of the load rolling faces **43***a* and **43***b* whereby the shielding the molten synthetic resin filled in the cavities **64, 65** and **66** is carried out. Further, the projected support portion **63** is brought into contact with the smooth faces **50** to span across the load rolling faces **43***a* and **43***b* to prevent the load rolling faces **43***a* and **43***b* which have been finished in a predetermined accuracy from damaging by the contact with the projected support portion **63**.

Further, after inserting the block main body **8** into the molds **61** and **62**, the molten synthetic resin is filled in the cavities **64, 65** and **66** formed by the block main body **8** and the mold **61** and the synthetic resin is built on the main body **8** whereby the moving block as illustrated by FIG. **3** and FIG. **4** is completed.

According to the step of the insert molding which is carried out as has been described above, in positioning the block main body **8** in the mold **61** in this embodiment, the projected support portion **63** erected on the mold **61** for fitting to the block main body **8**, is brought into contact with the pairs of smooth faces **50** which are formed along the both edges of the load rolling faces. Therefore, the following advantages is achieved in comparison with the conventional manufacturing method in which the positioning of the block main body is carried out by bringing the projected support portion in direct contact with the load rolling faces.

That is, the smooth faces **50** are formed by polishing them simultaneously with the load rolling faces **43***a* and **43***b* and therefore, the accuracy of the formed positions and the smoothness are significantly excellent and by bringing the projected support portion **63** into contact with the smooth faces **50** which have been formed with such a high accuracy, the projected support portion **63** and the smooth faces **50** are brought into close contact with each other whereby the molten synthetic resin can be shielded with certainty by the smooth faces **50**. Therefore, according to the moving block **4** manufactured by the method of this embodiment, no burr of synthetic resin is caused on the load rolling faces **43***a* and **43***b* whereby smooth running of hall can be guaranteed.

Also, it is possible to promote the positioning accuracy of the block main body **8** inserted into the molds **61** and **62** by bringing the projected support portion **63** into contact with the smooth faces **50** which have been formed with high accuracy, whereby the locations of forming the ball retaining portions **45** in respect of the load rolling faces **43***a* and **43***b* of the block main body **8** are made accurate. Therefore, the balls **3** running on the load rolling faces **43***a* and **43***b* can be prevented from being brought into contact with the ball retaining portions **45** and generation of noise can be avoided as less as possible in circulating the balls **3**.

Incidentally, according to the embodiment, when the block main body **8** is inserted into the molds **61** and **62**, the load rolling faces **43***a* and **43***b* with a predetermined accuracy prior to the insert molding, are not damaged by the step of the insert molding since spaces are formed between the load rolling faces **43***a* and **43***b* and the projected support portion **63** whereby the smooth running of the balls **3** can be guaranteed.

What is claimed is:

1. A method of making a slider of a linear guide device comprising:

a first step of forming a block main body made of a metal which becomes a core part of the slider in a predetermined shape by machining and forming load rolling faces of balls on the block main body;

a second step of inserting the block main body formed by the first step into a mold and executing an injection molding of a synthetic resin by which ball retaining portions are built up on both sides of the load rolling faces of the block main body;

wherein pairs of smooth faces for shielding the molten synthetic resin are formed along both edges in a longitudinal direction of the load rolling faces formed in the block main body in the first step; and

wherein the block main body is fixed at a predetermined position in the mold by bringing a projected support portion erected on the mold into contact with the smooth faces for shielding the molten synthetic resin in the second step.

2. The method of making a slider of a linear guide device according to claim **1**, wherein spaces are formed between the load rolling faces of the block main body and the projected support portion of the mold when the block main body is fixed into the mold in the second step.

[57] **ABSTRACT**

A ball connecting body in which a multiplicity of balls are arranged in a line at a predetermined interval and in a freely rotating manner. The ball connecting body is installed and used in a ball endless track of a ball screw apparatus in which a screw shaft and a nut member are meshed with each other through a multiplicity of balls. The ball connecting body is constituted by a multiplicity of balls circulating on a substantially circular ring-like ball endless track provided in a bearing apparatus, and a flexible connecting body belt arranging the balls in a line at a predetermined interval and holding each of the balls in a freely rotating manner. Further, the connecting body belt is constituted by a plurality of spacer portions inserted between the mutually adjacent balls and having a spherical seat for bringing the balls into contact therewith formed, and a flange-like connecting band portion mutually connecting the spacer portions so as to outwardly surround the spacer portions, and is formed in a substantially circular ring shape at a time of arranging the balls.

BALL CONNECTING BODY AND BALL SCREW APPARATUS USING THE SAME

TECHNICAL FIELD

The present invention relates to a ball connecting body in which a multiplicity of balls are arranged in a line at a predetermined interval and in a freely rotating manner, and more particularly to a ball connecting body installed and used in a ball endless track of a ball screw apparatus in which a screw shaft and a nut member are meshed with each other through a multiplicity of balls and a ball screw apparatus using the same.

BACKGROUND OF THE INVENTION

A ball screw apparatus is frequently used in a straight sliding portion of an industrial robot, and is mainly used for a purpose of giving a straight moving amount in accordance with a rotating amount of a motor to a movable body such as a table. Such a ball screw apparatus is generally constituted by a screw shaft having a spiral ball rolling groove formed on an outer peripheral surface, and a nut member meshed with the screw shaft through a multiplicity of balls and provided with an endless track on which the balls circulate, and is structured such that when the screw shaft is connected to the motor and is rotated, a multiplicity of balls interposed between the screw shaft and the nut member circulate within the endless track provided in the nut member, and the nut member lightly performs a straight movement in an axial direction of the screw shaft in order to this.

On the contrary, in this kind of ball screw apparatus, each of the balls circulating within the ball endless track is mutually brought into contact with the balls positioned in front of and at the rear of the ball, whereby there are disadvantages such that the ball is prevented from smoothly circulating and a contact noise between the balls is rasping at a high rotation of the screw shaft, and as a structure for solving the disadvantages, a ball screw apparatus disclosed in Japanese Unexamined Utility Model Publication No. 5-27408 is suggested.

In the ball screw apparatus disclosed in the publication, a band-like retainer having a flexibility is provided within a ball endless track of a nut member in such a manner as to be capable of circulating and moving, and a ball pocket for receiving a ball is arranged in such a band-like retainer at a predetermined interval. Accordingly, the balls are received in the ball endless track of the nut member in a state of being arranged in the band-like retainer at a predetermined interval, whereby in the ball screw apparatus, the balls circulating within the endless track are prevented from being mutually brought into contact with each other.

In this case, as a structure of forming the ball endless track in the nut member of the ball screw apparatus, as shown in Japanese Unexamined Utility Model Publication No. 5-27408 mentioned above, a structure in which a ball circulating pipe for jumping over some winds of ball rolling grooves in the screw shaft is provided and a ball endless track is constructed with including some winds of ball rolling grooves, and as shown in FIG. **11**, a deflector **103** for scooping up a ball **102** from a ball rolling groove **101** in the screw shaft **100** is fitted to an inner peripheral surface of a nut member **104** and the ball **102** rolling on the ball rolling groove **101** of the screw shaft **100** is returned only for a wind of the ball rolling groove **101** through the deflector **103** have been known.

In the former structure using the ball circulating pipe, since the pipe is formed to have a length such as to jump over some winds of ball rolling grooves and is relatively gently curved, even when the band-like retainer mentioned above is assembled in the ball endless track and circulated, the band-like retainer can be smoothly inserted to the ball circulating pipe by curbing the band-like retainer after bending it within the pipe in a proper direction.

However, in the structure using the latter deflector, although the ball endless track is formed in a substantially circular ring shape corresponding to a wind of the ball rolling groove, the ball rolling in an inner portion of the deflector suddenly displaces in an axial direction of the screw shaft only for a lead of the ball rolling groove, so that in the case of assembling the band-like retainer of Japanese Unexamined Utility Model Publication No. 5-27408 formed in a band plate shape in the ball endless track as it is, the band-like retainer is forcibly curbed in the inner portion of the deflector. Accordingly, there is a risk that the band-like retainer can not smoothly circulate in the inner portion of the ball endless track.

DISCLOSURE OF THE INVENTION

The present invention is made by taking the problems mentioned above into consideration, and an object of the invention is to provide a ball connecting body applicable to a ball screw apparatus in which a screw shaft and a nut member are meshed with each other through a multiplicity of balls, and a substantially circular ring-like ball endless track is constructed by using a deflector, and capable of smoothly circulating within the ball endless track.

Further, another object of the invention is to provide a ball screw apparatus which can achieve a smooth ball circulation by assembling such a ball connecting body.

Accordingly, in accordance with the invention, there is provided a ball connecting body comprising a multiplicity of balls circulating on a substantially circular ring-like ball endless track provided in a bearing apparatus; and a flexible connecting body belt arranging the balls in a line at a predetermined interval and holding each of the balls in a freely rotating manner; wherein the connecting body belt is constituted by a plurality of spacer portions inserted between the mutually adjacent balls and having a spherical seat for bringing the balls into contact therewith formed; and a flange-like connecting band portion mutually connecting the spacer portions in such a manner as to outwardly surround the spacer portions; and the connecting body belt is formed in a substantially circular ring shape at a time of arranging the balls in the connecting body belt.

Further, the ball connecting body of the invention as structured in the above manner is approximately applied to, for example, a ball screw apparatus comprising a screw shaft having a spiral ball rolling groove formed on an outer peripheral surface; a nut member having a load rolling groove opposite to the ball rolling groove of the screw shaft on an inner surface and meshed with the screw shaft through a multiplicity of balls rolling with applying a load between the ball rolling groove and the load rolling groove; a deflector fitted to the inner peripheral surface of the nut, having a ball returning groove to return a ball rolling on said load rolling groove for a wind of the load rolling groove and forming a substantially circular ring-like ball endless track on which the balls circulate in an endless manner; and which is used in such a manner as to be assembled within the ball endless track and such that the ball applies a load between the load rolling groove of the nut member and the ball rolling groove of the screw shaft.

Since the ball connecting body in accordance with the invention is formed in a substantially circular ring shape at a time of arranging the ball in the connecting body belt, it is not necessary to circulate with forcibly curbing the connecting body belt even in the case of assembling it within the substantially circular ring-like ball endless track provided in the ball screw apparatus, so that the ball connecting body can be smoothly circulated and the ball held by the connecting body belt can be smoothly circulated.

Further, since the connecting band portion of the a connecting body belt is formed in a flange shape outwardly surrounding each of the spacer portions, it can be flexibly bent in a direction perpendicular to a plane on which each of the spacer portions is arranged. Accordingly, even in the case that the ball rolling on the ball endless track is taken out from the ball rolling groove in the screw shaft through the deflector and jumps over the outer diameter portion of the screw shaft so as to move to the ball rolling groove before a lead, the connecting body belt can flexibly follow this, and can smoothly circulate in the inner portion of the ball endless track.

On the contrary, since the ball rolling on the ball endless track jumps over the outer diameter portion of the screw shaft at a time of passing through the ball returning groove formed in the deflector, it is desirable that the connecting body belt can be flexibly bent also with respect to a radial direction of the nut member so as to prevent the ball from moving in this manner. Accordingly, in view of this, it is preferable that the spherical seat formed in the spacer portions of the connecting body belt is formed in a recessed spherical surface having a curvature larger than a spherical surface of the ball so as to freely change a contact angel between each of the spacer portions and the ball.

Further, the ball connecting body in accordance with the invention can be connected in an endless manner after assembled in the ball endless track of the ball screw apparatus, however, in the case of taking an extension of the connecting body belt in a periodical use into consideration, it is preferable to use both end portions as a shape having an end in place of connecting them.

As mentioned above, since the ball connecting body in accordance with the invention can be formed in a substantially circular ring shape at a time of arranging the ball in the connecting body belt and can be flexibly bent with respect to a direction perpendicular to the plane on which each of the spacer portions is arranged, it is optimum to the ball screw apparatus in which the screw shaft and the nut member are meshed with each other through a multiplicity of balls and a substantially circular ring-like ball endless track is constructed by using the deflector, so that it can smoothly circulate therewithin at a time of being used by assembling in the ball endless track, thereby making it possible to smoothly circulate the ball and to smoothly perform a relative rotation between the screw shaft and the nut member.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a front elevational view which shows an embodiment of a ball connecting body in accordance with the invention;

FIG. **2** is a side elevational view of a ball connecting body in accordance with an embodiment;

FIG. **3** is a cross sectional view along a line III—III in FIG. **1**;

FIG. **4** is a partly cut-away perspective view showing an embodiment of a ball screw apparatus in which a ball connecting body shown in FIG. **1** is assembled;

FIG. **5** is a front elevational view which shows a deflector in accordance with a ball screw apparatus of an embodiment;

FIG. **6** is a bottom elevational view which shows a deflector in accordance with a ball screw apparatus of an embodiment;

FIG. **7** is a cross sectional view along a line VII—VII in FIG. **6**;

FIG. **8** is a cross sectional view along a line VIII—VIII in FIG. **6**;

FIG. **9** is a front cross sectional view showing a state in which a ball connecting body of an embodiment circulates on a ball endless track of a ball screw apparatus;

FIG. **10** is a plan view showing a state in which a ball connecting body of an embodiment circulates on a ball endless track of a ball screw apparatus; and

FIG. **11** is a partly cut-away perspective view which shows a conventional ball screw apparatus.

BEST MODE FOR CARRYING OUT THE INVENTION

A ball connecting body in accordance with the invention will be described in detail below with reference to the accompanying drawings.

FIGS. **1** and **2** show a first embodiment of a ball connecting body in accordance with the invention. The ball connecting body **1** is structured such as to be formed in a substantially circular ring-like by arranging a plurality of balls **3** in a synthetic resin connecting body belt **2** in a line at a predetermined interval, and the balls **3** can be freely rotated in a state of being held in the connecting body belt **2**.

The connecting body belt **2** is constituted by a plurality of spacer portions **4** interposed between the mutually adjacent balls **3** so as to prevent the balls from being in contact with each other, and a flange-like connecting band portion **5** mutually connecting the spacer portions **4** in such a manner as to outwardly surround the spacer portions **4**, in this embodiment, it is formed in a substantially C shape in which a part of the circular ring is cut away. Further, each of the spacer portions **4** is formed in a thin shape at an inner diameter end of the ball connecting body **1**, and on the contrary, is formed in a thick shape at an outer diameter end, thereby smoothly arranging the balls **3** in a circular ring-like manner at a time of arranging the ball **3** between the spacer portions **4**.

A recessed spherical seat **6** with which the ball is brought into contact is formed in each of the spacer portions **4**, and the ball **3** is held in the connecting body belt **2** by being held between a pair of spherical seats **6**. Further, a curvature of the spherical seat **6** is set to be slightly larger than a curvature of a spherical surface of the ball **3**, whereby a contact angle between the ball **3** and the spherical seat **6** can be freely changed at a certain degree. As a result, the ball connecting body **1** can be freely deformed at a certain degree with respect to a radial direction thereof.

As shown in FIGS. **2** and **3**, the connecting band portion **5** is formed in such a manner as to project outside the ball row arranged in a circular ring manner, as a result, the ball connecting body **1** can be freely bent to a direction (a direction shown by an arrow A in FIG. **2**) perpendicular to the plane on which the balls **3** are arranged.

Further, spacer portions **4*a*** and **4*b*** positioned at both ends of the connecting body belt **2** are formed in a steeple manner, and on the contrary, a front end of the connecting band portion **5** connected to these spacer portions **4*a*** and **4*b*** is also formed in a circular arc shape, thereby preventing the front end of the connecting body belt **2** from generating a hook portion within the ball endless track at a time when the ball connecting body **1** circulates the ball endless track of the ball screw apparatus.

The connecting body belt **2** is manufactured by an injection molding of a synthetic resin. In such an injection molding, a plurality of dummy balls having a diameter slightly larger than the ball **3** to be arranged in the connecting body belt **2** are inserted into a molding metal mold as a core, and they are arranged within the metal mold in the same manner as the arranging state of the ball **3** with respect to the connecting body belt **2**. Then, the connecting body belt **2** holding the dummy ball between the spacer portions **4** is formed by injecting the synthetic resin into the metal mold from this state. After the formed connecting body belt **2** is taken out from the metal mold, the dummy ball is removed, and in place of this, the ball **3** is inserted between the spacer portions **4**, so that the ball connecting body **1** in accordance with this embodiment is completed.

As mentioned above, when the connecting body belt **2** is formed by using the dummy ball having a diameter larger than the ball **3** as a core, the spherical seat **6** of each of the spacer portions **4** is formed in a recessed spherical surface following the spherical surface of the dummy ball, so that the spherical seat **6** having a curvature larger than a curvature of the spherical surface of the ball **3** can be easily formed. Further, since the ball **3** finally arranged, in the connecting body belt **2** has a diameter smaller than the dummy ball, a significantly small gap is formed between the spacer portions **4** and the ball **3**, so that it is possible to secure a free rotation of the ball with respect to the spacer portions **4**.

On the contrary, it is possible to form the connecting body belt **2** holding the ball **3** between the spacer portions **4** by inserting the ball **3** within the forming metal mold as a core without using the dummy ball, and in accordance with this method, a replacing operation between the dummy ball and the ball **3** is not required, so that the ball connecting body **1** can be further easily manufactured. In this case, since the ball **3** and the spacer portions **4** of the connecting body belt **2** are in close contact with each other, the ball connecting body **1** taken out from the metal mold is immersed into a mineral oil type lubricating oil as it is and the synthetic resin connecting body belt **2** is swelled by the lubricating oil. Accordingly, the spherical seat **6** of each of the spacer portions **4** becomes a recessed spherical surface having a curvature larger than a curvature of the spherical surface of the ball **3**, a gap is formed between the ball **3** and the spacer portions **4**, and it is also possible to secure a free rotation of the ball **3** with respect to the spacer portions **4**.

FIG. **4** shows an embodiment of the ball screw apparatus in which the ball connecting body **1** is assembled.

In the drawing, reference numeral **10** denotes a screw shaft on which a spiral ball rolling groove **11** is formed at a predetermined lead, and reference numeral **20** denotes a nut member having an endless track in which the ball connecting body **1** mentioned above is assembled and being meshed with the screw shaft **10** through the ball **3**, and the structure is made such that the nut member **20** moves in an axial direction of the screw shaft **10** by a relative rotation between the screw shaft **10** and the nut member **20**.

The nut member **20** mentioned above is formed in a cylindrical shape through which the screw shaft **10** extends, and a flange portion **21** for fixing the nut member **20** to a movable body such as a table is provided on an outer peripheral surface thereof in a projecting manner. Further, a spiral load rolling groove **22** opposing to the ball rolling groove **11** of the screw shaft **10** is formed on an inner peripheral surface of the nut member **20**, so that the ball **3** rolls between the ball rolling groove **11** and the load rolling groove **22** with applying the load. The load rolling groove **22** is formed in a so-called Gothic arch shape in which two ball rolling surfaces are crossed, and an escape groove for receiving the connecting band portion **5** of the ball connecting body **1** mentioned above is formed at a deepest portion of the groove.

On the contrary, a deflector **30** for circulating the ball **3** between the screw shaft **10** and the nut member **20** in an endless manner is fitted on the inner peripheral surface of the nut member **20**. As shown in FIG. **4**, the deflector **30** is fixed to the nut member **20** in such a manner as to jump over the ball rolling groove **11** of the screw shaft **10** for only a wind, so that the ball **3** rolling on the ball rolling groove **11** of the screw shaft **10** is changed a progressing direction thereof by the deflector **30** and returned to the ball rolling groove **11** a wind before by jumping over the outer diameter of the screw shaft **10**, whereby it is structured such that the ball **3** circulates within the nut member **20** in an endless manner. Further, in the nut member **20** in accordance with this embodiment, four deflectors **30** are fixed in such a manner as to uniformly separate the circumference of the nut member **20** into four portions, so that all four endless tracks are formed on the ball **3**. Accordingly, four ball connecting bodies **1** are assembled in the nut member **20** mentioned above.

FIGS. **5** to **8** show a detailed structure of the deflector **30** mentioned above.

A substantially S-shaped ball returning groove **31** is formed on the deflector **30**, and a guide groove **32** for guiding the connecting band portion **5** of the ball connecting body **1** is formed in a center portion of the ball returning groove **31**. Further, the ball returning groove **31** is formed in a most recessed shape at a center position of the deflector **30** so that the ball **3** entering to the ball returning groove **31** can jump over the outer diameter of the screw shaft **10**.

In accordance with the ball screw apparatus of this embodiment structured in the above manner, when the screw shaft **10** and the nut member **20** are relatively rotated, the ball **3** assembled in the ball connecting body **1** rolls on the load rolling groove **22** of the nut member **20** and the ball rolling groove **11** of the screw shaft **10**, and the ball connecting body **1** circulates in the inner portion of the endless track formed on the nut member **20**.

FIGS. **9** and **10** show a state in which the ball connecting body **1** in accordance with this embodiment circulates in the inner portion of the ball endless track. The ball endless track is formed in a substantially circular ring shape surrounding a periphery of the screw shaft **10**, however, is expanded outward in a radial direction of the screw shaft **10** at a position where the deflector **30** is mounted. Accordingly, the ball connecting body **1** is expanded toward an outer side in a radial direction of the endless track at a time of passing through the ball returning groove **31** of the deflector **30**, and is come out from the ball rolling groove **11** of the screw shaft **10** so as to jump over the outer diameter portion of the screw shaft **10**, on the contrary, goes along the ball returning groove **31** in a zigzag manner and moves along the axial direction of the screw shaft **10** for a lead of the ball rolling groove **11** (for a distance L in FIG. **10**). Therefore, the ball **3** jumps over the outer diameter of the screw shaft **10** together with the connecting body belt **2** so as to be returned to the ball rolling groove **11** a wind before, and circulates on the periphery of the screw shaft **10** in an endless manner.

At this time, since the ball connecting body **1** in accordance with this embodiment is formed in a substantially circular ring shape in a state of arranging the ball **3** on the connecting body belt **2**, a unreasonable force intending to forcibly bend it against the connecting body belt **2** does not act even when it is assembled within the ball endless track also formed in a substantially circular ring shape, so that it is possible to smoothly circulate within the ball endless track.

Further, in the connecting body belt **2**, the connecting band portion **5** is formed in a flange shape outwardly surrounding each of the spacer portions **4**, and is softly bent with respect to a direction shown by an arrow A (refer to FIG. **2**) perpendicular to the plane on which the balls **3** are arranged, so that even in the case of being guided in the inner portion of the deflector **30** in an S-shaped manner as shown in FIG. **10**, it can smoothly pass through the inner portion of the ball returning groove **31** in the deflector **30**. Accordingly, also in this point, the ball connecting body **1** in accordance with this embodiment can smoothly circulate in the inner portion of the ball endless track.

In addition, since the spherical seat **6** formed in each of the spacer portions **4** of the connecting body belt **2** is formed in a recessed spherical surface having a curvature larger than the spherical surface of the ball **3**, a slight gap is formed between the spherical seat **6** and the ball **3**, and both can freely change a contact angle thereof at a certain degree. Accordingly, as shown in FIG. **9**, even in the case that only a part of the peripheral direction of the ball connecting body **1** expands outward in a radial direction at a position of arranging the deflector **30**, no external force intending to forcibly bend this against the ball connecting body **1** acts, so that the ball connecting body **1** can be smoothly circulated within the ball endless track.

Accordingly, in the case of using the ball connecting body **1** in accordance with this embodiment in a state of being assembled in the ball endless track of the ball screw apparatus shown in FIG. **4**, the ball connecting body **1** can significantly smoothly circulate within the ball endless track, so that a relative rotation between the screw shaft **10** and the nut member **20** can be smoothly performed.

What is claimed is:

1. A ball connecting body comprising:

a multiplicity of balls circulating on a substantially circular ring-like ball endless track provided in a bearing apparatus; and

a flexible connecting body belt arranging the balls in a line at a predetermined interval and holding each of the balls in a freely rotating manner; wherein

said connecting body belt is constituted by a plurality of spacer portions inserted between mutually adjacent balls and having a spherical seat for bringing the balls into contact therewith, and a flange-like connecting band portion mutually connecting on only one side of the spacer portions; and

said connecting body belt is formed in a substantially circular ring shape at a time of arranging the balls in the connecting body belt so as to radially outwardly surround the spacer portions and the balls.

2. A ball connecting body as recited in claim **1**, wherein said connecting body belt is formed so as to have an end, and a length thereof is substantially equal to a length of a periphery of said ball endless track.

3. A ball screw apparatus comprising:

a screw shaft having a spiral ball rolling groove formed on an outer peripheral surface;

a nut member having a load rolling groove opposite to the ball rolling groove of the screw shaft on an inner surface and meshed with said screw shaft through a multiplicity of balls rolling with applying a load between the ball rolling groove and the load rolling groove;

a deflector fitted to an inner peripheral surface of the nut, having a ball returning groove to return a ball rolling on said load rolling groove for a wind of the load rolling groove and forming a substantially circular ring-like ball endless track on which the balls circulate in an endless manner; and

wherein a ball connecting body is assembled within said ball endless track, said ball connecting body comprising a ball connecting body comprising:

a multiplicity of balls circulating on a substantially circular ring-like ball endless track provided in a bearing apparatus; and

a flexible connecting body belt arranging the balls in a line at a predetermined interval and holding each of the balls in a freely rotating manner; wherein

said connecting body belt is constituted by a plurality of spacer portions inserted between mutually adjacent balls and having a spherical seat for bringing the balls into contact therewith and a flange-like connecting band portion mutually connecting on only one side of the spacer portions; and

said connecting body belt is formed in a substantially circular ring shape at a time of arranging the balls in the connecting body belt so as to radially outwardly surround the spacer portions and the balls, and said ball is structured such as to apply a load between the load rolling groove of the nut member and the ball rolling groove of the screw shaft.

[57] **ABSTRACT**

A method of molding a movable block for a rolling motion guide device can effectively prevent the formation of burrs in the rolling member rolling groove and accurately positioning the movable block body in a molding die.

The positioning of the movable block body in width, vertical and longitudinal directions is performed at plain surfaces that are different from the rolling member rolling groove, so that damage or injury of the rolling member rolling groove can be prevented. Further, the molding material is shut off at either both end portions or both side peripheries of the rolling member rolling grooves, so that the molding material can be prevented from invading into the rolling member rolling grooves.

METHOD OF FORMING A MOVING BLOCK OF A ROLLING MOTION GUIDING DEVICE

TECHNICAL FIELD

The present invention relates to a method of molding a movable block for a rolling motion guide device in which a movable block is movably assembled to a track rail through rows of rolling members.

BACKGROUND ART

The rolling motion guide device of this type has a structure comprising a track rail formed with rolling member rolling grooves, a movable block provided to the track rail so as to be movable along the track rail, the movable block having a rolling member rolling groove which is opposed to the rolling member rolling groove formed to the track rail, and a row of rolling members (hereinafter referred to simply as "rolling members") disposed between the opposing rolling member rolling grooves formed to the track rail and the movable block.

The applicant of this invention had already proposed a rolling motion guide device in which a movable block is provided with a circulation passage for circulating the row of rolling members and at least part of the circulation passage is constituted as a molded portion (see Japanese Patent Laid-open Publication No. HEI 7-317762).

The molding operation is performed in such a manner that a movable block body is disposed in a molding die, then an integrally-molding is conducted by injecting molding material into a cavity formed between an inner surface of the molding die and the movable block body when the molding die is closed. In this case, conventionally, a supporting portion which engages with the rolling member rolling groove is provided in the molding die, so that the movable block body is positioned with reference to the rolling member rolling groove.

However, in the conventional method of molding the movable block described above, since the rolling member rolling groove is engaged with the supporting portion provided in the molding die, there may be a fear of the rolling member rolling groove being damaged or injured. In order to prevent such damage or injury of the rolling member rolling groove, it may be effective to reduce an engaging force between the supporting portion and the rolling member rolling groove. In this case, however, there may be a fear that the molding material will disadvantageously invade into the rolling member rolling groove and burrs are liable to occur thereto. Further, the positioning of the movable block body will be unstable.

The present invention has been achieved for solving the aforementioned problems encountered in the prior art, and an object of the present invention is to provide a method of molding a movable block for a rolling motion guide device which is capable of effectively preventing the formation of burrs in the rolling member rolling groove and accurately positioning the movable block body.

DISCLOSURE OF THE INVENTION

In order to achieve the aforementioned object, the present invention provides a method of molding a movable block for a rolling motion guide device comprising a track rail formed with rolling member rolling grooves, a movable block having rolling member rolling grooves opposing to the rolling member rolling grooves formed to the track rail, the movable block being movably provided along the track rail

and a row of rolling members disposed between the opposing rolling member rolling grooves formed to the track rail and the movable block, wherein a circulation passage for circulating the rows of rolling members is formed to the movable block, at least a part of the circulation passage is constituted by a die-molded portion, and the die-molded portion is integrally molded with a movable block body by an inserting molding method in which the movable block is disposed in a molding die, the method comprising the steps of:

- positioning the movable block body in a width direction and in a vertical direction in the molding die by supporting a plain surface having no rolling member rolling groove of the movable block body;
- positioning the movable block body in a longitudinal direction by supporting both end surfaces in a longitudinal direction of the movable block body;
- preventing a molding material from invading into the rolling member rolling grooves by shutting off the molding material at both ends or both side peripheries of the rolling member rolling grooves; and
- integrally molding the die-molded portion with the movable block body.

The molding die comprises a block supporting portion for positioning the movable block body in a width direction and in a vertical direction in the molding die by supporting a plain surface having no rolling member rolling groove of the movable block body, for positioning the movable block body in a longitudinal direction by supporting both end surfaces in a longitudinal direction of the movable block body, and for preventing a molding material from invading into the rolling member rolling grooves by shutting off the molding material at both end portions or both side peripheries of the rolling member rolling grooves.

According to the present invention described above, the positioning of the movable block body in width, vertical and longitudinal directions is performed at the plain surface which is different from the rolling member rolling groove, so that the damage or injury of the rolling member rolling groove can be prevented.

In addition, since the molding material is shut off at least at both end portions or both side peripheries of the rolling member rolling grooves, the molding material can be prevented from invading into the rolling member rolling grooves.

Accordingly, the movable block body can be stably positioned by being supported with a large supporting force regardless of the rolling member rolling grooves.

In another aspect of this invention, the method is characterized in that the movable block body comprises a horizontal portion extending in width and longitudinal directions, and a pair of leg portions protruding in a height direction from both the end portions in a width direction of the horizontal portion so as to oppose to side surfaces of the track rail, and in a case where inner side surfaces of the leg portions have inclined surfaces extending toward the protruded portions of the leg portions and gradually inclined toward a side of the track rail, the movable block body is positioned within the molding die in a width direction and in a height direction by supporting at least the inclined surfaces of both the inner side surfaces of both the leg portions and a lower surface of the horizontal portion.

The molding die comprises a block supporting portion for positioning the movable block in a width direction and in a height direction by supporting at least the inclined surfaces of both the inner surfaces of both the leg portions of the movable block body and a lower surface of the horizontal portion.

In this case, a backlash in a height direction of the movable block body is restricted and supported by the inclined surfaces of the inner surfaces of both the leg portions, while a backlash in a width direction of the movable block body is restricted and supported by the inner surfaces of both the leg portions.

In a further aspect of this invention, the method is characterized in that the movable block body comprises a horizontal portion extending in a width direction and a longitudinal direction and a pair of leg portions protruding in a height direction from both the end portions in a width direction of the horizontal portion so as to oppose to side surfaces of the track rail, and in a case where inner side surfaces of the leg portions have an almost vertical surfaces, the movable block body is positioned in a width direction and in a height direction by supporting at least the vertical surfaces of both the inner side surfaces of both the leg portions and both upper and lower surfaces of the horizontal portion.

The molding die comprises a block supporting portion for positioning the movable block body in a width direction and in a height direction by supporting at least the vertical surfaces of both the inner surfaces of both the leg portions and both upper and lower surfaces of the horizontal portion.

In this case, since the inner side surfaces of both the leg portions are vertical surfaces, a backlash in a height direction of the movable block body is restricted and supported by the lower surface of the horizontal portion, while a backlash in a width direction of the movable block body is restricted and supported by the inner surfaces of both the leg portions.

In a still further aspect of this invention, the method is characterized in that the movable block body comprises a horizontal portion extending in a width direction and in a longitudinal direction, and a pair of leg portions protruding in a height direction from both the end portions in a width direction of the horizontal portion so as to oppose to side surfaces of the track rail, and in a case where inner side surfaces of the leg portions have inclined surfaces extending toward the protruded portions of the leg portions and gradually inclined toward a side opposite to the track rail, the movable block body is positioned in a width direction and in a height direction by supporting at least the inclined surfaces of both the inner side surfaces of both the leg portions and an upper surface of the horizontal portion.

The molding die comprises a block supporting portion for positioning the movable block body in a width direction and in a height direction by supporting at least the inclined surfaces of both the inner surfaces of both the leg portions of the movable block body and an upper surface of the horizontal portion.

In this case, a backlash in a height direction of the movable block body is restricted and supported between the inner surfaces of both the leg portions and an upper surface of the horizontal portion, while a backlash in a width direction of the movable block body is restricted and supported by the inner surfaces of both the leg portions.

In a still further aspect of this invention, the method is characterized in that the movable block body comprises a horizontal portion extending in a width direction and in a longitudinal direction, and a leg portion protruding in a height direction from one end portion in a width direction of the horizontal portion so as to oppose to one side surface of the track rail, and in a case where an inner side surface of the leg portion has an almost vertical surface or an inclined surface extending toward a protruded end portion and gradually inclined to a side of the track rail, the movable block body is positioned within the molding die in a width direction and in a height direction by supporting at least both the inner and outer side surfaces of the leg portion and both upper and lower surfaces of the horizontal portion.

The molding die comprises a block supporting portion for positioning the movable block body in a width direction and in a height direction by supporting at least both the inner and outer side surfaces of the leg portion and both upper and lower surfaces of the horizontal portion.

In a case where the inner side surface of the leg portion is a vertical surface, a backlash in a height direction of the movable block body is restricted and supported by both the upper and lower surfaces of the horizontal portion, while a backlash in a width direction of the movable block body is restricted and supported by both the inner and outer side surfaces of the leg portion.

In a case where the inner side surface of the leg portion is an inclined surface, a backlash in a height direction of the movable block body is restricted and supported by both the upper and lower surface of the horizontal portion.

In a still further aspect of this invention, the method is characterized in that the positioning in a longitudinal direction of the movable block body in the molding die is performed by supporting a direction changing guide portion formed to both end portions of the rolling member rolling groove of the movable block body.

The molding die comprises a block supporting portion for positioning the movable block body in a longitudinal direction by supporting the direction changing guide portion formed to both end portions of the rolling member rolling groove of the movable block body.

The direction changing guide portion is provided for allowing the rolling members to smoothly change the rolling direction of the rolling members such that a load is gradually applied to the rolling members when the rolling members are moved from a non-loaded region to a loaded region. When the movable block body is positioned with reference to this direction changing guide portion, the positioning of the movable block body and the shutting off the molding material can be performed simultaneously.

In a still further aspect of this invention, the method is characterized in that the circulation passage comprises the rolling member rolling groove to be formed to the movable block, a rolling member return passage to be formed in parallel to the rolling member rolling groove, and a direction changing passage for connecting the rolling member rolling groove to the rolling member return passage, wherein the die molded portion constitutes at least one of a rolling member retaining portion to be formed at both side peripheries of the rolling member rolling groove, a return passage forming portion for forming the rolling member return passage, and a direction changing inner peripheral guide forming portion for forming an inner peripheral portion of the direction changing passage.

The position of the movable block body in the molding die is accurately determined, so that the boundary portion between the end portion of the rolling member rolling groove formed to the movable block and the direction changing passage inner peripheral portion can be formed without causing irregularities.

Further, in a case where the rolling member return passage and the movable block body are integrally molded, a location of the rolling member return passage with respect to the movable block body can be accurately made.

Furthermore, in a case where the rolling member retaining portion and the movable block body are integrally molded, a location of the rolling member retaining portion with respect to the rolling member rolling groove can be accurately made.

In addition, when both the rolling member returning passage and the direction changing passage inner periphery guide portion are integrally formed with the movable member, the joint portion between the rolling member returning passage and the direction changing inner periphery guide portion can be molded so as to provide a continuous surface without causing irregularities.

In a case where the direction changing passage inner periphery guide portion and the rolling member retaining portion are integrally formed, the joint portion between the rolling member retaining portion and the direction changing inner periphery guide portion can be molded without causing irregularities.

In addition, in a case where all of the rolling member retaining portion, the direction changing passage inner periphery guide portion and the rolling member returning passage are integrally molded with the movable block body, each of the joint portions to be formed at an entire circumference of the circulation passage can be molded without causing irregularities.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a view showing a first embodiment of a rolling motion guide device according to the present invention, in which

FIG. **1**(*a*) is a cross sectional view taken along the plane orthogonal to the track rail,

FIG. **1**(*b*) is a view showing a structure of a ball circulating passage,

FIG. **1**(*c*) is a partially exploded sectional view showing a direction changing passage, and

FIG. **1**(*d*) is a sectional view showing a ball retaining portion.

FIG. **2** is a view showing a first embodiment of a rolling motion guide device according to the present invention, in which

FIG. **2**(*a*) is a front view of a half-sectioned movable block and

FIG. **2**(*b*) is a side view of a half sectioned movable block.

FIG. **3** is a view showing a method of molding the movable block, in which

FIG. **3**(*a*) is a cross sectional view of a fixed molding-die to which the movable block body is inserted,

FIG. **3**(*b*) is a longitudinal sectional view showing a molding die in an opened-state,

FIG. **3**(*c*) is a longitudinal sectional view showing a molding die in a closed-state,

FIG. **3**(*d*) is a view showing a state where the molding material is shut off at side peripheries of the ball rolling groove, and

FIG. **3**(*e*) is a schematically and partially cross sectional view showing a state where the molding material is shut off at both ends of the ball rolling groove.

FIG. **4** is a view showing a second embodiment of a rolling motion guide device according to the present invention, in which

FIG. **4**(*a*) is a cross sectional view taken along a plane orthogonal to the track rail,

FIG. **4**(*b*) is a view showing a structure of a circulation passage, and

FIG. **4**(*c*) is a partially exploded sectional view showing a direction changing passage.

FIG. **5** is a view showing a second embodiment of a rolling motion guide device according to the present invention, in which

FIG. **5**(*a*) is a front view of a side cover of the movable block of which half portion is omitted and

FIG. **5**(*b*) is a side view showing the movable block.

FIG. **6** is a view showing a second embodiment of the method of molding the movable block according to the present invention, in which

FIG. **6**(*a*) is a cross sectional view of a fixed molding die to which the movable block body is inserted,

FIG. **6**(*b*) is a longitudinal sectional view showing a molding die in an opened-state,

FIG. **6**(*c*) is a longitudinal sectional view showing a molding die in a closed-state,

FIG. **6**(*d*) is a view showing a state where the molding material is shut off at side peripheries of the ball rolling groove, and

FIG. **6**(*e*) is a schematically and partially cross-sectional view showing a state where the molding material is shut off at both end portions of the ball rolling groove.

FIG. **7** is a view showing a third embodiment of a rolling motion guide device according to the present invention, in which

FIG. **7**(*a*) is a front view, half in section, of a movable block in a state where a side cover is detached from the end surface of the movable block,

FIG. **7**(*b*) is a side view, partially broken, of the movable block, and

FIG. **7**(*c*) is a partially enlarged cross sectional view showing a direction changing passage.

FIG. **8** is a view showing a third embodiment of the method of molding the movable block according to the present invention, in which

FIG. **8**(*a*) is a cross sectional view of a fixed molding die into which the movable block body is inserted and

FIG. **8**(*b*) is a partially omitted longitudinal sectional view showing a molding die in a closed-state.

FIG. **9** is a view showing a fourth embodiment of a rolling motion guide device according to the present invention, in which

FIG. **9**(*a*) is a cross sectional view in a direction orthogonal to the track rail,

FIG. **9**(*b*) is a view showing a structure of a ball circulating passage, and

FIG. **9**(*c*) is a partially exploded sectional view showing a direction changing passage.

FIG. **10** is a view showing a fourth embodiment of a rolling motion guide device according to the present invention, in which

FIG. **10**(*a*) is a front view of a half-sectioned movable block and

FIG. **10**(*b*) is a side view of the movable block.

FIG. **11** is a view showing a fourth embodiment of the method of molding the movable block according to the present invention, in which

FIG. **11**(*a*) is a cross sectional view of a fixed molding die into which the movable block body is inserted and

FIG. **11**(*b*) is a partially omitted longitudinal sectional view showing a molding die in a closed-state.

FIG. **12** is a view showing a fifth embodiment of a rolling motion guide device according to the present invention, in which

FIG. **12**(*a*) is a cross sectional view in a direction orthogonal to the track rail, FIG. **12**(*b*) is a view showing a structure of a ball circulating passage, and

FIG. **12**(*c*) is a partially exploded sectional view showing a direction changing passage.

FIG. **13** is a view showing a fifth embodiment of a rolling motion guide device according to the present invention, in which

FIG. **13**(*a*) is a front view, half in section, of an end surface of the movable block and

FIG. **13**(*b*) is a side view of the movable block.

FIG. **14** is a view showing a molding die used in the fifth embodiment of the method of molding the movable block according to the present invention, in which

FIG. **14**(*a*) is a cross sectional view of a fixed molding die,

FIG. **14**(*b*) is a partially sectional view, in a longitudinal direction, showing a molding die in a closed-state,

FIG. **14**(*c*) is a partially sectional view, in a longitudinal direction, showing a molding die in an opened-state, and

FIG. **14**(*d*) is a partially sectional view showing a state where the molding material is shut off at both end portions of the ball rolling groove.

BEST MODE FOR EMBODYING THE INVENTION

In order to explain the present invention in more detail, the preferred embodiments of this invention will be described hereunder with reference to the accompanying drawings.

First Embodiment

FIGS. **1** and **2** show a first embodiment of a rolling motion guide device according to the present invention.

As shown in FIG. **1**(*a*), the rolling motion guide device **1** is constructed by comprising a track rail **2** and a movable block **4** having a U-shape in section and movably supported by the track rail **2** through four rows in total of balls **3** in which two rows of balls are disposed to an upper surface side of the track rail **2** while one row of balls is disposed to each of right and left side surfaces of the track rail **2**.

The track rail **2** is an elongated member formed to provide a rectangular shape in section. Upper half portions of both right and left side surfaces of the track rail **2** are formed to provide tapered surfaces **21** so that the upper half portions gradually protrude outside as position advances upward. Each of the right and left tapered surfaces **21** is formed with one row of ball rolling groove as a rolling member rolling groove, respectively. In contrast, an upper surface of the track rail **2** is a plain surface and each of both right and left end portions thereof is formed with one row of ball rolling groove **5**, two rows in total.

The movable block **4** is a block body having a high rigidity and a U-shaped cross section, and has a movable block body **40** comprising a horizontal portion **41** opposing to the upper surface of the track rail **2** and a pair of leg portions **42** and **42** extending downward from both right and left side end portions of the horizontal portion **41** so as to clamp both the right and left side surfaces of the track rail **2**. At the lower surface of the horizontal portion **41** is formed with a pair of ball rolling grooves **7** and **7** corresponding to the paired ball rolling grooves **5** and **5** formed to the upper surface of the track rail **2**, while the inner side surfaces of both the right and left leg portions **42** and **42** are formed with ball rolling grooves **8**, **8** corresponding to the ball rolling grooves **6**, **6** formed to the right and left side surfaces of the track rail **2**.

The right and left leg portions **42** and **42** comprise outwardly directing inclined surfaces **421** each obliquely extending toward the protruded end portions so as to be gradually apart from the track rail **2** and comprise inwardly directing inclined surfaces **422** each obliquely extending in a direction so as to be close to the track rail **2**. The inwardly directing inclined surfaces **422** are formed with ball rolling grooves **7** and **7**.

The ball rows for receiving loads to be applied between the track rail **2** and the movable block **4** are constituted by disposing a number of balls **3** to portions between the four paired ball rolling grooves **5**, **7**; **6**, **8** that mutually correspond to each other and are formed to the opposing surfaces of the movable block **4** and the track rail **2**. The balls **3** are applied with a predetermined preload. As the rolling member other than balls, rollers or the like may be also applicable.

Both end portions of the ball rolling grooves **7**, **8** are performed with a crowning-working so as to provide a ball guide portion **48** having an inclination of which depth gradually increases toward the end portions of the ball rolling grooves. The ball guide portion **48** has a function of rolling and moving the balls from the direction changing passage **10** in a non-loaded region to portions between the ball rolling grooves **5**, **7**; **6**, **8** in a loaded region by gradually applying the load to the balls.

With respect to the balls **3** disposed between the upper surface of the track rail **2** and the horizontal portion **41** of the movable block body **40**, a contact angle line L1 connecting contact points of the respective balls to the ball rolling grooves **5**, **7**; **6**, **8** is set to almost about 90° with respect to a horizontal line H passing through a center of the ball **3**. In contrast, with respect to the balls **3** disposed between the right and left side surfaces of the track rail **2** and the right and left leg portions **42**, **42** of the movable block body **40**, a contact angle line L1 connecting contact points of the respective balls to the ball rolling grooves is set to upwardly incline with a predetermined angle of α with respect to a horizontal line H passing through a center of the ball **3** so as to extend toward a center of the track rail **2**. As a result, the balls have a structure that both the upper end right and left corner portions **22**, **22** of the track rail **2** are clamped by the two rows of balls **3** disposed to the right and left side surfaces and the two rows of balls **3** disposed to the upper surface of the track rail **2**.

The movable block **4** is provided with four rows of ball returning passages **9** for circulating and guiding the four rows of balls **3**. The ball returning passage **9** is constituted by a bore linearly extending in parallel to the respective ball rolling grooves **7**, **8** formed to the movable block **4**. Two rows of the ball returning passages are formed to the horizontal portion **41**, while two rows of the ball returning passages are formed to each of the right and left leg portions **42**, respectively.

The horizontal portion **41** of the movable block **4** is formed with a large-diameter through bore **43** having a diameter larger than that of a cross sectional area of the ball returning passage **9**. A first pipe portion **91** composed of resin as return passage forming member for forming the ball returning passage **9** is integrally bonded to an inner periphery of the through bore **43**.

On the other hand, outer side surface lower end corner portions of the right and left leg portions **42** of the movable block body **40** are formed with a concave portion **44** to which a second pipe portion **92** composed of resin for forming the ball returning passage **9** is integrally bonded. The second pipe portion **92** is formed to be continuous to a thickened lower end surface resin portion **93** covering a lower end surface of the leg portion **42** and to a side surface resin portion **94** covering an outer side surface lower end portion of the leg portion **42**. An upper end of the side surface resin portion **94** is formed with an engaging projection **94***a* which engages with an engaging groove **42***a* formed to an outer side surface of the leg portion **42**.

As shown in FIGS. **1**(*b*), (*c*) and FIG. **2**, a side cover **11**, constituting the direction changing passage **10** in a U-shaped-pipe form for changing the direction of the balls **3** disposed between the track rail **2** and the movable block body **40** toward the ball returning passage **9**, is attached to an end portions of the movable block body **40**. The side cover **11** per se is formed with only an outer peripheral portion **10***a* among the entire direction changing passage **10** in the U-shaped pipe form. Further, a direction changing passage inner peripheral piece portion **12** as a direction changing inner periphery forming member for forming an inner peripheral portion **10***b* of the direction changing passage **10** is integrally bonded to the end portions of the movable block body **40**, and the direction changing passage **10** is constituted by the side covers **11** and the direction changing inner peripheral piece portions **12**. In this regard, the reference numeral **11***a* in figures denotes an end seal for sealing a gap formed between the track rail **2** and the side cover **11** and a reference numeral **11***b* denotes a grease nipple.

In addition, as shown in FIG. **1**(*a*), the movable block **4** is provided with ball retaining members **13** along the four rows of balls **3** for preventing the balls **3** from dropping off from the movable block **4** when the movable block **4** is detached from the track rail **2**. The ball retaining members **13** are composed of resin and comprises a first retainer portion **13***a* integrally bonded to the lower surface of the horizontal portion **41** of the movable block body **40**, right and left second retainer portions **13***b* integrally bonded to a concave corner portion between the horizontal portion **41** and the right and left leg portions **42**, and right and left third retainer portions **13***c* integrally bonded to the inner surface lower end portions of the right and left leg portions **42**. The third retainer portions **13***c* are formed to be continuous to the lower end covering portion **93** covering the lower end portion of the leg portion **42** and integrally formed to the second pipe portion **92**.

The two rows of balls **3** disposed to upper surface of the track rail **2** are retained between both the right and left end portions of the first retainer portion **13***a* and the upper end portion of the second retainer portion **13***b*, while the right and left two rows of balls **3** disposed to the right and left side surfaces of the track rail **2** are retained between the right and left second retainer portions **13***b* and the third retainer portion **13***c*.

The first retainer portion **13***a* and the second retainer portion **13***b* are provided with first and second concave portions **45, 46** at which the lower surface of the horizontal portion **41** and the inwardly directing inclined surfaces **422** of the inner side surfaces of the movable block body **40** are exposed. The first and second concave portions **45, 46** are formed to have a shape corresponding to a convex portion for supporting the movable block body **40** within the molding die at the time of the insert molding operation. The first and second concave portions **45, 46** can be continuously formed to the movable block body **40** over an entire length thereof or can also be discontinuously and partially formed to the movable block body **40**.

On the other hand, as shown in FIG. **1**(*d*), at periphery portions of the first to third retainer portion **13***a*–**13***c* contacting to the ball rolling grooves **7, 8**, a plain portion **47** is exposed to a portion between side peripheries of the ball rolling grooves **7, 8**. The convex portion for preventing the molding material from penetrating into the ball rolling grooves **7, 8** at the time of the insert molding operation is abutted against the plain portion **47**.

In addition, all of the first and second pipe portions **91, 92** as the return passage forming member, the first to third retainer portions **13***a*, **13***b* as the ball retaining member **13** and the direction changing inner peripheral piece portion **12** is composed of a die-molded portion which is integrally molded with the movable block body **40**.

This integral molding is performed in accordance with an insert molding method in which a cavity corresponding to the die molded portion to be formed is formed between an inner wall of the molding die **14** and the movable block body **40** by disposing the movable block body **40** within a molding die **14** with reference to the ball rolling groove **7** formed to the movable block body **40**, and then the molding material is injected into the cavity.

FIG. **3** includes schematic views showing states where the movable block body **40** and the molding die **14** are closed or opened at the time of the insert molding operation.

A fixed die **14***a* comprises a first convex portion **14***a***1** abutting against the lower surface as the plain surface of the horizontal portion **41** of the movable block **40**, a second convex portion **14***a***2** abutting against the outwardly directing inclined surface **421** of the inner side surface of the leg portion **42**, a third convex portion **14***a***3** for shutting off the molding material by abutting against the plain portion **47** of the side periphery of the ball rolling grooves **7, 8** formed to the lower surface of the horizontal portion **41**, and a fourth convex portion **14***a***4** abutting against the plain portion **47** of the side periphery of the ball rolling grooves **8** formed to the inwardly directing inclined surface **422** of the inner side surface.

The first convex portion **14***a***1** and the second convex portions **14***a***2** are not required to be continuously formed to the movable block body **40** over an entire length thereof, and the convex portions can also be discontinuously formed to the movable block body **40**. However, the third convex portion **14***a***3** and the fourth convex portions **14***a***4** are required to be continuously formed to the movable block body **40** over an entire length of the ball rolling grooves **7, 8**.

On the other hand, a movable die **14***c* is provided with a pin **14***d* for forming the ball returning passage **9**.

Note, FIGS. **3**(*b*), (*c*) show only a circumference of the ball returning passage **9** formed to the side of the leg portion **42**.

Further, a cavity **15***a* for forming the first pipe portion **91** is provided in the through bore **43** formed to the horizontal portion **41** of the movable block body **40**, a cavity **15***b* for forming the second pipe portion **92** is provided in an outer side of the concave portion formed an outer corner portion of the leg portion **42**, cavities **15***c*–**15***e* for forming the first to third retainer portions **13***a*–**13***c* are provided at the horizontal portion **41** and inner circumferences of the leg portion **42**, and a cavity **15***f* for forming the direction changing passage inner peripheral piece portion **12** is provided at both front and rear end portions of the movable block body **40**, respectively.

The first convex portion **14***a***1** and the second convex portions **14***a***2** are projected into the cavities **15***c*, **15***d*, respectively, and abut against the lower surface of the horizontal portion **41** of the movable block body **40** and the outwardly directing inclined surface **421** of the inner side surface of the leg portion **42**, the lower surface and the inclined surface **421** being plain surfaces other than a surface having the ball rolling grooves **7**, **8**. Further, the third convex portion **14***a***3** abuts against the side periphery of the ball rolling grooves **7**, **8** formed to the horizontal portion **41**, while the fourth convex portion **14***a***4** abuts against the inwardly directing inclined surface **422** of the inner side surface of the leg portion **42**, whereby a position of the movable block body **40** in a width and height directions is determined.

That is, a backlash in a height direction of the movable block body **40** is restricted and supported by the first convex portion **14***a***1** abutting against the lower surface of the horizontal portion **41**, the second convex portion **14***a***2** abutting against the outwardly directing inclined surfaces **421** of the inner surfaces of both the leg portions **42**, and the third and fourth convex portions **14***a***3**, **14***a***4**. While, a backlash in a width direction of the movable block body **40** is restricted and supported by the second to fourth convex portions **14***a***2**–**14***a***4**.

In addition, as shown in FIG. **3**(*d*), by the action of the third and fourth convex portions **14***a***3** and **14***a***4**, the molding material such as resin material or the like can be prevented from invading into the ball rolling grooves **7**, **8** formed to the movable block body **40**.

On the other hand, the position of the movable block body **40** in a longitudinal direction is determined by a bottom wall **14***a***5** of the fixed die **14***a* and an end wall **14***c***1** of the movable die **14***c* against which both end portions in a longitudinal direction of the movable block body **40** are abutted.

As shown in FIGS. **3**(*b*), (*e*), the shutting-off the molding material between the both end portions of the ball rolling grooves **7**, **8** and the direction changing inner peripheral piece portion **12** can be performed by the engaging convex portions **14***a***6**, **14***c***2** to be engaged with the ball guide portion **48** subjected to a crowning working and provided to both end portions of the ball rolling grooves **7**, **8**.

According to the present invention described above, the positioning of the movable block body **40** in width, vertical and longitudinal directions is performed at the plain surface which is different from the ball rolling grooves **7**, **8**, so that the damage or injure of the ball rolling grooves **7**, **8** can be prevented. Further, the movable block body **40** can be stably positioned by being supported with a large supporting force regardless of the ball rolling grooves **7**, **8**.

Accordingly, the positions of the cavity **15***a* for forming the first pipe portion **91**, the cavity **15***b* for forming the second pipe portion **92**, the cavities **15***c*–**15***e* for forming the first to third retainer portions **13***a*–**13***c* and the cavity **15***f* for forming the direction changing passage inner peripheral piece portion **12** with respect to the movable block **4** can be accurately determined. As a result, there is no fear of causing irregularities due to assembling errors at a joint portion formed between the direction changing passage inner peripheral piece portion **12** and the ball rolling grooves **7**, **8** and at a joint portion between the direction changing passage inner peripheral piece portion **12** and the ball returning passages **9** to be formed of the first and second pipe portions **91**, **92**, so that it becomes possible to smoothly circulate the balls **3**, and to reduce the noise generation.

By the way, in order to prevent the generation of burr, it is not always necessary to completely or tightly contact the respective members such as the plain portion **47** of the side periphery of the ball rolling grooves **7**, **8** formed to the movable block body **40** and the third and fourth convex portions **14***a***3**, **14***a***4**; or the engaging convex portions **14***a***6**, **15***c***2** and each of the ball guide portions **48**. Even if a gap is formed between the members, such gap is within an allowable range as far as the gap has a size capable of preventing the invasion of the molding material.

In the present embodiment, although all of the first and second pipe portions **91**, **92** as the ball returning passage forming member, the first, second and third retainer portions **13***a*–**13***c* as the ball retaining member, and the direction changing passage inner peripheral piece portion **12** as the direction changing passage inner peripheral portion forming member is integrally formed with the movable block body **40** by the insert molding method to form a die-molded portion, there may be also applicable a method in which at least one of the aforementioned members is integrally molded by the insert molding method.

That is, there will be applicable various cases e.g., a case where only the first and second pipe portions **91**, **92** are integrally molded, a case where only the first to third retainer portions **13***a*–**13***c* are integrally molded, a case where only the direction changing passage inner peripheral piece portion **12** is integrally molded, a case where the first and second pipe portions **91**, **92** and the first to third retainer portions **13***a*–**13***c* are integrally molded, a case where the first to third retainer portions **13***a*–**13***c* and the direction changing passage inner peripheral piece portion **12** are integrally molded, a case where the first and second pipe portions **91**, **92** and the direction changing passage inner peripheral piece portion **12** are integrally molded.

Second Embodiment

FIG. **4** shows a second embodiment of a rolling motion guide device according to the present invention.

The rolling motion guide device **201** is constructed by comprising a track rail **202** and a movable block **204** having a U-shape in section and movably supported by the track rail **202** through four rows, in total, of balls **203** in which two rows of balls are vertically disposed to each of the right and left side surfaces of the track rail **202**.

The track rail **202** is an elongated member formed to provide a rectangular shape in section. Both right and left side surfaces of the track rail **202** are provided with protruded portions **2021** each protruding outside. Each of upper and lower side surfaces of the right and left protruded portions **2021** is formed with rows of ball rolling grooves **205**, **206** as the rolling member rolling grooves.

The movable block **204** is a block body having a high rigidity and a U-shaped cross section and has a movable block body **2040** comprising a horizontal portion **2041** opposing to the upper surface of the track rail **202** and a pair of leg portions **2042** and **2042** extending downward from both right and left side end portions of the horizontal portion **2041** so as to clamp both the right and left side surfaces of the track rail **202**. The inner side surfaces of the right and left leg portions **2042** have a vertical surfaces **20423** each extending in an almost vertical direction, outwardly directing inclined surfaces **20421** formed at base portions of the right and left leg portions **2042**, and inwardly directing inclined surfaces **20422** formed at top portions of the leg portions **2042**.

The outwardly directing inclined surfaces **20421** and the inwardly directing inclined surfaces **20422** are formed with two rows of ball rolling grooves **207** and **208** corresponding to the paired ball rolling grooves **205** and **206** formed to the right and left side surfaces of the track rail **202**.

The ball rows for receiving loads to be applied between the track rail **202** and the movable block body **2040** are constituted by disposing a number of balls **203** to portions between the four paired ball rolling grooves **205**, **208**; **206**, **207** that mutually correspond to each other and are formed to the opposing surfaces of the movable block body **2040** and the track rail **202**. The balls **203** are applied with a predetermined preload. As the rolling member other than balls, rollers or the like can be also applied.

Both end portions of the ball rolling grooves **207, 208** are performed with a crowning-working so as to provide a ball guide portion **2048** having an inclination of which depth gradually increases toward the end portions of the ball rolling grooves. The ball guide portion **2048** has a function of rolling and moving the balls from the direction changing passage **210** in a non-loaded region to portions between the ball rolling grooves **205, 207; 206, 208** in a loaded region by gradually applying the load to the balls.

Contact angle lines each connecting contact points of the respective balls **203** to the ball rolling grooves **205, 208; 206, 207** have an inclined structure so as to be close toward a center of the track rail **202,** and the contact angle is set to almost about 45° with respect to a horizontal line H.

The right and left leg portions **2042** of the movable block body **2040** are provided with four rows of ball returning passages **209** for circulating and guiding the four rows of balls. The ball returning passage **209** is constituted by a bore linearly extending in parallel to the respective ball rolling grooves **207, 208** formed to the movable block body **2040**.

The outer side surfaces of the right and left leg portions **2042** of the movable block body **2040** are formed with a cutout portion **2043**. A return passage forming member **2091** composed of resin for forming the ball returning passage **209** is integrally bonded to the cutout portion **2043**. Upper and lower two rows of the ball returning passage **209, 209** are formed to the return passage forming member **2091**.

The return passage forming member **2091** is formed to be continuous to an end surface resin portion **2092** covering a lower end surface of the leg portion **2042**.

A side cover **211** constituting the direction changing passage **210**, in a U-shaped-pipe form for changing the direction of the balls **203** disposed between the track rail **202** and the movable block body **2040** toward the ball returning passage **209**, is attached to an end portions of the movable block body **2040**. The side cover **211** per se is formed with only an outer peripheral portion **210***a* of the entire direction changing passage **210** in the U-shaped pipe form. Further, a direction changing passage inner peripheral piece portion **212** as a direction changing inner periphery forming member for forming an inner peripheral portion **210***b* of the direction changing passage **210** is integrally bonded to the end portions of the movable block body **2040,** and the direction changing passage **210** is constituted by the side covers **211** and the direction changing inner peripheral piece portions **212**.

In addition, the movable block body **2040** is provided with ball retaining members **213** along the four rows of balls **203** for preventing the balls **203** from dropping off from the movable block **204** when the movable block **204** is detached from the track rail **202**. The ball retaining members **213** are composed of resin and comprises a first retainer portion **213***a* integrally bonded to the lower surface of the horizontal portion **2041**, right and left second retainer portions **213***b* integrally bonded to an inner side surface center portion of the right and left leg portions **242**, and right and left third retainer portions **213***c* integrally bonded to the inner surface lower end portions of the right and left leg portions **242**. The third retainer portions **213***c* is formed to be continuous to the lower end covering portion **2092** covering the lower end portion of the leg portion **242** and integrally formed to the ball returning passage forming member **2091**.

The upper side two rows of balls **203** are retained between both the right and left end portions of the first retainer portion **213***a* and the upper end portion of the second retainer portion **213***b*, while the right and left two rows of balls **203** disposed to the right and left side surfaces of the track rail **202** are retained between the right and left second retainer portions **213***b* and the third retainer portion **213***c*.

The second retainer portion **213***b* is provided with a second concave portion **2046** at which the vertical surface of the inner side surface of the leg portion **242** is exposed. The second concave portion **2046** is formed to have a shape corresponding to a convex portion for supporting the movable block body **2040** within the molding die **214** at the time of the insert molding operation. The second concave portions **2046** can be continuously formed to the movable block body **2040** over an entire length thereof or can also be discontinuously and partially formed to the movable block body **2040**.

On the other hand, at periphery portions of the first to third retainer portion **13***a*–**13***c* contacting to the ball rolling grooves **207, 208**, plain surfaces of the outwardly and inwardly directing inclined surfaces **20421, 20422** are exposed to a portion between side peripheries of the ball rolling grooves **207, 208**. The outwardly and inwardly directing inclined surfaces **20421, 20422** each having a plain surface becomes shutting-off surfaces for preventing the molding materials such as resin material or the like from penetrating into the ball rolling grooves **207, 208** at the time of the insert molding operation.

In addition, all of the aforementioned return passage forming member **209**, the first to third retainer portions **213***a*–**213***c* as the ball retaining member **213** and the direction changing inner peripheral piece portion **212** is integrally molded with the movable block body **2040**.

This integral molding is performed in accordance with an insert molding method in which a cavity corresponding to the resin molded portion to be formed is formed between an inner peripheral wall of the molding die **214** and the movable block body **2040** by disposing the movable block body **2040** within a molding die **214**, and then, the molding material is injected into the cavity.

FIG. **6** is a schematic view showing an engaging state of the movable block body **2040** with the molding die **214** at the time of the insert molding operation.

A fixed die **214***a* comprises a first convex portion **214***a***1** abutting against the lower surface of the horizontal portion **2041** of the movable block body **2040**, a second convex portion **214***a***2** abutting against the vertical surface **20423** of the inner side surface of the leg portion **2042**, a third convex portion **214***a***3** for shutting off the molding material by abutting against the outwardly directing inclined surface **20422**, and a fourth convex portion **214***a***4** for shutting off the molding material by abutting against the inwardly directing inclined surface **20422**.

The first convex portion **214***a***1** and the second convex portions **214***a***2** are not required to be continuously formed to the movable block body **2040** over an entire length thereof, and the convex portions can also be discontinuously formed to the movable block body **2040**. However, the third convex portion **214***a***3** and the fourth convex portions **214***a***4** are required to be continuously formed to the movable block body **2040** over an entire length of the ball rolling grooves **207, 208**.

A movable die **214***c* is provided with a pin **214***d* for forming the ball returning passage **209**.

Further, a cavity **215***a* for forming the return passage forming member **2091** is provided at the cutout portions **2043** of outer side surfaces of the right and left leg portions **2042**, cavities **215***b*–**215***d* for forming the first to third retainer portions **213*a*–213*c*** are provided at the horizontal portion **241** and inner circumferences of the leg portion **242**, and a cavity **215*e*** for forming the direction changing passage inner peripheral piece portion **212** is provided at both front and rear end portions of the movable block body **2040**, respectively.

The first convex portion **214*a*1** is projected into the right and left cavities **215*b*** while the second convex portions **214*a*2** is projected into the cavities **215*c***, respectively, and the convex portions abut against the lower surface of the horizontal portion **2041** of the movable block body **2040** and the vertical surface **20423** of the inner side surface of the leg portion **2042**, the lower surface and the vertical surface being plain surfaces other than a surface having the ball rolling grooves **207**, **208**. Further, the third convex portion **214*a*3** abuts against the side periphery of the ball rolling grooves **207** formed to the horizontal portion **2041**, while the fourth convex portions **214*a*4** abuts against the inwardly directing inclined surface **20422** of the inner side surface of the leg portion **2042**, whereby a position of the movable block body **2040** in a width and height directions is determined.

That is, a positioning in a height direction of the movable block body **2040** is performed by the first convex portion **214*a*1** abutting against the lower surface of the horizontal portion **2041**, and the third and fourth convex portions **214*a*3**, **214*a*4** abutting against the outwardly and inwardly directing inclined surfaces **20421**, **20422** of the inner side surfaces of both the leg portions **2042**. While, a positioning of the movable block body **2040** in a width direction is performed by the second to fourth convex portions **214*a*2–214*a*4**.

In addition, by the action of the third and fourth convex portions **214*a*3** and **214*a*4**, the molding material such as resin or the like can be prevented from invading into the ball rolling grooves **207**, **208** formed to the movable block body **2040**.

On the other hand, the position of the movable block body **2040** in a longitudinal direction is determined by a bottom wall **214*a*5** of the fixed die **214*a*** and an end wall **214*c*1** of the movable die **214*c*** against which an elongated end wall in a longitudinal direction of the movable block body **2040** are abutted.

As shown in FIGS. **6**(*b*), (*e*), the shutting-off of the molding material at the both end portions of the ball rolling grooves **207**, **208** can be performed by the engaging convex portions **214*a*6**, **214*c*2** to be engaged with the ball guide portion **2048** which had been subjected to a crowning working and provided to both end portions of the ball rolling grooves **207**, **208**.

According to the present invention described above, the positioning of the movable block body **2040** in width, vertical and longitudinal directions is performed at the plain surface which is different from the ball rolling grooves **207**, **208**, so that the damage or injure of the ball rolling grooves **207**, **208** can be prevented. Further, the movable block body **2040** can be stably positioned by being supported with a large supporting force regardless of the ball rolling grooves **207**, **208**.

In particular, the positional relation between the cavity **215*a*** for forming the ball returning passage forming member **2091**, the cavities **215*c*–215*e*** for forming the first to third retainer portions **213*a*–213*c*** and the cavity **215*f*** for forming the direction changing passage inner peripheral piece portion **212** with respect to the movable block body **2040** can be accurately determined.

Third Embodiment

FIGS. **7** and **8** show a third embodiment of the present invention.

The rolling motion guide device **301** is constructed by comprising a track rail **302** and a movable block **304** having a U-shape in section and movably supported by the track rail **302** through four rows, in total, of balls **303** in which two rows of balls are vertically disposed to each of the right and left side surfaces of the track rail **302**.

The track rail **302** is an elongated member formed to provide a rectangular shape in section. Each of the right and left side surfaces of the track rail **302** is formed to provide an almost vertical surface and is provided with two rows of ball rolling grooves **305**, **306** as the rolling member rolling grooves, respectively.

The movable block **304** is a block body having a high rigidity and a U-shaped cross section and has a movable block body **3040** comprising a horizontal portion **3041** opposing to the upper surface of the track rail **302** and a pair of leg portions **3042** extending downward from both right and left side end portions of the horizontal portion **3041** so as to clamp both the right and left side surfaces of the track rail **302**. Each of the inner side surfaces of the right and left leg portions is almost a vertical surface and is formed with two rows of ball rolling grooves **307** and **308** corresponding to the paired ball rolling grooves **305** and **306** formed to the right and left side surfaces of the track rail **302**.

The ball rows for receiving loads to be applied between the track rail **302** and the movable block body **3040** are constituted by disposing a number of balls **303** to portions between the four paired ball rolling grooves **305**, **307**; **306**, **308** that mutually correspond to each other and are formed to the opposing surfaces of the movable block body **3040** and the track rail **302**. The balls **303** are applied with a predetermined preload. As the rolling member other than balls, rollers or the like can be also applied.

Both end portions of the ball rolling grooves **307**, **308** are performed with a crowning-working so as to provide a ball guide portion **3048** having an inclination of which depth gradually increases toward the end portions of the ball rolling grooves. The ball guide portion **3048** has a function of rolling and moving the balls from the direction changing passage **310** in a non-loaded region to portions between the ball rolling grooves **305**, **307**; **306**, **308** in a loaded region by gradually applying the load to the balls.

The right and left leg portions **3042** of the movable block body **3040** are provided with four rows of ball returning passages **309** for circulating and guiding the four rows of balls. The ball returning passage **309** is constituted by a bore linearly extending in parallel to the respective ball rolling grooves **307**, **308** formed to the movable block body **3040**.

The right and left leg portions **3042** of the movable block body **3040** are formed with a through bore **3043**. A return passage forming member **3091** composed of resin for forming the ball returning passage **309** is integrally bonded to the through bore **3043**. Upper and lower two rows of the ball returning passage **309**, **309** are formed to the return passage forming member **3091**.

A side cover **311** constituting the direction changing passage **310** in a U-shaped pipe form for changing the rolling direction of the balls **303** disposed between the track rail **302** and the movable block body **3040** toward the ball returning passage **309** is attached to an end portions of the movable block body **3040**. The side cover **311** per se is formed with only an outer peripheral portion **310*a*** of the entire direction changing passage **310** in the U-shaped pipe form. Further, a direction changing passage inner peripheral piece portion **312** as a direction changing inner periphery forming member for forming an inner peripheral portion **310***b* of the direction changing passage **310** is integrally bonded to the end portions of the movable block body **3040**, and the direction changing passage **310** is constituted by the side covers **311** and the direction changing inner peripheral piece portions **312**.

The present embodiment is different from the previous first and second embodiments in a point that the side peripheries of the ball rolling grooves **307, 308** formed to the movable block body **3040** is not provided with ball retaining members for preventing the balls **303** from dropping off from the movable block body.

Further, the aforementioned return passage forming member **309** and the direction changing passage inner peripheral piece portion **312** are integrally formed with the movable block body **3040**.

This integral molding is performed in accordance with an insert molding method in which a cavity corresponding to the resin molded portion to be formed is formed between an inner peripheral wall of the molding die **314** and the movable block body **3040** by disposing the movable block body **3040** within a molding die **314**, and then, the molding material is injected into the cavity.

FIG. **8** is a schematic view showing an engaging state of the movable block body **3040** and the molding die **314** at the time of the insert molding operation.

A fixed die **314***a* comprises a first convex portion **314***a***1** abutting against the lower surface of the horizontal portion **3041** of the movable block body **3040**, a second convex portion **314***a***2** abutting against the vertical surface **30423** of the leg portion **3042**, and a third convex portion **314***a***3** for suppressing the upper surface of the horizontal portion **3041**.

The first to third convex portions **314***a***1**–**314***a***3** are not required to be continuously formed to the movable block body **3040** over an entire length thereof, and the convex portions can also be discontinuously formed to the movable block body.

A movable die **314***c* is provided with a pin **314***d* for forming the ball returning passage **309**.

Further, a cavity **315***a* for forming the return passage forming member **3091** is provided at the through bore **3043** of the right and left leg portions **3042**, and a cavity **315***e* for forming the direction changing passage inner peripheral piece portion **312** is provided at both front and rear end portions of the movable block body **3040**, respectively.

The first to third convex portions **314***a***1**–**314***a***3** support the lower surface of the horizontal portion **3041** of the movable block body **3040**, the inner side surfaces **30423** of the leg portions **3042** and the upper surface of the horizontal portion **3041**, the respective surfaces being plain surfaces other than a surface having the ball rolling grooves **307, 308**, whereby a position of the movable block body **3040** in a width and height directions is determined.

That is, a positioning in a height direction of the movable block body **3040** is performed by the first convex portion **314***a***1** abutting against the lower surface of the horizontal portion **3041** and the third convex portion **314***a***3** abutting against the upper surface of the horizontal portion. In addition, a positioning of the movable block body **3040** in a width direction is performed by the second convex portion **314***a***2** abutting against the inner side surfaces of the right and left leg portions **3042**.

On the other hand, the position of the movable block body **3040** in a longitudinal direction is determined by a bottom wall **314***a***5** of the fixed die **314***a* and an end wall **314***c***1** of the movable die **314***c* against which an elongated end wall in a longitudinal direction of the movable block body **3040** are abutted.

The shutting-off the molding material at both the end portions of the ball rolling grooves **307, 308** can be performed by the engaging convex portions **314***a***5**, **314***c***2** to be engaged with the ball guide portion **348** which had been subjected to a crowning working and provided to both end portions of the ball rolling grooves **307, 308**.

According to the present invention described above, the positioning of the movable block body **3040** in width, vertical and longitudinal directions is performed at the plain surface, which is different from the ball rolling grooves **307, 308**, so that the damage or injure of the ball rolling grooves **307, 308** can be prevented. Further, the movable block body **3040** can be accurately positioned to a predetermined position.

In particular, the positional relation between the cavity **315***a* for forming the ball returning passage forming member **3091** and the cavity **315***f* for forming the direction changing passage inner peripheral piece portion **312** with respect to the movable block body **3040** can be accurately determined.

When the molding material is shut off at the ball guide portion **348** provided to both the end portions of the ball rolling grooves **307, 307**, it becomes possible to prevent the molding materials such as resin or the like from invading into the ball rolling grooves **307, 307**, while preventing the damage or injure of the ball rolling grooves.

Fourth Embodiment

FIGS. **9** to **11** show a fourth embodiment of a rolling motion guide device according to the present invention.

The rolling motion guide device **401** is constructed by comprising a track rail **402** and a movable block **404** having a U-shape in section and movably supported by the track rail **402** through two rows, in total, of balls **403** in which one row of balls is disposed to each of the right and left side surfaces of the track rail **402**.

The track rail **402** is composed of an elongated member formed to provide a rectangular shape in section. Upper half portions of both the right and left side surfaces of the track rail **402** are formed to provide tapered surfaces **4021** so that the upper half portions are gradually narrowed inside as the position advances upward. Each of the right and left tapered surfaces **4021** is formed with one row of ball rolling groove **405** as a rolling member rolling groove, respectively.

The movable block **404** is a block body having a high rigidity and a U-shaped cross section and has a movable block body **4040** comprising a horizontal portion **4041** opposing to the upper surface of the track rail **402** and a pair of leg portions **4041** and **4041** extending downward from both right and left side end portions of the horizontal portion **4041** so as to clamp both the right and left side surfaces of the track rail **402**. Each of the inner surfaces of the right and left leg portions **4042, 4042** is formed with one row of ball rolling groove **407** corresponding to the ball rolling grooves **405** formed to the right and left side surfaces of the track rail **402**. The inner side surfaces **40421** of both the right and left leg portions **405** and **405** provide an outwardly directing inclined surface which inclined in a direction so as to open downwardly.

The ball rows for receiving loads to be applied between the track rail **402** and the movable block **404** are constituted by disposing a number of balls **403** to portions between the two paired ball rolling grooves **405, 407** that mutually correspond to each other and are formed to the opposing surfaces of the movable block **404** and the track rail **402**. The balls **403** are applied with a predetermined preload. As the rolling member other than balls **403**, rollers or the like can be also applied.

Both end portions of the ball rolling grooves **407** are performed with a crowning-working so as to provide a ball guide portion **4048** having an inclination of which depth gradually increases toward the end portions of the ball rolling grooves. The ball guide portion **4048** has a function of rolling and moving the balls from the direction changing passage **410** in a non-loaded region to portions between the ball rolling grooves **405, 407** in a loaded region by gradually applying the load to the balls.

A contact angle line L4 connecting contact points of the respective balls **403** to the ball rolling grooves **405, 407** is inclined with a predetermined angle of α 4 so as to be gradually lowered toward a center of the track rail **402**.

The movable block **404** is provided with two rows of ball returning passages **409** for circulating and guiding the two rows of balls **403**. The ball returning passage **409** is constituted by a bore linearly extending in parallel to the respective ball rolling grooves **407** formed to the movable block **404**. One row of the ball returning passage **409** is formed to the right and left leg portions **4042**, respectively.

Outer side surface lower end corner portions of the right and left leg portions **4042** of the movable block body **4040** are formed with a circular-arc-shaped concave portion **4043** to which a pipe portion **4091** composed of resin for forming the ball returning passage **409** is integrally bonded. The pipe portion **4091** is formed to be continuous to a lower end surface resin portion **4092** covering a lower end surface of the leg portion **4042**. A top end of the lower end surface resin portion **4092** is formed with an engaging projection **4092*a*** which engages with an engaging groove **4042*a*** formed to the lower end surface of the leg portion **4042**.

A side cover **411** constituting the direction changing passage **410** in a U-shaped-pipe form for changing the rolling direction of the balls **403** disposed between the track rail **402** and the movable block body **4040** toward the ball returning passage **409** is attached to an end portions of the movable block body **4040**. The side cover **411** per se is formed with only an outer peripheral portion **410*a*** of the entire direction changing passage **410** in the U-shaped pipe form. Further, a direction changing passage inner peripheral piece portion **412** as a direction changing inner periphery forming member for forming an inner peripheral portion **410*b*** of the direction changing passage **410** is integrally bonded to the end portions of the movable block body **4040**, and the direction changing passage **410** is constituted by the side covers **411** and the direction changing inner peripheral piece portions **412**.

In addition, the pipe portions **4091** as the return passage forming member and the direction changing inner peripheral piece portion **412** are integrally molded with the movable block body **4040**.

This integral molding is performed in accordance with an insert molding method in which a cavity corresponding to the die molded portion to be formed is formed between an inner wall of the molding die and the movable block **4040** by disposing the movable block **4040** within a molding die, and then the molding material is injected into the cavity.

FIG. **11** is a schematic view showing an engaging state of the movable block **4040** and the molding die **414** at the time of the insert molding operation.

A fixed die **414*a*** comprises a first convex portion **414*a*1** abutting against the upper surface of the horizontal portion **4041** of the movable block **4040**, and a second convex portion **414*a*2**. The side surfaces of the second convex portion **414*a*2** are tightly contacted to outwardly directing inclined surfaces **40421** of the right and left leg portions **4042**. Further, each of the outer surfaces of the leg portions **4042** is formed with a concave portion **4043** into which a pin **414*b*** for forming the ball returning passage **409** is inserted. The fixed die **414*a*** is formed with a step portion **414*a*3** engaging with a corner portion of the concave portion **4043**. A cavity **415*a*** for forming a pipe portion **4091** is formed between the concave portion **4043** and the pin **414*b***.

Further, a cavity **415*b*** for forming the direction changing passage inner peripheral portion **412** is formed to both the front and rear end portions of the movable block **4040**, respectively.

In this embodiment, the upper surface of the horizontal portion **4041** is supported by the first convex portion **414*a*1**, while the lower surface of the horizontal portion **4041** is supported by the second convex portion **414*a*2**, whereby the a position of the movable block **4040** in a height direction is determined. In addition, the inner side surfaces **40421** of the leg portions **4042** of the movable block **4040** are supported by both right and left side surfaces of the second convex portion **414*a*2**, whereby the position of the movable block **4040** in a width direction is determined.

In addition, both the right and left side surfaces of the second convex portion **414*a*2** are interfitted to the inner side surfaces **40421** of the leg portions **4042** in a wedge form, so that there is no fear of causing burrs at inner peripheries of the ball rolling grooves **407, 407**.

Furthermore, the end portions of the movable block **4040** in a longitudinal direction are supported by the bottom surface **414*a*4** of the fixed die **414*a*** and the end wall **414*c*1** of the movable die **414*c*** in a die-closing direction, whereby the position of the movable block is determined.

As described above, the position of the movable block **4040** is stably determined in the molding die **414** without causing any backlash, so that the cavity **415*a*** for molding the pipe portion **4091** for forming the ball returning passage **409** can be accurately formed at circumference of the movable block **4040**.

In this embodiment, the upper end portions **4043*a*** of the concave portions **4043** formed to outer corner portions of the right and left leg portions **4042** abut against the step portion **414*a*3** formed to the inner periphery of the molding die **4014**, so that the movable block **4040** is supported more stably.

The shutting-off the molding material at the both end portions of the ball rolling groove **407** can be performed by the engaging convex portions **414*a*5, 414*c*2** to be engaged with the ball guide portion **4048** which had been subjected to a crowning working and provided to both end portions of the ball rolling groove **407**.

Fifth Embodiment

FIGS. **12** to **14** show a fifth embodiment of a rolling motion guide device according to the present invention.

The rolling motion guide device **501** is constructed by comprising a track rail **502** and a movable block **504** movably supported by the track rail **502** through balls **503** disposed to one side end portion of both the right and left side ends of an upper surface side of the track rail **502** and another balls **503** disposed to the other side end portion of both the right and left side surfaces of the track rail **502**.

The track rail **502** is an elongated member formed to provide a rectangular shape in section. One row of ball rolling groove **507** as rolling member rolling groove is formed to a left side end (as shown in figure) of an upper surface of the track rail **502**. On the other hand, an upper half portion of a right side surface (as shown in figure) of the track rail **502** is formed to provide a tapered surface **5021** so that the upper half portion gradually protrudes outside as the position advances upward. The tapered surfaces **5021** is formed with one row of ball rolling groove **506** as a rolling member rolling groove.

The movable block **504** is a block body having a high rigidity and an L-shaped cross section and has a movable block body **5040** comprising a horizontal portion **5041** opposing to the upper surface of the track rail **502** and a leg portion **5042** extending downward from the right side end portion of the horizontal portion **5041** so as to oppose to the right side surface of the track rail **502**. At the lower surface of the horizontal portion **5041**, is formed with a ball rolling groove **507** corresponding to the ball rolling groove **505** formed to the upper surface of the track rail **502**, while the inner side surface of the leg portions **5042** is formed with a ball rolling groove **508** corresponding to the ball rolling groove **505** formed to the right and left side surfaces of the track rail **502**.

The ball rolling groove **507** to be formed to the lower surface of the horizontal portion **5041** is formed to an inclined upper bottom **50412** of the concave portion **50411** formed to the lower surface of the horizontal portion **5041**. Further, a portion close to a lower end portion of the inner side surface of the leg portion **5042** is provided with an inwardly directing inclined surface **50422** which protrudes inside as a position is lowered. The inwardly directing inclined surface **50422** is formed with a ball rolling groove **507**.

The ball rows for receiving loads to be applied between the track rail **502** and the movable block body **5040** are constituted by disposing a number of balls **503** to portions between the two paired ball rolling grooves **505, 507**; **506, 508** that mutually correspond to each other and are formed to the opposing surfaces of the movable block body **5040** and the track rail **502**. The balls **503** are applied with a predetermined preload. As the rolling member other than balls **503**, rollers or the like can be also applied.

Both end portions of the ball rolling grooves **507, 508** are performed with a crowning-working so as to provide a ball guide portion **5048** having an inclination of which depth gradually increases toward the end portions of the ball rolling grooves. The ball guide portion **5048** has a function of rolling and moving the balls from the direction changing passage **510** in a non-loaded region to portions between the ball rolling grooves **505, 507**; **506, 508** in a loaded region by gradually applying the load to the balls.

With respect to the balls **503** disposed to the upper surface of the track rail **502**, a contact angle line L3 connecting contact points of the respective balls **503** to the ball rolling grooves **505, 507** is set so as to provide an inclined line which is counter-clockwisely inclined with a predetermined inclination angle of α 1 with respect to a vertical line V passing through a center of the ball. In contrast, with respect to the balls **503** disposed to the side surface of the track rail **502**, a contact angle line L3 connecting contact points of the respective balls **503** to the ball rolling grooves **506, 508** is set so as to provide an inclined line which is clockwisely inclined with a predetermined inclination angle of α 2 with respect to a horizontal line H passing through a center of the ball **503**.

The movable block **504** is provided with two rows of ball returning passages **509** for circulating and guiding the two rows of balls **503**. The ball returning passage **509** is constituted by a bore linearly extending in parallel to the respective ball rolling grooves **505, 506** formed to the movable block **504**. The ball returning passage **509** is formed to a left upper corner portion of the horizontal portion **5041** and to a right lower corner portion of the leg portion **5042**, respectively.

An upper left corner portion of the horizontal portion **5041** of the movable block body **5040** is formed with an arc-shaped concave portion **5043** to which a first pipe portion **5091** composed of resin for forming the ball returning passage **509** is integrally bonded. The first pipe portion **5091** is formed to be continuous to a side surface resin portion **5093** covering a left side surface of the horizontal portion **5041** and to a lower surface resin portion **5094** covering a left lower surface of the horizontal portion **5041**.

On the other hand, a right lower corner portion of the leg portion **5042** of the movable block body **5040** is formed with a concave portion **5044** to which a second pipe portion **5092** composed of resin for forming the ball returning passage **509** is integrally bonded. The second pipe portion **5092** is formed to be continuous to a side surface resin portion **5095** covering an outer side surface of the leg portion **5042** and to an end surface resin portion **5094** covering a lower end surface of the leg portion **5042**.

A side cover **511** constituting the direction changing passage **510** in a U-shaped-pipe form for changing the direction of the balls **503** disposed between the track rail **502** and the movable block body **5040** toward the ball returning passage **509** is attached to an end portion of the movable block body **5040**. The side cover **511** per se is formed with only an outer peripheral portion **510***a* of the direction changing passage **510** in the U-shaped pipe form. Further, a direction changing passage inner peripheral piece portion **512** as a direction changing inner periphery forming member for forming an inner peripheral portion **510***b* of the direction changing passage **510** is integrally bonded to the end portion of the movable block **504**, and the direction changing passage **510** is constituted by the side covers **511** and the direction changing inner peripheral piece portions **512**.

In addition, the movable block body **5040** is provided with ball retaining members **513** along the two rows of balls **503** for preventing the balls **503** from dropping off from the movable block body **5040** when the movable block body **5040** is detached from the track rail **502**. The ball retaining members **513** are composed of resin and comprise a pair of first and second retainer portions **513***a* and **513***b* extending so as to clamp both side peripheries of the ball rolling groove **507** formed to the horizontal portion **5041**, and a pair of third and fourth retainer portions **513***c* and **513***d* extending so as to clamp both side peripheries of the ball rolling groove **508** formed to the leg portion **5042**.

The first retainer portions **513***a* is formed to be continuous to a left lower surface covering portion **5094**, and is integrally formed with the first pipe portion **5091**. The second retainer portion **513***b* and the third retainer portion **513***c* are formed to be continuous through a center lower surface covering portion **5097** which covers the lower surface of the horizontal portion **5041**. Further, the fourth retainer portions **513***d* is formed to be continuous to an end surface covering portion **5096** and is integrally formed with the second pipe portion **5092**.

On the other hand, at periphery portions of the first to third retainer portions **513***a*–**513***c* contacting to the ball rolling grooves, a plain portion **547** is exposed to a portion between side peripheries of the ball rolling grooves **507, 508**. The convex portion for preventing the molding material from invading into the ball rolling grooves **507, 508** at the time of the insert molding operation is abutted against the plain portion **547**.

In addition, all of the first and second pipe portions **5091, 5092** as the return passage forming member, the first to fourth retainer portions **513***a*–**513***d* as the ball retaining member **513** and the direction changing inner peripheral piece portion **512** is integrally molded with the movable block body **5040**.

This integral molding is also performed in accordance with the insert molding method in which a cavity corresponding to the die molded portion to be formed is formed between an inner wall of the molding die and the movable block body **5040** by disposing the movable block body **5040** within a molding die with reference to the ball rolling grooves **507**, **508** formed to the movable block body **5040**, and then the molding material is injected into the cavity.

FIG. **14** is a schematic view showing an engaging state of the movable block body **5040** and the molding die **514** at the time of the insert molding operation. A fixed die **514***a* of the molding die comprises first and second convex portions **514***a***1**, **514***a***2** abutting against the lower surface of the horizontal portion **5041** of the movable block body **5040**, a third convex portion **514***a***3** abutting against the upper bottom portion **50412** of the concave portion formed to the horizontal portion **5041** and engaging with both the side peripheries of the ball rolling groove **507**, and a fourth convex portion **514***a***4** engaging with the inwardly directing inclined surface **50422** of the inner side surfaces of the leg portion **5042**.

The first convex portion **514***a***1** and the second convex portions **514***a***2** are not required to be continuously formed to the movable block body **5040** over an entire length thereof, and the convex portions can also be discontinuously formed to the movable block body **5040**. However, the third convex portion **514***a***3** and the fourth convex portions **514***a***4** are required to be continuously formed to the movable block body **5040** over an entire length of the ball rolling grooves **507**, **508**.

A pin **514***d* is inserted into the concave portion **5043** formed to the left upper corner portion of the horizontal portion **5041**, whereby a cavity **515***a* for forming the first pipe portion **5091** is formed. Further, a pin **514***d* is also inserted into the concave portion **5044** formed to the outer side surface of the leg portion **5042** of the movable block body **5040**, whereby a cavity **515***b* for forming the second pipe portion **5092** in the concave portion **5045** is formed.

A first step portion **514***a***5** abutting against an upper end portion of the concave portion **5043** formed to the left upper corner portion of the horizontal portion **5041**, and a second step portion **514***a***6** abutting against an upper end portion of the concave portion **5044** formed to the right lower corner portion of the leg **5042** are provided to the inner periphery of the fixed die **514***a*.

Cavities **515***c*–**515***f* for forming the first to fourth retainer portions **513***a*–**513***d* are provided at the horizontal portion **5041** and an inner circumference of the leg portion **5042**. Further, a cavity **515***f* for forming the direction changing passage inner peripheral piece portion **512** is provided at both the front and rear end portions of the movable block body **5040**, respectively.

In this embodiment, the upper surface of the horizontal portion **5041** of the movable block body **5040** is supported by the first convex portion **514***a***1**, while the lower surface of the horizontal portion **5041** is supported by the second convex portion **514***a***2**, whereby the position of the movable block body **5040** in a height direction is determined.

Further, the position of the movable block body **5040** in a width direction is determined by the third convex portion **514***a***3**, the fourth convex portions **514***a***4**, the first step portion **514***a***5** and the second step portion **514***a***6**.

In addition, by the action of the third and fourth convex portions **514***a***3** and **514***a***4**, the molding material can be prevented from invading into the ball rolling grooves **507**, **508** formed to the movable block body **5040**. As described above, the position of the movable block body **5040** is determined in the molding die **514** to a predetermined position.

On the other hand, the position of the movable block body **5040** in a longitudinal direction is determined by being supported by a bottom wall **514***a***5** of the fixed die **514***a* and an end wall portion **514***c***1** of the movable die **514***c*.

The shutting-off of the molding material at the both end portions of the ball rolling grooves **507**, **508** can be performed by the engaging convex portions **514***a***8**, **514***c***2** to be engaged with the direction changing guide portion **548** which had been subjected to a crowning working and provided to both end portions of the ball rolling grooves **507**, **508**.

According to the present invention described above, the positioning of the movable block body **5040** in width, vertical and longitudinal directions is performed at plain surfaces that are different from the ball rolling grooves **507**, **508**, so that the damage or injure of the ball rolling grooves can be prevented.

In addition, since the molding material is shut off at either both end portions or side peripheries of the ball rolling grooves **507**, **508**, the molding material can be prevented from invading into the ball rolling grooves **507**, **508**.

Accordingly, the movable block body **5040** can be stably positioned by being supported with a large supporting force regardless of the ball rolling grooves **507**, **508**.

As described above, according to the present invention, the positioning of the movable block body in a width, vertical, and longitudinal directions is performed at the plain surface which is different from the rolling member rolling groove, so that the damage or injure of the rolling member rolling groove can be prevented.

In addition, since the molding material is shut off at either both end portions or both side peripheries of the rolling member rolling grooves, the molding material can be prevented from invading into the rolling member rolling grooves.

Accordingly, the movable block body can be stably positioned by being supported with a large supporting force regardless of the rolling member rolling grooves.

INDUSTRIAL APPLICABILITY

As described above, the method of molding a movable block for a rolling motion guide device according to the present invention is effective to a movable block used for various rolling motion guide devices such as linear guide device, ball spline, ball bush or the like in which the movable block is movably assembled to a track rail through various rolling members and particularly effective for the integral molding of a resin portion with the movable block body.

What is claimed is:

1. A method of molding a movable block for a rolling motion guide device comprising a track rail formed with rolling member rolling grooves, a movable block having rolling member rolling grooves opposing said rolling member rolling grooves formed in said track rail, said movable block being movably provided along said track rail and a row of rolling members disposed between the opposing rolling member rolling grooves formed in said track rail and the movable block, wherein a circulation passage for circulating the rows of rolling members is formed to said movable block, at least a part of said circulation passage is constituted by a die-molded portion, and said die-molded portion is integrally molded with a movable block body by an inserting molding method in which said movable block is disposed in a molding die, the method comprising the steps of:

positioning said movable block body in a width direction and in a vertical direction in the molding die by supporting said movable block body with a die portion abutting against a plain surface of said movable block body having no rolling member rolling groove of said movable block body;

positioning said movable block body in a longitudinal direction by supporting both end surfaces in a longitudinal direction of said movable block body;

preventing a molding material from invading into said rolling member rolling grooves by shutting off the molding material at both side peripheries of said rolling member rolling grooves; and

integrally molding said die-molded portion with the movable block body.

2. A method of molding a movable block for a rolling motion guide device according to claim **1**, wherein said movable block body comprises a horizontal portion extending in a width direction and in a longitudinal direction and a pair of leg portions protruding in a height direction from both the end portions in a width direction of said horizontal portion so as to oppose to side surfaces of said track rail, and in a case where inner side surfaces of said leg portions have inclined surfaces extending toward the protruded portions of said leg portions and gradually inclined toward a side of the track rail, said movable block body is positioned within the molding die in a width direction and in a height direction by supporting at least the inclined surfaces of both the inner side surfaces of both the leg portions and a lower surface of said horizontal portion.

3. A method of molding a movable block for a rolling motion guide device according to claim **1**, wherein said movable block body comprises a horizontal portion extending in a width direction and in a longitudinal direction, and a pair of leg portions protruding in a height direction from both the end portions in a width direction of said horizontal portion so as to oppose to side surfaces of said track rail, and in a case where inner side surfaces of said leg portions have an almost vertical surfaces, said movable block body is positioned in a width direction and in a height direction by supporting at least the vertical surfaces of both the inner side surfaces of both the leg portions and both upper and lower surfaces of said horizontal portion.

4. A method of molding a movable block for a rolling motion guide device according to claim **1**, wherein said movable block body comprises a horizontal portion extending in a width direction and in a longitudinal direction and a pair of leg portions protruding in a height direction from both the end portions in a width direction of said horizontal portion so as to oppose to side surfaces of said track rail, and in a case where inner side surfaces of said leg portions have inclined surfaces extending toward the protruded portions of said leg portions and gradually inclined toward a side opposite to said track rail, said movable block body is positioned in a width direction and in a height direction by supporting at least the inclined surfaces of both the inner side surfaces of both the leg portions and an upper surface of said horizontal portion.

5. A method of molding a movable block for a rolling motion guide device according to claim **1**, wherein said movable block body comprises a horizontal portion extending in a width direction and in a longitudinal direction and a leg portion protruding in a height direction from one end portion in a width direction of said horizontal portion so as to oppose to one side surface of said track rail, and in a case where an inner side surface of said leg portion has an almost vertical surface or an inclined surface extending toward a protruded end portion and gradually inclined to a side of said track rail, said movable block body is positioned within the molding die in a width direction and in a height direction by supporting at least the vertical surface or the inclined surface of the inner side surfaces and outer side surfaces of said leg portion and both upper and lower surfaces of said horizontal portion.

6. A method of molding a movable block for a rolling motion guide device according to any one of claims **1** to **5**, wherein said positioning in a longitudinal direction of said movable block body in the molding die is performed by supporting a direction changing guide portion formed to both end portions of said rolling member rolling groove of said movable block body.

7. A method of molding a movable block for a rolling motion guide device according to claim **1**, wherein said circulation passage comprises a rolling member rolling groove to be formed to said movable block, a rolling member return passage to be formed in parallel to said rolling member rolling groove, and a direction changing passage for connecting said rolling member rolling groove to said rolling member return passage,

wherein said die molded portion constitutes at least one of a rolling member retaining portion to be formed at both side peripheries of said rolling member rolling groove, a return passage forming portion for forming said rolling member return passage, and a direction changing inner peripheral guide forming portion for forming an inner peripheral portion of said direction changing passage.

ROLLING MOTION GUIDE APPARATUS AND METHOD OF MANUFACTURING MOVABLE MEMBER OF ROLLING MOTION GUIDE APPARATUS

TECHNICAL FIELD

The present invention relates to a rolling motion guide apparatus in which a movable member is movably assembled to a track shaft through a rolling member, particularly to a structure for an inner periphery guide portion of a rolling member rolling direction changing passage which is integrally formed to a movable member body.

BACKGROUND ART

As an example of the conventional rolling motion guide apparatus of this type, the applicant had already proposed a rolling motion guide apparatus, as disclosed in Japanese Patent Laid-Open Publication No. HEI 7-317762, in which a circulating passage of the rolling member is integrally formed to the movable member body as a molding shaped portion composed of resin or the like.

That is, the movable member has a structure comprising: a movable member body having a loaded rolling member rolling portion corresponding a loaded rolling member rolling portion formed to the track shaft, and a rolling member return passage for returning a rolling member from one end of the loaded rolling member rolling portion to the other end thereof; and a direction changing passage member provided both end portions of the movable member body, the direction changing passage member constituting a rolling member rolling direction changing passage for scooping up the rolling member from the loaded rolling member rolling portion and then guiding the rolling member to the rolling member return passage.

Further, a rolling member retaining portion provided at a side peripheral portion of the loaded rolling member rolling portion, the inner periphery guide portion of the rolling member rolling direction changing passage and the rolling member return passage portion are integrally formed to the movable member body as a molding shaped portion composed of resin or the like (see Japanese Patent Laid-Open Publication No. HEI 7-317762).

However, in a case of the prior art technics described above, a boundary between the molding shaped portion and the movable member body consists of three boundary portions i.e., a boundary portion between both end surfaces of the movable member body and a shaped portion of the direction changing passage inner periphery guide portion, a boundary portion between the rolling member rolling portion and a shaped portion of the rolling member retaining portion formed at both side peripheral portion of the rolling member rolling portion, and a boundary portion between a side surface of the movable member opposing to a side surface to which rolling member rolling portion is formed and a shaped portion of a rolling member return bore. As a result, the three boundary portions are ranged over three side surfaces of the movable member.

When a clearance between the respective boundary portions between the movable member body and the molding shaped portion and a molding die supporting portion are not set to within a predetermined range, burrs will be disadvantageously formed from a molding material, so that it is required to take a countermeasure against the burrs. In this regard, the conventional movable member is inevitably required to take the countermeasure against the burrs with respect to the three side surfaces of the movable member.

Accordingly, the molding die and the movable member were required to be precisely formed so that each of the three side surfaces thereof should have an accurate dimension.

The present invention was conceived for solving the aforementioned problems and an object of the present invention is to provide a rolling motion guide apparatus and a method of manufacturing a movable member for the apparatus enabling to enhance a working efficiency by sufficiently minimizing the boundary portion between the molding shaped portion and the movable member body.

DISCLOSURE OF THE INVENTION

In order to achieve the afore-mentioned object, the present invention provides a rolling motion guide apparatus comprising a track shaft and a movable member movably disposed to the track shaft through a number of rolling members,

- wherein the movable member comprises: a movable member body having a loaded rolling member rolling portion corresponding to a loaded rolling member rolling portion formed to the track shaft, and a rolling member return passage for returning the rolling member from one end of the loaded rolling member rolling portion to the other end thereof; and a direction changing passage member provided both end portions of the movable member body, the direction changing passage member constituting a rolling member rolling direction changing passage for scooping up the rolling member from the loaded rolling member rolling portion and then guiding the rolling member to the rolling member return passage,
- wherein a rolling member retaining portion, the direction changing passage inner periphery guide portion and the rolling member return passage constituting portion to be provided at side peripheral portion of the loaded rolling member rolling portion are integrally formed to the movable member body by inserting the movable member body into a molding die,
- wherein the rolling member return passage constituting portion is integrally provided to an inner peripheral portion of a through bore formed so as to penetrate the movable member body, and
- wherein boundary portions between each of the rolling member retaining portion, the direction changing inner periphery guide portion, the rolling member return passage constituting portion and the movable member body are limited to portions between an end portion of the movable member body and the direction changing passage inner periphery guide portion and between the rolling member rolling portion and the rolling member retaining portion.

Accordingly, the countermeasure against the burrs is required for only two portions of the end surface of the movable member body and the rolling member rolling groove portion, so that an accuracy in dimension is not required for a portion between a side surface opposing to the side surface of the movable member body to which rolling member rolling groove is formed and the molding die. In this case, the direction changing passage inner periphery guide portions provided at both end portions of the movable member body are connected to the rolling member return passage member through the rolling member retaining portion, so that the direction changing passage inner periphery guide portions are not detachable therefrom.

In addition, in a case where the rolling member retaining portion is not provided to a side peripheral portion of the rolling member rolling groove of the movable member body, the apparatus is characterized in that the boundary portions between the direction changing passage inner periphery guide portion, the rolling member return passage member and the movable member body are limited to portions i.e., a portion between the end portion of the movable member body and the direction changing passage inner periphery guide portion, and a portion between both the end portions of the rolling member rolling portion and the direction changing passage inner periphery guide portion.

According to the structure described above, the portions to be required to take the countermeasure against the burrs are limited to the portions of the end surface of the movable member body and both the end portions of the rolling member rolling portion. In this case, the direction changing passage inner periphery guide portions provided at both end portions of the movable member body are connected by the rolling member return passage member, so that the direction changing passage inner periphery guide portions are not detachable therefrom.

Further, in a case where the rolling member retaining portion is not provided to a side peripheral portion of the rolling member rolling groove of the movable member body and the rolling member return passage is not molding-shaped, the apparatus is characterized in that the boundary portion between the direction changing passage inner periphery guide portion and the movable member body is limited to portions i.e., a portion between both the end portions of the movable member body and the direction changing passage inner periphery guide portion, a portion between both the end portions of the rolling member rolling portion and the direction changing passage inner periphery guide portion, and a portion between both the end portions of the rolling member return passage and the direction changing passage inner periphery guide portion.

According to the structure described above, the portion to be required to take the countermeasure against the burrs is limited to the portions of the end surface of the movable member body, both the end portions of the rolling member rolling portion, and both the end portions of the rolling member return passage.

In this case, when the direction changing passage inner periphery guide portion member is constructed so that both end surfaces of the movable member body are provided with engaging holes and the direction changing passage inner periphery guide portion is provided with an engaging convex portion for locking which is formed from a molding material flowing into the engaging hole, the direction changing passage inner periphery guide portion can be prevented from dropping off.

In this regard, when the engaging hole is formed to be a screwed hole having a thread groove formed at inner periphery portion of the screwed hole and the engaging convex portion is formed to have a male thread groove with which the thread groove of the screwed hole is engaged, the prevention of the dropping-off can be further ensured.

The method of manufacturing a movable member for the rolling motion guide apparatus having a movable member comprising: a movable member body having a loaded rolling member rolling portion corresponding to a loaded rolling member rolling portion formed to the track shaft, and a rolling member return passage for returning a rolling member from one end of the loaded rolling member rolling portion to the other end thereof; and a direction changing passage member provided both end portions of the movable member body, the direction changing passage member constituting a rolling member rolling direction changing passage for scooping up the rolling member from the loaded rolling member rolling portion and then guiding the rolling member to the rolling member return passage; the method characterized by comprising the steps of:

- forming a through bore for forming the rolling member return passage to the movable member body;
- supporting the movable member body within a molding die with reference to the end surfaces and the rolling member rolling portion of the movable member body, and setting each of contact conditions between the end surface of the movable member body and an end surface supporting portion of the molding die and between the rolling member rolling portion of the movable member body and a rolling member rolling portion supporting portion to a contact condition enabling to shut off a circulation of the molding material therebetween;
- forming a cavity for forming the direction changing passage inner periphery guide portion at a portion between the end portion of the movable member body and the end surface supporting portion of the molding die, forming a cavity for forming the rolling member retaining portion at a portion between the rolling member rolling portion of the movable member body and a side periphery portion of a rolling member rolling portion supporting portion of the molding die, and forming a cavity for forming the rolling member return passage at a portion between a core pin to be inserted into the through bore of the movable member body and the inner periphery portion of the through bore; and
- injecting the molding material into the respective cavities for forming the direction changing passage inner periphery guide portion, the rolling member retaining portion and the rolling member return passage, thereby to integrally form the direction changing passage inner periphery guide portion, the rolling member retaining portion and the rolling member return passage to the movable member body.

According to the molding method described above, each of positions of the direction changing passage inner periphery guide portion, the rolling member retaining portion and the rolling member return passage is determined with reference to the rolling member rolling portion. Therefore, each of joint portions between the rolling member rolling portion and the direction changing passage inner periphery guide portion and between the direction changing passage and the rolling member return passage can be formed as a continuous surface having no difference in level, so that smooth circulation and movement of the rolling member can be effectively secured.

In another aspect of the present invention of a case where the rolling member retaining portion is not provided at the side peripheral portion of the rolling member rolling groove of the movable member body, the method comprises the steps of:

- forming a through bore for forming the rolling member return passage at the movable member body;
- supporting the movable member body within a molding die at both the end surfaces of the movable member body and an end portion of the rolling member rolling portion, and setting each of contact conditions between the the end surface of the movable member body and an end surface supporting portion of the molding die and between the rolling member rolling portion of the movable member body and a rolling member rolling portion end supporting portion of the molding die to a

contact condition enabling to shut off a circulation of the molding material therebetween;

forming a cavity for forming the direction changing passage inner periphery guide portion at a portion between the end portion of the movable member body and the end surface supporting portion of the molding die and forming a cavity for forming the rolling member return passage at a portion between a core pin to be inserted into the through bore of the movable member body and the inner periphery portion of the through bore; and

injecting the molding material into the respective cavities for forming the direction changing passage inner periphery guide portion and the rolling member return passage, thereby to integrally form the direction changing passage inner periphery guide portion and the rolling member return passage to the movable member body.

Furthermore, in another aspect of this invention of a case where the rolling member retaining portion is not provided to a side peripheral portion of the rolling member rolling groove of the movable member body and the rolling member return passage is not constituted by the molding-shaped portion, the method is characterized by comprising the steps of:

supporting the movable member body within a molding die at both the end surfaces of the movable member body and an end portion of the rolling member rolling portion, and setting each of contact conditions between the end surface of the movable member body and an end surface supporting portion of the molding die, between an end portion of the rolling member rolling portion of the movable member body and a rolling member rolling portion end supporting portion of the molding die and between an end portion of the rolling member return passage of the movable member body and an return passage end supporting portion of the molding die to a contact condition enabling to shut off a circulation of the molding material therebetween;

forming a cavity for forming the direction changing passage inner periphery guide portion at a portion between the end portion of the movable member body and the end surface supporting portion of the molding die; and

injecting the molding material into the cavity for forming the direction changing passage inner periphery guide portion, thereby to integrally form the direction changing passage inner periphery guide portion to the movable member body.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a view showing one embodiment of a rolling motion guide apparatus according to the present invention, in which FIG. **1**(*a*) is a cross sectional view of the apparatus, FIG. **1**(*b*) is a side view of the apparatus and FIG. **1**(*c*) is a cross sectional view showing a direction changing passage of the apparatus.

FIG. **2** is a view showing a movable block body of the apparatus according to the present invention, in which FIG. **2**(*a*) is a view showing an end surface of the movable block body, FIG. **2**(*b*) is a side view of the movable block body, FIG. **2**(*c*) is a rear end view showing a part of a direction changing passage of the movable block body and FIG. **2**(*d*) is a cross sectional view taken along the line D—D of FIG. **2** (*a*).

FIG. **3** is a view showing a shape-molding method of the movable block body.

FIG. **4** is a view showing another embodiment of a rolling motion guide apparatus according to the present invention in which FIG. **4**(*a*) is a front view, half in section, showing a movable block body and FIG. **4**(*b*) is a view showing a construction of a molding die for forming a round piece portion.

FIG. **5** is a view showing still another embodiment of a rolling motion guide apparatus according to the present invention in which FIG. **5**(*a*) is a front view, half in section, showing a movable block body, FIG. **5**(*b*) is a view showing a construction of a molding die for forming a round piece portion and FIG. **5**(*c*) is a cross sectional view showing a construction in which an engaging convex portion is provided to the round piece portion.

BEST MODE FOR EMBODYING THE INVENTION

In order to explain the present invention in more detail, the preferred embodiments of this invention will be described hereunder with reference to the accompanying drawings.

FIGS. **1** to **3** are views each showing one embodiment of a rolling motion guide apparatus according to the present invention.

In FIG. **1**, a reference numeral **1** denotes an entire rolling motion guide apparatus which substantially comprises a track rail **2** as the track shaft and a movable block **4** as the movable member disposed to be movable on the track rail **2** through a ball row **3** consisting of a number of balls **3***a* as the rolling members.

The track rail **1** is an elongated member formed to provide a rectangular shape in section so that each of lateral right and left side surfaces of the track rail **1** is provided with two ball rows, respectively, i.e., totally four ball rows B**1**, B**2**, B**3** and B**4** through which the movable block **4** is guided. The right and left side surfaces of the track rail **1** are provided with four rows of loaded ball rolling grooves **5**, **5**, **5** and **5** as the loaded rolling member rolling portions corresponding to the four ball rows B**1**, B**2**, B**3** and B**4** so as to extend to an entire length of the track rail **4**.

The movable block **4** comprises a movable block body **6** and a pair of end plates **7** constituting the direction changing passage member that are provided at both end portions of the movable block body **6**. The movable block body **6** is composed of a block body having an inverted U-shaped cross-section and further comprises a horizontal portion **8** opposing to an upper surface of the track rail **2** and a pair of supporting leg portions **9** and **9** opposing to right and left side surfaces of the track rail **2**. The inner side surfaces of the respective right and left supporting leg portions **9** and **9** are provided with loaded ball rolling grooves **10**, **10**, **10** and **10** corresponding to the loaded ball rolling grooves **5**, **5**, **5** and **5** formed to the right and left side surfaces of the track rail **2**. Further, at the inner side surfaces of the respective right and left supporting leg portions **9** and **9**, ball retaining portions **12** and **12** are provided between the loaded ball rolling grooves **5**, **5** and **5**, **5** so as to prevent the ball from dropping off therefrom when the movable block **4** is detached from the track rail.

Further, solid portions of the respective supporting leg portions **9** and **9** are provided with four rows of ball return passages **11**, **11**, **11** and **11** as the rolling member return passages extending in an axial direction for returning the ball from one end portion to the other end portion of the respective loaded ball rolling grooves **10**, **10**, **10** and **10**. The ball return passages **11**, **11**, **11** and **11** are formed from pipe portions **14**, **14**, **14** and **14** as the return passage members which are bonded to the inner circumferential portions of the through bores **13**, **13** **13** and **13** formed to the respective supporting leg portions **9** and **9**.

On the other hand, the end plate **7** is also formed to have an inverted U-shaped cross-section corresponding to the shape of the movable block body **6** and is provided with ball direction changing passage **15**, **15**, **15** and **15** for scooping up the balls **3***a* from the loaded ball rolling grooves **10**, **10** **10** and **10** and then guiding the balls **3***a* to the ball return passages **11**, **11**, **11** and **11**. The end plate **7** is provided with outer periphery guide portions **15***a*, **15***a*, **15***a* and **15***a* of the ball direction changing passages **15**, **15**, **15** and **15**. The ball direction changing passage **15** is constructed by fitting the end plate **7** to the round piece portions **16** and **16** provided with inner periphery guide portions at the end surface of the movable block body **6**.

In this regard, as shown in FIG. **2**, the ball retaining portions **12** and **12** to be formed at side peripheral portions of the loaded ball rolling grooves **5**, **5**, **5** and **5**, the round piece portions **16** and **16** as the direction changing passage inner periphery guide portions and the pipe portions **14**, **14**, **14** and **14** as the rolling member return passage member are integrally formed to the movable block body **6** by inserting the movable block body **6** into a molding die. In this case, the die-molding operation can be performed by utilizing a resin molding method or a die-casting molding method using aluminum material or the like.

In addition, boundary portions between each of the round piece portion **15**, the ball retaining portion **12**, the pipe portion **14** and the movable member body **6** are limited to portions between the end surface **61** of the movable member body **6** and the round piece portions **15** and **16** as the direction changing passage inner periphery guide portion and between the ball rolling grooves **10**, **10**, **10** and **10** and the ball retaining portions **12** and **12**.

Accordingly, the countermeasure against the burrs is required for only the portions of the end surface **61** of the movable member body **6** and the ball rolling grooves **10**, **10**, **10** and **10**, so that an accuracy in dimension is not required for a portion between a side surface opposing to the side surface of the movable member body **6** to which rolling member rolling groove **10**, **10**, **10** and **10** are formed and the molding die. In this case, the round piece portions **16** and **16** provided at both end portions of the movable member body **6** are connected to the pipe portions **14**, **14**, **14** and **14** through the ball retaining portions **12** and **12**, so that the round piece portions **16** and **16** are not detachable therefrom.

Further, as shown in FIG. **3**, a method of manufacturing a movable block **4** for the rolling motion guide apparatus of the present invention comprises the steps of forming a through bore **13** for forming the ball return passage **11** at the movable block body **6** and supporting the the movable block body **6** within a first and a second molding dies **201** and **202** with reference to both the end surfaces **61** and the rolling member rolling grooves **10** of the movable block body **6**, and setting each of contact conditions between the end surface **61** of the movable block body **6** and the end surface supporting portions of the molding dies **201** and **202**, and between the ball rolling groove **10** of the movable block body **6** and a ball rolling groove supporting portion **22** of the first molding die **201** to a contact condition enabling to shut off a circulation of a fluidized resin material therebetween.

In this regard, the respective members are not required to be completely close-contacted to each other. As far as gaps of portions between the respective members are small enough, the circulation of the resin material can be shut off, so that a gap enabling to shut off the circulation shall be allowed. Both the end surfaces **61** and **61** can be securely shut off the resin circulation by a mold clamping force of the first and second molding dies **201** and **202**.

Then, a cavity **23** for forming the round piece portion **16** as the direction changing passage inner periphery guide portion is formed at a portion between both the end portions **61** and **61** of the movable block body **6** and the end surface supporting portions **21** and **21** of the first and second molding dies **201** and **202**, a cavity **24** for forming the ball retaining portion **12** is formed at the ball rolling groove **10** of the movable block body **6** and the side periphery portion of the ball rolling groove supporting portion **22** of the first molding die **201** and a cavity **26** for forming the ball return passage **11** at a portion between a core pin **25** to be inserted into the through bore **13** of the movable block body **6** and the inner periphery portion of the through bore **13**.

The respective cavities described above are communicated with each other. When the molding material is injected into the respective cavities **23**, **24** and **26**, the round piece portion **16**, the ball retaining portion **12** and the pipe portion **14** constituting the ball return passage **11** are integrally formed to the movable block body **6**.

[Other Embodiments]

Next, the other embodiments of the present invention will be explained hereunder. Notes, in the following explanations, only the points different from those of the aforementioned embodiment will be explained. Namely, detailed explanations regarding to the same constitutional elements or parts as those in the aforementioned embodiment will be omitted by adding the same reference numerals to the corresponding elements or parts.

A mode of an embodiment shown in FIG. **4** shows a case where the ball retaining portion **12** is not provided to a side peripheral portion of the ball rolling groove **10** of the movable block body **6**.

Namely, in this embodiment, the boundary portion between the round piece portion **16** to be die-molded and the movable block body **6** is limited to portions i.e., a portion between the end surface of the movable block body **6** and the round piece portion, and a portion between both the end portions of the ball rolling groove **10** and the round piece portion **16**.

According to the structure described above, the portion to be required to take the countermeasure against the burrs is limited to only the end surface of the movable block body **6** and both the end portions of the ball rolling groove **10**. As a result, the number of portions required for pressing the movable block body can be reduced in comparison with that of the afore-mentioned embodiment. At the time of the mold-shaping operation, as shown in FIG. **4**(*b*), when a groove end supporting portion **27** for supporting only a groove end of the ball rolling groove **10** is provided, the formation of the burrs of the molding material to the ball rolling groove **10** can be prevented. As a matter of course, a ball rolling groove supporting portion **22** for supporting the ball rolling groove can also be provided in the entire length of the ball rolling groove **10**.

In this case, the round piece portion **16** provided at both end portions of the movable block body **6** is connected by the pipe portion **14** for forming the ball return passage member, so that the round piece portion is not detachable therefrom.

Further, a mode of an embodiment shown in FIG. **5** shows a case where the ball retaining portion **12** is not provided at a side peripheral portion of the ball rolling groove **12** of the movable block body **6** and the ball return passage **11** is not formed by mold-shaping. The apparatus is characterized in that the boundary portion between the round piece portion **16** and the movable block body **6** is limited to portions i.e., a portion between the end portion **61** of the movable block body **6** and the round piece portion **12**, a portion between both the end portions of the ball rolling groove **10** and the round piece portion **16**, and a portion between both the end portions of the ball return passage **11** and the round piece portion **16**.

According to the structure described above, the portion to be required for taking the countermeasure against the burrs is limited to the portions of the end surface of the movable block body **6**, both the end portions of the ball rolling groove **10** and both the end portions of the ball return passage **11**.

That is, at the time of die-molding operation, as shown in FIG. **5**(*b*), when a groove end supporting portion **27** for supporting only the groove end of the ball rolling groove **10** and a passage end supporting portion **28** for supporting a passage end portion of the ball return passage **11** are provided, the molding material can be prevented from flowing into the ball rolling groove **10** and the ball return passage **11**, so that the formation of the burrs due to the molding material to the ball rolling groove **10** can be prevented.

In this case, as shown in FIG. **5**(*c*), when the round piece portion **16** is constructed so that both end surfaces **61** of the movable block body **6**, to which the round piece portion **16** is bonded, are provided with an engaging hole **62** while the round piece portion **16** is provided with an engaging convex portion **63** for locking which is formed from a molding material flowing into the engaging hole **62**, the dropping-off of the round piece portion **16** can be prevented.

In particular, when the engaging hole **62** is formed to be a screwed hole having a thread groove formed to an inner periphery portion of the screwed hole while the engaging convex portion **63** is formed to have a male thread groove with which the thread groove of the screwed hole is engaged, the prevention of the dropping-off can be further secured.

By the way, although the embodiments have been explained by exemplifying the linear motion guide apparatus as the rolling motion guide apparatus, the present invention is not limited to those embodiments, and it should be understood, as a matter of course, that the present invention is also generally applicable to various rolling motion guide apparatuses in which a movable member is movably assembled to a guide shaft through various rolling members such as ball spline, ball bush or the like.

According to the present invention described above, the portion requiring for the countermeasure against the burrs is limited to only the end surface of the movable member body and the rolling member rolling groove portion, while an accuracy in dimension is not required for a portion between a side surface opposing to the side surface of the movable member body to which rolling member rolling groove is formed and the molding die. Therefore, the preparation of the movable member body and the molding die can be simplified, so that a productivity of the apparatus can be increased.

In addition, according to the method of manufacturing the movable member of the present invention, the movable member body portion is supported by the end surface of the movable member body and the rolling member rolling portion, and each of the positions of the rolling member retaining portion, the direction changing passage inner periphery guide portion and the rolling member return passage are determined with reference to the rolling member rolling portion. Therefore, each of the joint portions between the rolling member rolling portion and the direction changing passage inner periphery guide portion and between the direction changing passage and the ball return passage can be formed as continuous surfaces each having no difference in level, so that smooth circulation and movement of the rolling member can be effectively achieved.

Industrial Applicability

As described above, the rolling motion guide apparatus and the method of manufacturing the movable member for the apparatus according to the present invention are effective to the linear motion guide apparatus in which a movable member is movably assembled to a guide shaft through various rolling members such as linear ball guide device, ball spline, ball bush or the like, and particularly effective to apparatus in which a resin molded portion is integrally formed to the movable member body.

What is claimed is:

1. A rolling motion guide apparatus comprising a track shaft and a movable member movably disposed on said track shaft through a number of balls,

wherein said movable member comprises: a movable member body having a loaded rolling member rolling portion corresponding to a loaded rolling member rolling portion formed on said track shaft and a rolling member return passage for returning the balls from one end of said loaded rolling member rolling portion to the other end thereof; and a direction changing passage member provided at both end portions of said movable member body, said direction changing passage member constituting a rolling member rolling direction changing passage for scooping up the balls from said loaded rolling member rolling portion and then guiding the balls to said rolling member return passage,

wherein a rolling member retaining portion, a direction changing passage inner periphery guide portion and the rolling member return passage constituting portion to be provided at side peripheral portions of said loaded rolling member rolling portion are integrally formed to said movable member body by inserting said movable member body into a molding die,

wherein said rolling member return passage constituting portion is integrally formed to an inner peripheral portion of a through bore formed so as to penetrate said movable member body, and

wherein boundary portions between each of said rolling member retaining portion, said direction changing inner periphery guide portion, said rolling member return passage constituting portion and the movable member body are limited to a boundary portion between an end portion of the movable member body and said direction changing passage inner periphery guide portion and a single boundary portion between said rolling member rolling portion and said rolling member retaining portion.

[57] **ABSTRACT**

The present invention relates to a slider of a linear guide device for guiding a movable body such as a work table or an industrial robot or the like of a machine tool under load which moves along a track rail arranged at a fixed portion such as a bed, or a column. The block main body is made of a metal which becomes a core part of the slider in a predetermined shape and forming load rolling faces of balls on the block main body by machine. The block main body is inserted into a mold and injection molding of a synthetic resin is performed by which ball retaining portions are built on both sides of the load rolling faces of block main body. Pairs of smooth faces for shielding the molten synthetic resin are formed along the both edges in the longitudinal direction of the load rolling faces formed on block main body whereas the block main body is fixed at a predetermined position in the mold by bringing a projected support portion on the side of the mold into contact with the smooth faces for shielding the molten synthetic resin.

METHOD OF MAKING A SLIDER OF A LINEAR GUIDE DEVICE

This application is a division of Ser. No. 08/845,151 filed Apr. 21, 1997.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a method of making a slider of a linear guide device for guiding a movable body such as a work table of a machine tool or an industrial robot or the like moving along a track rail arranged at a fixed portion such as a bed, a column or the like while applying a load on the track rail, particularly to a method of forming a slider by building up a synthetic resin onto a block main body made of a metal.

2. Description of the Related Art

There has been known a conventional linear guide device of such a kind constituted by a track rail that is arranged at a fixed portion such as a bed or the like and on which rolling faces of balls are formed and a slider integrated to the track rail via a number of balls for moving along the track rail while supporting a movable body such as a table or the like.

Further, the above-described slider is constituted by a movable block having load rolling faces opposed to the rolling faces of the track rail via balls and ball return holes in parallel to the load rolling faces, which is movable along the track rail by rolling the balls, a pair of end caps respectively fixed to forward and backward end faces of the moving block and having direction change paths of the balls for communicating and connecting the load rolling faces with the ball return holes and ball retainers attached to the moving block for preventing the balls from coming off from the load rolling faces when the slider is removed from the track rail. Also, end portions of the load rolling faces and the ball return holes are connected by the direction change paths by fixing the end caps to the forward and rearward end faces of the moving block whereby infinite circulation paths of balls are completed in the slider.

Meanwhile, according to the conventional slider for the linear guide device constituted as described above, boring of the ball return hole, attaching operation of the ball retainers and the like are needed with respect to the moving block and considerable time and labor is required in manufacturing the slider. Therefore, the applicants have proposed to manufacture the slider by utilizing an injection molding process of a synthetic resin (Japanese Unexamined Patent Publication No. JP-7-317762).

Specifically, a synthetic resin is built up by injection molding onto a block main body made of a metal where the above-described load rolling faces have been ground and the ball return holes and the ball retainers are integrally formed with the block main body in the injection molding by which the moving block is manufactured, which is provided with an advantage whereby a moving block having a complicated shape can easily be manufactured.

Meanwhile, in building up a synthetic resin onto the block main body made of a metal, the ball retaining portions are formed on the both sides of the load rolling faces of the block main body as described above, where it is necessary to expose the load rolling faces per se on which the balls run without putting the synthetic resin on the load rolling faces. Therefore, it is necessary to cover the load rolling faces against the molten synthetic resin in the injection molding.

Accordingly, conventionally, in fixing the block main body in the mold of the injection molding, a projected

support portion provided on the side of the mold is brought into contact with the load rolling faces of the block main body and the load rolling faces are covered against the molten synthetic resin by the projected support portion.

However, when the load rolling faces are covered by bringing the projected support portion of the mold into direct contact with the load rolling faces, since the load rolling faces are formed in a curved face corresponding to the curvature of the ball, it is necessary to form the projected support portion in contact with the load rolling faces also in a curved face in compliance with the curvature of the load rolling faces and if the curved faces of both are not brought into accurate alignment, the molten synthetic resin forming the retainers invades a clearance therebetween.

Furthermore, when the molten synthetic resin invades the clearance between the load rolling faces and the projected support portion of the mold, the molten synthetic resin constitutes burrs of the synthetic resin covering the load rolling faces and the smooth running of the balls is significantly hampered under such a state. Also, once the ball retainers are formed on the both sides of the load rolling faces, the load rolling faces cannot be polished since the ball retainer becomes a hazard for the polishing operation and therefore, the constituted burrs cannot be removed. Accordingly, in the method of manufacturing the moving block utilizing the injection molding, a countermeasure for preventing the occurrence per se of burrs covering the load rolling face is indispensable.

Meanwhile, it is preferable to set the block main body to the mold with the load rolling faces which have been formed, as positioning references in fixing the block main body in injection molding, since the ball retaining portions are needed to form accurately in the positional relationship thereof with the load rolling faces.

However, it is difficult to position the block main body by bringing the load rolling faces in contact with the projected support portion on the side of the mold, which is also formed in a curved face since the load rolling faces are formed in a curved face as described above. Especially, when the load rolling faces face in different four directions, it is extremely difficult to accurately position the block main body in the mold.

Also, when the projected support portion of the mold is brought into contact with the load rolling faces, the load rolling faces, which have been ground in the finishing operation, may be damaged with high probability and the grinding operation of the block main body prior to the injection molding operation may be completely be ruined.

SUMMARY OF THE INVENTION

The present invention has been carried out in view of such a problem and it is an object of the present invention to provide a method of making a slider of a linear guide device in which in forming the slider of the linear guide device installed with ball return holes and ball retaining portions by building up a synthetic resin onto a block main body made of a metal, the synthetic resin does not bring about burrs on load rolling faces of the block main body and the ball return holes and the retainers can be formed accurately.

In order to achieve the above-described object, a method of making a slider according to the present invention is comprising a first step of forming a block main body made of a metal which becomes a core part of the slider in a predetermined shape by machining and forming load rolling faces of balls on the block main body, and a second step of inserting the block main body formed in the first step into a mold and executing an injection molding of a synthetic resin whereby ball retaining portions are built on both sides of the load rolling faces of the block main body, wherein according to the first step pairs of smooth faces for shielding the molten synthetic resin are formed on both edges in the longitudinal direction of the load rolling faces formed on the block main body, whereas according to the second step the block main body is fixed at a predetermined position in the mold by bringing a projected support portion erected on the mold into contact with the smooth faces for shielding the molten synthetic resin.

As described above, in forming the ball retaining portions on the both sides of the load rolling faces by utilizing the injection molding of a synthetic resin, it is necessary to prevent the molten synthetic resin from invading the load rolling faces. According to the method having the above-described steps, with respect to the main body fixed in the mold the pairs of faces for shielding the synthetic resin formed along the both edges of the load rolling faces are brought into contact with the projected support portion erected on the mold and therefore, the molten synthetic resin for forming the ball retaining portions can be prevented from flowing to the load rolling faces by the smooth faces for shielding the molten synthetic resin. Moreover, the smooth faces for shielding a molten synthetic resin are not formed in a curved face as in the load rolling faces but in a smooth face and therefore, no clearance is formed between the smooth faces for shielding the molten synthetic resin and the projected support portion of the mold which are brought into contact with each other and the molten synthetic resin can firmly be prevented from invading the load rolling faces. Therefore, according to the invented method formation of burr of the synthetic resin on the load rolling faces can firmly be prevented.

Meanwhile, when the slider made by this method is observed, it is recognized that the pairs of smooth faces for shielding the molten synthetic resin mold which become positioning references for fixing the main body in the injection molding and which are disposed between the load rolling faces and the ball retaining portions on the both sides of the load rolling faces, are exposed without being covered by the ball retaining portions. Accordingly, whether a slider is made by the invented method, can be determined by whether the pairs of faces for shielding the molten synthetic resin, which has been finished smoothly to a degree whereby they can be utilized as positioning references, are exposed on the both edges along the longitudinal direction of the load rolling faces. That is, according to another aspect of the present invention, there is provided a slider of a linear guide device wherein pairs of faces for shielding a molten synthetic resin which become references for fixing a block main body in injection molding, are exposed on both edges along the longitudinal direction of load rolling faces.

Also, according to the invented method, in the second step the block main body is positioned and fixed in the mold by bringing the projected support portion of the mold into contact with the smooth faces for shielding the synthetic resin and therefore, the positioning accuracy of the block main body in the mold is promoted in comparison with the conventional case in which the positioning is carried out by using the load rolling faces in a curved face whereby the positioning relationship between the ball retaining portions built up on the block main body by injection molding and the load rolling faces can be made accurate. Thereby, it can be prevented that noise is caused due to contact of the balls running on the load rolling faces with the ball retaining portions or the circulation of the balls becomes unstable in using the linear guide device.

Further, according to the invented method the block main body is fixed in the mold by bringing the projected support portion of the mold into contact with the faces for shielding the synthetic resin. It is preferable in this procedure that the projected support portion is brought into contact with the faces for shielding the molten synthetic resin which are formed on the both edges to span across the load rolling faces whereby spaces are formed between the projected support portion and the load rolling faces. The reason is that according to the invented method the machining of the load rolling faces are completed in the first step prior to the injection molding and therefore, if the projected support portion in the mold is brought into contact with the load rolling faces in the second step, the load rolling faces which have been finished with a predetermined face accuracy will be roughened.

As described above, according to the invented method the both edges of load rolling faces of the block main body which becomes a core part of a slider, are formed with the pairs of smooth faces for shielding the molten synthetic resin and in the step of the insert molding for building the synthetic resin on the block main body the faces for shielding the molten synthetic resin and the projected support portion erected on the mold are brought into contact. Therefore, the formation of burrs of the synthetic resin on the load rolling faces through the process of the insert molding can be prevented and the ball retaining portions can be formed accurately on the block main body whereby the slider of a linear guide device on which the balls run smoothly and in which generation of noise accompanied by the circulation of the balls is restrained as less as possible, can be manufactured.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a partially cut front view showing a preferred exemplary embodiment of a linear guide device of the present invention;

FIG. **2** is a partially cut side view showing the preferred exemplary embodiment of the linear guide device of the present invention;

FIG. **3** is an exploded perspective view of a slider in accordance with the preferred exemplary embodiment of the present invention;

FIG. **4** is a sectional view taken along a line IV—IV of FIG. **3**;

FIG. **5** is a perspective view showing a block main body constituting a core part of a moving block according to the preferred exemplary embodiment of the present invention;

FIG. **6** is a sectional view taken along a line VI—VI of FIG. **5**;

FIG. **7** is a front view showing a behavior of grinding operation on load rolling faces and smooth faces with respect to the block main body;

FIG. **8** is an enlarged view showing details of a region encircled by a circle A described by a broken line in FIG. **6**;

FIG. **9** is a sectional view showing the block main body inserted into a mold; and

FIG. **10** is an enlarged view showing details of a region encircled by a circle B drawn by a broken line in FIG. **9**.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

A detailed explanation will be given of a slider of a linear guide device according to the present invention in reference to the attached drawings as follows.

FIG. **1** and FIG. **2** illustrate a preferred exemplary embodiment of a linear guide device in which a slider of the present invention is integrated with a track rail. In FIGS. **1** and **2**, numeral **1** designates a track rail arranged to a fixed portion such as a bed or the like of a machine tool, numeral **2** designates a slider for guiding a movable body such as a table or the like along the track rail **1** and numeral **3** designates a ball rolling under load between the track rail **1** and the slider **2** and infinitely circulated in the slider **2**.

Firstly, the section of the track rail **1** is formed in substantially a square shape in which a total of four tracks of ball rolling face **11***a* and **11***b* on which the balls **3** run, are formed along the longitudinal direction (orthogonal to the paper face of FIG. **1**). These ball rolling faces **11***a* and **11***b* are formed on the both side faces and the both edge portions of the upper face of the track rail **1** in which the ball rolling faces **11***a* on the both side faces are formed **30** downwardly from the left and right direction of the paper face whereas the ball rolling faces **11***b* on the upper face are formed upwardly in the vertical direction. Further, bolt attaching holes **12** are formed in the track rail **1** at pertinent intervals in the longitudinal direction and the track rail **1** is fixed to a fixed portion by fixing bolts, not illustrated, which are inserted into the bolt attaching holes **12**.

Meanwhile, the slider **2** is constituted by a moving block **4** having an attaching face **41** for attaching a movable body such as a table or the like and tap holes **42** for screwing fixing bolts of the movable body and a pair of end caps **5** fixed to the foreword and rearward end faces of the moving block **4** and infinite circulation paths of the balls **3** are provided in the slider by fixing the end caps **5** to the moving block **4**. Further, seal members **6** which are brought into abrasive contact with the track rail **1** are attached to the end caps **5** for preventing dust or dirt attached onto the track rail **1** from invading the inside of the slider **2** accompanied by the movement of the slider **2**.

As illustrated in FIG. **3** and FIG. **4**, the moving block **4** is provided with a horizontal portion **4***a* where the attaching face **41** is formed and a pair of skirt portions **4***b* hanging down from the horizontal portion **4***a* and the section thereof is formed in substantially a saddle form and four tracks of load rolling faces **43***a* and **43***b* are formed on the lower face of the horizontal portion **4***a* and on the inner faces of the respective skirt portions **4***b* opposingly to the ball rolling faces **11***a* and **11***b* of the track rail **1**. Also, ball return holes **44***a* and **44***b* respectively corresponding to the load rolling faces **43***a* and **43***b* are formed at the horizontal portion **4***a* and the skirt portions **4***b* and the respective load rolling faces **43***a* and **43***b* and the corresponding ball return holes **44***a* and **44***b* are connected by direction change paths **51** of the balls **3** formed in the end caps **5** thereby forming the infinite circulation paths of the balls.

Thereby, when the balls **3** which have been under load between the rolling faces **11***a* and **11***b* of the track rail **1** and the load rolling faces **43***a* and **43***b* of the moving block **4**, finish running on the load rolling faces **43***a* and **43***b* with the movement of slider **2**, they are relieved from the load and enter the direction change paths **51** of one of the end caps **5**, and run under no load in the ball return holes **44***a* and **44***b* of the moving block **4** toward a direction reverse to the running direction at the load rolling faces **43***a* and **43***b*. Further, the balls **3** which have finished running in the ball return holes **44***a* and **44***b*, enter again between the track rail **1** and the moving block **4** via the direction change paths **51** of the other one of the end caps **5** and run on the load rolling faces **43***a* and **43***b* under load.

Further, ball retaining portions **45** are formed on the both sides of the respective load rolling faces **43***a* and **43***b* as if covering the load rolling faces **43***a* and **43***b* thereby preventing the balls **3** which are disposed on the load rolling faces **43***a* and **43***b* from rolling down from the slider **2** when the slider **2** is removed from the track rail **1**.

Further, according to the preferred exemplary embodiment, in view of avoiding contact among balls in the infinite circulation paths and preventing as less as possible the wear of the balls **3**, ball chains are constituted by rotatably fitting the balls **3** in belt-like cages **7** made of a synthetic resin and the ball chains are integrated to the infinite circulation paths. Therefore, recessed grooves for supporting the both edge portions of the belt-like cages **7** circulating in the infinite circulation paths along with the balls **3**, are formed in the ball return holes **44***a* and **44***b* and the ball retaining portions **45**.

Furthermore, as illustrated in FIG. **3**, ball guide portions **46** in a semicircular shape are projected at the foreword and rearward end faces of the moving block **4** for guiding the balls **3** entering and leaving the ball return holes **44***a* and **44***b* in cooperation with the direction change paths **51** of the end caps **5**.

The moving block **4** is formed by building by injection molding a synthetic resin onto the block main body **8** made of a metal which is formed by mechanical working. Portions requiring mechanical strength such as the movable body attaching face **41**, the load rolling faces **43***a* and **43***b* of the balls **3** and the like, are formed in the block main body **8**, whereas portions with no significance in mechanical strength such as the ball return holes **44***a* and **44***b*, the ball retaining portions **45** and the ball guide portions **46** and the like, are formed by a synthetic resin whereby light weight formation of the moving block **4** is achieved as light as possible. FIG. **5** and FIG. **6** show the block main body **8** before building a synthetic resin thereon. According to the block main body **8**, after the outline shape of the horizontal portion **4***a* and the skirt portions **4***b* has been formed by drawing, the movable body attaching face **41** and reference side faces **47** are formed with a predetermined accuracy by polishing and through holes **48** which become base holes for the ball return holes **44***b*, are formed by boring. Further, in the drawing process, recessed portions **49** which become resin storages are formed on the outer side of the skirt portions **4***b* with a purpose of promoting adherence of a synthetic resin which is to be built in later steps with respect to the block main body **8**.

The load rolling faces **43***a* and **43***b* are needed to form on the block main body **8** and the load rolling faces **43***a* and **43***b* are formed as illustrated in FIG. **7** after forming the movable body attaching face **41** and the reference side faces **47**. That is, the movable body attaching face **41** and the reference side faces **47** which have already been formed, are brought into contact with attaching reference faces of a polishing stage **9** thereby fixing the block main body **8**, under which the grindstone **10** is brought into contact with the block main body **8** whereby the load rolling faces **43***a* and **43***b* are polished. At this occasion the load rolling faces **43***a* and **43***b* are polished in one machining operation by using the same grindstone **10** in order to render accurate the positional relationship among the load rolling faces **43***a* formed at the skirt portions and the load rolling faces **43***b* formed at the horizontal portion.

FIG. **8** is an enlarged view showing the surroundings of the load rolling faces **43***a* and **43***b* which have been polished. According to the polishing operation using the grindstone **10** not only the load rolling faces **43***a* and **43***b* are formed but pairs of smooth faces **50** are formed along both edges in the longitudinal direction of the respective load rolling faces. That is, the grindstone **10** is a formed polishing grindstone having a shape reverse to the shape of the load rolling faces **43**_a_ and **43**_b_ faces **50** and the smooth are formed with a constant positional accuracy in respect of the load rolling faces **43**_a_ and **43**_b_ which are disposed contiguously to the smooth faces **50**.

In steps of injection molding of a synthetic resin, mentioned later, the smooth faces **50** function as positioning reference faces of the block main body **8** in the mold and are used as measuring reference faces in measuring whether the load rolling faces **43**_a_ and **43**_b_ are formed with a predetermined dimensional accuracy.

Next, an explanation will be given of a step of building a synthetic resin by injection molding onto the block main body **8** which has been finished in a predetermined shape in this way.

The injection molding is executed by a process in which the block main body **8** all the machining of which has been finished, is arranged in a mold as a core, which is referred to as insert molding, whereby a synthetic resin is built only at predetermined positions of the block main body **8** by which the ball return holes **44**_a_ and **44**_b_, the ball retaining portions **45** and the like, are formed.

FIG. **9** is a sectional view showing the block main body **8** which is inserted into molds **61** and **62**. A projected support portion **63** for fixing the block main body **8** is erected on the mold **61** and positioning of the block main body **8** in the molds **61** and **62** is carried out by fitting the block main body **8** in respect of the projected support portion **63** from the axial direction (orthogonal to paper face) and cavities **64** and **65** corresponding to the ball retaining portion **45** of the moving block **4** are formed between the block main body **8** and the projected support portion **63** whereas cavities **66** for forming the ball return holes **44**_a_ are formed between the skirt portions **4**_b_ of the block main body **8** and the mold **61**. Further, rod-like mold bodies **67** having a sectional shape in agreement with the shape of the ball return holes **44**_a_ and **44**_b_, are inserted into the through holes **48** of the block main body **8** and the cavities **66** by which the ball return holes **44**_a_ and **44**_b_ are formed when the molten synthetic resin is filled in the through holes **48** and the cavities **66**.

Also, the mold **61** is brought into contact with the lower end edges of the reference side faces **47** of the block main body **8** by which the shielding of the molten synthetic resin filled in the cavities **66** is carried out and the synthetic resin is prevented from covering the reference side faces **47**.

Meanwhile, FIG. **10** is an enlarged view showing details of a state of contact between the projected support portion **63** and block main body **8**. When the synthetic resin is put on the load rolling faces **43**_a_ and **43**_b_ formed on the block main body **8**, it becomes a hazard against the running of the balls **3** and therefore, it is required in such an insert molding that shielding of the molten synthetic resin is firmly carried out between the load rolling faces **43**_a_ and **43**_b_ and the contiguous cavities **64**, **65** and **66**. Accordingly, in fitting the block main body **8** to the projected support portion **63**, the projected support portion **63** is brought into contact with the smooth faces **50** which are formed on the both edges of the load rolling faces **43**_a_ and **43**_b_ whereby the shielding the molten synthetic resin filled in the cavities **64**, **65** and **66** is carried out. Further, the projected support portion **63** is brought into contact with the smooth faces **50** to span across the load rolling faces **43**_a_ and **43**_b_ to prevent the load rolling faces **43**_a_ and **43**_b_ which have been finished in a predetermined accuracy from damaging by the contact with the projected support portion **63**.

Further, after inserting the block main body **8** into the molds **61** and **62**, the molten synthetic resin is filled in the cavities **64**, **65** and **66** formed by the block main body **8** and the mold **61** and the synthetic resin is built on the main body **8** whereby the moving block as illustrated by FIG. **3** and FIG. **4** is completed.

According to the step of the insert molding which is carried out as has been described above, in positioning the block main body **8** in the mold **61** in this embodiment, the projected support portion **63** erected on the mold **61** for fitting to the block main body **8**, is brought into contact with the pairs of smooth faces **50** which are formed along the both edges of the load rolling faces. Therefore, the following advantages are achieved in comparison with the conventional manufacturing method in which the positioning of the block main body is carried out by bringing the projected support portion in direct contact with the load rolling faces.

That is, the smooth faces **50** are formed by polishing them simultaneously with the load rolling faces **43**_a_ and **43**_b_ and therefore, the accuracy of the formed positions and the smoothness are significantly excellent and by bringing the projected support portion **63** into contact with the smooth faces **50** which have been formed with such a high accuracy, the projected support portion **63** and the smooth faces **50** are brought into close contact with each other whereby the molten synthetic resin can be shielded with certainty by the smooth faces **50**. Therefore, according to the moving block **4** manufactured by the method of this embodiment, no burr of synthetic resin is caused on the load rolling faces **43**_a_ and **43**_b_ whereby smooth running of ball can be guaranteed.

Also, it is possible to promote the positioning accuracy of the block main body **8** inserted into the molds **61** and **62** by bringing the projected support portion **63** into contact with the smooth faces **50** which have been formed with high accuracy, whereby the locations of forming the ball retaining portions **45** in respect of the load rolling faces **43**_a_ and **43**_b_ of the block main body **8** are made accurate. Therefore, the balls **3** running on the load rolling faces **43**_a_ and **43**_b_ can be prevented from being brought into contact with the ball retaining portions **45** and generation of noise can be avoided as less as possible in circulating the balls **3**.

Incidentally, according to the preferred exemplary embodiment, when the block main body **8** is inserted into the molds **61** and **62**, the load rolling faces **43**_a_ and **43**_b_ with a predetermined accuracy prior to the insert molding, are not damaged by the step of the insert molding since spaces are formed between the load rolling faces **43**_a_ and **43**_b_ and the projected support portion **63** whereby the smooth running of the balls **3** can be guaranteed.

What is claimed is:

1. A slider of a linear guide device comprising:

a block main body made of metal and having load rolling faces of balls which are infinitely circulated;

synthetic resin portions formed by injection molding on the block main body in a state of positioning the block main body in a mold as a core;

ball retaining portions including the synthetic resin portions and formed on both sides of the load rolling faces; and

pairs of polished faces formed on the block main body contiguously to each side of the load rolling faces, and brought into contact with the mold in the injection molding for positioning the block main body in the mold and shielding a molten synthetic resin,

wherein the pair of polished faces are exposed between the load rolling faces and the ball retaining portion.

[57] **ABSTRACT**

An object is to increase structural rigidity of a movable block by improving a contacting structure and arranging relations of four rows of rollers disposed between the movable block and a track rail.

The device is characterized in that upper two rows of rollers 21, 22 are arranged to portions close to a center side from side ends of the upper surface of the track rail 1, while roller rolling surfaces 61, 62 corresponding to the rollers 21, 22 are formed to the upper surface of the track rail 1 and a lower surface of a horizontal portion 4 of the movable block 3, that lower two rows of rollers 23, 24 are arranged such that one row of rollers is disposed to right and left side surfaces of the track rail 1, respectively, while roller rolling surfaces 63, 64 corresponding to the lower two rows of rollers 23, 24 are formed to the right and left side surfaces of the track rail 1 and inner side surfaces of the supporting leg portions 5, 5 of the movable block 3.

LINEAR ROLLER GUIDE DEVICE

TECHNICAL FIELD

The present invention relates to a linear roller guide device using rollers as rolling elements, and more particularly, to a linear roller guide device in which rigidity of a movable block is highly improved.

BACKGROUND ART

As a conventional linear roller guide device of this type, for example, a guide device shown in FIG. **15** is well known.

Namely, this linear roller guide device has a structure in which a movable block **102** is movably guided along a track rail **100** through a number of rollers **101** disposed to right and left portions of the track rail **100**. Two rows of the rollers **101** are disposed to each of the right and left portions of the track rail **100** in vertical direction. As a result, four rows of rollers **101** in total are disposed to the track rail **100**. Further, four rows of roller rolling surfaces **103** for rolling the four rows of rollers **101** are formed to the track rail **100** in an entire range in which the movable block **102** is moved.

On the other hand, the movable block **102** is provided with four rows of roller rolling surfaces **104** for clamping the rollers **101** so as to oppose to the roller rolling surfaces **103** formed to the track rail **100**. The movable block **102** is also provided with four rows of roller circulating passages **105** in unloaded region for circulating the rollers **101** clamped between the roller rolling surfaces **103;104** from one ends to the other ends of the roller rolling surface **103** of the movable block **102**.

These four rows of the rollers **101** are disposed in a form of four rows in total so that a pair of rows of rollers disposed vertically are arranged along each of right and left side surfaces of the track rail **100**. These four rows of the rollers **101** have a contacting structure in which a contact angle line S constituted by a line orthogonal to center axes of the rollers **101** disposed in upper two rows is set so as to downwardly incline towards the track rail **100** with an inclination angle of almost **45** with respect to a horizontal line H, while a contact angle line S constituted by a line orthogonal to center axes of the rollers **101** disposed in a pair of lower two rows is set so as to upwardly incline towards the track rail **100** with an inclination angle of almost 45° with respect to a horizontal line H, thus adopting a contacting structure in which the loads applied from every four directions are equally supported by the rollers.

In the linear roller guide device described above, however, there was posed a problem that a high rigidity property inherent in the roller **101** cannot be utilized.

In the case of this linear roller guide device, if deformations to be caused by pre-load or external loads applied to the movable block are not eliminated, a contacting state of the rollers **101** with respect to the roller rolling surfaces **103** and **104** are changed, so that a preferable result excellent in rigid performance cannot be obtained.

Namely, conventionally, the paired upper and lower rows of rollers **101** are arranged along the right and left side surfaces of the track rail **100** so as to be apart from each other in a vertical direction, so that a length L from a base portion of a supporting leg portion **106** of the movable block **102** to the lower roller **101** is made long. As a result, when the preload is applied to the roller **101** or when a load in a horizontal direction is applied to an upper surface of the movable block **102** from the right or left direction as an external load, a moment applied in a direction spreading the supporting leg portion **106** is disadvantageously increased.

Further, when a lifting load (i.e., a load applied in a direction detaching the movable block **102** from the track rail **100**) is applied as the external load, a force directing upward is applied to upper surfaces of both right and left end portions of the movable block **102** through screw holes **109** formed at upper surfaces of both right and left end portions of the movable block **102**. As a reaction of the upward force, a force directing downward is applied to the roller rolling surfaces **104** of the lower side of the rollers **101**. These vertically balancing forces are applied so as to be apart from each other with a lateral distance M between the screw hole **109** and the lower side roller **101**, so that a bending moment in a direction for spreading the supporting leg portion **106** will occur.

The bending moment due to this lifting load is caused by separating the screw hole **109** from the lower side roller **101** to each other in a horizontal direction, so that it is ideal to locate the screw hole **109** and the lower side roller **101** at the same position. However, due to exitence of the roller circulating passages **105** in unloaded region, it is difficult to form the screw hole **109** to a central portion of the movable block **102**.

With respect to the bending moment to be applied to these supporting leg portions **106**, a flexural rigidity at a horizontal portion **107** of the movable block **102** copes with the bending moment. However, when a thickness of the horizontal portion **107** is increased, a height dimension of the movable block **102** will be disadvantageously increased.

Further, conventionally, a skew of the roller **101** has been prevented by retaining both end surfaces of the roller **101** in an axial direction thereof by means of a vertical wall **104*a*** and a roller end surface guide member **108**, the vertical wall **104*a*** being provided to one side periphery of the roller rolling surface **104** of the movable block **102** while the roller end surface guide member **108** being provided to the other side periphery of the roller rolling surface **104**.

In this regard, the skew is a phenomenon of the roller **101** being rolled in a state where a central axis of the roller **101** is inclined with respect to an axis orthogonal to the rolling direction of the roller **101**. When this skew occurs, an excessive stress concentration will occur at the end portion of the roller **101** to thereby cause a deterioration in durability of the roller **101** and the roller rolling surfaces. Therefore, the generation of the skew must be sufficiently prevented.

However, even if the roller end surface guide member **108** is provided as conventionally made, when the movable block **102** per se is deformed as described above, the roller rolling surface **104** is displaced. As a result. thus bringing into the sane result as in the skew generation.

Furthermore, in a conventional art, since the roller end surface guide member **108** for retaining the roller **101** is interposed between the horizontal portion **107** and the upper surface of the track rail **100**, a space for installing the roller end surface guide member **108** is required to a portion between the horizontal portion **107** and the upper surface of the track rail **100**. As a result, the thickness of the horizontal portion **107** of the movable block **102** is obliged to be decreased and the rigidity thereof cannot be set to a large level.

The present invention has been achieved for solving the problems encountered to the prior art described above, and an object of this invention is to provide a linear roller guide device capable of increasing a structural rigidity of the movable block by improving the arranging relations of the rollers.

Another object of the present invention is to provide a linear roller guide device capable of sufficiently extending a contact length of the roller and sufficiently realizing high-rigidity characteristics of the roller by improving structures of the roller end surface guide portion and the roller retaining portion.

DISCLOSURE OF THE INVENTION

In order to achieve the afore-mentioned object, the present invention provides a linear roller guide device in which a movable block is guided along a track rail through four rows of rollers disposed on the track rail,

wherein the movable block comprises a horizontal portion opposing to an upper surface of the track rail and supporting leg portions projected downwardly from both end portions of the horizontal portion so as to oppose to right and left side surfaces of the track rail,

wherein the track rail is provided with four rows of roller rolling surfaces for rolling and guiding the rollers in an entire range of the track rail in which the movable block is moved, and

wherein, on the other hand, the movable block comprises four rows of roller rolling surfaces opposing to the roller rolling surfaces of the track rail for rollingly clamping the four rows of rollers and four rows of roller circulating passages provided at unloaded region for circulating the rollers clamped between the roller rolling surfaces of the track rail and the movable block from one end portion to the other end portion of the roller rolling surface of the movable block,

the linear motion guide device being characterized in that an upper two rows of rollers among the four rows of rollers are arranged to a portion close to a center side from a side end of the upper surface of the track rail, while roller rolling surfaces corresponding to the upper two rows of rollers are formed to the upper surface of the track rail and the lower surface of the horizontal portion of the movable block,

that the lower two rows of rollers among the four rows of rollers are arranged such that one row of rollers is disposed to an upper portion of right and left side surfaces of the track rail, respectively, while roller rolling surfaces corresponding to the lower two rows of rollers are formed to the right and left side surfaces of the track rail and inner side surfaces of the supporting leg portions of the movable block,

that the upper two rows of rollers has a structure in which a line orthogonal to a rotation axis of the roller is inclined with respect to a vertical line with a predetermined inclination angle, and

that the lower two rows of rollers has a structure in which a line orthogonal to a rotation axis of the roller is inclined with respect to a horizontal line with a predetermined inclination angle so as to upwardly extend towards a side of the track rail.

According to the structure described above, since the upper two rows of rollers are arranged to a portion close to center side from the end portion of the upper surface of the track rail and the lower two rows of the rollers are arranged to upper portions of the right and left side surfaces of the track rail, the lengths from the base portion of the right and left supporting leg portions of the movable block to the lower side rollers can be shortened in comparison with a conventional case where the two rows of rollers are arranged to the right and left sides surfaces of the track rail, respectively.

Accordingly, even if a reaction force of the preload applied to the roller or a lateral load acting in a direction so as to displace the movable block in a horizontal direction with respect to the track rail is applied, it becomes possible to decrease the bending moment acting in a direction spreading the supporting leg portions.

Further, in general, due to the moment acting in a direction spreading the supporting leg portions, a center portion of the horizontal portion is bent so as to close to the upper surface of the track rail. However, in the present invention, a bending deformation of the horizontal portion is suppressed by the action of the upper two rows of rollers disposed between the horizontal portion and the upper surface of the track rail, whereby the spreading of the supporting leg portions can be sufficiently decreased in co-operation with the reduction of the bending moment.

As described above, even if the preload is applied to the roller or a lateral load in a horizontal direction is applied, the deformation in a direction spreading the supporting leg portions of the movable block can be prevented and a degree of parallelization between the opposing roller rolling surfaces can be maintained to a constant level, whereby non-uniform contact of the rollers can be prevented.

In another aspect of this invention, the linear motion guide device may have a structure in which the upper two rows of rollers are arranged to portions close to a center side portion deviated from a side end of the upper surface of the track rail, while the roller circulating passages in unloaded region are also arranged to portions close to the center side portion with respect to the roller circulating passages in unloaded region corresponding to the lower two rows of the rollers, and wherein a screw hole for fixing the movable block is provided at portions on the upper surface of right and left end portions of the horizontal portion of the movable block, and the portions are set to upper positions of the roller circulating passages in unloaded region for the lower two rows of rollers or set to positions close to the center side.

When a lifting load in a direction so as to detach the movable block from the track rail is applied, a force directing upward is applied to the movable block through the screw holes. As a reaction of the upward force, a force directing downward is applied to the roller rolling surfaces of the lower side of the rollers. These vertically balancing forces are applied so as to be apart from each other with a lateral distance between the screw hole and the lower side roller, so that a bending moment in a direction for spreading the supporting leg portion will occur.

This bending moment is also basically supported by the upper two rows of rollers disposed between the horizontal portion and the upper surface of the track rail, thereby to sufficiently decrease the spreading of the supporting leg portions.

In general, the bending moment due to this lifting load is caused by separating the screw hole from the lower side roller so as to be apart from each other in a horizontal direction, so that it is ideal to form the screw hole and the lower side roller at the same position. However, due to existence of the roller circulating passages for the upper two rows of rollers in unloaded region, it is difficult to form the screw hole to a central portion of the movable block.

As a countermeasure of the above matter, in the present invention, the upper two rows of rollers are arranged to portions close to a center side portion deviated from a side end of the upper surface of the track rail, while the roller circulating passages in unloaded region corresponding to the upper two rows of rollers are also arranged to portions close to the center side portion with respect to the roller circulating passages in unloaded region corresponding to the lower two rows of the rollers, whereby an interference of the upper two rows of the rollers with the roller circulating passages can be avoided.

Simultaneously, the screw hole is provided at the roller circulating passages in unloaded region for the lower two rows of rollers or inside of the roller circulating passages, whereby the length in the horizontal direction between the screw hole and the lower side rollers is sufficiently shortened.

According to the structure described above, not only in a case when the preload is applied to the roller or the lateral load is applied but also in a case when the lifting load is applied, the moment can be decreased, the deformation in a direction so as to spread the supporting leg portions is prevented, and the degree of parallelization between the roller rolling surfaces is maintained to a constant level whereby the non-uniformity in contacting of the rollers can be prevented.

Further, when an angle between a line orthogonal to the rotation axis of each of the upper two rows of rollers disposed on the upper surface of the track rail and a vertical line is set at almost 45° and an angle between a contact angle line of the lower two rows of rollers disposed on the side surfaces of the track rail and a horizontal line is set at almost 45°, the same rated load can be obtained with respect to a radial load applying from upper direction (i.e., a load in a direction pressing the movable block onto the track rail), lifting load and the lateral loads applied from right and left directions, whereby any of the load applied from every direction can be supported. In other words, the device can be used in any attitudes or positions, and available to wide applications.

Further, it is effective to adopt a structure in which a track rail having a track groove having a V-shape in cross section comprising two inclined surfaces is used, and the roller rolling surfaces to be formed to the track rail and the movable block so as to correspond to the four rows of rollers are formed to one of the inclined surfaces while the other inclined surface is used as a guide surface for guiding the roller end surfaces, whereby the end surfaces of the rollers are guided while a pitch of the rollers is maintained to a predetermined value in a portion between the guide surface of the track groove of the track rail side and the guide surface of the movable block side which are opposed to each other.

If the track groove is formed to have a V-shaped in cross section described above, a locating relation between the respective track grooves can be accurately measured by using a roller pin, whereby the locating relation between the respective track grooves can be molded or formed with a high accuracy. Accordingly, the four rows of rollers disposed between the track rail and the movable block accurately contact to the roller rolling surfaces formed to a pair of track grooves corresponding to the four rows of rollers, and the end surfaces of the roller are accurately guided by the action of the guide surfaces of the paired track grooves.

As described above, the movable block has a rigidity regardless of the direction of the loads, so that the locating relation between the track rail and the movable block is normally maintained to a constant value. Further, the movable block is supported by the track rail at a position where the preload applied to the respective four rows of rollers and the reaction force of the preload are balanced, so that a gap between the end surface of the roller and the guide surface can be normally maintained to a constant level in co-operation with the effect of accurately forming the locating relation between the respective track grooves as described above.

In particular, the movable block is formed in a shape having a high rigidity, so that a high preload can be applied. Therefore, the high rigidity of the movable block and the high preload are synergistically effected to realize an effect such that the gap between the end surface of the roller and the guide surface can be maintained to a constant level. As a result, the skew preventing effect for the roller can be enhanced and a smooth circulation and a rolling accuracy of the rollers can be secured.

Further, the space for installing the roller end surface guide member, which is conventionally required to be provided to the lower surface of the movable block, becomes unnecessary in this invention, so that the thickness of the horizontal portion of the movable block can be increased with an amount equivalent to the space, whereby the the flexural rigidity of the horizontal portion can be increased and also the rigidity of the movable block can be enhanced. In addition, by enhancing the rigidity of the movable block, the effect of preventing the skew generation can be further synergistically improved.

When the roller rolling surfaces and the end surface guide surfaces are constituted by the track groove having a V-shape in cross section, the roller rolling surfaces and the end surface guide portions of the track groove can be simultaneously finished by a grinding work, so that a guiding accuracy of the rollers and surface roughness are improved and an enhanced effect in skew prevention can be obtained. In addition, the working amount for the track groove can be minimized.

Further, when a retainer for the roller is eliminated and the roller contacts to the roller rolling surface at an entire length of the roller, the rigidity of the roller per se can be effectively utilized.

Further, another invention is as follows.

Namely, there is also provided a linear roller guide device in which a movable block is guided along a track rail through rollers disposed on the track rail,

wherein the track rail is provided with roller rolling surfaces for rolling and guiding the rollers, and

wherein, on the other hand, the movable block comprises roller rolling surfaces opposing to the roller rolling surfaces formed to the track rail for rollingly clamping the rollers and roller circulating passages provided at unloaded region for circulating the rollers clamped between the roller rolling surfaces of the track rail and the movable block from one end portion to the other end portion of the roller rolling surface of the movable block,

the linear motion guide device being characterized in that a first end surface guide portion for guiding one end surface of the roller is provided to one side periphery of the roller rolling surface formed to the movable block so as to rise up at an almost right angle with respect to the roller rolling surface, while a second end surface guide portion for guiding the other end surface of the roller is provided to the other side periphery of the roller rolling surface formed to the track rail so as to rise up at an almost right angle with respect to the roller rolling surface,

that a radial direction retaining portion having a projection for preventing the roller from falling out in a radial direction by being engaged with a peripheral corner portion of the roller end surface is provided to one side periphery of the roller rolling surface formed to the track rail, while the roller is contacted to the roller rolling surface formed to the track rail at an almost entire contact length in a peripheral surface of the roller except an engaging width required for engaging with the radial direction retaining portion, and

that, on the other hand, an axial direction retaining portion for preventing the roller from falling out in an axial direction is provided to a side periphery of the roller rolling surface formed to the movable block, the side periphery being opposite to the side periphery to which the first end surface guide portion is provided.

According to this invention, one end surface of the roller is guided by the first end surface guide portion provided to one side periphery of the roller rolling surface formed to the movable block, while the other end surface of the roller is guided by the second end surface guide portion provided to the other side periphery of the roller rolling surface formed to the track rail, whereby the skew of the roller can be prevented.

In this regard, the skew is a phenomenon of the roller being rolled in a state where a central axis of the roller is inclined with respect to an axis orthogonal to the rolling direction of the roller. When this skew occurs, an excessive stress concentration will occur at the end portion of the roller to thereby cause a deterioration in durability of the roller and the roller rolling surfaces. Therefore, the generation of the skew must be sufficiently prevented.

In the present invention, the roller end surfaces are guided by the first and second end surface guide portions, whereby the center axis of the roller is maintained in an orthogonal direction with respect to the rolling direction of the roller.

On the other hand, when the movable block is detached from the track rail, the second end surface guide portion provided to the track rail is also detached from the other end surface of the roller. However, the roller is retained between the first end surface guide portion provided to one side of the roller rolling surface formed to the movable block and the axial direction retaining portion provided to the other side periphery thereof, so that the falling-out of the roller in an axial direction can be prevented.

Further, a peripheral portion of the one end surface of the roller is retained by the radial direction retaining portion provided to a portion of the track rail side from the first end surface guide portion with respect to the roller rolling surface, so that the falling-out of the roller in a radial direction can be also prevented.

As described above, the radial direction retaining portion is engaged with only a periphery of the one end surface of the roller, and the second end surface guide portion is provided to the other side periphery of the roller rolling surface formed to the track rail, so that a peripheral surface of the roller except the engaging portion for engaging with the radial direction retaining portion can be contacted to the roller rolling surface formed to the track rail so that the end surface is closely contacted to the second end surface guide portion, whereby the contact length of the roller can be sufficiently secured in a long length. Accordingly, the high rigidity characteristic of the roller can be sufficiently utilized.

In another aspect of this invention, the linear motion guide device is characterized in that the first end surface guide portion is integrally formed with a member for constituting a block body of the movable block.

According to this structure, the block body and the first end surface guide portion can be worked so as to have a high rigidity and high accuracy, and the end surfaces of the roller are guided in a portion between the first end surface guide portion and the second end surface guide portion provided to the track rail also having a high rigidity, whereby the skew generation can be further securely prevented.

In still another aspect of this invention, the device is characterized in that the first end surface guide portion is integrally formed with the block body by inserting the block body into a molding die.

According to this structure, the end surface guide portions can be accurately positioned without causing any attaching error, and the gap between the roller end surface and the first end surface guide portion can be further decreased without impairing the circulating motion of the rollers, so that the skew preventing effect for the roller can be enhanced.

Further, when this first end surface guide portion is constituted by a resin member, the roller end surface is guided by the resin member, so that a friction resistance is decreased whereby a smoothness in roller guiding can be increased.

Furthermore, the roller end surface would not wear, so that the skew prevention can be stably secured.

In still another aspect of this invention, the linear motion guide device is characterized in that a guide wall opposing to the roller end surface in a non-contact state is provided to one side periphery of the roller rolling surface formed to the movable block, the radial direction retaining portion is provided to an end portion of the guide wall, and the first end surface guide portion contacting to a circumferential portion of the roller end surface is constituted by an opposing surface of the radial direction retaining portion so that the opposing surface is opposed to the roller end surface.

According to this structure, contact areas of the first end surface guide portion and the roller end surface are decreased, so that a friction resistance can be decreased whereby a smoothness in roller circulation can be increased.

When both the first and second end surface guide portions are integrally formed with the block body by inserting the block body into a molding die, both the radial and axial direction retaining portions can be accurately positioned without causing any attaching error, so that a predetermined gap between the roller and the radial direction retaining portion or the axial direction retaining portion can be accurately formed during the rolling of the rollers, whereby the roller would not interfere with the radial and axial direction retaining portions. Accordingly, the rollers are smoothly rolled and moved in co-operation with the skew preventing effect for the rollers by the action of the first and second end surface retaining portions.

On the other hand, the linear motion guide device is characterized in that the roller circulating passage in unloaded region comprises an unloaded roller returning passage extending in an axial direction and a direction changing passage for connecting both ends of the unloaded roller returning passage to both ends of a roller rolling passage in loaded region to be formed between the opposing roller rolling surfaces of the track rail and the block body, wherein a direction changing passage inner periphery member for constituting an inner periphery portion of the direction changing passage, together with both radial and axial direction retaining portions, are integrally formed with the block body by inserting the block body into a molding die.

According to this structure, a connected portion of the loaded roller rolling surface and the direction changing passage inner periphery portion can be continuously formed without causing irregularities, so that the rollers are smoothly rolled and moved.

Further, in still another aspect of this invention, the linear motion guide device is characterized in that an unloaded roller returning passage member for constituting the unloaded roller returning passage, together with the direction changing passage inner periphery member and both the radial and axial direction retaining portions, are integrally formed with the block body by inserting the block body into a molding die.

According to this structure, each of the connected portions between the loaded roller rolling surface, the direction changing passage inner periphery portion and the unloaded roller returning passage can be continuously formed without causing irregularities, so that the rollers are smoothly circulated and moved in all around a circulating passage.

Further, in still another aspect of this invention, the linear motion guide device is characterized in that the direction changing passage inner periphery member and the unloaded roller returning passage member are integrally provided with an end surface guide portion for guiding at least one end surface of the roller.

According to this structure, the end surface guide portions of the direction changing passage inner periphery member and the unloaded roller returning passage member are continuously formed without causing irregularities, so that the skew of the roller can be prevented in all around the circulating passage and the rollers are smoothly circulated.

In still another aspect of this invention, the linear motion guide device is characterized in that four rows of rollers are provided in total among which two rows of the rollers are disposed on an upper surface of a track rail, and one row of the rollers is disposed to right and left side surfaces of the track rail, respectively,

wherein the movable block comprises a horizontal portion opposing to the upper surface of the track rail and supporting leg portions each extending downwardly from both ends of the horizontal portion and opposing to the right and left side surfaces of the track rail,

wherein among the four rows of the rollers, two rows of the rollers disposed on the upper surface of the track rail are arranged to portions close to a center side apart from a side end of the upper surface of the track rail with a predetermined distance, while roller rolling surfaces corresponding to the upper two rows of rollers are formed to the upper surface of the track rail and the lower surface of the horizontal portion of the movable block, and roller rolling surfaces corresponding to the lower two rows of rollers are formed to the right and left side surfaces of the track rail and inner side surfaces of the supporting leg portions of the movable block,

wherein the upper two rows of rollers has a structure in which a line orthogonal to a rotation axis of the roller is inclined with respect to a vertical line at a predetermined inclination angle, and

wherein the lower two rows of rollers has a structure in which a line orthogonal to a rotation axis of the roller is inclined with respect to a horizontal line at a predetermined inclination angle so as to upwardly extend towards a side of the track rail.

According to the structure described above, when the upper two rows of rollers are arranged to portions close to center side apart from the end portion of the upper surface of the track rail and the lower two rows of the rollers are arranged to upper portions of the right and left side surfaces of the track rail, the lengths from the base portions of the right and left supporting leg portions of the movable block to the lower side rollers can be shortened in comparison with a conventional case where the two rows of rollers are arranged to the right and left sides surfaces of the track rail, respectively.

Accordingly, even if a reaction force of the preload applied to the roller or a lateral load acting in a direction so as to displace the movable block in a horizontal direction with respect to the track rail is applied, it becomes possible to decrease the bending moment acting in a direction so as to spread the supporting leg portions.

Further, in general, due to the moment acting in a direction so as to spread the supporting leg portions, a center portion of the horizontal portion is bent so as to close to the upper surface of the track rail. However, in the present invention, a bending deformation of the horizontal portion is suppressed by the action of the upper two rows of rollers disposed between the horizontal portion and the upper surface of the track rail, whereby the spreading of the supporting leg portions can be sufficiently decreased in co-operation with the reduction of the bending moment.

As described above, even if the preload is applied to the roller or a lateral load in a horizontal direction is applied, the deformation in a direction so as to spread the supporting leg portions of the movable block can be prevented and a degree of parallelization between the opposing roller rolling surfaces can be maintained to a constant level, whereby non-uniform contact of the rollers can be prevented.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a view showing one embodiment of a linear roller guide device according to the present invention.

FIG. **2** is a perspective view partially in section of the linear roller guide device shown in FIG. **1**.

FIG. **3** is a view showing a modification of a roller contact structure for the upper two rows of the rollers used in the linear roller guide device shown in FIG. **1**.

FIG. **4** is a view showing a modification of a roller returning passage for the lower two rows of the rollers used in the linear roller guide device shown in FIG. **1**.

FIG. **5** is a view showing another embodiment of a linear roller guide device according to the present invention in which FIG. **5**(*a*) is a longitudinal sectional view and FIG. **5**(*b*) is an enlarged view of a portion close to the rollers disposed at an upper surface and a side surface.

FIG. **6** is a perspective view partially in section of the linear roller guide device shown in FIG. **5**.

FIG. **7**(*a*) is a view showing a structure of an end portion of the movable block used in the linear roller guide device shown in FIG. **1**,

FIG. **7**(*b*) is a view partially in section showing a structure of a roller circulating passage for upper surface side roller.

FIG. **7**(*c*) is a cross sectional view taken along the line c—c of FIG. **7**(*b*).

FIG. **7**(*d*) is a view partially in section showing a structure of a roller circulating passage for side surface side roller, and

FIG. **7**(*e*) is a cross sectional view taken along the line e—e of FIG. **7**(*d*).

FIGS. **8**(*a*)–(*c*) are views each showing a molding state of the linear roller guide device shown in FIG. **1**.

FIGS. **9**(*a*)–(*c*) are views showing modifications of radial and axial direction retaining portions for the upper surface side rollers.

FIGS. **10**(*a*)–(*c*) are views showing modifications of radial and axial direction retaining portions for the side surface side rollers.

FIGS. **11**(*a*), (*b*) are views showing another embodiments of a first end surface guide portion.

FIG. **12** is a view showing another embodiment of a linear roller guide device.

FIGS. **13**(*a*), (*b*) are views showing still another embodiments of a linear roller guide device.

FIG. **14**(*a*) is a view showing still another embodiment of a linear roller guide device, and

FIG. **15** is a view showing a conventional linear roller guide device.

BEST MODE FOR EMBODYING THE INVENTION

Hereunder, the present invention will be explained with reference to the accompanying drawings.

FIGS. **1** and **2** are views showing an embodiment of a linear roller guide device according to the present invention. The linear roller guide device has a structure in which a number of rollers **21–24** are arranged in a form of four rows of rollers in total of which two rows of rollers are vertically disposed to right and left portions of a track rail **1** respectively, and a movable block **3** is guided along a track rail **1** through a number of rollers **21–24**.

The movable block **3** comprises a horizontal portion **4** opposing to an upper surface of the track rail **1**, and supporting leg portions **5**, **5** extending downwardly from both end portions of the horizontal portion **4** so as to oppose to right and left side surfaces of the track rail **1**.

The track rail **1** has a rectangular shape in section, an upper surface of the track rail is formed with two rows of roller rolling surfaces while each of right and left side surfaces of the track rail is formed with one row of roller rolling surface, respectively, i.e., totally four rows of the roller rolling surfaces **61–64** are formed to the track rail **1** over entire length of a range in which the movable block **3** is moved. Further, the track rail **1** is forced with a plurality of bolt insertion holes **11** for fixing the track rail in a longitudinal direction, and an upper opening portion of each bolt insertion holes **11** is formed at a center of the upper surface of the track rail **1**.

On the other hand the movable block **3** is provided with four rows of roller rolling surfaces **71–74** for rollingly clamping the four rows of rollers **21–24** so as to oppose to the roller rolling surfaces **61–64** of the track rail **1**. The movable block **3** is also provided with four rows of roller circulating passages **81–84** at unloaded region for circulating the rollers **21–24** clamped between the roller rolling surfaces **61, 71**; **62, 72**; **63, 73**; **64, 74** formed to the track rail **1** and the movable block **3** from one end to the other end of the roller rolling surfaces **71–74** of the movable block **3**.

The movable block **3** comprises a block body **31** and side covers **32, 32** to be attached to both end surfaces in an axial direction of the block body **31**. The roller rolling surfaces **61–64** are formed to the block body **31**. The roller circulating passages **81–84** comprises roller returning passages **81***a*–**84***a* formed to the block body **31** so as to be in parallel to each of the roller rolling surfaces **61–64** and direction changing passages **81***b*–**84***b* having a U-shape to be formed to the side covers **32, 32**.

The roller returning passages **81***a*, **82***a* for the upper two rows of rollers **21, 22** are constituted by penetration bores penetratingly formed to the block body **31**. Each of the roller returning passages **83***a*, **84***a* for the lower two rows of rollers **23, 24** has a rectangular shape in cross section and comprises an inverse V-shaped groove **85** formed to lower end surface of the supporting leg portion **5**, and a retainer **86** having a V-shape in cross section for covering the groove **85**.

The upper two rows of rollers **21, 22** are arranged to portions close to a center side from side ends of the upper surface of the track rail with a predetermined distance C, while roller rolling surfaces **61, 71**; **62, 72** corresponding to the upper two rows of rollers **21, 22** are formed to the upper surface of the track rail **1** and the lower surface of the horizontal portion **4** of the movable block **3**.

Further, the roller returning passages **81***a*, **82***a* constituting the upper two rows of the roller circulating passages together with the roller returning passages **81***a* in unloaded region are arranged to portions close to center side portion with respect to the roller circulating passages **83***a*, **84***a* in unloaded region corresponding to the lower two rows of the rollers **23, 24**.

In addition, a screw hole **33** for fixing the movable block is provided at portions on the upper surface of both right and left end portions of the horizontal portion **31** of the movable block, and the portions are set to upper positions of the roller returning passages **83***a*, **84***a* for the lower two rows of rollers **23, 24** or set to positions close to the center side. Owing to this structure, a pitch P between the right and left screw holes **33, 33** is narrowed whereby the screw holes can be formed to the position close to the lower side rollers **23, 24**.

When a lifting load in a direction so as to lift the movable block **3** from the track rail **1** is applied. a force in a direction so as to detach the movable block **3** from the track rail **1** is applied while the above described screw holes **33, 33** are acting as points of application, in contrast, a reaction force against the force is applied to the roller rolling surfaces **73, 74** for the lower two rows of rollers **23, 24**. The force applied to the screw hole **33** and the reaction force constitute a relation of a couple of forces, whereby a bending moment in a direction for spreading the supporting leg portions **5, 5** will occur.

In the case of this embodiment, the upper two rows of rollers **21, 22** are arranged to portions close to a center side portion, so that an interference of the upper two rows of the rollers **21, 22** with the screw hole **33** can be avoided. Simultaneously, the screw hole **33** is provided at a portion close to the lower side rollers **23, 24**, so that a distance M in the horizontal direction between the screw hole **33** and the lower side rollers **23, 24** can be sufficiently shortened, whereby the bending moment in a direction for spreading the supporting leg portions **5, 5** can be reduced.

In addition, a relation between a lateral width W and a height A of the track rail **1** is set so as to satisfy $A/W<1$, so that stability of the track rail **1** can be enhanced, and simultaneously, an interference with an upper end opening portion **11**a of a bolt inserting hole to be opened at a center of the upper surface of the track rail **1** can be avoided.

Furthermore, the lower two rows of rollers **23, 24** among the four rows of rollers **21–24** are arranged such that one row of rollers is disposed to right and left side surfaces of the track rail **1** respectively, while the roller rolling surfaces **63, 73**; **64, 74** corresponding to the lower two rows of rollers **23, 24** are formed to the right and left side surfaces of the track rail **1** and inner side surfaces of the supporting leg portions **5, 5** of the movable block **3**.

The upper two rows of rollers **21, 22** have a structure in which contact angle lines **S1, S2** each constituted by a line orthogonal to a center axis of the upper two rows of rollers **21, 22** are inclined with respect to a vertical line V passing through a center between the rollers **21, 22** with predetermined inclination angles of α **1**, α **2** so as to open in a direction towards an opposite side of the track rail **1**. These contact angle lines **S1, S2** are indicated as lines connecting centers in a width direction of the respective roller rolling surfaces **61, 71**; **62, 72**.

In this case, the positions of the roller returning passages **81***a*, **82***a* are located at outside the rollers **21, 22** in right and left directions, respectively. Therefore, at a time of formation of the screw holes **33, 33**, it is required to take the interference with the roller returning passages **81***a*, **82***a* into consideration.

In a case shown in Figure, the positions of the roller returning passages **81***a*, **82***a* are located at almost upper portions of the rollers **23**, **24**, while the positions of the screw holes **33**, **33** are located at almost upper portions of the roller returning passages **83***a*, **84***a*. When the positions of the upper side rollers **21**, **22** and the roller returning passages **81***a*, **82***a* are shifted to portions further close to the center side, the positions of the screw holes **33**, **33** can be shifted from the upper positions of the roller returning passages **83***a*, **84***a* to the center side, close to the upper positions of the lower side rollers **23**, **24**.

As to this contact structure, as shown in FIG. **3**, there can be also proposed another structure in which the contact angle lines S1, S2 constituted by lines orthogonal to center axes of the upper two rows of rollers **21**, **22** are inclined with respect to a vertical line V passing through a center of between the rollers **21**, **22** with predetermined inclination angles of $\alpha1'$, $\alpha2'$ so as to close in a direction towards an opposite side of the track rail **1**.

According to this structure, the positions of the roller returning passages **81***a*, **82***a* are shifted to the center side with respect to positions of the rollers **21**, **22**, so that it becomes unnecessary to take an interference of the screw holes **33**, **33** with the roller returning passages **81***a*, **82***a* into consideration. Therefore, the positions of the screw holes **33**, **33** can be set to portions close to the center side from the upper position of the roller returning passages **83***a*, **84***a* for the lower two rows of the rollers **23**, **24** i.e., the screw holes **33**, **33** can be set to almost the upper portions of the lower two rows of the rollers **23**, **24**.

On the other hand, the linear motion guide device has a structure in which the contact angle lines S3, S4 constituted by lines orthogonal to center axes of the lower two rows of rollers **23**, **24** are inclined with respect to a horizontal line H passing through a center of between the rollers **21**, **22** with predetermined inclination angles of $\alpha3$, $\alpha4$ so as to upwardly direct to the track rail **1** side. These contact angle lines S3, S4 are also indicated as lines connecting the centers in a width direction of the respective roller rolling surfaces **63**, **73**; **64**, **74**.

In particular, in this embodiment, the contact angles $\alpha1$–$\alpha4$ are set to almost 45°.

Further, in a case of the device shown in Figure, the roller returning passages **81***a*–**84***a* are formed to be positioned on extended lines of the contact angle lines for respective rollers **21**–**24**. According to this structure, the rolling directions of the rollers **21**–**24** coincide with the directions of the direction changing passages **81***b*–**84***b*, so that the rollers **21**–**24** can be smoothly rolled and moved.

With respect to the roller returning passages **83***a* and **84***a* for the lower two rows of the rollers **23** and **24**, as shown in FIG. **4**, height positions of the passages **83***a* and **84***a* are set to almost the same as that of the roller rolling surface **73** in loaded region, so that a projecting length of each supporting leg portions **5**, **5** can be shortened, whereby the height of the track rail **1** can be reduced. As a result, an entire height B of the device can be lowered, and thus realizing the stabilized state of the linear motion guide device.

Further, in the present invention, the track rail **1** having track grooves **6**, **7** each having a V-shape in cross section comprising two inclined surfaces is used, and the roller rolling surfaces **61**, **71**; **62**, **72**; **63**, **73**; **64**, **74** to be formed to the track rail **1** and the movable block **3** are formed to one of the inclined surfaces, while the other inclined surface is used as guide surfaces **6***a*, **7***a* for guiding the roller end surfaces.

According to the present invention, since the upper two rows of rollers **21**, **22** are arranged so as to be shifted to a portion close to center side from the end portions of the upper surface of the track rail **1**, it is sufficient to form one row of roller rolling surface **73** or **74** to each of the inner side surfaces of the supporting leg portions **5**, **5** of the movable block **3**. As a result, the lengths L from the base portion of the supporting leg portions **5**, **5** to the lower side two rows of rollers **23**, **24** can be shortened, so that even if a reaction force of the preload applied to the rollers **21**–**24** or an external load is applied, it becomes possible to decrease the bending moment to be applied to the supporting leg portions **5**, **5**.

Further, in general, due to the moment acting in a direction spreading the supporting leg portions **5** and **5**, a center portion of the horizontal portion **4** will be bent so as to close to the upper surface of the track rail **1** However, in the present invention, a bending deformation of the horizontal portion **4** is suppressed by the action of the upper two rows of rollers **2** disposed between the horizontal portion **4** and the upper surface of the track rail **1**, whereby the spreading of the supporting leg portions **5** and **5** can be sufficiently decreased synergistically in co-operation with the reduction of the bending moment.

As described above, even if the preload is applied by the two rows of the rollers **21**, **22** disposed to the upper surface side of the track rail **1** or a lifting load is applied, the deformation in a direction so as to spread the supporting leg portions **5**, **5** of the movable block **3** can be prevented and a degree of parallelization between the opposing roller rolling surfaces **61**, **71**; **62**, **72**; **63**, **73**; **64**, **74** can be maintained to a constant level, whereby non-uniform contact of the rollers **21**–**24** can be prevented.

Further, when the angles between the contact angle lines S1, S2 of the upper two rows of rollers **21**, **22** disposed on the upper surface of the track rail **1** and a vertical line V is set at almost 45°, or a state shown in FIG. **3**, when the contact angle lines S1', S2' are set to be inclined with respect to the vertical line V with an inclination angle of almost 45 ° so as to open in a direction towards the track rail **1**, and when the angles between the contact angle lines S3, S4 of the lower two rows of rollers **23**, **24** disposed on the side surfaces of the track rail **1** with respect to a horizontal line H are set at almost 45°, the same rated loads can be obtained with respect to a radial load being applied from upper direction (i.e., a load in a direction so as to press the movable block **3** onto the track rail **1**), lifting load and the lateral loads applied from right and left directions, whereby any of the load applied from every direction can be supported. In other words, the device can be used in any attitudes or positions, and available to wide applications.

Further, the roller rolling surfaces **61**, **71**; **62**, **72**; **63**, **73**; **64**, **74** to be formed to the track rail **1** and the movable block **3** so as to correspond to the four rows of rollers **21**–**24** are formed to one of the inclined surfaces of the track grooves **6**. **7** each having a V-shape in cross section while the other inclined surface is used as guide surfaces **6***a*, **7***a* for guiding the roller end surfaces. whereby the end surfaces of the rollers are guided while a pitch of the rollers is maintained to a predetermined value in a portion between the guide surfaces **6***a*, **7***a* of the track grooves **6**, **7** formed to the track rail **1** side and the movable block **3** side which are opposed to each other.

As a result, a locating relation between the respective track grooves **6**, **7** can be accurately measured by using a roller pin or the like, whereby the above locating relation between the respective track grooves **6**, **7** can be formed or molded with high accuracy. Accordingly, the four rows of rollers **21–24** disposed between the track rail **1** and the movable block **3** can accurately contact to the roller rolling surfaces **61**, **71**; **62**, **72**; **63**, **73**; **64**, **74** formed to a pair of track grooves **6**, **7** corresponding to the four rows of rollers **21–24** disposed between the track rail **1** and the movable block **3**, and the end surfaces of the roller are accurately guided by the action of the guide surfaces **6***a*, **7***a* of the paired track grooves **6**, **7**.

As described above, the movable block **3** has a rigidity regardless of the direction of the loads, so that the locating relation between the track rail **1** and the movable block **3** is normally maintained to a constant value. Further, the movable block **3** is supported by the track rail **1** at a position where the preload applied to the respective four rows of rollers **21–24** and the reaction force of the preload are balanced, so that a gap between the end surfaces of the rollers and the guide surfaces **6***a*, **7***a* can be normally maintained to a constant level in co-operation with the effect of accurately forming the locating relation between the respective track grooves **6**, **7** as described above.

In particular, the movable block **3** is formed in a shape having a high rigidity, so that a high preload can be applied. Therefore, the high rigidity of the movable block **3** and the high preload are synergistically effected to realize an effect such that the gap between the end surfaces of the rollers **21–24** and the guide surfaces **6***a*, **7***a* can be maintained to a constant level. As a result, the skew preventing effect for the rollers **21–24** can be enhanced and a smooth circulation and a rolling accuracy of the rollers **21–24** can be secured.

Further, since the roller end surface guide member to be separately formed from the movable block **3** is not necessary in this invention, the thickness of the horizontal portion **31** of the movable block **3** can be increased with an amount equivalent to a space required for the roller end surface guide member, whereby the flexural rigidity of the horizontal portion **31** can be increased. In addition, by enhancing the rigidity of the movable block **3**, the effect of preventing the skew generation can be further synergistically improved.

Since the roller rolling surfaces **61**, **71**; **62**, **72** **63**, **73**; **64**, **74** and the guide surfaces **6***a*, **7***a* for guiding the end surfaces of the rollers are constituted by the track grooves **6**, **7** having a V-shape in cross section, the roller rolling surfaces **61**, **71**; **62**, **72**; **63**, **73**; **64**, **74** and the end surface guide surfaces **6***a*, **7***a* can be simultaneously finished by a grinding work, whereby a guiding accuracy and surface roughness of the roller rolling surfaces **61**, **71**; **62**, **72**; **63**, **73**; **64**, **74** and the guide surfaces **6***a*, **7***a* for guiding the end surfaces of the rollers are improved and a remarkable effect in skew prevention can be obtained. In addition, the working amount for the track grooves can be minimized.

As described above, according to the present invention, since the upper two rows of rollers are arranged to be shifted to portions close to center side apart from the end portions of the upper surface of the track rail and the lower two rows of the rollers are arranged to be shifted to upper portions of the right and left side surfaces of the track rail, the lengths from the base portions of the right and left supporting leg portions of the movable block to the lower side rollers can be shortened in comparison with a conventional case where the two rows of rollers are arranged to the right and left sides surfaces of the track rail, respectively.

Accordingly, even if a reaction force of the preload applied to the roller or a lateral load acting in a direction so as to displace the movable block in a horizontal direction with respect to the track rail is applied, it becomes possible to decrease the bending moment acting in a direction spreading the supporting leg portions.

Further, in general, due to the moment acting in a direction spreading the supporting leg portions, a center portion of the horizontal portion is bent so as to close to the upper surface of the track rail. However, in the present invention, such bending deformation of the horizontal portion is suppressed by the action of the upper two rows of rollers disposed between the horizontal portion and the upper surface of the track rail, whereby the spreading of the supporting leg portions can be sufficiently decreased in co-operation with the reduction of the bending moment.

As described above, even if the preload is applied to the roller or a lateral load in a horizontal direction is applied, the deformation in a direction spreading the supporting leg portions of the movable block can be prevented and a degree of parallelization between the opposing roller rolling surfaces can be maintained to a constant level, whereby non-uniform contact of the rollers can be prevented.

When a screw hole for fixing the movable block is provided at portions on the upper surface of right and left end portions of the horizontal portion of the movable block, and the portions are set to upper positions of the roller circulating passages in unloaded region for the lower two rows of rollers or set to portions close to the center side, whereby an interference of the upper two rows of the rollers with the roller circulating passages can be avoided and the length in the horizontal direction between the screw hole and the lower side rollers is sufficiently shortened, so that it becomes possible to decrease the bending moment acting in a direction so as to spread the supporting leg portions due to the lifting load.

According to the structure described above, not only in a case when the preload is applied to the roller or the lateral load is applied but also in a case when the lifting load is applied, the moment can be also decreased, the deformation in a direction spreading the supporting leg portions of the movable block can be prevented, and the degree of parallelization between the roller rolling surfaces is maintained to a constant level whereby the non-uniformity in contacting of the rollers can be prevented.

Further, when an angle between a line orthogonal to the rotation axis of the upper two rows of rollers disposed on the upper surface of the track rail and a vertical line is set at almost 45° and an angle between a line orthogonal to the rotation axis of the lower two rows of rollers disposed on the side surfaces of the track rail and a horizontal line is set at almost 45° the same rated load can be obtained with respect to a radial load being applied from the upper direction (i.e., a load in a direction so as to press the movable block onto the track rail), the lifting load and the lateral loads applied from right and left directions, whereby any of the load applied from every direction can be supported. In other words, the device can be used in any attitudes or positions, and available to wide applications.

Further, when a structure in which a track rail having a track groove having a V-shaped in cross section comprising two inclined surfaces is used and the roller rolling surfaces to be formed to the track rail and the movable block so as to correspond to the four rows of rollers are formed to one of the inclined surfaces while the other inclined surface is used as a guide surface for guiding the roller end surface whereby the end surfaces of the rollers are guided while a pitch of the rollers is maintained to a predetermined value in a portion between the guide surface of the track groove of the track rail side and the guide surface of the movable block side which are opposed to each other, a locating relation between the respective track grooves can be accurately measured by using a roller pin or the like. On this premise, the locating relation between the respective track grooves can be molded or formed with high accuracy. Accordingly, the contacting state between the rollers and the roller rolling surfaces as well as the gap between the roller end surface and the guide surface can be maintained with a higher accuracy.

As described above, the movable block has a rigidity regardless of the direction of the loads, so that the locating relation between the track rail and the movable block is normally maintained to a constant value. Further, the movable block is supported by the track rail at a position where the preload applied to the respective four rows of rollers and the reaction force of the preload are balanced, so that a gap between the end surface of the roller and the guide surface can be normally maintained to a constant level in co-operation with the effect of accurately working the locating relation of the respective track grooves as described above.

Accordingly, the four rows of rollers disposed between the track rail and the movable block accurately contact to the roller rolling surfaces formed to a pair of track grooves corresponding to the four rows of rollers. and the end surfaces of the roller are accurately guided by the action of the guide surfaces formed to the paired track grooves.

In particular, the movable block is formed in a shape having a high rigidity, so that a high preload can be applied. Therefore, the high rigidity of the movable block and the high preload are synergistically effected to realize an effect such that the gap between the end surface of the roller and the guide surface can be maintained to a constant level. As a result, the skew preventing effect for the rollers can be enhanced and a smooth circulation and a rolling accuracy of the rollers can be secured.

Further, the space for installing the roller end surface guide member, which is conventionally required to be provided to the lower surface of the movable block, becomes unnecessary in this invention, so that the thickness of the horizontal portion of the movable block can be increased with an amount equivalent to the space, whereby the flexural rigidity of the horizontal portion can be increased and also the rigidity of the movable block can be enhanced. In addition, by enhancing the rigidity of the movable block, the effect of preventing the skew generation can be further synergistically improved.

Further, since the roller rolling surfaces and the guide surfaces for guiding the roller end surfaces are constituted by the track groove having a V-shape in cross section, the roller rolling surfaces and the guide surfaces for guiding roller end surface can be simultaneously finished by a grinding work, so that the roller rolling surfaces and the guide surfaces for guiding roller end surfaces can be easily worked. In addition, a guiding accuracy of the rollers and surface roughness are also improved and a high effect in skew prevention can be obtained. In addition, the working amount for the track groove can be minimized.

Further, since a retainer for the roller is eliminated and the roller contacts to the roller rolling surface at an entire length of the roller, the rigidity of the roller per se can be effectively utilized. [Another Embodiment]

FIGS. **5** to **7** are views showing another embodiment of a linear roller guide device according to the present invention. Namely, the linear roller guide device of this embodiment has also a structure in which a number of rollers **21–24** are arranged in a form of four rows of rollers in total of which two rows of rollers are disposed on an upper surface of a track rail **1** and one row of rollers are disposed to right and left side surfaces of the track rail **1**, respectively, and a movable block **3** is guided along a track rail **1** through the upper surface side rollers **21**, **22** and the side surface side rollers **23**, **24**.

The movable block **3** comprises a horizontal portion **4** opposing to an upper surface of the track rail **1**, and supporting leg portions **5**, **5** extending downwardly from both end portions of the horizontal portion **4** so as to oppose to right and left side surfaces of the track rail **1**.

The track rail **1** has a rectangular shape in section, an upper surface of the track rail is formed with two rows of roller rolling surfaces while each of right and left side surfaces of the track rail is formed with one row of roller rolling surface, respectively, i.e., totally four rows of the roller rolling surfaces **61–64** are formed to the track rail **1** over entire length of the track rail **1**. Further, the track rail **1** is formed with a plurality of bolt insertion holes **11** for fixing the track rail in a longitudinal direction, and an upper opening portion of each bolt insertion holes **11** is formed at a center of the upper surface of the track rail **1**.

On the other hand, the movable block **3** is provided with four rows of roller rolling surfaces **71–74** for rollingly clamping the four rows of rollers **21–24** so as to oppose to the roller rolling surfaces **61–64** of the track rail **1**. The movable block **3** is also provided with four rows of roller circulating passages **81–84** at unloaded region for circulating both the upper surface side and side surface side rollers **21–24** clamped between the roller rolling surfaces **61**, **71**; **62**, **72**; **63**, **73**; **64**, **74** of the track rail **1** and the movable block **3** from one end to the other end of the roller rolling surfaces **71–74** of the movable block **3**.

As shown in FIGS. **6** and **7**, the movable block **3** comprises a block body **31** and side covers **32**, **32** to be attached to both end surfaces in an axial direction of the block body **31**. The roller rolling surfaces **71–74** are formed to the block body **31**. The roller circulating passages **81–84** comprises roller returning passages **81**a–**84***a* formed to the block body **31** so as to be in parallel to each of the roller rolling surfaces **71–74** and direction changing passages **81***b*–**84***b* having an U-shape a part of which is constituted by the side covers **32**, **32**.

As shown in FIG. **5**, the two rows of the upper surface side rollers **21**, **22** disposed to the upper surface of the track rail **1** has a contact structure in which contact angle lines **S1** and **S2** constituted by lines orthogonal to the rolling axes of the rollers **21**, **22** are inclined with respect to a center longitudinal axial line (vertical line) V, which equally divides the track rail **1** into right and left portions, with a predetermined inclination angle of α 1 so as to open upwardly. These contact angle lines **S1**, **S2** are indicated as lines connecting centers in a width direction of the respective roller rolling surfaces **61**, **71**; **62**, **72**.

In addition, the surface side rollers **23**, **24** disposed to the right and left side surfaces of the track rail **1** has a contact structure in which contact angle lines **S3** and **S4** constituted by lines orthogonal to the rolling axes of the rollers **23**, **24** are inclined with respect to the above vertical line m with a predetermined inclination angle of $\alpha 2$ so as to open downwardly. These contact angle lines **S3**, **S4** are also indicated as lines connecting centers in a width direction of the respective roller rolling surfaces **63**, **73**; **64**, **74**.

In particular, in this embodiment, each of the contact angles α 1–$\alpha°4$ is set to almost 45°. Further, in case of the device shown in Figure, the roller returning passages **81**a–**84**a are formed to be positioned on extended lines of the contact angle lines for respective upper surface side and side surface side rollers **21**–**24**. According to this structure, the rolling directions of the upper surface side and side surface side rollers **21**–**24** coincide with the directions of the direction changing passages **81**b–**84**b, so that the upper surface side and side surface side rollers **21**–**24** can be smoothly rolled and moved.

The two rows of the roller rolling surfaces **71, 72** to be formed to the lower surface of the horizontal portion **4** opposing to the roller rolling surfaces **61, 62** formed to the upper surface of the track rail **1** and the roller rolling surfaces **73, 74** to be formed to the inner side surfaces of the right and left supporting leg portions **5, 5** opposing to the roller rolling surfaces **63, 64** formed to the right and left side surfaces of the track rail **1** are formed so as to be laterally symmetric with respect to the center longitudinal axial line (vertical line) V passing through the center of the track rail **1**.

As shown in FIG. **5**(b) in detail, upper surface side roller first end surface guide portions **211, 221** for guiding one end surface at a side (inner side) of the center longitudinal axial line (vertical line) V of the upper surface side rollers **21, 22** are provided to one side periphery at a side the center longitudinal line (vertical line) V of the roller rolling surfaces **71, 72** to be formed to the lower surface of the horizontal portion **4** of the movable block **3** so as to rise up at an almost right angle with respect to the roller rolling surfaces **71** and **72**, while upper surface side second end surface guide portions **212, 222** for guiding the other end surface of the upper surface side rollers **21, 22** are provided to the other side (outer side) periphery at an opposing side with respect to the center longitudinal line (vertical line) V of the roller rolling surfaces **61, 62** formed to the track rail **1** so as to rise up at an almost right angle with respect to the roller rolling surfaces **61, 62**.

The upper surface side roller first end surface guide portions **211, 221** are constituted by a member per se constituting the block body **31**, while the upper surface side second end surface guide portions **212, 222** are constituted by the block body **31** per se.

In this embodiment, the roller rolling surfaces **61, 71; 62, 72** to be formed to the upper surface of the track rail **1** and the lower surface of the horizontal portion **4** of the movable block **3** are constituted by one inclined surface of the grooves each having a V-shape in cross section comprising two inclined surfaces, while the other inclined surface is used as both the upper and side surface sides first and second end surface guide portions **211, 221;231, 241** for guiding both end surfaces of the upper surface side rollers **21, 22**.

Each of the upper and side surface side first end surface guide portions **211, 221;231, 241** almost has a width equivalent to a diameter of each upper and side surface sides rollers **21** and **22**, while each of the upper surface side second end surface guide portions **212, 222** almost has a width equivalent to a radius of each upper surface side rollers **21** and **22**.

Further, radial direction retaining portions **21**a, **22**a each having a projection for preventing the upper surface side rollers **21, 22** from falling out in a radial direction by being engaged with peripheral corner portions of the upper surface side rollers **21, 22** when the movable block **3** is detached from the track rail **1**, are provided to one side periphery of the roller rolling surfaces **71, 72** formed to the lower surface of the horizontal portion **4**, the periphery being a position of a track rail **1** side which is shifted from the upper surface side roller first end surface guide portions **211, 221** with respect to the roller rolling surfaces **71** and **72**.

The radial direction retaining portions **21**a, **22**a are composed of resin moldings, and fixed through adhesion to the lower surface of the horizontal portion **4** so as to have a predetermined thickness. The projections **13, 13** are projected from a lower end portion of the roller end surface almost with a right angle so as to cover the peripheral corner portions **21**c, **22**c of the upper surface side rollers **21** and **22**. A projecting width is suppressed to a minimum degree to prevent the upper surface side rollers **21** and **22** from falling out.

In this embodiment, a length of each of the upper surface side rollers **21, 22** is slightly longer than a width of the roller rolling surfaces **61** and **62** formed to the track rail **1**. The end portions of the upper surface side rollers **21, 22** are slightly projected from upper side periphery of the roller rolling surfaces **61** and **62**. The projections **13, 13** of the radial direction retaining portions **21**a, **22**a are engaged with the projected periphery portions of the roller end surfaces.

The upper surface side rollers **21, 22** contact to the roller rolling surfaces **61, 62** at an almost entire length thereof except an engaging width (which is equivalent to a width projecting from the side periphery of the roller rolling surfaces **61** and **62**) which engages with the projections **13, 13** formed to the radial direction retaining portions **21**a and **22**a, whereby an effective contact length **1**w is secured to have a sufficiently long length.

On the other hand, axial direction retaining portions **21**b, **22**b for preventing the roller from falling out in an axial direction by opposing to the other end surface of the upper surface side rollers **21, 22** are provided to a side periphery of the roller rolling surfaces **71, 72** formed to the movable block **3**, the side periphery being opposite to the side periphery to which the first end surface guide portions **211** and **212** are provided.

The axial direction retaining portions **21**b, **22**b are provided to the other side peripheries of the roller rolling surfaces **71, 72** formed to the block body **31** and are opposing to the end surface portion of the upper surface side rollers **21, 22** which are not guided by the upper surface side roller second end surface guide portions **212, 222** formed to the side periphery of the roller rolling surfaces **61, 62** formed to the track rail **1**, so as to have a small gap therebetween.

The axial direction retaining portions **21**b, **22**b are also composed of resin moldings and fixed through adhesion to both right and left end portions of the lower surface of th e horizontal portion **4** so as to have a predetermined thickness.

The roller rolling surfaces **73, 74** to be formed to the inner side surfaces of the supporting leg portions **5, 5** so as to oppose to the roller rolling surfaces **63, 64** formed to right and left side surfaces of the track rail **1** are also formed so as to be laterally symmetric with respect to the center longitudinal axial line (vertical line) V.

Side surface side roller first end surface guide portions **231, 241** for guiding upper end surface of the upper surface side rollers **23, 24** are provided to an upper periphery of the roller rolling surfaces **73, 74** so as to rise up at an almost right angle with respect to the roller rolling surfaces **73** and **74**, while side surface side second end surface guide portions **232, 242** for guiding the lower end surface of the side surface side rollers **23, 24** are provided to an lower side periphery of the roller rolling surfaces **63, 64** formed to the track rail **1** so as to rise up at an almost right angle with respect to the roller rolling surfaces **63** and **64**.

The side surface side roller first end surface guide portions **231, 241** are constituted by a member per se constituting the block body **31**, while the side surface side second end surface guide portions **232**, **242** are constituted by the block body **31** per se.

The roller rolling surfaces **63**, **73**; **64**, **74** to be formed to the right and left side surfaces of the track rail **1** and the inner side surfaces of the right and left supporting leg portions **5**, **5** of the movable block **3** are constituted by one inclined surface of the grooves each having a V-shape in cross section comprising two inclined surfaces which open in a side direction, while the other inclined surface is used as both the side surface side first and second end surface guide portions **231**, **241**; **232**, **242** for guiding both end surfaces of the side surface side rollers **23**, **24**.

Each of the side surface side roller first end surface guide portions **231**, **241** almost has a width equivalent to a diameter of each side surface side rollers **23** and **24**, while each of the side surface side second end surface guide portions **232**, **242** almost has a width equivalent to a radius of each side surface side rollers **23** and **24**.

Further, radial direction retaining portions **23***a*, **24***a*, each having projections **13**, **13** for preventing the side surface side rollers **23**, **24** from falling out in a radial direction by being engaged with peripheral corner portions of the end surfaces of the side surface side rollers **23**, **24** when the movable block **3** is detached from the track rail **1**, are provided to upper slide periphery of the roller rolling surfaces **73** and **74**, the periphery being a position of a track rail **1** side which is shifted from the side surface side roller first end surface guide portions **232**, **242** with respect to the roller rolling surfaces **73** and **74**.

The radial direction retaining portions **23***a*, **24***a* are also composed of resin moldings and integrally bonded to the inner side surfaces of the supporting leg portions **5**, **5** of the movable block **3** so as to have a predetermined thickness. Upper end portions of the radial direction retaining portions **23***a*, **24***a* are formed to be continuous to the axial direction retaining portions **21***b*, **22***b* of the upper surface side rollers **21** and **22**.

In this embodiment, a length of each of the upper surface side rollers **21**, **22** is slightly longer than a width of the roller rolling surfaces **63** and **64** formed to the track rail **1**. The end portions of the side surface side rollers **23**, **24** are slightly projected from upper side periphery of the roller rolling surfaces **63** and **64**. The projections **13**, **13** of the radial direction retaining portions **23***a*, **24***a* are engaged with the projected periphery portions of the end surfaces of the side surface side rollers **23** and **24**.

The side surface side rollers **23**, **24** contact to the roller rolling surfaces **63**, **64** at an almost entire length thereof except an engaging width (which is equivalent to a width projecting from the side periphery of the roller rolling surfaces **63** and **64**) which engages with the projections **13**, **13** formed to the radial direction retaining portions **23***a* and **24***a*.

On the other hand, axial direction retaining portions **23***b*, **24***b* for preventing the roller from falling out in an axial direction by opposing to the other end surface of the side surface side rollers **23**, **24** are provided to a lower side periphery of the roller rolling surfaces **73**, **74** formed to the movable block **3**, the side periphery being opposite to the side periphery to which the first end surface guide portions **231** and **242** are provided.

The axial direction retaining portions **23***b*, **24***b* are also composed of resin moldings and fixed through adhesion to a portion lower than the roller rolling surface **74** formed to the inner side surfaces of the supporting leg portions **5** and **5**.

The upper surface side roller returning passages **81***a*, **82***a* for the upper surface side two rows of rollers **21**, **22** are constituted by upper surface side roller returning passage resin portions **81***a***2** and **82***a***2** as the roller returning passage forming material which fills large-sized penetration bores **81***a***1** and **82***a***1** penetratingly formed to the block body **31**. Each of the upper surface side roller returning passage resin portions **81***a***2** and **82***a***2** are formed to have a rectangular shape in cross section which correspond to a cross-sectional shape of the upper surface side rollers **21** and **22**.

The side surface side roller returning passages **83***a*, **84***a* for the side surface side rollers **23**, **24** are constituted by a V-shaped groove **83***a***1** provided to the supporting leg portions **5**, **5** of the block body **31** so as to open downwardly and by a side surface side roller returning passage resin portion **14** to be adhesively and integrally fixed to the lower end surface of the supporting leg portions **5** and **5**, the side surface side roller returning passage resin portion **14** having a V-shaped groove **83***a***2** which is provided so as to correspond to the V-shaped groove **83***a***1** and to open upwardly.

The side surface side roller returning passage resin portion **14** covers an entire lower surface of the supporting leg portions, and is integrally formed to be continuous to the axial direction retaining portions **23***b*, **24***b* of the side surface side rollers **23** and **24**, inner side end portions of the axial direction retaining portions **23***b*, **24***b* being adhesively fixed to the inner side surfaces of the supporting leg portions **5** and **5**. Further, an outer end of the side surface side roller returning passage resin portion **14** is integrally formed so as to be continuous to an outer resin portion **15** for covering lower portions of outer side surfaces of the lovable block **3**.

Further, at the end surface of the movable block **31** is provided with end surface resin portions **16** and **17** to which the direction changing passage inner periphery portions **81***b***1** –**84***b***1** of the direction changing passages **81***b*–**84***b* for the upper surface side rollers **21**, **22** and the side surface side rollers **23**, **24** are formed so that the end surface resin portions **16** and **17** are independently provided at right and left sides with respect to the center longitudinal axial line, respectively.

In addition, these end surface resin portions **16** and **17**, the upper surface side roller returning passage resin portions **81***a***2** and **82***a***2**, the radial direction retaining portions **21***a*, **22***a* and the axial direction retaining portions **21***b*, **22***b* for the upper surface side rollers **21** and **22**, the radial direction retaining portions **23***a*, **24***a* and the axial direction retaining portions **23***b*, **24***b* for the side surface side rollers **23** and **24**, the side surface side roller returning passage resin portion **14** and the supporting leg portion outer side surface resin portion **15** are integrally formed with the block body **31** by inserting the block body **31** into a molding die.

These end surface resin portions **16**. **17** are provided with a boss portion **34** corresponding to a tapped hole **33** so as to open the tapped hole **33** for fastening the side cover **32** attached to the end surface of the block body **31**.

The movable block of the linear roller guide device of this invention is manufactured in accordance with the following processes.

The movable block **31** is previously formed with the roller rolling surfaces **71**–**74**. Then, as shown in FIG. **8**, the movable block **31** is subjected to an insert molding in which the end surface resin portions **16** and **17**, the upper surface side roller returning passage resin portions **81***a***2** and **82***a***2**, the radial direction retaining portions **21***a*, **22***a* and the axial direction retaining portions **21***b*, **22***b* for the upper rollers **21** and **22**, the radial direction retaining portions **23***a*, **24***a* for the side surface side rollers **23** and **24**, the axial direction retaining portions **23***b*, **24***b* for the side surface side rollers **23** and **24**, the side surface side roller returning passage resin portions **14**, **14** and the outer side surface resin portion **15**, are integrally formed with the block body **31** by inserting the block body **31** into the molding die.

FIG. **8** is a schematic view showing a structure of the molding die in which cavities **5***a* for forming the upper surface side roller returning passage resin portions **81***a***2** and **82***a***2** are provided to the block body **31**, cavities **5***b* for forming the end surface resin portions **16** and **17** each having the direction changing passage inner peripheral portion are provided to both front and rear end portions of the supporting leg portion **5**, cavities **5***c* for forming the axial direction retaining portions **21***b*, **22***b* for the upper rollers **21**, **22** and the radial direction retaining portions **23***a*, **24***a* for the side surface side rollers **23** and **24** are provided to a corner portion between the supporting leg portion **5** and the horizontal portion **4**, cavities **5***d* for forming the radial direction retaining portions **21***a*, **22***a* for the upper surface side rollers **21** and **22** are provided to the lower surface of the horizontal portion **4**, and cavities **5***e* for forming the axial direction retaining portions **23***b*, **24***b* for the side surface side rollers **23** and **24**, the side surface side roller returning passage resin portion **14** and the outer side surface resin portion **15** are provided to a circumference from the lower end surface to both inner and outer side surfaces of the supporting leg portion **5**, respectively.

In addition, a fixed molding die **50** is provided with convex portions **52** for positioning by engaging the roller rolling surfaces **71**–**74** with the convex portions **52**, while a movable molding die **51** is provided with pins **53** for forming unloaded roller returning holes **81***a***1**–**84***a***1**.

At the time of the insert molding, as shown in FIG. **8**(*a*), the movable block **31** is positioned on the basis of the roller rolling surfaces **71**–**74**. As described above, the positions of the unloaded roller returning passages **81***a*–**84***a* and both radial and axial direction roller retaining portions **21***a*–**24***a*; **21***b*–**24***b* are determined on the basis of the roller rolling surfaces **71**–**74**, so that it is possible to accurately set the relatively positional relations between the roller rolling surfaces **71**–**74**, the direction changing passages **81***b*–**84***b* and the unloaded roller returning passages **81***a*–**84***a* which constitute roller circulating passages.

Further, at the time of positioning the block body **31** within the fixed molding die, when the block body **31** is positioned on the basis of the roller rolling surfaces **71**–**74**, the contact portions of the block body **31** are limited and minimized to the roller rolling surfaces **71**–**74**, while the other portions of the fixed molding die **50** can be maintained in a non-contacted state, so that it becomes unnecessary to accurately work the fixed molding die **50** and a manufacturing of the fixed molding die **50** can be simplified.

In this embodiment, gaps are formed between the fixed molding die **50** and the block body in a range from the upper surface of the horizontal portion of the block body **31** to the upper end portion of the outer side surfaces of the supporting leg portion lower resin portion formed to the outer side surfaces of the supporting leg portions. The block body **31** contacts to inner peripheral surfaces of the fixed molding die at an upper end portion of the cavities **5***e* in a contacting state enabling to seal resin material. A contacting state where a small gap is formed may be allowed as far as the resin material can be sealed.

Further, the direction changing passage inner periphery portions **81***b***1**–**84***b***4** together with the unloaded roller returning passages **81***a*–**84***a* are integrally formed with the block body **31** by utilizing the insert molding method.

According to this process, as well as the upper surface side roller returning passage resin portions **81***a***2**–**84***a***2** and the end surface resin portions **16** and **17**, the radial direction roller retaining portions **21***a*, **22***a* and the axial direction roller retaining portions **21***b*, **22***b* for the upper surface side rollers **21** and **22**, the radial direction roller retaining portions **23***a*, **24***a* for the side surface side rollers **23**, **24** and the axial direction roller retaining portions **23***b*, **24***b* for the side surface side rollers **23** and **24**, the side surface side roller returning passage resin portions **14**, **14** and the outer side surface resin portions **15** are also integrally formed with the block body **31** by utilizing the insert molding method.

Thereafter, a side cover **32** is assembled to both end portions of the block body **31** to thereby complete the direction changing passages.

According to the present invention, one end surface of the upper surface side and the side surface side rollers **21**–**24** is guided by the first end surface guide portions **211**, **221**, **231** **241** provided to one side periphery portions of the roller rolling surfaces **71**–**74** formed to the movable block **3**, while the other end surface of the upper surface side and the side surface side rollers **21**–**24** is guided by the second end surface guide portions **212**, **222**, **232**, **242** provided to the other side periphery portions of the roller rolling surfaces **61**–**64** formed to the track rail **1**.

Further, when the movable block **3** is detached from the track rail **1**, the second end surface guide portions **212**, **222**, **232**, **242** provided to the track rail **1** are also detached from the other end surfaces of the upper surface side and side surface side rollers **21**–**24**. However, the upper surface side and side surface side rollers **21**–**24** are retained between the first end surface guide portions **211**, **221**, **231**, **241** provided to one side of the roller rolling surfaces **71**–**74** formed to the movable block **3** and the axial direction retaining portions **21***b*, **22***b*, **23***b*, **24***b* provided to the other side periphery portions thereof.

Further, the peripheral portions **21***c*–**24***c* of the one end surface of the upper surface side and side surface side rollers **21**–**24** are retained by the upper surface side and side surface side roller radial direction retaining portions **21***a*, **22***a*;**23***a*, **24***a* provided to the first end surface guide portions **211**, **221**, **231** and **241**, so that the falling-out of the rollers in a radial direction can be prevented.

As described above, the radial direction retaining portions **21***a*–**24***a* for the both upper surface side and side surface side rollers are engaged with only periphery portions of the one end surface of the rollers **21**–**24**, and the second end surface guide portions **212**–**242** are provided to the other side periphery portions of the roller rolling surfaces **71**–**74** formed to the track rail **1**, so that a peripheral surface of each rollers **21**–**24** except the engaging portion for engaging with the radial direction retaining portions **21***a*–**24***a* can be contacted to the roller rolling surfaces **61**–**64** formed to the track rail **1** so that the end surface is closely contacted to the second end surface guide portions **212**–**242**, whereby the effective contact length of the rollers **21**–**24** can be sufficiently secured in a long length. Accordingly, the high rigidity characteristics of the rollers **21**–**24** can be sufficiently utilized.

Further, since the second end surface guide portions **212**–**242** are provided to a side of the roller rolling surfaces **61**–**64** of the track rail **1**, the second end surface guide portions **212**–**242** can be worked with a high accuracy, whereby the skew generation at the rollers **21**–**24** can be further securely prevented.

In addition, since the first end surface guide portions **211–241** are constituted by the member for constituting the block body **31** of the movable block **3**, the first end surface guide portions **211–241** can be worked so as to have a high rigidity and high accuracy, and the end surfaces of the rollers are guided at portions between the first end surface guide portions and the second end surface guide portions **212–242** provided to the track rail **1** also having a high rigidity, whereby the skew generation can be further securely prevented.

Further, since both the radial and axial direction retaining portions **21**_a_–**24**_a_; **221**_b_–**24**_b_ are integrally formed with the block body **31** by inserting the block body **31** into the molding die, both the radial and axial direction retaining portions **21**_a_–**24**_a_; **21**_b_–**24**_b_ can be accurately positioned without causing any attaching error. so that a predetermined small gap between the upper surface side and side surface side rollers **21–24** and the radial direction retaining portions and the axial direction retaining portions **21**_a_–**24**_a_; **21**_b_–**24**_b_ can be accurately formed during the rolling of the rollers, whereby the upper surface side and side surface side rollers **21–24** would not interfere with the radial and axial direction retaining portions **21**_a_–**24**_a_; **21**_b_–**24**_b_.

Accordingly, the rollers are smoothly rolled and moved in co-operation with the skew preventing effect for the upper surface side and side surface side rollers **21–24** by the action of the first and second end surface retaining portions **211–241**, **212–242**.

On the other hand, the end surface resin portions **16**, **17** as the direction changing passage inner periphery member constituting the direction changing passage inner periphery portions **81**_b_**1**–**84**_b_**1** , together with both the radial and axial direction retaining portions **21**_a_–**24**_a_; **21**_b_–**24**_b_, are integrally formed with the block body **31** by inserting the block body **31** into the molding die, so that the connected portions of the loaded roller rolling surfaces **71–74** and the direction changing passage inner periphery portions **81**_b_**1**–**84**_b_**1** can be continuously formed without causing irregularities, so that both the upper surface side and side surface side rollers **21–24** are smoothly rolled and moved.

Further, the returning passage forming resin portions **81**_a_**2**, **82**_a_**2** and the lower surface resin portions **83**_a_**2**, **84**_a_**2** as the unloaded roller returning passage member for constituting the unloaded roller returning passages **81**_a_–**84**_a_, together with the end surface resin portion **16** and **17**, the inner side resin portion **12** of the supporting leg portion and the lower surface resin portion **13** of the horizontal portion, are integrally formed with the block body **31** by inserting the block body **31** into the molding die, so that each of the connected portions between the loaded roller rolling surfaces **71–74**, the direction changing passage inner periphery portions **81**_b_**1**–**84**_b_**1** and the unloaded roller returning passages **81**_a_–**84**_a_ can be continuously formed without causing irregularities, whereby both the upper surface side and side surface side rollers **21–24** are smoothly circulated and moved in all around a circulating passage.

Further, the direction changing passage inner periphery portions **81**_b_**2**–**84**_b_**2** of the end surface resin portions **16**, **17** and the unloaded roller returning passage forming member of the returning passage forming resin portions **81**_a_**2**, **82**_a_**2** are integrally provided with end surface guide portions **85**, **86** for guiding at least one end surface of the upper surface side and side surface side rollers **21–24**.

According to this structure, the end surface guide portions **85**, **86** of the direction changing passage **81**_b_ and the unloaded roller returning passage **81**_a_ are continuously formed without causing irregularities, so that the skew of both the upper surface side and side surface side rollers **21–24** can be prevented in all around the circulating passage and the rollers are smoothly circulated.

On the other hand, the upper surface side rollers **21**, **22** disposed on the upper surface of the track rail **1** are arranged to a portion close to a center side apart from a side end of the upper surface of the track rail **1** with a predetermined distance, while the roller rolling surfaces **61**, **71**; **62**, **72** corresponding to the upper two rows of rollers **21**, **22** are formed to the upper surfaces of the track rail **1** and the lower surface of the horizontal portion **4** of the movable block **3**.

The roller returning passages **81**_a_, **82**_a_ constituting the circulation passage for the upper rollers are arranged to portions close to a center side with respect to the roller circulating passages **83**_a_, **84**_a_ in unloaded region corresponding to the side surface side two rows of the rollers **23**, **24**.

According to this invention, the upper two rows of rollers **21**, **22** are arranged so as to be shifted to portions close to center side from the end portion of the upper surface of the track rail **1**, so that it is sufficient to form one row of the roller rolling surface **73**, **74** to the inner side surfaces of the supporting leg portions **5**, **5**, and the length L from the base portion of the right and left supporting leg portions **5**, **5** to the lower side two rows of rollers **23**, **24** can be shortened. As a result, the bending moment to be applied to the supporting leg portions due to the reaction force of the preload applied to the rollers **21–24** or an external load can be reduced.

Further, due to the moment acting in a direction spreading the supporting leg portions **5**, **5**, a center portion of the horizontal portion **4** is liable to be bent so as to close to the upper surface of the track rail **1**. However, in the present invention, such a bending deformation of the horizontal portion **4** is suppressed by the action of the upper two rows of rollers **21**, **22** disposed between the horizontal portion **4** and the upper surface of the track rail **1**, whereby the spreading of the supporting leg portions **5**, **5** can be sufficiently and synergistically decreased in co-operation with the reduction of the bending moment.

According to the structure described above, in a case where the preload is applied by means of the upper two rows of the rollers **21**, **22** disposed to the upper surface side of the track rail **1** and the lower two rows of rollers **23**, **24** disposed to the side surface side of the track rail **1** or in a case where the lifting load is applied, the deformation of the movable block **3** in a direction spreading the supporting leg portions **5**, **5** can be prevented, and the degree of parallelization between the roller rolling surfaces **61**, **71**; **62**, **72**; **63**, **73**; **64**, **74** are maintained to a constant level, whereby the non-uniformity in contacting of the rollers **21–24** can be prevented.

Further, the angle between each of the contact angle lines S1, S2 of the upper two rows of rollers **21**, **22** disposed on the upper surface of the track rail **1** and the central longitudinal axial line (vertical line) V is set at almost 45° and the angle between each of the contact angle lines S3, S4 of the side lower two rows of rollers **23**, **24** disposed on the side surfaces of the track rail **1** and a horizontal line H is set at almost 45° so at to upwardly direct to the track rail **1**, so that the same rated load can be obtained with respect to a radial load applied from upper direction (i.e., a load in a direction so as to press the movable block **3** onto the track rail **1**), lifting load and the lateral loads applied from right and left directions, whereby any of the load applied from every direction can be supported. In other words, the device can be used in any attitudes or positions, and available to wide applications.

Further, the track rail **1** having grooves each having a V-shape in cross section is used, and the roller rolling surfaces **61**, **71**; **62**, **72**; **63**, **73**; **64**, **74** to be formed to the track rail **1** and the movable block **3** so as to correspond to the four rows of rollers **21**–**24** are formed to one of the inclined surface of the V-shaped groove, while the other inclined surface is used as the first and second end surface guide portions **211**–**241**, **212**–**242** for guiding the roller end surfaces, whereby the end surfaces of the rollers are guided.

As a result, the locating relation between the respective V-shaped grooves can be accurately measured by using a roller pin or the like, whereby the locating relation between the respective V-shaped grooves can be molded or formed with a high accuracy. Accordingly, the upper surface side and side surface side four rows of rollers **21**–**24** disposed between the track rail **1** and the movable block **3** accurately contact to the roller rolling surfaces **61**, **71**; **62**, **72**; **63**, **73**; **64**, **74** corresponding to the four rows of rollers **21**–**24**, and the end surfaces of the rollers are accurately guided by the action of the first and second end surface guide portions **211**–**241**;**212**–**242**.

As described above, the movable block **3** has a rigidity regardless of the direction of the loads, so that the locating relation between the track rail **1** and the movable block **3** is normally maintained to a constant level. Further, the movable block **3** is supported by the track rail **1** at a position where the preload applied to the respective four rows of rollers **21**–**24** and the reaction force of the preload are balanced, so that a gap between the end surface of the roller and the first and second end surface guide portions **211**–**241**;**212**–**242** can be normally maintained to a constant level in co-operation with the effect of accurately forming the locating relation between the respective roller rolling surfaces **61**, **71**; **62**, **72**; **63**, **73**; **64**, **74** as described above.

In particular, the movable block **3** is formed in a shape having a high rigidity, so that a high preload can be applied. Therefore, the high rigidity of the movable block **3** and the high preload are synergistically effected to realize an effect such that the gap between the end surface of the upper surface side and side surface side rollers **21**–**24** and the first and second end surface guide portions **211**–**241**; **212**–**242** can be maintained to a constant level. As a result, the skew preventing effect for the rollers **21**–**24** can be enhanced and a smooth circulation and a rolling accuracy of the rollers **21**–**24** can be secured.

Further, the first end surface guide portions **211**, **212** for the upper rollers **21**, **22** are constituted by the block body **31** per se, so that the thickness of the horizontal portion **4** can be increased, whereby the flexural rigidity of the horizontal portion **4** can be increased. Further, the rigidity of the movable block **3** can be enhanced. In addition, by enhancing the rigidity of the movable block **3**, the effect of preventing the skew generation can be further synergistically improved.

Further, the roller rolling surfaces **61**, **71**; **62**. **72**; **63**, **73**; **64**, **74** and the first and second end surface guide portions **211**–**241** **212**–**242** are constituted by the grooves each having a V-shape in cross section, so that the roller rolling surfaces **61**, **71**; **62**, **72**; **63**, **73**; **64**, **74** and the first and second end surface guide portions **211**–**241**; **212**–**242** can be simultaneously finished by a grinding work. As a result, a guiding accuracy for the rollers and surface roughness of the roller rolling surfaces **61**, **71** **62**, **72**; **63**, **73**; **64**, **74** and the first and second end surface guide portions **211**–**241**; **212**–**242** are improved and a high effect in skew prevention can be obtained. In addition, the working amount for the grooves can be minimized.

In addition a screw hole **33** for fixing the movable block is provided at portions on the upper surface of both right and left end portions of the horizontal portion **31** of the movable block, and the portions are set to upper positions of the roller returning passages **83***a*, **84***a* for the lower two rows of rollers **23**, **24** or set to positions close to the center side. Owing to this structure, a pitch P between the right and left screw holes **33**, **33** is narrowed, whereby the screw holes are arranged to the positions close to the lower side rollers **23**, **24**.

In addition, the relation between a lateral width W and a height A of the track rail **1** is set so as to satisfy $A/W<1$, so that stability of the track rail **1** is enhanced, and simultaneously, an interference with an upper end opening portion **11***a* of a bolt inserting hole to be opened at a center of the upper surface of the track rail **1** is avoided.

When a lifting load in a direction lifting the movable block **3** from the track rail **1** is applied, a force in a direction detaching the movable block **3** from the track rail **1** is applied while the above described screw holes **33**, **33** are acting as points of application, in contrast, a reaction force against the force is applied to the roller rolling surfaces **73**, **74** for the lower two rows of rollers **23**, **24**. The force applied to the screw hole **33** and the reaction force constitute a relation of a couple of forces, whereby a bending moment in a direction for spreading the supporting leg portions **5**, **5** will occur.

In the case of this embodiment, the upper two rows of rollers **21**, **22** are arranged to portions close to a center side portion, so that an interference of the upper two rows of the rollers **21**, **22** with the screw hole **33** can be avoided. Simultaneously, the screw hole **33** is formed at a portion close to the lower side rollers **23**, **24**, so that a distance M in the horizontal direction between the the screw hole **33** and the lower side rollers **23**, **24** can be sufficiently shortened, whereby the bending moment in a direction for spreading the supporting leg portions **5**, **5** can be reduced.

As shown in FIG. **12**, when the position of this screw hole **33** is set so as to coincide with the position of the side surface side rollers **23** and **24**, the distance between the screw hole **33** and the lower side rollers **23**, **24** in a horizontal direction becomes zero, so that the bending moment in a direction spreading the supporting leg portions **5**, **5** would not be applied, thus being advantageous. In the case shown in Figure, each of the screw holes **33** is arranged to a portion between the roller rolling surfaces **71**, **72** and the roller returning passages **81***a*, **82***a* for the upper side rollers **21**, **22**.

In this connection, as shown in FIG. **13**, a flange portion **34** can be provided to the movable block so as to laterally project therefrom, and the screw hole **33** for fixing the movable block way also be formed to the flange portion **34**.

FIG. **13**(*a*) shows an example in which a screw is formed to the screw hole **33**, and FIG. **13**(*b*) shows an example in which a screw inserting hole **35** is formed to the flange portion **34**.

In the embodiment described above, although there is shown an example in which the radial direction retaining portions and axial direction retaining portions **21***a*–**24***a*, **21***b*–**24***b* composed of resin materials for retaining the upper surface side rollers **21**, **22** and the side surface side rollers **23**, **24** are integrally formed to the block body **31**, the radial direction retaining portions **21***a*–**24***a* and axial direction retaining portions **21***b*–**24***b* may also be formed by mechanically working the block body **31** per se as shown in FIGS. **9** and **10**.

FIG. **9** shows an example of a structure for retaining the upper surface side roller **21**, **22**. Namely, FIG. **9**(*a*) shows an example in which both the radial direction retaining portions **21***a*, **22***a* and the axial direction retaining portions **21***b*, **22***b* are constituted by the block body **31**, FIG. **9**(*b*) shows an example in which the radial direction retaining portions **21***a*, **22***a* are constituted by the block body **31**, while the axial direction retaining portions **21***b*, **22***b* are constituted by the resin material, and FIG. **9**(*c*) shows an example in which the radial direction retaining portions **21***a*, **22***a* are constituted by the resin material, while the axial direction retaining portions **21***b*, **22***b* are constituted by the block body **31**.

FIG. **10** shows an example of a structure for retaining the side surface side roller **23**, **24**. Namely, FIG. **10**(*a*) shows an example in which both the radial direction retaining portions **23***a*, **24***a* and the axial direction retaining portions **23***b*, **24***b* are constituted by the block body **31**; FIG. **10**(*b*) shows an example in which the radial direction retaining portions **23***a*, **24***a* are constituted by the block body **31**, while the axial direction retaining portions **23***b*, **24***b* are constituted by the resin material; and FIG. **10**(*c*) shows an example in which the radial direction retaining portions **23***a*, **24***a* are constituted by the resin material, while the axial direction retaining portions **23***b*, **24***b* are constituted by the block body **31**.

FIG. **11** shows another example of a structure of the first end surface guide portion for the upper surface side and side surface side rollers.

FIG. **11**(*a*) shows a structure in which the first end surface guide portions **211**–**241** are integrally formed with the block body **31** by inserting the block body **31** into the molding die.

According to this structure, the first end surface guide portions **21**–**24** can be accurately positioned, so that the gap between the roller end surface and the first end surface guide portions **211**–**241** can be further decreased without impairing the circulating motion of the rollers **21**–**24**, whereby the skew preventing effect for the rollers **21**–**24** can be enhanced.

In particular, in this embodiment, the first end surface guide portions **211**–**241** are constituted by resin member **18**, and the roller end surfaces are guided by the resin member **18**, so that a friction resistance is decreased whereby a smoothness in roller guiding can be increased. Furthermore, the roller end surface would not wear, so that the skew prevention can be stably secured.

In the example shown in Figure, a guide wall **75** is constituted by the inclined surface of the V-shaped groove, and the inclined surface opposing to another inclined surface to which the roller rolling surfaces **71**–**74** are formed. The guide wall **75** is covered with the resin material having a predetermined thickness.

FIG. **11**(*b*) shows an example in which the first end surface guide portions **211**–**241** are constituted by the radial direction retaining portions **21***a*–**24***a*.

Namely, the guide wall **76** opposing to the roller end surface in a non-contact state is provided to one side periphery of the roller rolling surfaces **71**–**74** formed to the movable block **3**, the radial direction retaining portions **21***a*–**24***a* are provided to end portions of the guide wall **76**, and the first end portion guide portions **211**–**241** contacting to a circumferential portion of the roller end surface are constituted by opposing surfaces of the radial direction retaining portions **21***a*–**24***a*, the opposing surfaces being opposed to the roller end surface.

According to this structure, contact areas of the first end surface guide portions **211**–**241** and the roller end surface are decreased, so that a friction resistance can be decreased, whereby a smoothness in roller circulation can be increased.

In the respective embodiments described above. there has been explained examples in which the roller returning passages **83***a*, **84***a* in the unloaded region for the side surface side rollers **23**, **24** are constituted by the V-shaped grooves formed to the lower end surfaces of the supporting leg portions **5**, **5** of the movable block **3**.

However, in the same manner as in the roller returning passages **81***a*, **82***a* for the upper surface side rollers **21** and **22**, as shown in FIG. **14**, the roller returning passages **83***a*, **84***a* way also be constituted by covering the inner peripheral portions of the penetration bores **83***a***1**', **84***a***1**' with the resin portions **83***a***2**', **84***a***2**'.

In the case of this embodiment, the resin would not enter or flow toward the lower end surfaces and outer side surfaces of the supporting leg portions **5**, **5** of the movable block **3**.

Further, in the case of the former embodiment. the direction changing passages **81***b*–**84***b* are constituted by the side cover **32** to be attached to both end portions of the movable block **3**. However, in the case of this embodiment, the side cover **32** is integrally formed with the block body **31**, and a deflector **36** for constituting only the direction changing passage outer periphery portions **81***b***1**–**84***b***1** is used. The deflector **36** is attached to a recessed portion **36***a* to which the inner periphery guide portions **81***b***2**–**84***b***2** of the direction changing passages **81***b*–**84***b* of the side cover **32** is provided.

According to the present invention as described above, the radial direction retaining portion is engaged with only a periphery of the one end surface of the roller, and the second end surface guide portion is provided to the other side periphery of the roller rolling surface formed to the track rail, so that a peripheral surface of the roller except the engaging portion for engaging with the radial direction retaining portion can be contacted to the roller rolling surface formed to the track rail so that the end surface is closely contacted to the second end surface guide portion, whereby the contact length of the roller can be sufficiently secured in a long length. Accordingly, the high rigidity characteristic of the roller can be sufficiently utilized.

When the first end surface guide portion is integrally formed with a member for constituting a block body of the movable block, the first end surface guide portion can be worked so as to have a high rigidity and high accuracy, and the end surfaces of the roller are guided in a portion between the first end surface guide portion and the second end surface guide portion provided to the track rail also having a high rigidity, whereby the skew generation can be further securely prevented.

When the first end surface guide portion is integrally formed with the block body by inserting the block body into a molding die, the end surface guide portions can be accurately positioned without causing any attaching error, the gap between the roller end surface and the first end surface guide portion can be further decreased without impairing the circulating motion of the rollers, so that the skew preventing effect for the roller can be enhanced.

A guide wall opposing to the roller end surface in a non-contact state is provided to one side periphery of the roller rolling surface formed to the movable block, the radial direction retaining portion is provided to an end portion of the guide wall, and the first end surface guide portion contacting to a circumferential portion of the roller end surface is constituted by an opposing surface of the radial direction retaining portion, the opposing surface being opposed to the roller end surface.

According to this structure, contact areas of the first end surface guide portion and the roller end surface are decreased, so that a friction resistance can be decreased whereby a smoothness in roller circulation can be increased.

When both the first and second end surface guide portions are integrally formed with the block body by inserting the block body into the molding die, both the radial and axial direction retaining portions can be accurately positioned without causing any attaching error, so that a predetermined gap between the roller and the radial direction retaining portion or the axial direction retaining portion can be accurately formed during the rolling of the rollers, whereby the roller would not interfere with the radial and axial direction retaining portions. Accordingly, the rollers are smoothly rolled and moved in co-operation with the skew preventing effect for the rollers by the action of the first and second end surface retaining portions.

On the other hand, when the direction changing passage inner periphery member, together with both radial and axial direction retaining portions, is integrally formed with the block body by inserting the block body into the molding die, a connected portion of the loaded roller rolling surface and the direction changing passage inner periphery portion can be continuously formed without causing irregularities, so that the rollers can be smoothly circulated.

When the unloaded roller returning passage member, together with the direction changing passage inner periphery member and both the radial and axial direction retaining portions, is integrally formed with the block body by inserting the block body into the molding die, each of the connected portions between the loaded roller rolling surface, the direction changing passage inner periphery portion and the unloaded roller returning passage can be continuously formed without causing irregularities, so that the rollers can be smoothly circulated in all around the circulating passages.

When the direction changing passage inner periphery member and the unloaded roller returning passage member are integrally provided with an end surface guide portion for guiding the roller, the end surface guide portions of the direction changing passage inner periphery member and the unloaded roller returning passage member are continuously formed without causing irregularities, so that the skew of the roller can be prevented all around the circulating passages and the rollers can be smoothly circulated.

When the upper two rows of rollers are arranged to portions close to center side from the end portions of the upper surface of the track rail and the lower two rows of the rollers are arranged to upper portions of the right and left side surfaces of the track rail, the lengths from the base portion of the right and left supporting leg portions of the movable block to the lower side rollers can be shortened in comparison with a conventional case where the two rows of rollers are arranged to the right and left side surfaces of the track rail, respectively.

Accordingly, even if the reaction force of the preload applied to the roller or the lateral load acting in a direction so as to displace the movable block in a horizontal direction with respect to the track rail is applied, it becomes possible to decrease the bending moment acting in a direction so as to spread the supporting leg portions.

Further, due to the moment acting in a direction spreading the supporting leg portions, a center portion of the horizontal portion is bent so as to close to the upper surface of the track rail. However, in the present invention, a bending deformation of the horizontal portion is suppressed by the action of the upper two rows of rollers disposed between the horizontal portion and the upper surface of the track rail, whereby the spreading of the supporting leg portions can be sufficiently decreased in co-operation with the reduction of the bending moment.

As described above, even if the preload is applied to the roller or the lateral load in a horizontal direction is applied, the deformation in a direction spreading the supporting leg portions of the movable block can be prevented and a degree of parallelization between the opposing roller rolling surfaces can be maintained to a constant level, whereby the rollers can be smoothly circulated in co-operation with the effect of preventing the skew of the rollers by the action of the first and second end surface guide portions.

INDUSTRIAL APPLICABILITY

As described above, the linear roller guide device according to the present invention is widely applicable to linear guide mechanisms for various industrial equipments such as machine tool, robot operating system, inspecting or measuring apparatus, or the like.

I claim:

1. A linear roller guide device in which a movable block is guided along a track rail through four rows of rollers disposed on said track rail,

wherein said movable block comprises a horizontal portion opposing to an upper surface of said track rail and supporting leg portions projected downwardly from both end portions of said horizontal portion so as to oppose to right and left side surfaces of said track rail,

wherein said track rail is provided with four rows of roller rolling surfaces for rolling and guiding the rollers in an entire range of said track rail in which the movable block is moved, and

wherein, on the other hand, said movable block comprises four rows of roller rolling surfaces opposing to the roller rolling surfaces formed to said track rail for rollingly clamping the four rows of rollers and four rows of roller circulating passages provided at unloaded region for circulating the rollers clamped between the roller rolling surfaces formed to the track rail and the movable block from one end portion to the other end portion of the roller rolling surface of said movable block,

said linear motion guide device being characterized in that upper two rows of rollers among said four rolls of rollers are arranged in the upper surface of said track rail at portions spaced from side ends of the upper surface of said track rail, while roller rolling surfaces corresponding to said upper two rows of rollers are formed to the upper surface of said track rail and the lower surface of said horizontal portion of the movable block,

that said lower two rows of rollers among the four rows of rollers are arranged such that one row of rollers is disposed to an upper portion of right and left side surfaces of said track rail, respectively, while roller rolling surfaces corresponding to said lower two rows of rollers are formed to the right and left side surfaces of said track rail and inner side surfaces of said supporting leg portions of the movable block,

that each of said upper two rows of rollers has a structure in which a line orthogonal to a rotation axis of the roller is inclined with respect to a vertical line with a predetermined inclination angle, and that each of said lower two rows of rollers has a structure in which a line orthogonal to a rotation axis of the roller is inclined with respect to a horizontal line with a predetermined inclination angle so as to upwardly extend towards a side of the track rail.

2. A linear roller guide device according to claim **1**, wherein said upper two rows of rollers are arranged to portions close to a center side portion deviated from side ends of the upper surface of said track rail, while the roller circulating passages in unloaded region are also arranged to portions close to the center side portion with respect to the roller circulating passages in unloaded region corresponding to the lower two rows of the rollers and wherein a screw hole for fixing said movable block is provided at portions on the upper surface of right and left end portions of said horizontal portion of the movable block, and the portions are set to upper positions of the roller circulating passages in unloaded region for the lower two rows of rollers or set to positions close to the center side.

3. A linear roller guide device according to claim **1** or **2**, wherein an angle between a line orthogonal to a rotation axis of each of said upper two rows of rollers and a vertical line is set at almost 45°.

4. A linear roller guide device according to claim **1** or **2**, wherein an angle between a line orthogonal to a rotation axis of each of said lower two rows of rollers and a horizontal line is set at almost 45°.

5. A linear roller guide device according to claim **1** or **2**, wherein said track rail has a track groove having a V-shape in cross section comprising two inclined surfaces, and said roller rolling surfaces to be formed to said track rail and said movable block so as to correspond to said four rows of rollers are formed to one of said inclined surfaces, while the other inclined surface is used as a guide surface for guiding the roller end surfaces.

6. A linear roller guide device according to claim **5**, wherein said rollers contact to said roller rolling surfaces at an entire length of the roller.

7. A linear roller guide device according to claim **1** or **2**, wherein said rollers are applied with preload.

8. A linear roller guide device according to claim **1** or **2**, wherein a first end surface guide portion for guiding one end surface of said roller is provided to one side periphery of said roller rolling surface formed to said movable block, while a second end surface guide portion for guiding the other end surface of said roller is provided to the other side periphery of said roller rolling surface formed to said track rail,

wherein a radial direction retaining portion having a projection for preventing the roller from falling out in a radial direction by being engaged with a peripheral corner portion of the roller end surface is provided to one side periphery of said roller rolling surface formed to the track rail, while said roller is contacted to the roller rolling surface formed to the track rail in an almost entire contact length in a peripheral surface of the roller except an engaging width required for engaging with said radial direction retaining portion, and

wherein, on the other hand, an axial direction retaining portion for preventing the roller from falling out in an axial direction is provided to a side periphery of the roller rolling surface formed to the movable block, said side periphery opposing to the side periphery to which the first end surface guide portion is provided.

9. A linear roller guide device according to claim **8**, wherein said first end surface guide portion is integrally formed with a member for constituting a block body of said movable block.

10. A linear roller guide device according to claim **8**, wherein said first end surface guide portion is constituted by resin member which is integrally formed with the block body by inserting the block body into a molding die.

11. A linear roller guide device according to claim **8**, wherein a guide wall opposing to said roller end surface in a non-contact state is provided to one side periphery of said roller rolling surface formed to said movable block, said radial direction retaining portion is formed to an end portion of said guide wall, and said first end surface guide portion contacting to a circumferential portion of the roller end surface is constituted by an opposing surface of the radial direction retaining portion, the opposing surface being opposed to said roller end surface.

12. A linear roller guide device according to claim **8**, wherein both said radial and axial direction retaining portions are integrally formed with the block body by inserting the block body into a molding die.

13. A linear roller guide device according to claim **8**, wherein the roller circulating passage in unloaded region comprises an unloaded roller returning passage extending in an axial direction and a direction changing passage for connecting both ends of the unloaded roller returning passage to both ends of a roller rolling passage in loaded region to be formed between the opposing roller rolling surfaces of said track rail and said block body and wherein a direction changing passage inner periphery member for constituting an inner periphery portion of said direction changing passage, together with both radial and axial direction retaining portions, are integrally formed with said block body by inserting the block body into a molding die.

14. A linear roller guide device according to claim **13**, wherein an unloaded roller returning passage member for constituting the unloaded roller returning passage, together with said direction changing passage inner periphery member and both the radial and axial direction retaining portions, are integrally formed with said block body by inserting the block body into the molding die.

15. A linear roller guide device according to claim **14**, wherein said direction changing passage inner periphery member and said unloaded roller returning passage member are integrally provided with an end surface guide portion for guiding at least one end surface of the roller.

[57] **ABSTRACT**

An endless retainer of a guide device including a number of rolling bodies arranged at predetermined intervals for rolling at an inside of an infinite track formed in the guide device, a flexible resin connector having interposing portions interposed among the respective rolling bodies and connecting portions for connecting the respective interposing portions for holding the number of rolling bodies in an aligned state and rotatably, and the resin connector is molded by an injection molding with the rolling bodies as cores by using a resin having a dimension change rate before and after an oil absorbing or a water absorbing treatment larger than a mold shrinkage rate and is provided with clearances between the resin connector and the rolling bodies formed by the oil absorbing or the water absorbing treatment whereby handling thereof is facilitated without detaching the rolling bodies, automation of integrating the endless retainer to the guide device can be carried out and extremely smooth rotatability can be provided to the rolling bodies with certainty.

ENDLESS RETAINER OF GUIDE DEVICE AND FABRICATION METHOD THEREOF

FIELD OF THE INVENTION

The present invention relates to an endless retainer in a guide device of, for example, a linear guide device, a curved guide device, a pivoting bearing or the like for infinite sliding, which is inserted into an infinite track thereof and which supports relative linear movement or rotational movement between a pair of bearing races forming the infinite track, and its fabrication method.

DESCRIPTION OF RELATED ART

According to various guide devices having bearings, linear movement or rotational movement between bearing races can be carried out by utilizing rolling movement of rolling bodies comprising balls or rollers sandwiched between a pair of the bearing races. It is general to integrate a number of the rolling bodies between the bearing races by holding them by a retainer or a cage made of a metal thin plate or synthetic resin with purposes of preventing detachment of the rolling bodies when the pair of bearing races are separated from each other, achieving reduction in frictional resistance by avoiding contact among the respective rolling bodies, obtaining smooth movement by aligning the respective rolling bodies at predetermined positions and so on.

However, according to a conventional guide device using a retainer, the guide device is integrated by integrating the retainer to a side of either of the bearing races, integrating the rolling bodies to a formed rolling path of the rolling bodies and successively integrating other of the bearing races. Particularly when the guide device includes an infinite track of the rolling bodies, skill is required in the operation of integrating the guide device using the retainer and its automation is difficult.

Further, according to a conventional guide device using a cage, the cage is provided with a number of pockets and the respective rolling bodies are rotatably held in the pockets and accordingly, there is provided an advantage where the operation of integrating a number of the rolling bodies to the guide device is facilitated. However, there poses other problem in which a number of the rolling bodies need to be integrated in the respective pockets of the cage and held thereby such that the rolling bodies are not detached and enormous time and labor is required in fabricating the cage per se.

Hence, in order to resolve such problems, there have been proposed a ball retainer or a ball cage in a chain-like shape which is fabricated by injection molding of resin where balls are arranged as cores at a substantially flat face in a mold and forms a predetermined shape by being folded or bent in using it (Japanese Examined Patent Publication No. JP-B-6-56181, Japanese Unexamined Patent Publication No. JP-A-5-52217, Japanese Unexamined Patent Publication No. JP-A-5-126149, Japanese Unexamined Patent Publication No. JP-A-5-196036 and Japanese Unexamined Patent Publication No. JP-A-5-196037).

However, according to the ball retainer or the ball cage in a chain-like shape, rotatability is provided to the balls which have been cast as cores in the resin by utilizing a property of the resin that it is contracted after the injection molding. Accordingly, there are cases where an extremely long period of time is required for providing the rotatability to the balls, it is difficult to provide the smooth rotatability and the rotatability cannot be provided to the balls depending on the kind of resin.

SUMMARY OF THE INVENTION

The present invention has solved difficulty in handling a conventional retainer or a cage for rolling bodies and resolved the problem of the ball cage or the ball retainer in a chain-like shape which has previously been proposed and it is an object of the present invention to provide an endless retainer not only having advantages where the retainer can be fabricated extremely easily, handling thereof is extremely facilitated without detaching rolling bodies and an automation in integrating the retainer to a guide device can be carried out, but being capable of extremely smooth rotatability to the rolling bodies with certainly, and its fabrication method.

Hence, according to an aspect of the present invention, there is provided an endless retainer of a guide device, the endless retainer comprising a number of rolling bodies arranged at predetermined intervals for rolling at an inside of an infinite track formed in the guide device, a flexible resin connector having interposing portions interposed among the respective rolling bodies and connecting portions for connecting the respective interposing portions for holding the number of rolling bodies in an aligned state and rotatably, and the resin connector is molded by an injection molding with the rolling bodies as cores by using a resin having a dimension change rate before and after an oil absorbing or a water absorbing treatment larger than a mold shrinkage rate and is provided with clearances between the resin connector and the rolling bodies formed by the oil absorbing or the water absorbing treatment.

Further, according to another aspect of the present invention, there is provided a method of fabricating an endless retainer for molding the resin connector holding the number of rolling bodies by an injection molding with the number of rolling bodies as cores by using a resin having a dimension change rate before and after an oil absorbing or a water absorbing treatment larger than a mold shrinkage rate, and forming clearances between the resin connector and the respective rolling bodies for rotating the rolling bodies by subjecting the resin connector to the oil absorbing or the water absorbing treatment after having been removed from a mold.

According to the present invention, resin used for molding the resin connector must be a resin having the dimension change rate before and after the oil absorbing or the water absorbing treatment larger than the mold shrinkage rate and a difference between the dimension change rate before and after the oil absorbing or the water absorbing treatment and the mold shrinkage rate preferably falls in a range of 0.1 through 2.0%, more preferably, 0.5 through 1.5%. When the difference between the dimension change rate before and after the oil absorbing or the water absorbing treatment and the mold shrinkage rate falls in a range of 0.1 through 2.0%, excellent rotatability of the rolling bodies can be provided by forming the clearances between the resin connector and the rolling bodies with certainty by the oil absorbing or the water absorbing treatment. Further, when the dimension change rate before and after the oil absorbing or the water absorbing treatment becomes excessively large by exceeding the magnitude of the mold shrinkage rate, there is a concern where the rolling bodies are detached from the resin connector after the oil absorbing or the water absorbing treatment, however, according to experiments by the inventors, the difference is the utmost of about 2 through 3% and there is no concern of detaching the rolling bodies from the resin connector with such a degree of the magnitude.

Here, the dimension change rate before and after the oil absorbing or the water absorbing treatment is a percentage of a value (elongation amount) of a length (length after treatment) of the resin connector (endless retainer) after the oil absorbing or the water absorbing treatment subtracted by a length (length before treatment) of the resin connector (endless retainer) before the oil absorbing or the water absorbing treatment as compared with the length (length before treatment) of the resin connector (endless retainer) before the oil absorbing or the water absorbing treatment and the mold shrinkage rate is a value calculated by the following equation in accordance with JIS K6911,5.7.

Mold shrinkage rate={(mold dimension−molded product dimension)÷mold dimension}×100

Further, in respect of the resin used for molding the resin connector according to the present invention, it is necessary that the molded resin connector can smoothly be moved along with the rolling bodies in an infinite track of the rolling bodies formed by bearing races of the guide device and for that purpose, the resin of the resin connector needs to have flexibility and Shore hardness of the resin preferably falls in a range of 35 through 75, more preferably, 40 through 60.

As the resin preferable in fabricating the resin connector having such a flexibility, for example, there are polyamide-base elastomer such as Pebax (commercial name made by Toray Corporation) or the like, polyester-base elastomer such as Hytrel (commercial name made by Toray and DuPont Corporations) or the like, elastomers of polyurethane-base elastomer, styrene-base elastomer, olefin-base elastomer and the like, soft polyvinyl chloride and so on and elastomers are preferable. Further, among the elastomers, in consideration of properties required for the resin connector, particularly, softness or flexibility, the dimension change rate in absorbing oil or absorbing water, chemical proof, elongation and the like, polyamide-base or polyester-base elastomer is more preferable and further, in consideration of a time period whereby the elongation amount reaches a saturated state in the oil absorbing or the water absorbing treatment, in other words, a time period until a change in dimension is stabilized (dimension stabilizing time), polyester-base elastomer is preferable.

Further, according to the present invention, a ball or a roller is pointed out as the rolling body used in the guide device and the ball is preferable in an endless retainer used in a guide device necessitating smooth slidability and the roller is preferable for an endless retainer used in a guide device necessitating to apply comparatively heavy load.

In fabricating an endless retainer according to the present invention, resin having the dimension change rate before and after the oil absorbing or the water absorbing treatment larger than the mold shrinkage rate is used, the resin connector holding the number of rolling bodies is molded by injection molding with the number of rolling bodies as cores and after removing the resin connector from a mold, clearances for rotating the rolling bodies are formed between the resin connector and the respective rolling bodies by subjecting the resin connector to the oil absorbing or the water absorbing treatment.

Here, in respect of injection molding with a number of rolling bodies as cores, so-called insert molding processes such as methods described in Japanese Examined Patent Publication No. JP-B-6-56181, Japanese Unexamined Patent Publication No. JP-A-5-52217, Japanese Unexamined Patent Publication No. JP-A-5-126149, Japanese Unexamined Patent Publication No. JP-A-5-196036 and Japanese Unexamined Patent Publication No. JP-A-5-196037 mentioned above are applicable.

Further, in respect of the oil absorbing or the water absorbing treatment for providing rotatability to the respective rolling bodies in the molded endless retainer, although arbitrary methods of a method of dipping an endless retainer which has been removed from a mold into oil or water, a method of spraying misty oil or water to an endless retainer which has been removed from a mold, a method of making an endless retainer which has been removed from a mold absorb oil or water under predetermined heating and pressing by using an autoclave or the like, a method of leaving an endless retainer which has been removed from a mold under high humidity, a method of leaving an endless retainer which has been removed from a mold in the atmosphere for a predetermined time period, and the like can be adopted, the preferable method is the method of dipping an endless retainer which has been removed from a mold into oil or into water and the more preferable method is the method for dipping the endless retainer into oil.

Further, also in respect of treatment conditions of the oil absorbing or the water absorbing treatment in this case, pertinent conditions can be selected and adopted depending on the method of treatment, the kind of resin used and the like, for example, according to the method of dipping an endless retainer which has been removed from a mold into oil or into water, normally, the endless retainer is normally dipped at temperature of normal temperature through 50° C. for several minutes through several hours, although the conditions differ also depending on the kind of resin.

The oil absorbing or the water absorbing treatment is for providing rotatability to a rolling body of a molded endless retainer and although when the rotatability is provided to the rolling body by the oil absorbing treatment, the rolling body can be integrated to a guide as it is, when, for example, moisture is adhered to the surface of the endless retainer after the treatment as in the case where the water absorbing treatment is carried out by dipping the endless retainer into water, the endless retainer is integrated to the guide device preferably after removing the moisture adhered to the surface.

As oil used in the oil absorbing treatment, although liquid lubricant, grease or petrolatum of semi-solid lubricant or the like having lubricating performance may be used, the oil is preferably liquid lubricant having lubricating performance, for example, lubricant of mineral oil-base or synthetic oil-base, lubricant of emulsion-base, liquid metal-base, water-base or the like can be pointed out.

Although in the oil absorbing or the water absorbing treatment, an elongation amount of an endless retainer after the treatment as compared with that before the treatment, that is, the elongation amount of the resin connector reaches to a saturated state after a constant period of time, the oil absorbing or the water absorbing treatment is not always necessary to carry out until the elongation amount reaches the saturated state, it is sufficient that the elongation amount of at least 0.1% or more, preferably, 0.3% or more in respect of the length before the treatment is shown and free rotatability of respective rolling bodies is provided to the resin connector.

However, when an endless retainer provided by finishing the oil absorbing or the water absorbing treatment is used by integrating it to a guide device before reaching the saturated state, the resin connector of the endless retainer absorbs lubricant used in the guide device and is elongated until it reaches the saturated state and there is a concern of effecting a hazard in the smooth sliding movement of the endless retainer in the guide device and accordingly, the oil absorbing or the water absorbing treatment is preferably carried out until the elongation amount of the endless retainer reaches a state near to the saturated state before being integrated to the guide device. Accordingly, in such a point of view, with respect to resin used as the resin connector, in consideration of the productivity, polyester-base elastomer having a comparatively short time period whereby elongation amount reaches the saturated state in the oil absorbing treatment (dimension stabilizing time) is preferable.

Further, according to the endless retainer of the present invention, chamfered guide portions are preferably formed at both distal ends of the resin connector by which in moving an infinite track formed by bearing races of the guide device, particularly when the front end portion of the endless retainer moves into a direction change path of the infinite track or when it moves out from the direction change path, the endless retainer can be moved by guiding the front end portion by the chamfered guide portion.

The chamfered guide portions formed at the both distal ends of the resin connector, are designed by considering a radius of curvature of the direction change path of the infinite track formed by the bearing races of the guide device and determining the size of the radius of curvature, the shape and so on. By forming the chamfered guide portions at the both distal ends of the resin connector, in the reciprocating movement of the guide device, the endless retainer can smoothly be guided in either of direction of progressing and regressing.

Further, although the length of the molded endless retainer is determined by considering the length of the infinite track of the guide device where it is used, when the guide device is large-sized and the length of the infinite track is large, the endless retainer may be molded by dividing it in a plural number of 2, 3 or the like by which the size of a mold for molding the endless retainer can be reduced. Further, in that case, it is preferable to form the chamfered guide portions respectively at both distal ends of the resin connector of each of the endless retainers divided in the plural number.

According to the present invention, in molding the resin connector by injection molding with the rolling bodies as cores, the resin connector holding the rolling bodies after having been removed from a mold, is shrunk in accordance with the magnitude of the mold shrinkage rate, by subjecting the resin connector to the oil absorbing or the water absorbing treatment, the resin connector is expanded in accordance with the magnitude of the dimension change rate before and after the oil absorbing or the water absorbing treatment and further, the dimension change rate before and after the oil absorbing or the water absorbing treatment is larger than the mold shrinkage rate and accordingly, portions surrounding the rolling bodies expand to exceed lengths at surroundings of the rolling bodies and as a result, clearances are formed between the rolling bodies and the resin connector with certainty by which excellent rotatability seems to be provided to the rolling bodies.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a plane view showing an endless retainer in a chain-like shape according to an embodiment of the present invention;

FIG. **2** is a front view of FIG. **1**;

FIG. **3** is a sectional view taken along a line III—III of FIG. **1**;

FIG. **4** is a partially enlarged plane view showing an end portion of the endless retainer of FIG. **1** by enlargement;

FIG. **5** is a graph diagram showing a time-sequential change in an elongation rate when an oil absorbing treatment is carried out in accordance with Method A;

FIG. **6** is a graph diagram showing a time-sequential change in an elongation rate when an oil absorbing treatment is carried out in accordance with Method B;

FIG. **7** is a graph diagram showing a time-sequential change of an elongation rate when a water absorbing treatment is carried out in accordance with Method C;

FIG. **8** is a graph diagram showing a relationship between an elapse time and the elongation rate after dipping endless retainers in respect of two kinds of endless retainers provided in Embodiment 2;

FIG. **9** is a partially sectional side view showing a linear guide device for infinite sliding integrated with an endless retainer fabricated by the invented method (Method B);

FIG. **10** is a partially sectional front view of FIG. **9**; and

FIG. **11** is a graph diagram of measuring rolling resistance by using a load cell which has been measured in respect of the linear guide device of FIG. **9**.

DESCRIPTION OF REFERENCE NUMERAL

E_R: endless retainer, **1** or **1***a:* ball, **2**: resin connector, **2***a:* interposing portion, **2***b:* connecting portion, **3**: chamfered guide portion, **4**: track rail (one bearing race), **5**: sliding base (other bearing race), **5***a:* loaded ball rolling face, **5***b:* through hole, **6**: ball guide member, **6***a:* unloaded ball guide hole, **6***b:* loaded ball guide groove, **6***c:* direction change guiding unit, **7**: lid, **8**: direction change path.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

A specific explanation will be given of an endless retainer according to the present invention and its fabrication method based on embodiments, test examples and application examples shown by attached drawings as follows.

Embodiment 1

FIG. **1** through FIG. **4** show an endless retainer E_R in a chain-like shape according to the embodiment of the present invention. The endless retainer E_R is constituted by a number of balls **1** made of bearing steel (SUJ 2) arranged at predetermined intervals and a flexible resin connector **2** having interposing portions **2***a* interposed among the respective balls **1** and connecting portions **2***b* for connecting the respective interposing portions **2***a* for holding a number of balls **1** linearly and rollably.

Further, according to the embodiment, as shown by FIG. **4**, at both distal ends of the resin connector **2**, chamfered guide portions **3** each having a section substantially in a circle concentric to the balls **1***a,* are formed at distal end portions surrounding the balls **1***a* disposed at the distal ends.

The endless retainer E_R is fabricated by the following procedure.

First, a mold with a number of the balls **1** as cores is used and the resin connector **2** is molded by injection molding of 6•6 nylon-polyamide-base elastomer (made by Toray Corporation, commercial name: Pebax® 5533SA, mold shrinkage rate: 0.43% in flow direction and 0.74% in direction orthogonal to flow, Shore hardness: 55) and fabricated by removing it from the mold along with the number of balls **1**.

Next, the endless retainer E_R fabricated in this way is subjected to an oil absorbing treatment or a water absorbing treatment by the following methods, length dimensions before and after the treatment are measured and dimension change rates before and after the oil absorbing or the water absorbing treatment are calculated.

Further, in calculating the dimension change rates before and after the oil absorbing or the water absorbing treatment, the dimension change rates are measured by preparing 5 pieces of samples of the endless retainer E_R and in respect of each of the samples.

[Method A]

The molded endless retainer E_R is immediately dipped into a mineral-base lubricant at normal temperature and left in the lubricant as it is and the dimension change rates (elongation rates) are calculated by measuring the lengths of the samples of the endless retainer E_R after 1 hour, after 6 hours, after 50 hours, after 80 hours and after 124 hours since the dipping operation has been started.

Table 1 shows the lengths of the samples of the endless retainer E_R in starting dipping operation, 1 hour after start of dipping and 6 hours after start of dipping and the elongation rates at the respective measurements are shown by FIG. **5**.

TABLE 1

	Length (mm, upper column) and Elongation rate (%, lower column)		
Sample No.	Start of dipping	1 hour after start of dipping	6 hours after start of dipping
No. 1	115.988	116.144	116.552
	(0.00)	(0.13)	(0.49)
No. 2	115.973	116.207	116.656
	(0.00)	(0.20)	(0.59)
No. 3	116.058	116.155	116.548
	(0.00)	(0.08)	(0.42)
No. 4	116.017	116.220	116.636
	(0.00)	(0.17)	(0.53)
No. 5	115.883	116.292	116.655
	(0.00)	(0.35)	(0.67)

The rotatability of ball is investigated as follows in respect of the samples of the endless retainer E_R. That is, the sample of the endless retainer E_R is sandwiched between two sheets of plates, one of the plates is fixed while the other thereof is moved and whether the sample of the endless retainer E_R is moved at the occasion and smoothness of movement when the sample is moved are qualitatively investigated.

As a result, in respect of the samples of 1 hour after start of dipping, the rotatability of ball is confirmed except the sample of No. 3, the comparatively smooth rotatability of ball is confirmed in respect of the samples of 6 hours after start of dipping and the extremely excellent rotatability of ball is confirmed in respect of samples of 50 hours after start of dipping.

[Method B]

The molded samples of the endless retainer E_R are immediately dipped into a mineral-base lubricant at normal temperature for 5 minutes, thereafter taken out from the lubricant and left in a room, and the dimension change rates (elongation rates) are calculated by measuring lengths of the samples of the endless retainer E_R at immediately after taking them out from the lubricant (0 hour), 24 hours thereafter, 45 hours thereafter, 69 hours thereafter, 118 hours thereafter and 190 hours thereafter, respectively.

The result is shown by FIG. **6**. Further, as a result of investigating the rotatability of ball similar to the case of Method A mentioned above, the rotatability of ball is recognized in respect of the samples of the endless retainer E_R immediately after having been taken out from the lubricant except the sample of No. 2 and the comparatively excellent rotatability of ball is recognized in respect of the samples of 24 hours or longer after starting to leave them in the room.

[Method C]

The molded samples of the endless retainer E_R are left in the atmosphere as they are (temperature 23° C., humidity 50 through 60%) and the dimension change rates (elongation rates) are calculated by measuring lengths of the samples of the endless retainer E_R of 24 hours after starting to leave them, 40 hours thereafter and 96 hours thereafter, respectively. The result is shown in FIG. **7**.

Further, as a result of investigating the rotatability of ball similar to the case of Method A mentioned above, the rotatability of ball is recognized in respect of the samples of the endless retainer E_R of 24 hours after starting to leave them in the atmosphere except the sample of No. 1 and the rotatability of ball is recognized in respect of all the samples of the endless retainer E_R of 48 hours after starting to leave them.

Embodiment 2

6•6 nylon-polyamide-base elastomer (made by Toray Corporation, commercial name: Pebax 5533SA) the same as that used in Embodiment 1 mentioned above and polyester-base elastomer (made by Toray Corporation and DuPont Corporation, commercial name: Hytrel® 4767, mold shrinkage rate: 1.2 through 1.5%, hardness under JIS K7215: 47) are used, the resin connectors **2** are molded similar to Embodiment 1 mentioned above, a oil absorbing treatment is successively carried out in accordance with the dipping method of Method A, the dimension change rate (elongation rate) in this occasion is time-sequentially investigated and a time period (dimension stabilizing time) until the change in dimensions is stabilized within a range of the elongation rate of 0.5 through 1.5% in carrying out the oil absorbing treatment, is investigated. The result is shown by FIG. **8**.

As is apparent from the result of FIG. **8**, in the case of 6•6 nylon-polyamide-base elastomer, the elongation rate exceeds about 0.8% at 100 minutes after starting to dip the sample in the oil absorbing treatment, successively, rapid change in dimension is observed up to about 200 hours and little by little change in dimension is caused thereafter even after 460 hours has elapsed. By contrast, in the case of polyester-base elastomer, the elongation rate exceeds 0.5% at about 50 hours after staring to dip the sample in the oil absorbing treatment and reaches about 0.8% for 100 hours, a gradual change in dimension is successively observed up to about 200 hours, however, almost no change in dimension is observed thereafter even exceeding 500 hours.

As a result, it is known that by using polyester-base elastomer, a time period for reaching a range of the preferable elongation rate of 0.5 through 1.5% is prolonged compared with the case of 6•6 nylon-polyamide-base elastomer, however, the dimension stabilizing time period for stabilizing the change in dimension is significantly shortened, which is advantageous in fabricating the endless retainer E_R.

Application Example 1

A linear guide device for infinite sliding shown by FIG. **9** and FIG. **10** is constituted by using the endless retainer E_R which has been subjected to the oil absorbing or the water absorbing treatment in accordance with Method B in Embodiment 1.

The linear guide device for infinite sliding is basically constituted by a rigid track rail (one bearing race) **4** made of metal, a rigid sliding base (other bearing race) **5** made of metal, a ball guide member **6** made of synthetic resin and attached to the sliding base **5** by insert molding and lids **7** made of synthetic resin and attached to the sliding base **5** along with the ball guide member **6**.

Further, the track rail **4** is formed with rolling faces **4***a* of balls **1** at both shoulder portions thereof and the sliding base **5** is formed with loaded ball rolling faces **5***a* of the balls **1** on which load is applied and through holes **5***b* through which the balls **1** in an unloaded state pass. Further, the ball guide member **6** is formed with unloaded ball guide holes **6***a* for guiding rolling of the balls **1** under the unloaded state, loaded ball guide grooves **6***b* for guiding rolling of the balls **1** under a loaded state and direction change guiding units **6***c* for guiding to change the direction of the balls **1** by communicating and connecting the unloaded ball holes **6***a* with the loaded ball guide grooves **6***b* by a predetermined radius of curvature. Further, the lid **7** is formed with direction change guide grooves **7***a* for constituting direction change paths **8** of the balls **1** along with the direction change guide portions **6***c* of the ball guide members **6** mentioned above.

According to the embodiment, an infinite track of the ball **1** is constituted by the loaded ball rolling face **5***a* of the sliding base **5** as well as the loaded ball guide groove **6***b* of the ball guide member **6** opposed thereto, the unloaded ball guide hole **6***a* of the ball guide member **6**, the direction change guide portions **6***c* of the ball guide members **6** and the direction change guide grooves **7***a* of the lids **7** opposed thereto.

In respect of the linear guide device fabricated in this way, rolling resistance of the sliding base **5** with respect to the track rail **4** is measured by fixing the track rail **4** and pushing the sliding base **5** by a load cell at a sampling frequency of 500 Hz of the load cell.

The result is as shown by FIG. **11** in which values of the rolling resistance in a moving region partitioned by bold lines are 1.389 Newton (N) in starting, 1.439 N as maximum rolling resistance, 1.179 N as minimum rolling resistance and 1.302 N as average rolling resistance which is found to be extremely smooth.

Industrial Applicability

An endless retainer according to the present invention is not only provided with advantages where fabrication thereof is extremely facilitated, handling thereof is extremely easy without detachment of rolling bodies and automation in integrating the retainer to a guide device can be carried out but is capable of providing extremely smooth rotatability to the rolling bodies with certainty.

Accordingly, the endless retainer of the present invention is extremely useful for use of, for example, a linear guide device or a curved guide device for infinite sliding and a guide device of pivoting bearing or the like.

What is claimed is:

1. An endless retainer of a guide device, said endless retainer comprising:

a number of rolling bodies arranged at predetermined intervals for rolling at an inside of an infinite track formed in the guide device;

a flexible resin connector having interposing portions interposed among the respective rolling bodies and connecting portions for connecting the respective interposing portions for holding the number of rolling bodies in an aligned state and rotatably; and

wherein the resin connector is molded by an injection molding with the rolling bodies as cores by using a resin having a dimension change rate before and after an oil absorbing or a water absorbing treatment larger than a mold shrinkage rate and is provided with clearances between the resin connector and the rolling bodies formed by the oil absorbing or the water absorbing treatment.

2. The endless retainer of a guide device according to claim **1**:

wherein a difference between the dimension change rate before and after the oil absorbing or the water absorbing treatment of the resin forming the resin connector falls in a range of 0.1 through 2.0%.

3. The endless retainer of a guide device according to claim **1** or **2**:

wherein an oil used in the oil absorbing treatment is a mineral oil-base or a synthetic oil-base lubricant.

4. The endless retainer of a guide device according to any one of claim **1** or **2**:

wherein chamfered guide portions for guiding a front end portion of the resin connector are installed at both distal ends of the resin connector.

5. The endless retainer of a guide device according to any one of claim **1** or **2**:

wherein Shore hardness of the resin forming the resin connector falls in a range of 35 through 75.

6. The endless retainer of a guide device according to any one of claim **1** or **2**:

wherein the resin forming the resin connector is any of polyamide-base elastomer, polyester-base elastomer, polyurethane-base elastomer, styrene-base elastomer and olefin-base elastomer.

7. The endless retainer of a guide device according to any one of claim **1** or **2**:

wherein the rolling body is a ball.

8. A method of fabricating an endless retainer of a guide device, said endless retainer comprising:

a number of rolling bodies arranged at predetermined intervals for rolling at an inside of an infinite track formed in the guide device;

a flexible resin connector having interposing portions interposed among the respective rolling bodies and connecting portions for connecting the respective interposing portions for holding the number of rolling bodies in an aligned state and rotatably, said method of fabricating the endless retainer comprising the steps of:

molding the resin connector holding the number of rolling bodies by an injection molding with the number of rolling bodies as cores by using a resin having a dimension change rate before and after an oil absorbing or a water absorbing treatment larger than a mold shrinkage rate; and

forming clearances between the resin connector and the respective rolling bodies for rotating the rolling bodies by subjecting the resin connector to the oil absorbing or the water absorbing treatment after having been removed from a mold.

9. The method of fabricating an endless retainer according to claim **8**:

wherein the oil absorbing or the water absorbing treatment is carried out by dipping the resin connector holding the rolling bodies into an oil or water.

10. The method of fabricating an endless retainer according to claim **8** or **9**:

wherein the oil used in the oil absorbing treatment is a mineral oil-base or a synthetic oil-base lubricant.

11. The method of fabricating an endless retainer according to claim **8**:

wherein the resin forming the resin connector is any of polyamide-base elastomer, polyester-base elastomer, polyurethane-base elastomer, styrene-base elastomer and olefin-base elastomer.

12. A guide device comprising:

a pair of bearing races;

a number of rolling bodies rolling at an inside of an infinite track formed between the pair of bearing races;

wherein the number of rolling bodies are formed in an endless retainer in a chain-like shape by being held in an aligned state and rotatably by a flexible resin connector having interposing portions interposed among the respective rolling bodies and connecting portions for connecting the respective interposing portions; and

wherein the resin connector is molded by an injection molding with the rolling bodies as cores by using a resin having a dimension change rate before and after an oil absorbing or a water absorbing treatment larger than a mold shrinkage rate and is provided with clearances between the resin connector and the rolling bodies formed by the oil absorbing or the water absorbing treatment.

[57] **ABSTRACT**

A rolling guide unit comprises a movable member provided with a pair of support portions extending from lateral end portions of a main body portion so as to provide a recessed portion between the main body portion and both the support portions, a guide rail disposed in the recessed portion of the movable member so that side surfaces of the guide rail face the inner surfaces of the support portions, respectively, and a number of rolling members disposed to be rollable between corresponding rolling member rolling grooves formed to the guide rail and the support portions of the movable member so that each of the rolling members contact the rolling member rolling grooves at two contact points and the rolling members apply load to the rolling member rolling grooves, the movable member and the guide rail being relatively movable through the rolling of the rolling members. Each of the rolling member rolling grooves has an arcuate shape in section having radius of curvature larger than that of the rolling member and the contact points are displaceable along the arcuate shape of the rolling member rolling groove.

FIG. 21

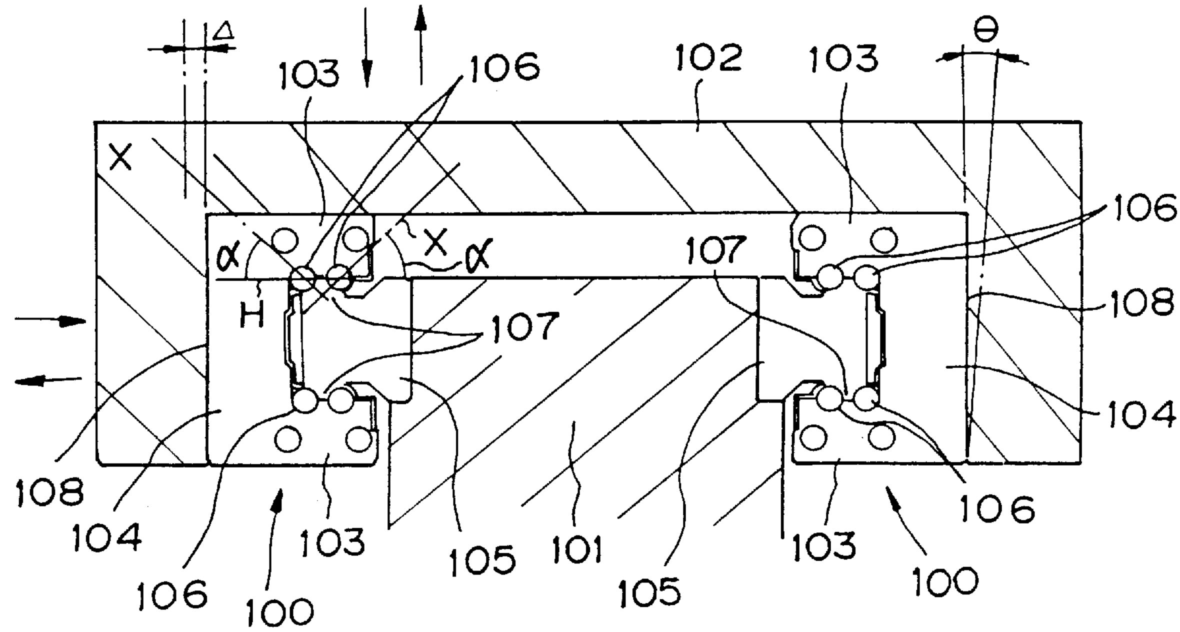

FIG. 22 PRIOR ART

ROLLING GUIDE UNIT

This is a divisional of application Ser. No. 08/404,925 filed Mar. 15, 1995, now U.S. Pat. No. 5,716,139.

BACKGROUND OF THE INVENTION

The present invention relates to a rolling guide unit of rolling contact type linear or curved, such as circular, guide passage, particularly capable of being excellent in misalignment adjustment performance.

As a known example of such rolling guide unit, there is provided an example shown in FIG. **22** in which a rolling guide unit **100** is disposed so as to guide a table **102** with respect to a fixed base **101**.

The rolling guide unit **100** is assembled in a manner that a movable member **104** having a U-shape in cross section is provided with a pair of upper and lower support portions **103** extending in a lateral direction, i.e. longitudinal direction of the movable member, and upper and lower surfaces of a guide rail disposed in the U-shaped hollow portion of the movable member **104** are supported by the support portions through upper and lower two rows of balls **106**. In general, high rigidity is required for such rolling guide unit, and in the known art, the rigidity in every direction including vertical and horizontal directions is made high by applying a preload to the balls **106** and forming projecting ribs **107** to the upper and lower side surfaces of the guide rail **105** so as to project therefrom thereby to clamp the ribs **107** by the respective two rows of the balls **106** from the upper and lower directions thereof. Particularly, in the illustrated example, in order to equally support the load in the every direction, a contact angle α of a line X connecting contacting points of the ball **106** to two ball rolling grooves with respect to a virtual horizontal line is set to 45°.

The known rolling guide unit of the type shown in FIG. **22**, however, has high rigidity, and accordingly, when a working error, for example, an angular error θ and a dimensional error Δ in the horizontal direction, is caused to a mounting surface of the movable member **104**, a misalignment is caused between the guide rail **105** and the movable member **104** at the time of clamping and fixing the rolling guide unit between the table **102** and the fixed base **101**. Such misalignment constitutes a cause of an application of excessive force to the movable member **104**, resulting in the increasing of a sliding resistance and abrasion of the balls **106** and the ball rolling groves, thus providing a problem.

Such misalignment will be avoided by increasing the working performance of the respective members of the rolling guide unit. However, the increasing of the working performance has a limit itself and involves cost increasing.

In the meantime, the misalignment will be somewhat reduced by making small the preload to be applied to the balls **106**, but the high rigidity of the rolling guide unit will be reduced by making small the preload to be applied. As mentioned above, the requirement of the high supporting rigidity is contrary to the reduction of the misalignment of the members, and hence, in the prior art construction, it is difficult to satisfy both the requirements for the realization of the high rigidity and the less misalignment.

SUMMARY OF THE INVENTION

An object of the present invention is to substantially eliminate defects or drawbacks encountered in the prior art described above and to provide a rolling guide unit capable of absorbing misalignment in a horizontal direction while

maintaining vertical rigidity of the unit and also maintaining an allowable load bearing ability.

This and other objects can be achieved according to the present invention by providing a rolling guide unit comprising:

a movable member provided with a main body portion and a pair of support portions extending from lateral end portions of the main body portion so as to provide a recessed portion between the central portion and both the support portions, the support portions having inner surfaces to which rolling member rolling grooves are formed;

a guide rail disposed in the recessed portion of the movable member so that side surfaces of the guide rail face the inner surfaces of the support portions, respectively, the side surfaces of the guide rail being formed with rolling member rolling grooves at portions corresponding to the rolling member rolling grooves of the support portions, respectively; and

a number of rolling members disposed to be rollable between the corresponding rolling member rolling grooves of the guide rail and the support portions of the movable member so that each of the rolling members contact the rolling member rolling grooves at two contact points and the rolling members apply load to the rolling member rolling grooves, the movable member and the guide rail being relatively movable through the rolling of the rolling members;

wherein each of the rolling member rolling grooves has an arcuate shape in section having radius of curvature larger than that of the rolling member and the contact points are displaceable along the arcuate shape of the rolling member rolling groove.

In preferred embodiments, the rolling member is a ball and each of the rolling member rolling grooves has a depth of approximately ¼ to ½ of a diameter of the ball.

A plurality of rolling member rolling grooves are formed at least one of the side surfaces of the guide rail and at least corresponding one inner surface of the support portion of the movable member.

An initial contact angle constituted by a line connecting the two contact points of the rolling members to the rolling member rolling grooves and a horizontal line passing a center of the rolling member is set substantially 90°.

A plurality of rolling member rolling grooves are formed at least one of the side surfaces of the guide rail and at least corresponding one inner surface of the support portion of the movable member, and an initial contact angle constituted by a line connecting the two contact points of the rolling members in at least one of the plurality of rolling member rolling grooves to this rolling member rolling groove and a horizontal line passing a center of the rolling member is set so as to have an inclination by a predetermined angle with respect to the angle of substantially 90°. All the rolling members disposed in the plurality of rolling member rolling grooves have contact angles inclined in the same direction or in directions reverse to each other.

A plurality of rolling member rolling grooves are formed at least one of the side surfaces of the guide rail and at least corresponding one inner surface of the support portion of the movable member, and the rolling members disposed in at least one of the plurality of rolling member rolling grooves are formed as tubular members and the rolling member rolling groove in which the tubular members are rolled is formed so as to provide a flat groove bottom. The rolling member rolling grooves for the tabular members are formed to the inner surfaces of the support portions so as to provide a groove bottom shape corresponding to an outer shape of the tubular member and the side surfaces of the guide rail for the tubular members are formed to be flat. Three rows of the rolling member grooves are formed and a central one is formed for the tubular members.

The guide rail has substantially rectangular cross section and is bent in a curved shape or has substantially linear shape.

Retainer means are disposed between the facing inner surfaces of the support portions of the movable member and the side surfaces of the rail guide.

The support portions are integrally formed with the main body portion of the movable member. The support portions may be independently formed with the main body portion of the movable member and the support portions are fixed to the main body portion of the movable member by means of bolts. The support portions have extending lengths different from each other and the numbers of rows of the rolling members of the respective support portions are different from each other.

According to the structures and characters of the rolling guide unit according to the present invention described above, the vertical load is born by the rolling members disposed between the upper and lower, as viewed in the illustrations of the drawings, support portions of the movable member and the guide rail. Particularly, in an arrangement in which the initial contact angle of the rolling member is set to approximately 90°, a vertical large load can be effectively born. When a horizontal load is applied, the contact points of the rolling member to the rolling member rolling groove are displaced to change the contact angle by the load balance between the vertical load and the horizontal, i.e. Lateral, load, thereby to effectively bear both the loads.

With respect to the misalignment in the horizontal direction, the contact points of the rolling members are displaced along the arcuate shape of the rolling member rolling groove thereby to absorb the misalignment.

Since the rolling member rolling groove has an arcuate shape in section, the allowable load is represented by a sine function with a contact angle being variable. According to the present invention, the contact angle is set to a value near **90**- about which the sine function shows a curve having a gentle variation, so that the allowable load varies small in amount even if the contact angle varies.

Since the depth of the rolling member rolling groove is set to a value approximately ¼ to ½ of the diameter of the rolling member such as ball, the ball does not contact the edge portions of the groove even if the contact points are displaced, and hence, the edge load is eliminated.

Furthermore, according to the present invention, the guide rail can be prevented from forming with a complicated cross section such as provided with projection ribs as in a conventional structure and the rolling member rolling grooves can be worked through a horizontal grinding working. Particularly, when the guide rail having a curved shape is formed, it can be formed so as to provide a simple rectangular shape, thus being uniformly bent.

In the case of contact angle of 90°, the contact points are displaced by the application of the horizontal load, and the variation of the contact points can be absorbed immediately by changing the initial contact angle in accordance with the load to be applied. The contact angle can be changed to an optional value by applying a horizontal load of predetermined amount, and for example, the horizontal load can be

born by setting the contact angle to, for example, 30° or 45° in accordance with the load to be applied. In such case, since the contact points of the rolling member to the rolling member rolling groove can be displaceable, the misalignment can be effectively absorbed.

The nature and further characters of the present invention will be made more clear through the following descriptions made with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

In the accompanying drawings:

FIG. **1** represents one embodiment of a rolling guide unit according to the present invention, in which FIG. **1**A is a cross-sectional view of the guide unit, FIG. **1**B is a view showing a contacting condition of a ball to a ball rolling groove of FIG. **1**A in an enlarged scale, and FIG. **1**C is a view similar to FIG. **1**B at a time when loads are applied to the ball in both horizontal and vertical directions as viewed;

FIG. **2** includes FIGS. **2**A, **2**B and **2**C, in which FIG. **2**A is a perspective view of a portion of a guide rail of the guide unit in FIG. **1**A, FIG. **2**B is a side view, partially broken away, of FIG. **2**A, and FIG. **2**C is a partial sectional view showing an assembled arrangement of a retainer;

FIG. **3** is an illustration of a support portion for a railway rolling stock to which the rolling guide unit of the present invention is applicable;

FIG. **4** includes FIGS. **4**A and **4**B, in which FIG. **4**A is an illustration of an entire railway rolling stock to which the rolling guide unit of the present invention is applicable and FIG. **4**B is an enlarged view of the rolling guide unit of FIG. **4**A;

FIG. **5** includes FIGS. **5**A, **5**B and **5**C, in which FIG. **5**A is a view showing a condition of movement of a contacting point of the ball to the ball rolling groove, FIG. **5**B is a sine function graph with the contact angle of the ball being variable, and FIG. **5**C is a view in an enlarged scale at a point near the contact angle of 90° in FIG. **5**B;

FIG. **6** includes FIGS. **6**A to **6**H for the explanatory of steps for absorption of misalignment by means of the rolling guide unit according to the present invention in this order;

FIG. **7** includes FIGS. **7**A to **7**C representing structures of other embodiments of the rolling guide unit according to the present invention;

FIG. **8** represents a further embodiment of the rolling guide unit according to the present invention, in which FIG. **8**A is a side view thereof and FIGS. **8** to **8**E show various types of rolling members;

FIG. **9** represents an embodiment of a rolling guide unit of linear guide type according to the present invention, in which FIG. **9**A is a side view of the linear guide type rolling guide unit and FIG. **9**B is a perspective view of a guide rail to which the guide unit of FIG. **9**A is mountable;

FIG. **10** is a sectional view of a partial portion of another embodiment of the rolling guide unit in which a support structure is constructed as a separate member;

FIGS. **11**A and **11**B are schematic views showing the support structure of a movable member capable of increasing supporting rigidity both in the horizontal and vertical directions by utilizing the rolling guide unit according to the present invention;

FIG. **12** is a schematic view of the rolling guide unit representing one example of a tandem contact structure;

FIG. **13** is a schematic view, similar to that of FIG. **12**, representing another example of the tandem contact structure;

FIG. **14** is a schematic view of the rolling guide unit representing one example of a DF type compound contact structure;

FIG. **15** is a schematic view representing another example of the DF type compound contact structure;

FIG. **16** is a schematic view of the rolling guide unit representing one example of a DB type compound contact structure;

FIG. **17** is a schematic view representing another example of the DB type compound contact structure;

FIG. **18** is a schematic view of the rolling guide unit representing one example of a compound contact structure of both the DF type and DB type;

FIG. **19** is a schematic view representing another example of the compound contact structure of both the DF type and DB type;

FIG. **20** is a schematic view showing a further example of the contact structure;

FIG. **21** is a schematic view showing a still further example of the contact structure; and

FIG. **22** is a cross sectional view of a table moving apparatus utilizing a rolling guide unit of conventional structure.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

It is first to be noted that the terms "upper" and "lower" used herein for the following respective embodiments or examples are made with reference to the corresponding illustrations of the accompanying drawings.

FIGS. **1** and **2** represent one embodiment of the present invention, and this embodiment will be preferably described hereunder with reference to an example of a rolling guide unit for guiding on a curved line a pendulum type vehicle such as railway rolling stock such as shown in FIGS. **3** and **4**.

As shown in FIGS. **3** and **4**, the rolling guide unit **1** is one usable for the curve guide for a vehicle body such as railway rolling stock, and a pair of such rolling guide units **1**, **1** are oppositely arranged for supporting the vehicle body **3** swingably on a bogie **2**. Each of the rolling guide unit **1** comprises as shown in FIGS. **1** and **2**, a guide rail **4** and a movable member **6** assembled with the guide rail **4** so that the movable member **6** is movable along the guide rail **4** through rolling members **5** having a spherical outer shape such as balls.

The guide rail **4** has, as shown in FIG. **2**A, rectangular section and is bent in an arcuate shape so as to provide a predetermined radius of curvature. The guide rail **4** has upper and lower (as viewed) side surfaces to which ball rolling grooves **7** are formed entirely therealong. The ball rolling grooves **7** are formed in three rows in the illustrated example on the upper and lower sides as shown in FIG. **2**A. One row, two rows or more than three rows of the ball rolling grooves may be formed. The invention is not limited to the illustrated three-row arrangement.

Each of the ball rolling grooves **7** has an arcuate cross section having a radius of curvature larger than that of the ball **5** and has a depth of about ¼ to ½ of the diameter of the ball **5**.

The movable member **6** is formed of a block member provided with a pair of supporting portions **61** and **62** which extend sideway substantially perpendicularly from a central portion thereof so as to entirely provide a ⊐-shaped cross section, and as shown in FIG. **2**A, the movable member **6** is assembled with the guide rail **4** so that the supporting portions **61** and **62** are positioned on both the upper and lower sides of the guide rail **4** to be movable therealong. Each of the supporting portions **61** and **62** are formed with ball rolling grooves **8** corresponding to the ball rolling grooves **7** formed to the guide rail **4** in their positions and numbers. Each of the ball rolling grooves **8** also has an arcuate cross section having a radius of curvature larger than that of the ball **5** and has a depth of about ¼ to ½ of the diameter of the ball **5**.

When assembled, the balls **5** are disposed between these ball rolling grooves **7** and **8** each so as to contact at two points CP, in FIG. **1**B or **1**C, near groove bottoms thereof, and an angle α constituted by a line connecting these two contact points CP and a virtual horizontal line is set to approximately 90°. Accordingly, the contact points CP of the ball **5** is bilaterally displaceable with the position of contact angle α of 90° being the center of this displacement.

As shown in FIG. **2**B, the movable member **6** comprises a main body **10** of the movable member **6**, having the supporting portions **61** and **62**, and side covers **12** mounted to front and rear end portions of the main body **10**. The movable member main body **10** is provided with return passages **9** in an unloaded region for circulating the balls **5** in addition to the ball rolling grooves **8**, **8**, and each of the side covers **12** is formed with a ball turning passage **11** for changing the ball rolling direction.

The left side, as viewed in FIG. **1**A, surface of the movable member **6** is formed as a mounting surface **13** to which tap holes **14** for fixing bolts **13** are formed. The right side, as viewed in FIG. **1**A, surface of the guide rail **4** is formed as a mounting surface **16** which is fixed by means of bolts, not shown. Seal members **15** are disposed to the gaps between the inside surfaces of the upper and lower supporting portions **61** and **62** of the movable member **6** and the upper and lower side surfaces of the guide rail **4**, and retainers **24** for holding the balls **5** are also disposed between these gaps as shown in FIG. **2**C.

Preload is applied to the balls **5** by a suitable means.

In the rolling guide unit of the structure described above, load Fa applied in a vertical direction, as viewed in FIG. **1**C, is born by three row of balls **5** having the initial contact angle of 90°. On the other hand, when a load Fb from the horizontal direction is born by the balls **5** having the displaced contact angle of α' at which the line X' connecting the contact points CP of the balls **5** to the ball rolling grooves **7** and **8** substantially accords with a direction of composite vector F of the vertical load Fa and the horizontal load Fb. In the thus manner, the vertical and horizontal loads are applied to the balls **5** at the displaced contact angle α'.

In this embodiment, since the ball rolling grooves **7** and **8** are formed so as to provide the arcuate cross sections and the ball contact angle α is set to approximately 90°, variation of allowable load is small even if the contact angle α be changed.

That is, the allowable load will be expressed as follows.

$$Co=f(Da\cdot z\cdot i\cdot \sin\alpha)$$

Da: diameter of ball

z: number of balls

i: number of ball rows

α: contact angle (90° in the perpendicular case)

As shown in FIG. **5**B, the allowable load is expressed as sine function. A sine curve varies gently, as shown in FIG. **5**C, at a portion near 90°, and the sine function value is **1** at the contact angle α of 90°; 0.998 of 87°; 0.996 of 85°; and 0.992 even of 83°. This means that even if the contact angle varies in the range of 90°±7°, the reduction ratio of the allowable load is less than 1%, being very small, and of course, the displacement of the allowable contact angle can be properly selected.

In addition, since the depth h of the ball rolling grooves **7** and **8** are made deep as mentioned hereinbefore, the ball **5** does not contact the edge E of the ball rolling groove **7** as shown in FIG. **5**A even if the contact points CP are displaced, thus preventing the edge load from occurring. The depth h of the groove is determined in consideration of the edge load, but it is preferred to set the depth h to approximately ¼ to ½ oil the diameter of the ball **5**.

The misalignment absorbed according to the present invention basically corresponds to displacement of the guide rail and the movable member in the horizontal direction, and it is possible to absorb the following misalignments as shown in FIG. **6**: (1) a misalignment in the rotating direction about the central axis of the guide rail **4** (MC direction in FIG. **6**A); a misalignment in the rotating direction reversely changing the front and rear end portions of the movable member **6** (MA direction in FIG. **6**C); and a misalignment in the direction displacing the movable member **6** in the horizontal direction (Z direction in FIG. **6**B).

The above misalignments are caused by, for example, a working error of the mounting surface of the movable member **6** as shown in FIG. **3** and an error caused by an angular error θ or dimensional error Δ in the horizontal direction. In addition, an error in degree of parallelism of the bilateral guide rails **4**, **4** and an excessive clamping of the fastening bolt may also cause the misalignments.

FIGS. **6**D to **6**H represent the change of the contact angles in the absorption of the misalignments. FIG. **6**D represents a position at which the initial contact angle α of 90° being the reference value preliminarily set, FIGS. **6**E and **6**F represent a position at which the misalignment in the MC direction is absorbed and the contact angle is displaced in a direction reverse to the rotating direction, and FIGS. **6**G and **6**H represent a position at which the misalignment in the Z direction is absorbed and the contact angle is displaced in a direction reverse to the first displaced direction.

In the meantime, when the misalignment in the MC direction is absorbed, the front and rear end portions of the movable member **6** are displaced in the horizontal direction reverse to each other, and the contact angle of the ball **5** positioned at the front and rear end portions of the movable member **6** are displaced in directions reverse to each other as shown in FIGS. **6**G and **6**H.

As discussed above, since the contact angle is initially set to approximately 90°, it is not necessary as in the conventional technology for the guide rail to be formed with complicated structure having a projection, and since the ball rolling groove **7** can be ground by a horizontal grinding technique, the guide rail can be easily manufactured. In the case where a plurality of ball rolling grooves **7** are formed, they can be formed with high performance of a pitch between adjacent ones. Furthermore, since the grinding allowance is constant along the entire length of the guide rail **4** and hence is easily measured, the ball rolling grooves **7** can be worked so as to provide a smooth finishing surface with high performance.

Particularly, when the guide rail **4** is formed to provide a curved line shape, since it is not necessary to form the guide rail with the projected rib **107**, and the guide rail is formed so as to provide a simple rectangular shape, a plastical deformation in a bending working can uniformly progress with substantially no camber, thus being easily manufactured, and accordingly, the grinding allowance in the finishing working can be minimally suppressed, thus being effective in production.

FIG. **7** represents other embodiments of the present invention.

FIG. **7**A shows an embodiment, in which the upper end surface **17** of the movable member **6** and the lower end surface **18** of the guide rail **4** are formed as mounting surfaces of the movable member **6** and the guide rail **4**, respectively, and these members are fastened each by means of single fixing bolt **19** in the vertical direction as viewed. In the structure of FIG. **7**B, two fixing bolts **19** are utilized respectively for the movable member **6** and the guide rail **4**, respectively. In the embodiment of FIG. **7**C, two fixing bolts **19** are utilized for the movable member **6** and single fixing bolt **19** is utilized for the guide rail **4**. The numbers of rows of the balls **5** are different between the upper side surface and the lower side surface of the guide rail, and in the illustrated embodiment, three ball rows are formed on the upper side surface of the guide rail **4** and two ball rows are formed on the lower side surface thereof.

FIG. **8** represents a further embodiment of the present invention, which has a basic structure essentially identical to that of the embodiment shown in FIG. **1** and only has a different point that the balls rolling along the central ball rolling groove **7** in FIG. **1** are substituted with cylindrical rollers **20** rolling along a rolling groove **21**.

In accordance with this structural difference, the roller rolling groove **21** for the rollers **20** formed to the inside surfaces of the supporting portions **61** and **62** of the movable member **6** is formed so as to provide a rectangular cross section so as to accord with the shape or the cylindrical roller **20**. The bottom of the groove **21** is made flat accordingly. On the other hand, any roller rolling groove for the rollers **20** is not formed to the upper and lower side surfaces of the guide rail **4** and the upper and lower surfaces thereof are directly utilized for the roller rolling surface as they are.

According to this structure of the embodiment of FIG. **8**, the rollers **20** can move in the horizontal direction along the upper and lower side surfaces of the guide rail **4**, and hence, the misalignment in the horizontal direction can be absorbed by the embodiment of FIG. **1**. In addition, according to this embodiment of FIG. **8**, a larger load in the vertical direction can be born in comparison with the structure of the embodiment of FIG. **1**, thus being more advantageous.

Furthermore, the misalignments in the horizontal (Z) direction and the MA direction of the kind shown in FIGS. **6**B and **6**C can be absorbed in the same manner as described with reference to the embodiment of FIG. **1**, and the misalignment in the MC direction shown in FIG. **6**A does not constitutes a problem since the rollers **20** are positioned at the central portion of the guide rail side surface and the displacement of the roller **20** is hence small in comparison with the bilateral side ones.

However, since there may be a slight fear of causing the edge load at the end portion of the roller **20**, a crowning treatment will be effected to the edge portion **21** as shown in FIG. **8**C, or barrel shaped roller having a central portion swelled in section such as shown in FIG. **8**D may be utilized, as occasion demands. In the case where the barrel shaped rollers **20** are utilized, it: is necessary to form the roller rolling groove so as to provide an arcuate cross section having a radius of curvature larger than that of the barrel roller **20**.

In a modification, the barrel shaped rollers **20** or spherical, partially cut away, rollers **23** shown in FIG. **8**E may be utilized in substitution for the ball rollers **5**.

In the forgoing description, the embodiments of the curved line guiding structure were provided, the present invention is not limited to such curved line guiding structure and it can be applied as it is to the rolling guide units **1**A for the linear guiding structure as shown in FIG. **9**. That is, in comparison with the curved line guiding structure, the curved guide rail **4** is constructed to a linear guide rail **4**A and the respective ball rolling grooves are formed linearly so as to accord with the linear guide rail **4**A, and the other structure is the same as that of the former embodiment.

Furthermore, in the first described embodiment, the supporting portions **61** and **62** are formed integrally to the central portion of the movable member **6**, but these portions may be independently formed as shown in FIG. **10**, for example. That is, the supporting portion **61** is fixed to the main body **63** (FIG. **10**) of the movable member **6** by a fastening means **64** such as bolt. Both these portions or either one of these portions may be independently formed from the main body **63** of the movable member **6**.

In the present invention, the horizontal gap is formed between the ball and the ball rolling grooves for absorbing the misalignment of the ball. However, this gap may be eliminated by applying a horizontal preload, and in such arrangement, the horizontal supporting rigidity will be increased.

FIG. **11** shows an example increasing the horizontal supporting rigidity.

Referring to the example of FIG. **11**, a movable table **31** is movably supported by a fixed table **30** through a pair of opposing rolling guide units **1**, **1**, and the movable table **31** is formed with skirt portions **32** and **33**, as supporting portions, extending downward, as viewed, from both the bilateral ends thereof. The paired rolling guide units **1**, **1** are mounted between the inner surfaces of the skirt portions **32** and **33** and the outer side surfaces of the fixed table **30**.

In order to apply a preload to the structure shown in FIG. **11**A, in one example, a preload adjusting bolt **34** may be screwed to one of the skirt portion **32**, for example, thereby to push the side surface of one of the rolling guide unit **1** against the guide rail di fixed to the fixed table **30**, whereby the horizontal gap between the balls **5** and the ball rolling grooves **7** and **8** is eliminated, thus applying the horizontal preload in a state shown in FIG. **11**B. In a modification, a tapered wedge member, for example, not shown, may be inserted forcibly into the gap between the facing surfaces of the skirt portion **32** and the movable member **6** of the rolling guide unit **1**, thus also applying the horizontal preload.

That is, when one of the movable members **6** of the rolling guide unit **1** is pressed through one **32** of the skirt portions of the movable table **31** by, for example, the preload adjusting bolt **34**, a reaction force of the pressing force is transferred to the other one **33** of the skirt portions through the movable table **31**, and then, the other movable member **6** of the other rolling guiding unit **1** is pressed against the guide rail **4** fixed to the fixed table **30** through the other skirt portion **33**. Through this preload applying process, in the illustration of FIG. **11**A, the contact angles α of the upper and lower balls in the right rolling guide unit **1** are displaced such that the upper ball **5R1** is rotated clockwisely from the initial contact angle 90° position and the lower ball **5R2** is rotated counterclockwisely therefrom. On the other hand, the contact angles α of the upper and lower balls in the left rolling guide unit **1** are also displaced such that the upper ball **5L1** is rotated counterclockwisely from the initial contact angle 90° position and the lower ball **5L2** is rotated clockwisely therefrom. In the thus manner, the horizontal gap between the respective balls **5** can be eliminated.

In the assumption that lines connecting the contact points of the respective balls **5R1**, **5R2** **5L1** and **5L2** and the ball rolling grooves **7** and **8** into which theses balls disposed constitute contact angle lines XR**1**, XR**2**, XL**1** and XL**2**, upper and lower these contact angle lines in the right and left rolling guide units **1**, **1** are inclined outward of the guide units as shown in FIG. **11**A.

According to the arrangement of the ball contact angles, the supporting rigidity in the vertical direction can be improved as well as that in the horizontal direction.

Therefore, according to the rolling guide unit of the present invention, the supporting structure having improved load bearing performance in the vertical and horizontal directions, i.e. every direction, can be realized as well as achieving the misalignment absorbing performance.

FIGS. **12** to **21** represent various examples each having such a contact angle structure as mentioned above of a plurality of ball rows, typically through examples of the upper and lower three ball rows.

FIG. **12** shows an example of tandeim type, which has the respective upper and lower three rows, total six rows, of balls and the contact angles in the same directions as in the example of FIG. **11**.

That is, as like in FIG. **3**, a vehicle body **203** is movably supported by a bogie **202** through a pair of rolling guide units **201**, **201**. The paired rolling guide units **201**, **201** have guide rails **204**, **204** opposing to each other on the inner side, vehicle body side, thereof and movable members **206**, **206** opposing to each other on the outer side thereof such that the inner side surfaces of the guide rails **204**, **204** are fixed to the mounting surface of the vehicle body **203** and the outer side surfaces and the lower surfaces of the movable members **206**, **206** are fixed to stepped mounting portions **202**A, **202**A formed to the bogie **202**.

Each of the stepped portions **202**A, **202**A has an L-shaped cross section having a horizontal mounting surface **218** to which the lower side surface of the movable member **206** is fixed and a perpendicular mounting surface **213** to which the outer side surface of the movable member **206** is fixed.

Each of the movable members **206**, **206** has substantially a ⊐-shaped cross section having a pair of upper and lower supporting portions **261** and **262** extending in a horizontal direction as viewed in FIG. **12**, and each of the guide rails **204**, **204** having substantially rectangular cross section is fitted into a ⊐-shaped recessed portion of the corresponding movable member **206** from the horizontal direction.

The balls as rolling members in respectively three rows are rollably disposed between the facing surfaces of the upper and lower supporting portions **261** and **262** and the guide rails **204**, **204**. Supposing that the upper and lower respectively three rows of balls are referred to as upper first, second and third balls **5A1**, **5A2** and **5A3** and lower first, second and third balls **5B1**, **5B2** and **5B3** from the inner side to the outer side as in the illustration of FIG. **12**, these upper and lower balls have the same diameters and are arranged linearly symmetrically respectively with respect to a horizontal axis H passing the center of the guide rails **204**, **204**.

The upper first, second and third balls **5A1**, **5A2** and **5A3** and the lower first, second and third balls **5B1**, **5B2** and **5B3** are rollably disposed between upper first, second and third ball rolling grooves **207A1**, **208A1**; **207A2**, **208A2**; **207A3**, 208A3, and the lower first, second and third ball rolling grooves 207B1, 208B1; 207B2, 208B2; 207B3, 208B3 of the upper and lower supporting portions 261, 262 of the movable member 206 and the corresponding upper and lower side surfaces of the guide rails 204.

In such example of tandem type structure, the upper first, second and third ball rolling grooves 207A1, 208A1; 207A2, 208A2; 207A3, 208A3 formed to the upper supporting portion 261 and the upper side surface of the guide rail 204 are formed so as to provide the same phases and pitches as those of the lower first, second and third ball rolling grooves 207B1, 208B1; 207B2, 208B2; 207B3, 208B3 formed to the lower supporting portion 262 and the lower side surface of the guide rail 204. In a free arrangement of the balls, the initial contact angles of the upper first, second and third balls 5A1, 5A2 and 5A3 and lower first, second and third balls 5B1, 5B2 and 5B3 are made to substantially 90°.

In the illustrated example, the outer side surface of the movable member 206 of one of the rolling guide units 201 is pressed against the guide rail 204 mounted to the vehicle body side by means of a preload adjusting bolt such as shown in FIG. 6 or by using a tapered wedge member thereby to eliminate the horizontal gap between the balls 5A1—, 5B1—and the ball rolling grooves 207A1, 208A1; 207B1, 208B1—, whereby a horizontal preload is applied, thereby inclining the balls by a predetermined angle with respect to the initial contact angle 90° to the ball rolling grooves.

That is, the ball contact angles α of the upper first, second and third balls 5A1, 5A2 and 5A3 of the right side rolling guide unit 201 are displaced clockwisely in the illustration from the initial contact angle 90°, and the ball contact angles α of the lower first, second and third balls 5B1, 5B2 and 5B3 of the right side rolling guide unit 201 are displaced counterclockwisely in the illustration from the initial contact angle 90°. On the contrary, with respect to the upper and lower balls 5 of the left side rolling guide unit 201, the contact angles have linear symmetric arrangement with respect to the central perpendicular line between the right and left side rolling guide units 201, 201, and the contact angles of the upper first, second and third balls 5A1, 5A2 and 5A3 are displaced in the counterclockwisely in the illustration and the contact angles of the lower first, second and third balls 5B1, 5B2 and 5B3 are displaced clockwisely. In thus manner, the horizontal gaps of the respective balls can be eliminated, and the contact angle lines XR1, XR2, XR3 and XL1, XL2, XL3 of the upper and lower balls of the right and left side rolling guide units 201 are inclined to be opened outward.

As described above, the example of FIG. 12 represents the tandem type structure which has the respectively upper and lower three rows, total six rows, of balls having the contact angles in the same direction. In a modified example, as shown in FIG. 13, the inclination of the contact angle lines may be set in directions reverse to those of FIG. 12.

That is, referring to FIG. 13, the contact angle lines XR1, XR2, XR3 and XL1, XL2, XL3 of the upper and lower balls of the right and left side rolling guide units 201 are inclined to be opened inward. A structure having such contact angle arrangement will be easily realized by applying a force in the direction to outwardly draw out the movable member from the guide rail 204.

The basic structure of such tandem type example is identical to that shown in FIG. 6 in which the single row of balls are disposed at each of upper and lower sides, and accordingly, a moment load caused by the mounting error and eccentric load are not born, so that any inner load is not caused by such moment, thus being advantageous. That is, when the moment load MC acts, the movable member is moved in an inclined state in the direction of an arrow in FIG. 13.

Furthermore, according to this example, even in a case where the degree of parallelism between two axes of the respective guide rails are out of order, only the ball contact point varies and no forcible force acts on the balls, thus absorbing a geometric distortion of the parallelism between the axes of the guide rails.

Loads in the vertical and horizontal directions may be easily uniformly born.

According to the arrangement of the ball contact angles described above, the supporting rigidity in the horizontal direction can be improved as well as in the vertical direction. Accordingly, the rolling guide unit of these examples, the misalignment of the balls can be absorbed as well as realizing the support structure having high load bearing ability in the horizontal and vertical, i.e. every, directions in its use.

FIGS. 14 to 19 represent other examples of compound contact type structure in which the ball contact structure of respectively upper and lower three rows of balls is adapted such that at least one pair of balls of the upper or lower side rows have contact angles inclined reversely to each other. In such a compound contact type structure, the moment load caused by the mounting error or eccentric load can be born by one movable member.

As the basic structures of these examples are substantially identical to that of FIG. 12, the same reference numerals are added to members or portions corresponding to those of FIG. 12 and the descriptions thereof are omitted herein, and only the direction of the contact angle is referred to hereunder.

Elastic members 250 and 251 made of such as rubber material are interposed between the horizontal mounting surface 218 of the mounting stepped portion of the bogie and the lower side surface of the movable member 206, that is, between the perpendicular mounting surface 213 and the outer side surface of the movable member 206 for the purpose of absorbing the mounting error or the like. Of course, these mounting surfaces may be directly secured without interposing such elastic members 250 and 251.

In the example of FIG. 14, the contact angle lines are symmetrically inclined by predetermined angles with respect to the initial angle 90° so that the contact angle lines XA1 and XA2 of the upper first and second balls 5A1 and 5A2 are opened upward in the illustration and the contact angle lines XB1 and XB2 of the lower first and second balls 5B1 and 5B2 are opened downward. The contact angle line XA3 of the upper third ball 5A3 and the contact line XB3 of the lower third ball 5B3 are set in parallel to the contact angle lines XA2 and XB2 of the upper and lower second balls 5A2 and 5B2, respectively.

Such ball contact structure will be realized, for example, by setting a pitch P1 between the upper and lower first ball rolling grooves 207A1 and 207B1 and the upper and lower second ball rolling grooves 207A2 and 207B2 of the upper and lower supporting portions 261 and 262 to be smaller than a pitch P2 between the upper and lower first ball rolling grooves 208A1 and 208B1 and the upper and lower second ball rolling grooves 208A2 and 208B2 of the guide rails 204, and also setting a pitch between the upper and lower second ball rolling grooves 207A2 and 207B2 and the upper and lower third ball rolling grooves 207A3 and 207B3 of the upper and lower supporting portions **261** and **262** to be equal to a pitch between the upper and lower second ball rolling grooves **207**A**2** and **207**B**2** and the upper and lower third ball rolling grooves **207**A**3** and **207**B**3** of the guide rails **204**.

As described above, by adopting the ball contact structure of a pair of angular contact arrangement, the gap can be adjusted and the initial contact angle is made stable at the time of assembling the guide rail **204** and the movable member **206**.

FIG. **15** shows an example in which an angle between the upper and lower contact angle lines are opened outward, in which an angle of the contact angle lines XA**2** and XA**3** of the upper second and third balls **5**A**2** and **5**A**3** and an angle of the contact angle lines XB**2** and XB**3** of the lower second and third balls **5**B**2** and **5**B**3** are opened outward.

In the example of FIG. **16**, the contact angle lines are symmetrically inclined by predetermined angles with respect to the contact angle of 90° so that an angle between the contact angle line XA**1** and XA**2** of the upper first and second balls **5**A**1** and **5**A**2** is opened inward toward the inner guide rail **204**, and an angle between the contact angle line XB**1** and XB**2** of the lower first and second balls **5**B**1** and **5**B**2** is opened inward toward the inner guide rail **204**. On the other hand, the contact angle lines XA**3** and XB**3** of the upper and lower third balls **5**A**3** and **5**B**3** are set to be substantially parallel to the contact angle lines XA**2** and XB**2** of the upper and lower second balls **5**A**2** and **5**B**2**, respectively.

Such ball contact structure will be realized, for example, by setting a pitch P**1** between the upper and lower ball rolling grooves **207**A**1** and **207**B**1** and the lower second ball rolling grooves **207**A**2** and **207**B**2** of the upper and lower supporting portions **261** and **262** to be larger than a pitch P**2** between the upper and lower first ball rolling grooves **208**A**1** and **208**B**1** and the upper and lower second ball rolling grooves **208**A**2** and **208**B**2** of the guide rails **204**, and also setting a pitch between the upper and lower second ball rolling grooves **207**A**2** and **207**B**2** and the upper and lower third ball rolling grooves **207**A**3** and **207**B**3** of the upper and lower supporting portions **261** and **262** to be equal to a pitch between the upper and lower second ball rolling grooves **207**A**2** and **207**B**2** and the upper and lower third ball rolling grooves **207**A**3** and **207**B**3** of the guide rails **204**.

FIG. **17** shows an example in which an angle between the upper and lower contact angle lines are opened inward, in which an angle of the contact angle lines XA**2** and XA**3** of the upper second and third balls **5**A**2** and **5**A**3** and an angle of the contact angle lines XB**2** and XB**3** of the lower second and third balls **5**B**2** and **5**B**3** are opened inward.

Examples of FIGS. **18** and **19** shows an arrangement in which angles between respectively adjacent contact angle lines XA**1**, XA**2**, XA**3**, XB**1**, XB**2** and XB**3** are opened alternately outward and inward.

That is, FIG. **18** shows an example in which angles between the contact angle lines XA**1** and XA**2** of the upper first and second balls **5**A**1** and **5**A**2** and between the contact angle lines XB**1** and XB**2** of the lower first and second balls **5**B**1** and **5**B**2** are opened inward, and angles between the contact angle lines XA**2** and XA**3** of the upper second and third balls **5**A**2** and **5**A**3** and between the contact angle lines XB**2** and XB**3** of the lower second and third balls **5**B**2** and **5**B**3** are opened outward.

FIG. **19** shows an example in which angles between the contact angle lines XA**1** and XA**2** of the upper first and second balls **5**A**1** and **5**A**2** and between the contact angle lines XB**1** and XB**2** of the lower first and second balls **5**B**1** and **5**B**2** are opened outward, and angles between the contact angle lines XA**2** and XA**3** of the upper second and third balls **5**A**2** and **5**A**3** and between the contact angle lines XB**2** and XB**3** of the lower second and third balls **5**B**2** and **5**B**3** are opened inward.

In these examples, the numbers of ball rows, the numbers of the balls in each ball row, and the ball diameter are optionally selected in accordance with a load to be applied. For example, regarding the numbers of the ball rows, as shown in FIG. **20**, two ball rolling grooves corresponding to the upper and lower first and third balls **5**A**1**, **5**A**3** and **5**B**1**, **5**B**3**.

Furthermore, the contact structure of the respective balls of the upper and lower supporting portions **261** and **262** are made linearly symmetrical with respect to the horizontal axis, it is not always necessary to adapt the Linear symmetric structure, and as shown in FIG. **21**, in accordance with the load to be applied, an arrangement different in ball rows may be adapted such that two rows of the second and third balls **5**A**2** and **5**A**3** are formed on the upper side and three rows of the first, second and third balls **5**B**1**, **5**B**2** and **5**B**3** are formed on the lower side.

Further, it is to be noted that, in the above respective embodiments or examples, the rolling guide units are referred to for the guide support mechanism of a railway rolling stock, but the present invention is not limited to such specific utilization and many other applications may be adapted for guide mechanisms of, for example, various industrial robots or the like.

What is claimed is:

1. A rolling guide unit comprising:

a movable member provided with a main body portion and a pair of upper and lower support portions extending from lateral end portions of the main body so as to provide a recessed portion between the main body portion and both the support portions, said support portions having inner surfaces in which rolling member rolling grooves are formed;

a guide rail disposed in the recessed portion of the movable member so that upper and lower side surfaces of the guide rail face the inner surfaces of the support portions, respectively, the upper and lower side surfaces of said guide rail being formed with rolling member rolling grooves at positions cooperable with the rolling member rolling grooves of the upper and lower support portions, respectively, and the upper and lower side surfaces of said guide rail being substantially mutually parallel; and

a number of rolling members disposed to be rollable between the cooperating rolling member rolling grooves of said guide rail and said upper and lower support portions of the movable member so that each of the rolling members contact their associated rolling member rolling grooves at two contact points at which the rolling members apply load to the rolling member rolling grooves, said movable member and the guide rail being relatively movable through the rolling of the rolling members;

wherein each of said rolling member rolling grooves has an arcuate cross sectional shape having a radius of curvature larger than that of the rolling member and the contact points are displaceable along the arcuate shape of the respective rolling member rolling grooves and;

wherein an initial contact angle formed between a line connecting the two contact points on diametrally opposite sides of the rolling members to the rolling member rolling grooves and a line passing through a center of the rolling member and parallel to the facing surfaces containing said rolling member rolling grooves in said movable member and said guide rail is set to substantially 90°.

2. A rolling guide unit according to claim **1**, wherein the rolling member is a ball and each of said rolling member rolling grooves has a depth of approximately ¼ to ½ of a diameter of the ball.

3. A rolling guide unit according to claim **1**, wherein a plurality of rolling member rolling grooves are formed at least one of the side surfaces of the guide rail and at least corresponding one inner surface of the support portion of the movable member.

4. A rolling guide unit according to claim **1**, wherein a plurality of rolling member rolling grooves are formed at least on one of the side surfaces of the guide rail and at least on a corresponding one inner surface of the support portion of the movable member, and wherein an initial contact angle defined by a line connecting the two contact points of the rolling members in their associated rolling member rolling grooves and said line parallel to the facing surfaces containing said rolling member rolling grooves in said movable member and said guide rail passing a center of the rolling member is set to substantially 90°.

5. A rolling guide unit according to claim **4**, wherein lines connecting points of contact between all of said rolling members and their associated rolling member rolling grooves when said movable member and said guide rail are misaligned have contact angles inclined in the same direction.

6. A rolling guide unit according to claim **4**, wherein lines connecting points of contact between all of said rolling members and their associated rolling member rolling grooves when said movable member and said guide rail are misaligned have at least one pair of contact angles inclined in directions reverse to each other.

7. A rolling guide unit according to claim **1**, wherein a plurality of rolling member rolling grooves are formed at least on one of the side surfaces of the guide rail and at least corresponding to one inner surface of the support portion of the movable member, and the rolling members disposed in at least one of the plurality of rolling member rolling grooves are formed as cylindrical members and the rolling member rolling groove in which the cylindrical members are rolled is formed so as to provide a flat groove bottom.

8. A rolling guide unit according to claim **7**, wherein the rolling member rolling grooves for the cylindrical members are formed to the inner surfaces of the support portions so as to provide a groove bottom shape corresponding to an outer shape of the cylindrical member and the side surfaces of the guide rail for the cylindrical members are formed to be flat.

9. A rolling guide unit according to claim **7**, wherein three rows of the rolling member grooves are formed and a central one is formed for the cylindrical members.

10. A rolling guide unit according to claim **1**, wherein said guide rail has substantially rectangular cross section and is bent in a curved shape.

11. A rolling guide unit according to claim **1**, wherein said guide rail has substantially linear shape.

12. A rolling guide unit according to claim **1**, wherein retainer meals are disposed between the facing inner surfaces of the support portions of the movable member and the side surfaces of the rail guide.

13. A rolling guide unit according to claim **1**, wherein said support portions are integrally formed with the main body portion of the movable member.

14. A rolling guide unit according to claim **1**, wherein said support portions are independently formed with the main body portion of the movable member and the support portions are fixed to the central portion of the movable member by means of bolts.

15. A rolling guide unit according to claim **1**, wherein the numbers of rows of the rolling members of the respective support portions are different from each other.

16. A rolling guide unit assembly which comprises a first member, and a second member disposed in an opposing relation with respect to the first member, and relatively movable along the first member through a pair of rolling guide units arranged on bilateral side surfaces of said first member, said pair of rolling guide units comprising:

guide rails respectively secured to both side surfaces of said first member;

a movable member secured to said second member disposed so as to oppose bilateral side surfaces of said guide rails and having a pair of upper and lower support portions extending along lateral side portions thereof by which the guide rails are clamped at upper and lower side surfaces thereof; and

a number of rolling members rollably disposed in rolling member rolling grooves formed in the upper and lower side surfaces of the guide rails and opposing surfaces of the upper and lower support portions of the movable member in a mutually facing manner,

wherein each of said rolling member rolling grooves has an arcuate cross section having a curvature larger than a radius of each of the rolling members so that the rolling members are movable along the arcuate shape of the rolling member rolling grooves; and

wherein said guide rails are curved and each of said upper and lower side surfaces are parallel.

17. A rolling guide unit assembly according to claim **16**, wherein each of said rolling member rolling grooves has a depth of approximately ¼ to ½ of a diameter of the rolling member.

18. A rolling guide unit assembly according to claim **16**, wherein a plurality of rolling member rolling grooves are formed on at least one of the upper side surfaces and lower side surfaces of the guide rails.

19. A rolling guide unit assembly according to claim **18**, wherein a contact angle is determined by a line connecting contact points of the respective rolling members in the bilateral pair of the rolling guide units to the rolling member rolling grooves and a line passing through centers of the rolling members parallel to said guide rail side surfaces, and where contact point connecting lines of the respective rolling members have a symmetrical arrangement.

20. A rolling guide unit assembly according to claim **18**, wherein an initial contact angle constituted by a line connecting contact points of the rolling members to the rolling member rolling groove and a line parallel to said guide rail side surfaces and passing through a center of the rolling member is set to substantially 90°.

21. A rolling guide unit assembly according to claim **18**, wherein the contact angles of a plurality of rolling members disposed on the upper side surface or the lower side surface of the guide rails are bilaterally symmetrical and have inclinations in the same direction with respect to the rolling guide units, respectively.

22. A rolling guide unit assembly according to claim **18**, wherein a plurality of rows of the rolling members are disposed on at least one of the upper side surfaces and lower side surfaces of each of the guide rails, and further include cylindrical rolling members in at least one of said rows.

23. A rolling guide unit assembly according to claim **18**, wherein the lines connecting contact points of a plurality of rolling members disposed on the upper side surface or the lower side surface are bilaterally symmetrically inclined and have at least one pair of lines reversely inclined with each other with respect to the rolling guide units.

24. A rolling guide unit assembly according to claim **16**, wherein an elastic member is disposed between the movable member of the rolling guide unit and an attachment surface of the second member.

25. A rolling guide unit assembly according to claim **16** containing a plurality of movable members and wherein vertical mounting surfaces are formed on outer side surfaces of the movable members, each vertical mounting surface being respectively positioned opposite to one of the guide rails, and wherein horizontal mounting surfaces are formed on one of the upper and lower end surfaces of the movable members.

26. A rolling guide unit assembly according to claim **16**, wherein each of the guide rails of the paired rolling guide units has a substantially rectangular cross section and being bent along a longitudinal axis to provide an arcuate portion, and said guide rails relatively swingably supporting the first member with respect to the second member.

27. A rolling guide unit assembly according to claim **26**, wherein said first member is a pendulum type vehicle and said second member is a railway rolling stock which is swingably supported by the vehicle.

28. A rolling guide unit assembly according to claim **26**, wherein said first member is fixed to a pendulum type vehicle and said second member is fixed to a pantograph.

29. A rolling guide unit comprising:

a relatively movable member provided with a main body portion and a pair of upper and lower support portions extending from lateral end portions of the main body portion so as to provide a recessed portion between the main body portion and both the support portions, said support portions having inner surfaces in which rolling member rolling grooves are formed;

a guide rail disposed in the recessed portion of the movable member so that upper and lower side surfaces of the guide rail face the inner surfaces of the support portions, respectively, the upper and lower side surfaces of said guide rail being formed with rolling member rolling grooves at positions corresponding to the rolling member rolling grooves of the upper and lower support portions, respectively;

a number of rolling members disposed to be rollable between the corresponding rolling member rolling grooves of said guide rail and said upper and lower support portions of the relatively movable member so that each of the rolling members contact the rolling member rolling grooves at two contact points and the rolling members apply load to the rolling member rolling grooves associated therewith, said movable member and the guide rail being relatively movable through the rolling of the rolling members;

a transporting element, positioned in the vertical direction with respect to relatively movable member and the guide rail mounted to one of the relatively movable member and said guide rail;

wherein each of said rolling member rolling grooves has a cross section of arcuate shape and having a radius of curvature larger than that of the rolling members, and the contact points are displaceable along the arcuate shape of the rolling member rolling groove;

wherein an initial contact angle formed between a line connecting the two contact points on the rolling members to the rolling member rolling grooves and a horizontal line passing through a center of the rolling member is set to substantially 90°; and

wherein said horizontal line is perpendicular to said vertical direction and perpendicular to a direction of movement produced by said transportation element.

30. The rolling guide unit of claim **29**, wherein said transporting element is a wheel.

31. The rolling guide unit of claim **29**, wherein said transportation element is a bogie.

32. The rolling guide unit of claim **29**, wherein said relatively movable member is fixedly mounted to said bogie.

[57] **ABSTRACT**

At least a ball escape hole (**10**) of a ball circulation passage (**7**) is formed of a molded body (**12**) and the molded body (**12**) is formed integrally with a block body (**13**) having high rigidity through an insert molding process, thereby eliminating a drilling working, possibly reducing assembling processes and reducing generation of noise.

It is preferred that the molded body (**12**) is provided with an inner peripheral portion of a direction changing passage (**11**) integrally connected with the ball escape hole (**10**) and joined with both end surfaces of the block body (**13**).

Furthermore, it is preferred that the molded body (**12**) is provided with a retainer (**17**) extending along a loaded ball passage (**8**) and integrally connected, at its both ends, with the inner peripheral portion of the direction changing passage (**11**), thereby providing a closed sectional shape surrounded by the ball escape hole portion (**10**), the direction changing portion (**11**) and the retainer portion (**17**).

ROLLING GUIDE APPARATUS

This is a continuation of application Ser. No. 08/788,352 filed Jan. 27, 1997 U.S. Pat. No. 5,755,516; which is a continuation of application Ser. No. 08/569,125 filed Apr. 3, 1996, now abandoned; which is a 371 of PCT/JP95/00974 filed May 22, 1995.

TECHNICAL FIELD

The present invention relates to a rolling guide apparatus of contact-type for guiding a rolling member along a linear passage or the like, more particularly, to a structure of a rolling member circulation passage and also relates to a method of manufacturing a movable block of the rolling guide apparatus.

Background Art

A conventional rolling guide apparatus of this type generally has a structure in which a movable block is supported to be movable along a guide rail through a number of rolling members, the movable block is provided with a circulation passage through which the rolling members are guided and circulated. The rolling member circulation passage is formed with a loaded rolling member rolling passage composed of loaded rolling member rolling grooves formed to oppose surfaces of the movable block and the guide rail, respectively, and is formed with a return passage formed to a non-loaded area and connected at their both end portions with the loaded rolling member rolling passage so that the rolling member circulates through the loaded rolling member rolling passage and the return passage. The return passage is composed of a rolling member escape hole extending in parallel to the loaded rolling member rolling passage and a direction changing passage connecting both end portions of the rolling member escape hole to both ends of the loaded rolling member rolling passage to change the rolling direction of the rolling member.

In the conventional structure, however, the rolling member escape hole is formed by drilling a block body so as to penetrate it vertically, which requires a troublesome working and involves a factor of cost increasing.

In order to obviate this defect, a conventional technology has provided a structure in which a rolling member escape hole in a non-loaded area is formed by cutting away a side surface of the block body and the cut-out portion is covered by a cover member formed of a resin material, for example. However, according to this conventional structure, it is difficult to assemble the rolling member circulation passage, and noise is generated due to an assembling error, thus providing a problem.

Furthermore, in the conventional rolling guide apparatus, it has been attempted to construct the block body to have a sufficient rigidity so as not to be deformed even if a heavy load is applied to the guide apparatus. On the contrary, in a case where there is caused a large misalignment between the guide rail and the movable block (for example, an error in degree of parallelism between a fixing surface of the guide rail and a fixing surface of a conveyer table fixed to the movable block), an unnatural force is applied to a contact surface between the rolling member and the rolling member rolling groove. This unnatural force obstructs smooth rolling of the rolling member and, hence, the rolling member and the rolling member rolling groove are easily worn, providing a problem.

In view of this point, in the case of the structure in which the rolling member escape hole is formed by cutting away

the outside surface of the block body, the block body has a reduced thickness portion corresponding to the cut-away portion and hence the rigidity thereof is lowered correspondingly. However, in this type of this structure, the rolling member contacts the cutout portion of the block body and then is covered by the cover member. Therefore, the thickness of the block body is not reduced to a thickness more than that corresponding to a gap between the rolling member escape hole and the loaded rolling member rolling groove and the rigidity is also not reduced correspondingly. However, the gap between the rolling member escape hole and the rolling member rolling groove is not so much reduced because of the smooth rolling direction changing of the rolling member. Thus, there is a limit which the thickness of the block body can be reduced.

The rolling member circulates through the circulation passage formed in the loaded and non-loaded areas, and as far as the positional relationship of the rolling member escape hole with respect to the loaded rolling member rolling groove is not accurately decided, the direction changing passage between the loaded rolling member passage and the rolling member escape hole is not also accurately positioned. Further, in a case where the loaded rolling member rolling passage is not smoothly and continuously connected with the direction changing passage, the rolling member is not smoothly rolled and circulated therein.

Furthermore, a retainer is also disposed on both sides of the loaded rolling member rolling passage for preventing the rolling member from falling off at a time when the movable block is disassembled from the guide rail. It is necessary to form a gap between the retainer and the rolling member rolling passage so that the rolling member does not interfere with the retainer at a time when the rolling member rolls in and along the rolling member rolling passage, and for this reason, it is necessary to accurately position the retainer with respect to the loaded rolling member rolling passage and it is also required for the passage to have an accurate linearity.

Still furthermore, in the conventional structure, respective members or elements assembled with the movable block body made of steel are often fastened by insufficient fastening force, and for this reason, these members, or elements, resonate and generate noises; thus, also providing a problem at a time of the rolling circulation of the rolling member particularly in the non-loaded area at which the rolling member is rolled with no load.

The present invention was conceived to solve the above problems and aims to provide a rolling guide apparatus, which does not require drilling to produce a rolling member escape hole and, instead, produces such a hole by integrally molding a block body and at least the rolling member escape hole through a molding process. As a result, the assembling process can be possibly reduced and generation of noise during the rolling of the rolling member is effectively reduced. A method of manufacturing the movable block is also provided.

In addition to the above object, it is aimed to change the rigidity of the block body without changing a gap between the rolling member escape hole and the loaded rolling member rolling groove.

Furthermore, in addition to the above objects, it is aimed to ensure smooth circulation of the rolling member by accurately positioning the rolling member circulation passage with respect to the rolling member rolling groove.

Disclosure of Invention

The present invention relates to a rolling guide apparatus in which a movable block is supported to be movable along a guide rail through a number of rolling members, a circulation passage for guiding circulation of the rolling members is formed to the movable block, the rolling member circulation passage being composed of a loaded rolling member rolling passage in a loaded area between loaded rolling member rolling grooves formed to opposing surfaces of the movable block and the guide rail and a non-loaded return passage for returning the rolling members in the loaded area from one end of the loaded rolling member rolling passage to another end thereof, the return passage being composed of a rolling member escape hole extending in parallel to the loaded rolling member rolling passage and a direction changing passage having inner and outer peripheral portions connecting both ends of the rolling member escape hole to both ends of the loaded rolling member rolling passage, and the rolling guide apparatus being characterized in that at least one of the rolling member escape hole, the inner peripheral portion of the direction changing passage and a retainer extending along the loaded rolling member rolling passage is formed of a molded body and the molded body is integrally formed with a block body having high rigidity.

The molded body may be composed of only the rolling member escape hole, only the inner peripheral portion of the direction changing passage or only the retainer, or composed of integral combination thereof.

That is, the molded body may be provided with the rolling member escape hole and the inner peripheral portion of the direction changing passage integrally connected to the rolling member escape hole and joined with both end surfaces of the block body.

The molded body may be provided with the rolling member escape hole and the retainer extending along the loaded rolling member rolling passage.

The molded body may be provided with the inner peripheral portion of the direction changing passage joined with both end surfaces of the block body and the retainer extending along the loaded rolling member rolling passage and integrally connected at its both ends with the inner peripheral portion of the direction changing passage.

The molded body may be provided with the rolling member escape hole, the inner peripheral portion of the direction changing passage integrally connected to the rolling member escape hole and joined with both end surfaces of the block body and the retainer extending along the loaded rolling member rolling passage and integrally connected at its both ends with the inner peripheral portion of the direction changing passage, the molded body having a closed sectional shape surrounded by the rolling member escape hole, the direction changing passage and the retainer.

Furthermore, a recess-protrusion engaging portion is formed to joining surfaces of the molded body and the block body.

The molded body is formed of a resin material, and a portion between the loaded rolling member rolling groove and the rolling member escape hole of the movable block is formed as one portion of the resin molded body so as to produce a reduced thickness in the block body having high rigidity to provide an elastic property.

It is effective that the rolling members rolling in the loaded rolling member rolling passage are scooped by a guide, each a two point contact state, extending in the loaded area of the direction changing passage from the loaded rolling member rolling groove to the direction changing passage in a manner of being separated gradually from each other.

It is further characterized that the movable block is provided with a pair of leg portions between which the guide rail is interposed and a connection portion connecting the leg portions, and the rolling member circulation passages are formed to the leg portions.

It is characterized that a covering portion is provided for covering at least one of upper and lower surfaces of the connection portion of the movable block and the covering portion is integrally formed with the inner peripheral portion of the direction changing passage joined with both the end surfaces of the block body.

The rolling member escape hole has a sectional shape having a rolling member passing section through which the rolling member passes and a lubrication agent storing section capable of storing a lubrication agent bled outward from the rolling member passing section.

In another aspect, the present invention relates to a method of manufacturing a movable block, which is supported to be movable with respect to a guide rail through a number of rolling members, of a rolling guide apparatus provided with loaded rolling member rolling grooves formed to opposing surfaces of the movable block and the guide rail, a rolling member escape hole extending in parallel to the loaded rolling member rolling grooves, and a direction changing passage having inner and outer peripheral portions connecting both ends of the rolling member escape hole with both ends of the loaded rolling member rolling passage, the manufacturing method being characterized in that the block body is placed in a mold, and at least one of the rolling member escape hole, the inner peripheral portion of the direction changing passage and a retainer extending along the loaded rolling member rolling passage is formed integrally with the block body through an insertion molding process.

The rolling member escape hole and the inner peripheral portion of the direction changing passage may be integrally formed together through the insertion molding process.

The rolling member escape hole and the retainer extending along the loaded rolling member rolling passage may be integrally formed together through the insertion molding process.

The inner peripheral portion of the direction changing passage and the retainer extending along the loaded rolling member rolling passage may be integrally formed together through the insertion molding process.

The rolling member escape hole, the inner peripheral portion of the direction changing passage, and the retainer extending along the loaded rolling member rolling passage may be integrally formed together through the insertion molding process.

The block body is positioned in the mold with reference to the rolling member rolling groove formed to the movable block.

According to the present invention, since the rolling member escape hole is integrally formed with the block body through the molding process, the drilling working can be eliminated to thereby easily form the, structure.

Particularly, since the rolling member escape hole forming portion is integrally formed in the non-loaded area with the molded body, noise which will be caused by an insufficient fastening force can be prevented from being generated.

The degree of integral formation can be increased by integrally forming the inner peripheral portion of the direction changing passage with the rolling member escape hole, making easy the assembling process.

Furthermore, by integrally forming the rolling member escape hole, the inner peripheral portion of the direction changing passage and the retainer, the tensile stress is applied, by the shrinkage of the molded portions, to the rolling member escape hole, so that the fastening force can be increased by the remaining tensile stress, thus remarkably reducing the generation of the noise.

Particularly, with respect to the retainer, the degree of straightness can be made high by the function of the remaining tensile stress, so that the retainer is made parallel and straight with respect to the loaded rolling member rolling passage, and as a result, when the loaded rolling member is rolled and moved, the retainer does not contact and interfere with the rolling member and the rolling member is hence rolled smoothly and the movable block is also smoothly moved along the guide rail.

Furthermore, since the retainer is firmly secured to the block body through the tensile stress, no resonance is caused by the rolling vibration of the rolling member, thus remarkably reducing the noise.

Further, the thickness of the block constituting material, such as metal, constituting the block body at its portion between the loaded rolling member rolling groove to the rolling member escape hole which affects rigidity thereof can be made thin so as to provide an elastic property without changing the dimension between the rolling member rolling groove and the rolling member escape hole, in other words, with the dimension suitable for the smooth direction changing operation being maintained, by forming the rolling member escape hole by the molded resin body.

Accordingly, if an assembling error between the guide rail and the movable block (for example, misalignment such as an assembling error due to an error in parallelism between the fixing surface of the guide rail and the fixing surface of a conveyer table to be fixed to the movable block) is caused, such error can be absorbed through the flexibility of the thin portions of the block body and the contact portion between the rolling member and the rolling member rolling groove is prevented from being applied with an excessive force.

The rolling member escape hole is formed so as to provide a sectional shape having a rolling member passing section along which the rolling members roll and a lubrication agent storing section capable of storing lubrication agent bleed outward from the rolling member passing section, and according to such structure of the rolling member escape hole, since the lubrication agent can be retained without obstructing the circulating motion of the rolling member, the smooth circulating motion thereof can be surely maintained for the long time operation with no substantial maintenance. Furthermore, the escape hole having such complicated sectional shape can be easily formed through the molding process.

The positioning of the block body inserted into the mold is performed with reference to the rolling member rolling groove through the insertion molding process, and accordingly, since the position of the rolling member escape hole and the position of the retainer can be determined with reference to the rolling member rolling groove, the relative positional relationship among the loaded rolling member rolling passage, the direction changing passage and the escape hole constituting the rolling member circulation passage can be exactly determined. Accordingly, no staged portion is formed on the connection portion between the loaded rolling member rolling passage, the inner peripheral portion of the direction changing passage and the rolling member escape hole, thus smoothly circulating the rolling members.

Furthermore, when the position of the block body in the mold is determined, the contacting portion of the mold with the block body is minimally limited to the rolling member rolling groove by positioning it with reference to the rolling member rolling groove, and the other portions of the mold can be maintained with a non-contact state, which requires no precise working, thus easily performing the manufacturing process.

BRIEF DESCRIPTION OF DRAWINGS

FIGS. **1** through **5** show a rolling guide apparatus according to one embodiment of the present invention, in which: FIG. **1**(*a*) is a vertical sectional view and FIGS. **1**(*b*) to (show structures of a ball circulation passage;

FIG. **2**(*a*) s a perspective view of an outer appearance of the rolling guide apparatus of FIG. **1** and FIG. **2**(*b*) is a disassembled perspective view of a movable block;

FIG. **3***a*–**3***k* shows a disassembled perspective view of the block body and a molded body of the movable block of the rolling guide apparatus of FIG. **1**;

FIG. **4***a*–**4***d* shows the movable block body of the rolling guide apparatus of FIG. **1**, in which FIG. **4**(*a*) is a front view, FIG. **4**(*b*) is a side view, FIG. **4**(*c*) is a sectional view taken along the line C—C of FIG. **4**(*a*) and FIG. **4**(*d*) is a sectional view taken along the line D—D of FIG. **4**(*b*); and

FIG. **5** shows a side cover of the rolling guide apparatus of FIG. **1**, in which FIG. **5**(*a*) is a front view, FIG. **5**(*b*) is a sectional view taken along the line B—B of FIG. **5**(*a*), FIG. **5**(*c*) is backside view, FIG. **5**(*d*) is a sectional view taken along the line D—D of FIG. **5**(*c*), FIG. **5**(*d*) is a sectional view taken along the line E—E of FIG. **5**(*e*) and FIG. **5**(*f*) is a end view along the line F—F of FIG. **5**(*b*).

FIG. **6***a*–**6***c* is a view showing a manufacturing process of the movable block of the rolling guide apparatus of the present invention.

FIG. **7** shows a rolling guide apparatus according to another embodiment of the present invention, in which FIG. **7**(*a*) is a vertical sectional view, FIG. **7**(*b*) is a view showing an endless type retainer and FIG. **7**(*c*) is a plan view partially broken away.

FIG. **8** shows a structure of a further rolling guide apparatus utilizing the endless type retainer of FIG. **7**, in which FIG. **8**(*a*) is a vertical sectional view, FIG. **8**(*b*) is a plan view and FIG. **8**(*c*) is a view showing the retainer.

FIGS. **9**(*a*) to (*g*) represent structures of various types of the rolling guide apparatus of the present invention.

BEST MODE FOR THE INVENTION

The present invention will be described hereunder by way of the embodiments shown in the accompanying drawings.

FIGS. **1** and **2** represent a rolling guide apparatus of one embodiment according to the present invention.

The rolling guide apparatus **1** has a structure in which a movable block **2** is supported, through a plurality of balls as rolling members, by a guide rail **4** to be movable therealong.

The movable block **2** has a U-shape in section and is provided with a pair of leg portions **5**, **5** between which the guide rail **4** is interposed and a horizontal portion **6** to which the leg portions **5**, **5** are rigidly connected.

Four ball circulation passages **7** for guiding a number of balls **3** are formed in the movable block **2**. In the illustrated example, two pairs of upper and lower circulation passages **7** are formed in the bilateral leg portions **5**, **5**, respectively.

Each of the respective ball circulation passages **7** is composed of a loaded ball rolling passage **8** defined by loaded ball rolling grooves **8***a*, **8***b* respectively formed in the opposing surfaces of the movable block **2** and the guide rail **4** and a return passage **9**, formed in a non-loaded area, for returning the balls **3** from one end of the loaded ball rolling passage **8** to the other end thereof.

Contact lines showing directions of contact angles of the four rows of the loaded balls incline in directions to be closed with respect to horizontal line towards the center of the guide rail **4**. In such structure, the contact line means a line connecting contact portions of the balls contacting the ball rolling grooves of the movable block and the guide rail, and the term “contact line” used hereinafter means the same content.

The return passage **9** formed in the non-loaded area is composed of a ball escape hole **10** extending in parallel to the loaded ball rolling passage **8** and a ball rolling direction changing passage **11** connecting both ends of the ball escape hole **10** to both the ends of the loaded ball rolling passage **8**. The direction changing passage **11** is composed of an end surface cover portion **16** integrally joined with the end surface of a high rigid movable block body **13**, to which the loaded ball rolling passage is formed, and a side cover **14** as an outer periphery constituting member.

In the illustrated embodiment, an escape hole forming portion **15** to which the ball escape hole **10** of the ball circulation passage, the end surface cover portion **16** and a retainer **17** extending along the loaded ball rolling passage are formed with a resin molded body **12** integrally with the high rigid block body **13**.

The escape hole forming portions **15** are joined integrally with cutouts **18**, substantially rectangular in section, formed in the bilateral side surfaces of the metallic block body **13**, and the two rows of the upper and lower ball escape holes **10** are independently formed with space. Each of the ball escape holes **10** is entirely peripherally surrounded by the escape hole forming portion **15**. In the illustrated embodiment, an inside portion **10***a* of the ball escape hole **10** is formed in arc shape, and this inside portion **10***a* is integrally connected with the end surface cover portion **16** integrally joined to the end surface of the block body **13**.

The most simple structure of the end surface cover portion **16** is shown in FIG. **1**(*c*) and comprises only an inner peripheral portion **19** of each of the direction changing passages which is connected with the inside portion **10***a* of the ball escape hole **10**, but in the present embodiment, a staged protruded portion **20** fitted to the side cover **14** is formed, and an inner periphery guide surface **11***a* of the direction changing passage is formed in the shape of a recess in the staged protruded portion **20**. Further, a central staged protruded portion **21** is formed in the end surface of the horizontal portion **6** of the block body **13** so as to connect the bilateral staged protruded portions **20**, **20**.

Recess-protrusion engaging portions **23** are formed in surfaces of the bilateral staged protruded portions **20** and the end surface of the block body **13** to be joined for preventing the mold forming member and the block body from positionally shifting from each other through their recess-protrusion engagement. Each of these recess-protrusion engaging portions **23** is composed of a recess **23***a* formed in the end surface of the block body **13** and a protrusion **23***b* fitted to the recess **23***a*.

Screw tap holes **20***a* are formed to the end surfaces of the bilateral staged protruded portions **20** for fastening the side covers **14**. These screw tap holes **20***a* are formed to the end surfaces of the molded body **12**, and on the other hand, tap prepared holes each having a diameter smaller than that of the tap hole **20***a* are formed, through resin formation, to the end surfaces of the block body **13** to positions corresponding to the screw tap holes **20***a*, respectively, and screw tap holes **20***a* are also formed in these prepared holes. The side covers **14** are formed with bolt insertion holes **22***a* through which bolts **22** are inserted and screw-engaged with the screw tap holes **20***a*, thereby fastening the side covers **14**.

The staged protruded portions **20** and the central protruded portion **21** are both formed with positioning holes **25** at their end faces at portions near the ball rolling direction changing portions **11**, and the side covers **14** are formed with positioning projections **24**, at their end surfaces, at portions near the ball rolling direction changing portions **11** corresponding to the positioning holes **25**. These positioning projections **24** and holes **25** are engaged with each other when these members are joined together, whereby the outer peripheral side of the ball rolling direction changing portion **11** on the side cover side and the inner peripheral side of the ball rolling direction changing portion **11** on the mold forming member side of the block body **13** can be surely positioned.

The inner periphery of the ball escape hole **10** may have a simple circular section having a diameter slightly larger than that of the rolling ball, but a guide projection **10***b* as shown in FIG. **3**(*c*) will be provided for constituting three-point contact structure, or a spline shape guide projection **10***c* as shown in FIG. **3**(*b*) may be provided. Since the position of the ball is determined by three point support structure, it is desired to provide the guide projections contacting the ball at more than three points and portions other than the projections **10***b* and **10***c* may be formed. It is desired that the gap between the ball outer periphery and a virtual circle connecting the tip ends of the projections **10***b* and **10***c* is made small so as to be approximately equal to the diameter of the ball.

According to this structure, the balls **3** are guided by the tip ends of these projections, thus preventing meandering motion of the balls **3**.

Furthermore, a lubrication agent, such as grease, in the ball escape hole **10** stays in a portion between the guide projections **10***b* and **10***c*, and accordingly, resistance caused by the lubrication agent during the rolling motion of the balls **3** through the escape holes **10** can be made small, thus the balls **3** being smoothly rolled with less obstruction of the lubrication agent.

Still furthermore, as shown in FIG. **3**(*d*), a structure in which parallel two rows of the ball escape holes **10**, **10** are connected with each other to prevent the balls **3** from clogging due to the presence of the lubrication agent. In this arrangement, the connection groove **10***d* acts as a lubrication agent stay position so that the lubrication agent staying in front of the balls does not obstruct the rolling of the balls **3**.

The ball escape hole **10** is formed so as to provide other various shapes in its section, such as shown in FIGS. **3**(*h*), (*i*) and (*j*) showing triangular shape, square shape and grooved circular shape, respectively. That is, in other words, it will be said that it is desired for the ball escape hole to have a non-circular section provided with a virtual circular section **10**A as a rolling member passing section for passing the ball **3** as rolling member and a lubrication agent staying section **10**B capable of storing the lubrication agent bled out from the virtual circular section **10**A.

In the conventional drilling technology, it is impossible to form the ball escape hole having such section, as mentioned above, and such drilling working can be realized by the integral molding method according to the present invention.

Further, in order to make large the rotation radius of the ball in the direction changing passage **11**, the both end portions of the ball escape hole forming portion is cut away at the outer peripheral portion of the ball escape hole **10** by a predetermined length, and according to the ball escape hole forming portion **15** of the above structure provided for the side cover **14,** the cutout portion **27** is covered to thereby connect the end portion of the ball escape hole **10** with the end portion of the direction changing passage **11**. That is, since the balls **3** can be circulated more smoothly by making possibly large the rotation radius of the direction changing passage, it will not be desired to adopt the structure having a small curvature.

The escape hole outer periphery forming portion **26** of the side cover **14** is formed with positioning projections **28** and the end surfaces of the cutout portions **27** formed to both the ends of the escape hole forming portions **15** of the mold forming member **12** are formed with positioning holes **29,** which engage with the projections **28**. According to this structure, the ball escape holes **10** and the ball direction changing passages **11** are surely positioned at their outer peripheral and inner peripheral sides, providing no staged portion at the joined portions. Since the connection portions between the ball escape holes **10** and the direction changing passages **11** are formed as continuous guide surfaces with no staged portion, the smooth circulation of the balls **3** can be ensured. Particularly, as shown in FIG. **3**(*e*), it is desired for the ball escape hole **10** to have an annular tapered projection **10***e* and desired for the direction changing passage **11** to have a taper received portion **11***e* which is circumferentially entirely engaged with the tapered projection **10***e* as a faucet joint engagement. The tapered projection **10***e* and the taper receiving portion **11***e* are formed at the connection portion of the ball escape hole **10** and the direction changing passage **11**. According to this structure, the ball escape hole **10** and the direction changing passage **11** can be substantially completely joined together.

The retainer **17** acts to hold the balls **3** to prevent the balls **3** from falling off from the movable block **2** when the guide rail **4** is drawn out from the movable block **2**, and in the assembling state of the guide rail **4** and the movable block **2**, the retainer **17** is designed in its dimension so that a gap is formed between the retainer **17** and the balls **3** so as not to obstruct the rolling motion of the balls rolling in the loaded ball passage **8**.

In the described embodiment, the retainer **17** is disposed between the upper and lower two rows of loaded balls **3** formed in the bilateral leg portions **5, 5** and includes a first retainer section **30** for holding the lower edge portion of the ball **3** in the upper row of balls **3** and the upper edge portion of the ball **3** in the lower row of balls **3**, a second retainer section **31** for holding the upper edge portion of the ball **3** of the upper row of balls **3** and a third retainer section **32** for holding the lower edge portion of the ball **3** of the lower row of balls **3**. The upper ball row is held by the first and second retainer sections **30** and **31** and the lower ball row is held by the first and third retainer sections **30** and **32**. The portions of the balls **3** are exposed between these first to third retainer sections **30, 31** and **32** and contact the ball rolling groove **8***b* on the guide rail side to be capable of freely rolling.

These retainer sections **30, 31** and **32** are integrally connected, at their both ends, with the end surface cover portion **16**, and in the illustrated embodiment, the third retainer section **32** is integrally connected with the ball escape hole forming portions **15** of the bilateral leg portions **5, 5** of the block body **13** through the lower surface cover portion **33** covering the lower side surfaces of the leg portions **5, 5**.

The connection between the ball direction changing passage **11** and the loaded ball passage **8** is done by the manner such that each of the balls **3** is scooped gradually at two bilateral points by a tongue piece **34** having a boat shape serving as a guide suitable for scooping the ball **3** by invading the loaded area, the tongue piece **34** being provided at the outer peripheral end portion of the direction changing passage of the side cover **14**, thereby smoothly transferring the balls **3** to the direction changing passage **11** from the loaded ball passage **8**. That is, as shown in FIG. **3**(*f*), the tongue piece **34** is provided with a groove **34***a* having a width gradually reduced towards both the end portions, and as shown in FIG. **3**(*g*), the ball **3** is supported at two points and the loaded ball **3** then rolls apart from the ball rolling groove **8***b* of the guide rail **4**.

Accordingly, the ball **3** circulates to the direction changing passage **11** from the non-loaded ball hole **10** through the tapered projection and receiving portions **10***e* and **11***e*, then, to the loaded ball passage **8** in the loaded area through the boat shaped tongue piece **34**, to the direction changing passage **11** at the end portion of the tongue piece **34** and again to the ball escape hole **10** through the tapered projection and receiving portions **10***e* and **11***e*, thus the balls **3** being circulated in a rolling state through this circulation route. Thus, the connection portions of these portions are not formed with a staged portion to thereby smoothly perform the circulation of the balls **3**.

According to this structure, in which, as shown in FIG. **3**(*b*), the ball escape hole **10** has at least three point contact structure by providing the guide projections **10***b*, **10***c*, the balls **3** roll from the two point contact state in the scooping operation of the boat bottom shaped tongue piece **34** to the three point contact structure, and an ideal ball rolling route can be established throughout the entire ball circulation passage, so that the balls **3** can be smoothly rolled therealong, and hence, generation of noise caused by unbalanced rolling of the balls **3** can be also minimized. In addition, since the idle ball rolling is also reduced, the noise can be minimized.

The movable block **2** of the rolling guide apparatus according to the present invention of the structure described above will be manufactured in the following manner.

A loaded ball rolling groove **8***a* is preliminarily formed to the block body **13**, and the block body **13** is inserted into the mold **40** to integrally form the rolling member escape hole **10** in the block body **13** through the insertion molding process.

FIG. **6** shows a structure of the mold, which is formed with a cavity **41** for forming ball escape hole forming portions **15** outside the leg portions **5, 5**, a cavity **42** for forming the retainers **17** inside the leg portions **5, 5** and a cavity **43** for forming the inner peripheral portions of the direction changing passages **19** at both longitudinal ends of the leg portions **5, 5**. A stationary mold half **44** is provided with a protruded portion **45** to be fitted to the ball rolling groove **8***a* to position the same and a movable mold half **46** is provided with a pin **47** for forming the ball escape hole **10**.

At the time of the insertion molding process, as shown in FIG. **6**(*c*), the positioning inside the mold **40** is made with reference to the ball rolling groove **8***a* of the block body **13**. According to this manner, when the insertion molding process is performed with reference to the ball rolling groove **8***a*, since the positioning of the ball escape hole **10** and the retainer **17** can be done, relative positional relationship among the loaded ball rolling passage **8**, the direction changing passage **11** and the ball escape hole **10** can be accurately established.

In addition, at the time of the positioning in the mold **40** for the block body **13**, if the positioning is performed with reference to the ball rolling groove **8***a*, the contact point to the block body **13** is minimally made to the ball rolling groove **8***a* and the other portions of the mold **40** are allowed to take non-contact arrangement and an accurate working is hence not required to these portions of the mold **40**, resulting in easy manufacture thereof.

Furthermore, the inner peripheral portion **19** of the direction changing passage can be integrally formed with the block body **13** together with the ball escape hole **10** through the insertion molding process.

The retainer **17** can be also integrally formed with the block body **13** together with the ball escape hole formation portion **15** and the end surface covering portion **16** through the insertion molding process.

Thereafter, the direction changing passage **11** can be completed at both the end portions of the loaded ball rolling groove **8***a* by assembling the side covers **14**.

According to the rolling guide apparatus of the structure described above, the ball escape hole forming portion **15** is integrally formed with the block body **13** as the mold forming body **12** through the insertion molding process, so that the drilling working to produce the ball escape hole **10** can be eliminated, thus making simple the manufacturing process.

Furthermore, since the integral molding can be realized through the molding process, any assembling process can be eliminated, thus reducing the assembling working.

Still furthermore, according to the present embodiment, the ball escape hole forming portion **15**, the end surface covering portion **16** and the retainer **17** are integrally formed as the mold forming body **12**, thus making more simple the manufacturing process.

According to the structure for enclosing the outer periphery of the block body **13**, a tensile stress is applied by the shrinkage of the mold forming body **12** to the retainer **17**, the escape ball forming portion **15** and the end surface covering portion **16**, and hence, the ball escape hole forming portion **15** and the retainer **17** are formed with high degree of straightness. Particularly, the ball **3** and the respective retainer sections are not contacted by the application of the tensile stress to the thin retainer sections for the upper side loaded ball and the lower side loaded ball, thus realizing smooth circulation of the balls **3**.

However, in a case where the retainer **17** is formed of a resin material, there is a case of causing a shifting in position by temporary lowering of the tensile stress by a creeping phenomenon, and for such case, the joining surfaces of the first retainer section **30** of the retainer **17** and the block body **13** are formed with recesses and protrusions so as to be firmly joined together through the engagement of these recesses and protrusions. This engagement structure is composed of an engaging groove **35** formed to the joining surface of the block body **13** so as to extend entirely along the axial direction of the block body **13** and an engaging protrusion **36** fitted to the engaging groove **35**. This engaging protrusion **36** is formed by invading the forming material into the groove **35** at the molding time. It will be of course noted that substantially the same engagement is realized in the joining surfaces between the second and third retainer sections **31**, **32** and the block body **13**.

Furthermore, according to the present embodiment, the thickness of the block constituting material, such as metal, constituting the block body **13** at its portion between the loaded ball rolling groove **8***a* to the ball escape hole **10** which affects on rigidity thereof can be made thin so as to provide an elastic property without changing the dimension between the ball rolling groove **8***a* and the ball escape hole **10**, in other words, with the dimension suitable for the smooth direction changing operation being maintained, by forming the ball escape hole **10** by the resin molded body **12**. The thin thickness of the block body will be performed by making large the thickness of the circular portion as shown with two-dot chain line a in FIG. **1**(*a*) or by performing a linear cutting as shown with two-dot chain line b in FIG. **1**(*a*).

Accordingly, if an assembling error between the guide rail **4** and the movable block **2** (for example, misalignment such as assembling error due to an error in parallelism between the fixing surface of the guide rail **4** and the fixing surface of a conveyer table to be fixed to the movable block **2**) will be caused, such error can be absorbed through the flexibility of the thin leg portions of the block body **13** and the contact portion between the ball **3** and the ball rolling groove **8***a* is prevented from being applied by an excessive force.

The ball escape hole may be formed in a structure in which half of the ball escape hole **10** is integrally formed as shown in FIG. **3**(*k*). In such case, an effect due to the thin thickness of the block body will be expected in comparison with the drilling working to the metal block though this effect may be small in comparison with the above embodiment.

FIG. **7** represents another embodiment according to the present invention, in which like reference characters are added to elements or portions corresponding to those of the first mentioned embodiment and explanations thereof are omitted hereunder.

In this embodiment, one ball row is formed in each of the bilateral leg portions **5** of the movable block **2**, and the balls **3** are held by means of an endless retainer **50**, as shown in FIG. **7**(*b*).

The endless retainer **50** is a flexible belt-shaped member formed of a resin, or like material, and a number of ball retaining holes **50***a* are formed with predetermined space from each other. The ball **3** is held by the inner peripheral surface of the respective ball retaining holes **50***a* to be freely rollable and slidable to thereby guide the balls along the entire periphery of the ball circulation passage **7**. Spacers **50***b*, each having a recess of spherical crown shape corresponding to an outer spherical shape of the ball, are disposed between adjacent ball retaining holes **50***a* so as to squeeze the ball **3** from both axial sides of the retainer **50**.

Since the endless retainer **50** is vibrated during the rolling motion of the balls **3**, retainer support members **55** to **58** are disposed linearly along the loaded ball rolling passage **8** to suppress the vibration thereof, and a guide groove **59** is also formed to the ball escape hole **10** for guiding both side edges of the endless retainer **50**.

In this embodiment of FIG. **7**, the ball escape hole forming portion **15**, the end surface covering portion **16** and the retainer support members **55** to **58** are formed integrally as the molded body members **12**. The contact line of the left side ball **3** is inclined downward towards the central portion of the guide rail **4** by a predetermined angle with respect to the horizontal line H, and the contact line of the right side ball **3** is inclined upward towards the central portion of the guide rail **4** by a predetermined angle with respect to the horizontal line H. Thus, these contact lines are substantially in parallel with each other. In an arrangement of a certain contact angle case, there may appear a case wherein each of the retainer support members has a portion having insufficient thickness, so that a reinforcing member **60**, such as a metal plate, may be embedded to such portion as occasion demands. In the illustrated embodiment, the reinforcing members **60**, such as metal plates, are embedded in the right upper retainer support member **56** and the left lower retainer support member **57**.

An upper surface covering portion **51** for covering the upper surface of the block body **13** and an inner peripheral surface covering portion **54** for covering the upper surface of the inner periphery of the central recessed portion **13***a* of the block body **13** are provided on the block body **13**. These covering members **51** and **54** are formed integrally through the end surface covering portion **16** to thereby achieve the reinforcement of the block body **13** and the resin portion formed integrally with the block body **13**. The inner peripheral surface covering portions **54** are formed integrally with the left upper retainer support member **55** and the right upper retainer support member **56**. Lower surface covering portions **61** for covering the lower surfaces of the leg portions **5**, **5** of the block body **13** are also integrally provided on the block body **13** and formed integrally with the left and right lower retainer support members **57** and **58** to define jaw portions which cooperatively engage complementary surfaces on the guide rail **4** to hold the horizontal portion **6** thereon. As shown in FIG. **8**(*a*), each jaw portion is formed of resin having a thickness less than the diameter of the rolling members.

The upper surface of the block body **13** has a low level surface portion **52** and a high level surface portion **53** having a surface level higher than that of the lower level surface portion **52**, and the high level surface portion **53** is formed as a bearing surface formed with bolt holes **53***a* through which fixing bolts are inserted for clamping, whereby the upper surface covering portion **51** is covered over the lower level surface portion **52** to make equal the surface level to that of the high level surface portion **53**, providing a flat surface of the block body **13**. In this embodiment, two high level surface portions **53** are provided in correspondence to the left and right leg portions **5**, **5** of the block body **13**, and three low level surface portions **52** are provided at an intermediate portion between the two high level surface portions **53** and at bilateral both end portions of the block body **13**.

FIG. **8** shows an example of a structure which utilizes the endless retainer **50** described above.

In this example, the levels in arrangements of the left and right balls **3** are made different in a manner such that one of the ball rows is arranged to the right side edge of the upper surface of the guide rail **4** and the other of the ball rows is arranged to the intermediate portion of the left side surface of the guide rail **4**. The block body **13** is formed to have substantially an L-shape in section having one leg portion **5**, and one of the ball escape holes **10** is formed to the right side portion of the upper surface of the horizontal portion **6** of the block body **13** and the other of the ball escape holes **10** is formed to the leg portion **5**. That is, a cutout **62**' is formed in the right edge portion of the upper surface of the horizontal portion **6** of the block body **13**, and the ball escape hole forming portion **15** formed of the resin material is integrally joined with the cutout **62** and the other ball escape hole forming portion **15** is integrally joined with a cutout **63** formed in the lower surface of the leg portion **5** and the corner portion of the left side surface thereof.

The left side surface covering portion **64** of the leg portion **5** and the left upper retainer support member **55** disposed at the inner periphery of the leg portion **5** are formed integrally through the front and rear end surface covering portions **16** so as to surround the leg portion **5**. The inner side edge portion of the lower surface covering portion **61** for covering the lower surface of the leg portion **5** is integrally joined with the retainer support member **57** at the left side ball lower side edge portion. The ball escape hole forming portion **15** formed in the horizontal portion **6** and the lower surface covering portion **65** of the horizontal portion **6** are integrally joined together through the front and rear end surface covering portions **16** so as to vertically surround the horizontal portion **6**. The lower surface covering portion **65** and the ball escape hole forming portion **15** are integrally formed through the right side surface covering portion **65** of the block body **13**, and the inner side edge portion of the lower surface covering portion **65** is joined with the retainer support member **58** for the right lower ball row.

As described above, with the structure of the block body **13**, only the portions necessary for the positioning are exposed and portions not required to form with high precision are covered with resin materials, so that portions of the block body **13** requiring cut working or the like, are reduced, thus reducing manufacturing cost. As shown in the drawing figure, the molded body member forming the support may, in addition to guiding the edges of the retainer, also support the rolling members.

FIG. **9** shows a further example of an arrangement of the present invention, in which like reference numerals are added to elements or portions corresponding to those of the former examples and explanations thereof are omitted herein.

FIG. **9**(*a*) shows a structural example of the linear motion guide apparatus provided with four rows of ball circulation passages **7** as like the above first embodiment, in which the ball escape hole **10**, the inner peripheral portion of the direction changing passage and the retainer **17** are integrally formed. This example differs from the former one in that the contact angle lines to the bilateral upper and lower two ball rows are opened towards the guide rail **4** with respect to the horizontal line.

In the illustrated embodiment, one retainer **17** is disposed between each of the bilateral upper and lower ball rows.

An example shown in FIG. **9**(*b*) has a structure in which the left and right leg portions, such as shown in the embodiment of FIG. **1**, are independently separated and which is utilized for conveying and guiding a table **66**, or the like, by using a pair of linear motion guide apparatus. In this structure, the ball escape hole **10**, the direction changing passage inner peripheral surface **19** and the retainer **17** are also integrally formed.

An example shown in FIG. **9**(*c*) has a structure in which the left and right leg portions **5** of the linear motion guide apparatus, such as shown in FIG. **9**(*b*), are independently separated. In this structure, the ball escape hole **10**, the direction changing passage inner peripheral portion **19** and the retainer **17** are also integrally formed.

An example shown in FIG. **9**(*d*) represents a structure of a linear motion guide apparatus provided with four ball rows including two rows formed to the upper surface of the guide rail **4** and respective one row formed to left and right side surfaces thereof, and in this arrangement, the ball escape hole **10**, the direction changing passage inner peripheral portion **19** and the retainer **17** are integrally formed together.

In this example, the ball escape hole forming portion **15** of the molded body **12** is fitted in a lower hole **67** formed through the block body **13**.

In such arrangement, however, high precision is not basically required with respect to the lower hole **67** to be formed to the block body **13**, thus easily forming the same.

FIG. **9**(*g*) is an example employing the structure of the lower hole **67** to the left and right two ball rows, and particularly, in this example, no retainer is provided and an engaging portion **68** performing recess-protrusion engagement for preventing the positional shifting is formed to the end surface of the block body **13** at the direction changing passage inner peripheral portion.

FIGS. **9**(*e*) and **9**(*f*) show examples of arrangements of the linear motion guide apparatus in which rollers **3**' are used instead of the balls **3**, and FIG. **9**(*e*) shows a linear motion guide apparatus provided with four roller rows and FIG. **9**(*f*) shows a linear motion guide apparatus provided with two roller rows.

With respect to the above examples, it is to be noted that the present invention is described with reference to the linear motion guide apparatus, but it is of course applicable to a linear guide rail slidably assembled with a curved motion guide rail, and as the molded body, a die cast product, sintered metal or the like other than resin material may be utilized.

According to the present invention having the structures and functions mentioned hereinbefore, since the rolling member escape holes are integrally formed with the block body through the molding process, the drilling working can be eliminated to thereby easily form the structure.

In addition, since the integral structure can be provided through the molding process, the assembling process can be reduced.

The degree of integral formation can be increased by integrally forming the inner peripheral portion of the direction changing passage with the ball escape hole, making easy the assembling process.

By integrally forming the rolling member escape hole, the inner peripheral portion of the direction changing passage and the retainer to surround the periphery of the block body, the tensile stress is applied, by the shrinkage of the molded portions, to the rolling member escape hole, the inner peripheral portion of the direction changing passage and the retainer, so that the degree of straightness of the rolling member escape hole and the retainer can be made high, and the generation of resonance noise, at the time of rolling member circulation, to the respective parts of the guide apparatus by residual tensile stress can be prevented.

The low noise frequency due to the rolling member circulation can be prevented from being caused by the increasing of vibration frequency including mass of the block body.

Furthermore, the thickness of the block constituting material, such as metal, constituting the block body at its portion between the loaded rolling member rolling groove to the rolling member escape hole which affects rigidity thereof can be made thin so as to provide an elastic property without changing the dimension between the rolling member rolling groove and the rolling member escape hole, in other words, with the dimension suitable for the smooth direction changing operation being maintained, by forming the rolling member escape hole by the molded resin body. Accordingly, if an assembling error between the guide rail and the movable block (for example, misalignment such as an assembling error due to an error in parallelism between the fixing surface of the guide rail and the fixing surface of a conveyer table to be fixed to the movable block) is caused, such error can be absorbed through the flexibility of the thin portions of the block body and the contact portion between the rolling member and the rolling member rolling groove is prevented from being applied with an excessive force.

The rolling member escape hole is formed so as to provide a sectional shape having a rolling member passing section along which the rolling members roll and a lubrication agent storing section capable of storing lubrication agent bled outward from the rolling member passing section, and according to such structure of the rolling member escape hole, since the lubrication agent can be retained without obstructing the circulating motion of the rolling member, the smooth circulating motion thereof can be surely maintained for a long time operation with no substantial maintenance. Furthermore, the escape hole having such complicated sectional shape can be easily formed through the molding process.

The positioning of the block body inserted into the mold is performed with reference to the rolling member rolling groove through the insertion molding process, and accordingly, since the position of the rolling member escape hole and the position of the retainer can be determined with reference to the rolling member rolling groove, the relative positional relationship among the loaded rolling member rolling passage, the direction changing passage and the escape hole constituting the rolling member circulation passage can be exactly determined. Accordingly, no staged portion is formed to the connection portion between the loaded rolling member rolling passage, the inner peripheral portion of the direction changing passage and the rolling member escape hole, thus smoothly circulating the rolling members.

Furthermore, when the position of the block body in the mold is determined, the contacting portion of the mold to the block body is minimally limited to the rolling member rolling groove by positioning it with reference to the rolling member rolling groove, and the other portions of the mold can be maintained with a non-contact state, which requires no precise working, thus easily performing manufacturing process.

We claim:

1. A rolling guide apparatus in which a movable block is supported to be movable along a guide rail through a number of rolling members, a circulation passage for guiding circulation of the rolling members is formed in the movable block, said rolling member circulation passage being composed of a loaded rolling member rolling passage in a loaded area between loaded rolling member rolling grooves formed in opposing surfaces of the movable block and the guide rail, and a non-loaded return passage for returning the rolling members in the loaded area from one end of the loaded rolling member rolling passage to another end thereof, said rolling guide apparatus further including a continuous belt-shaped retainer extending about the length of said circulation passage formed in said movable block, said retainer being formed of flexible material and having mutually spaced holes operative to rollably mount said rolling members therein, and retainer support means defined by a molded body member integrally formed on said movable block and extending along said circulation passage thereof, said molded body member defining said retainer support means containing means to supportively engage said belt-shaped retainer for sliding movement along said movable block circulation passage.

2. A rolling guide apparatus according to claim **1**, wherein said molded body member defining said retainer support means contains means operative to also support the rolling members.

3. A rolling guide apparatus according to claim **2** wherein said retainer support member is formed with jaw portions adapted to support the retainer against the loaded ball rolling groove.

4. A rolling guide apparatus according to claim **3**, wherein each of said jaw portion is formed of resin having a thickness smaller than a diameter of each of the rolling members.

[57] **ABSTRACT**

A linear motion guide device provided with a plural ball row chain capable of achieving easy assembling working and realizing an improved smooth ball circulation.

It is characterized that ball retainer members **23**, **23** to which one sides of the respective two ball rows **3**, **3** arranged along loaded ball rolling grooves **10**, at a time of removing a movable block **4** from a track rail **1**, are formed to the movable block **4**, the falling-off of the balls in the ball rows can be prevented by the assembling of the ball retainer members **23**, **23** and a plural ball row chain **20**, and the hanging-down of an end portion of the plural ball row chain **20** can be also prevented.

LINEAR MOTION GUIDE APPARATUS EQUIPPED WITH A PLURALITY OF ROWS OF BALL CHAINS

TECHNICAL FIELD

The present invention relates to a linear motion guide device, particularly, having a plural ball row chain holding two rows of balls.

BACKGROUND ART

In a conventional art, as a linear motion guide device of this kind, the same applicant as that of the present invention had already proposed a linear motion guide device assembled with a chain for holding plural rows of balls in which two ball rows are held by one ball chain (see Japanese Patent Laid-open Publication No. HEI 5-126149). That is, this linear motion guide device is provided with a track rail and a movable block mounted to the track rail to be movable through a number of balls.

The movable block is composed of a movable block body having a loaded ball rolling groove corresponding to a loaded ball rolling groove formed to the track rail and a non-loaded ball return passage formed in parallel thereto and end plates disposed to both ends of the movable block body and adapted to form an endless ball circulation passage communicating the loaded ball rolling groove and the rolling member return passage.

The balls constitute two ball rows separated from each other with a predetermined distance and in parallel to each other, and these two ball rows are held by a plural ball row chain to thereby circulate in the endless circulation passage. The plural ball row chain has a structure composed of a flexible connection member disposed between two ball rows and spacer members located at both side edge portions of the connection member and adapted to be inserted into balls of the respective ball rows so as to smoothly perform the circulation of the balls.

However, in the conventional technique mentioned above, because the plural ball row chain is formed from a belt-shaped member having a cut end portion, the end portion of the ball chain hangs down at a time when the movable block is removed from the track rail.

In a state that the end portion of the chain hangs down, when only the movable block is assembled with a table or the like, the hung end portion of the chain may be engaged with the table, which may result in that the plural row ball chain is withdrawn from the movable block or, otherwise, is twisted or clamped thereby, thus providing a troublesome working problem and, in a certain case, damaging the ball chain.

Further, although the respective ball rows are circulated in alignment through the spacer members of the ball chain, the smooth circulation movement of the ball may be blocked in the presence of stepped portions, caused by, for example, assembling error, at connection portions between the loaded ball rolling groove and a direction changing passage inner periphery guide portion and between the direction changing passage and the non-loaded ball return passage.

Furthermore, there may easily be caused a positional error of an outer periphery guide portion with respect to the inner periphery guide portion of the movable block body by an assembling error at the time of clamping the end plates or self-deformation of the end plates. Since the end portion of the outer periphery portion approaches the loaded ball rolling groove of the track rail and constitutes a scooping

portion for scooping the balls, it is necessary to make such error as small as possible in order to perform further smooth circulation of the balls. Particularly, in the case of two ball rows, it is necessary to exactly set a pitch between the direction changing passage outer periphery guide portions of the end plates corresponding to two rows of loaded ball rolling grooves. However, in the conventional technology, the end plates have been formed through a molding process, so that it is extremely difficult to exactly perform a molding working because of deformation due to burr of a material in the molding process, and there is a limit for enhancing a mounting performance.

The present invention has been proposed to solve such problems in the conventional technique mentioned above and an object thereof is to provide a linear motion guide device having a plural ball row chain capable of being easily assembled and achieving an improved circulation of balls.

DISCLOSURE OF THE INVENTION

To achieve the above objects, according to the present invention, there is provided a linear motion guide device, provided with a plural ball row chain, which comprises a track rail and a movable block mounted to the track rail to be movable through a number of balls, the movable block comprising a movable block body provided with a loaded ball rolling groove corresponding to a loaded ball rolling groove formed to the track rail and a non-loaded ball return passage disposed in parallel to the loaded ball rolling groove of the movable block body and also provided with a direction changing passage forming members formed at both the ends of the movable block body and constituting ball direction changing passages forming an endless ball circulation passage communicating the loaded ball rolling groove and the rolling member return passage, the balls being composed of at least one set of two ball rows in parallel to each other with a predetermined space and the two ball rows being supported by a belt-shaped plural ball row chain enabling the balls to circulate the endless ball circulation passage, the plural ball row chain being composed of a flexible connection member disposed between the two ball rows and spacers disposed at both side edges of the connection member and adapted to be inserted into adjacent balls,

wherein a ball retainer portion is disposed to the movable block body so that the balls in respective ball rows along the loaded ball rolling groove are engaged at a time of removing the movable block from the track rail and the balls are prevented from falling off through an assembling of the ball retainer portion and the plural ball row chain.

According to the present invention, the assembling of the balls in the movable block is done by holding predetermined numbers of balls by the plural ball row chain, which is then inserted into the movable block body, now not assembled with the track rail, through the end portion of the plural ball row chain. Accordingly, by assembling the balls into the movable block through the plural ball row chain, the assembling working of the necessary numbers of balls can be done accurately and quickly without falling-off of the balls and the assembling workability can be also improved.

Furthermore, at the time when the assembling of the plural ball row chain has been completed, the balls of two ball rows exposed to the loaded ball rolling groove of the movable block to which the track rail is not assembled are supported by the spacers of the plural ball row chain positioned between the adjacent balls. One side of the ball row supported by the plural ball row chain is engaged with the ball retainer, and the balls are hence prevented from falling off by means of the plural ball row chain, and furthermore, the hanging-down of the end portion of the plural ball row chain can also be prevented.

Accordingly, in a case where the movable block is assembled to a table with the track rail being not inserted, there is no fear of falling-off of the plural ball row chain from the movable block and the assembling working can be hence quickly performed.

Furthermore, the ball retainer portion includes two retainer members disposed to side edge portion opposing to the location of the connection member of the plural ball row chain and an opening width of the retainer member is set smaller than a maximum width between balls of the respective ball rows.

According to this structure, two ball rows supported by the plural ball row chain can be held together with the plural ball row chain by the two ball retainer members positioned outside the plural ball row chain.

This structure is preferred for a contact angle structure in which a contact angle line connecting contact points of two ball rows to the loaded ball rolling grooves of the movable block and the track rail is inclined in a direction closed towards the track rail.

Furthermore, the ball retainer members are disposed between the two ball rows, a maximum width between the retainer members is set larger than a minimum width of two ball rows and a gap through which the connection member of the plural ball row chain passes is formed between the ball retainer portion and the movable block body.

In this structure, two ball rows held by the plural ball row chain are held together with the plural ball row chain by both the side edges of the ball retainer portion positioned inside the plural ball row chain.

This structure is preferred for a contact angle structure in which a contact angle line connecting contact points of two ball rows to the loaded ball rolling grooves of the movable block and the track rail is inclined in a direction opened towards the track rail.

Furthermore, a return passage forming portion constituting the non-loaded ball returning passage corresponding to the two ball rows, a direction changing inner periphery guide portion forming portion constituting an inner periphery guide portion of the ball direction changing passage, and a ball retainer forming portion constituting ball retainer members are constituted by a circulation passage forming portion integrally formed by inserting the movable block body into a mold.

According to this structure, the connected portions between the non-loaded ball return passage and the direction changing passage inner periphery guide portion and between the direction changing passage inner periphery guide portion and the loaded ball rolling groove can be formed as continuous surfaces with no stepped portion, thus performing smooth ball circulation. Furthermore, since the ball retainer portion can be exactly positioned, the balls do not contact the retainer portion at the ball rolling time and the balls can hence roll smoothly.

Furthermore, the direction changing passage inner periphery guide portion forming portion is composed of an end surface forming portion integrally formed with an end surface of the movable block body inclusive of the direction changing passage guide portion and an area in the vicinity thereof, a recessed portion exposing the direction changing passage inner periphery guide portion corresponding to ball rows is formed to the end surface forming portion, a deflector formed with an outer periphery guide portion of a rolling member rolling direction changing passage is engaged with the recessed portion, and the rolling member rolling direction changing passage is composed of the inner periphery guide portion and the outer periphery guide portion.

According to this structure, the deflector can be positioned by the recessed portion formed to the end surface forming portion integrally formed to the movable block body, and the outer periphery guide portion of the ball direction changing passage can be also positioned by the end surface forming portion. Since the recessed portion is integrally formed with the movable block body, the positional relationship to the loaded ball rolling groove can be exactly set.

Furthermore, the assembling working of the plural ball row chain can be easily done by inserting the same through the recessed portion, reducing the chain assembling working time.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a view showing a linear motion guide device according to one embodiment of the present invention, in which FIG. **1**(*a*) is a half elevational section and

FIG. **1**(*b*) is a half cross section showing an end face portion.

FIG. **2**(*a*) is a schematic perspective view showing an inserting state of a deflector of a movable block,

FIG. **2**(*b*) is a sectional view of an endless circulation passage,

FIG. **2**(*c*) is a perspective view showing a portion of a chain for plural ball row chain, and

FIG. **2**(*d*) is a partial plan view.

FIG. **3**(*a*) is a sectional view of a linear motion guide device according to another embodiment of the present invention, and

FIGS. **3**(*b*) and **3**(*c*) are views showing connection structures of a ball holding portion.

BEST MODE FOR EMBODYING THE INVENTION

Hereunder, the present invention will be described through exemplary embodiments with reference to the accompanying drawings.

FIGS. **1** and **2** represent a linear motion guide device provided with plural ball row chain according to the present invention.

Referring to FIG. **1**, reference numeral **1** denotes an entire structure of a linear motion guide device, and the linear motion guide device **1** is generally composed of a track rail **2** and a movable block **4** disposed to be movable, through a number of balls **3***a* as rolling members, with respect to the track rail **2**.

The track rail **2** is formed of a member having a long length in its longitudinal direction and forming so as to provide a]-shape in section. The track rail **2** has bilateral left and right side surfaces along which the movable block **4** is guided through a pair of two ball rows, totally four ball rows **3**, **3**, **3**, **3**, and the bilateral side surfaces are formed with four rows of loaded ball rolling grooves **5**, **5**, **5**, **5** along the longitudinal length of the track rail at positions corresponding to the four ball rows **3**, **3**, **3**, **3**, respectively. Each pair of these ball rolling grooves **5**, **5** and **5**, **5** are formed in an vertical arrangement, in an illustrated state, at each of the bilateral side surfaces of the track rail **2** with a projected portion, projecting sideaway at an upper portion of each side surface, being interposed therebetween.

The movable block **4** is composed of a movable block body **6** and end plates **7**, as direction changing passage constituting members, to be disposed at both ends of the movable block body **6**. The movable block body **6** is a block member providing a]-shape in section having a horizontal portion **8** facing an upper surface of the track rail **2** and a pair of supporting leg portions **9, 9** facing the right and left side surfaces of the track rail **2**. The supporting leg portions **9, 9** have inner side surface portions formed with loaded ball rolling grooves **10, 10, 10, 10** corresponding, in locations, to the loaded ball rolling grooves **5, 5, 5, 5** formed to the bilateral side surfaces of the track rail **2**. Four ball return passages **11, 11, 11, 11** are linearly formed to solid portions of the respective supporting leg portions **9, 9**, in parallel to the corresponding loaded ball rolling grooves **10, 10, 10, 10**, respectively.

The end plate **7** also provides a]-shape in section as like the movable block body **6** and is composed of a horizontal portion **12** corresponding to the horizontal portion **8** of the movable block body **6** and skirt portions **13, 13** corresponding to the supporting leg portions **9, 9** of the movable block body **6**. The skirt portions **13, 13** of the end plate **7** is formed with ball direction changing passages **14, 14, 14, 14** communicating the loaded ball rolling grooves **10, 10, 10, 10** and the ball returning passages **11, 11, 11, 11**, thus constituting the endless ball circulating passages at both ends of the movable block body **6**.

Contact angle lines S1, S2, S3, S4 connecting contact points of bilateral two, totally four, ball rows **3, 3** and **3, 3** to the corresponding ball rolling grooves **5, 5, 5, 5** and **10, 10, 10, 10** have inclinations bilaterally symmetrically in directions narrowing distances towards the track rail side with respect to the horizontal line H passing the central portion of the upper and lower vertical ball rows so as to provide outwardly opened contact structure. Contact angles constituted by these contact angle lines S1, S2, S3 and S4 and the horizontal line H are set to about 45°, thus providing a load supporting property for substantially equally supporting the load from vertical and horizontal directions, i. e. substantially every direction.

The respective right and left two rows of balls **3, 3** and **3, 3** are circulated through the endless circulation passage with being supported by two plural ball row chains **20**, and each of plural ball row chain **20** is composed of a flexible connection member **21** disposed between two rows of balls **3, 3** and spacer members **22** attached to both side edges of the connection member **21** and adapted to be inserted into adjacent two balls **3*a*** in each ball row **3**. The plural ball row chain **20** is formed from a flexible linear belt-shaped member and both the ends thereof are not connected and are separated.

Two ball retainer members **23, 23** for preventing the balls **3*a*** from falling off at a time of removing the movable block **4** from the track rail **1** are disposed to a side edge portions, i. e. upper and lower side edge portions in the illustrated embodiment, opposing to the connection member **21** of the plural ball row chain **20** for the ball rolling grooves **10, 10, 10, 10** of the movable block side through which two ball rows **3, 3** are rolled. According to the combination of the two ball retainer members **23, 23** and the plural ball row chain **20** prevents the balls **3*a*** in the respective ball rows from falling down. An opening width between the respective ball retainer members **23, 23** is set to a value smaller than the maximum width between the respective ball rows **3, 3**.

According to the present invention, the assembling working of the respective ball rows **3, 3** in the movable block **4** is performed by supporting predetermined numbers of the balls **3*a*** by the plural ball row chain **20** and inserting the balls **3*a*** into the movable block **4**, to which the track rail **1** has not been assembled, through the end portion of the plural ball row chain **20**. According to the manner that the balls **3*a*** are assembled into the movable block **4** through the plural ball row chain **20**, the necessary numbers of the balls **3*a*** can be assembled acurately and promptly without falling off, thus improving the workability in the assembling working.

Furthermore, in the state that the assembling of the plural ball row chain **20** has been completed, the balls in the bilateral two rows exposed in the loaded ball rolling grooves **10, 10, 10, 10** of the movable block **4**, which has not been assembled with the track rail, are supported by the spacer members of the plural ball row chain **20** disposed between the adjacent balls, respectively. One side portions of the respective two rows **3, 3** and **3, 3** of balls **3*a*** supported by the plural ball row chain **20** are engaged with the ball retainer members **23, 23** and **23, 23** disposed at both the upper and lower side edge portions of the respective loaded ball rolling grooves **10, 10**, and the balls **3*a*** can hence be prevented from falling off by means of the plural ball row chain **20**. Furthermore, the hang-down of the end portions of the plural ball row chain **20** can be also prevented.

Accordingly, in a case where the movable block **4** is assembled with a table with the track rail **1** being not inserted, there is no fear of falling off of the plural ball row chain **20** from the movable block **4**, thereby smoothly performing the assembling working.

Furthermore, a pair of bilateral return passage forming portions **31, 31** forming the non-loaded ball return passages **11, 11** and **11, 11** corresponding to the respective bilateral two ball rows **3, 3** and **3, 3**; a pair of bilateral direction changing passage inner periphery guide portion forming portions **32, 32** forming the inner periphery guide portions **14*a*, 14*a*** and **14*a*, 14*a*** of the ball direction changing passages **14, 14** and **14, 14**; and bilateral two rows of ball retainer member forming portions **33, 33** and **33, 33** forming the ball retainer members **23, 23** and **23, 23**, are formed by a circulation passage forming member **30** which is formed integrally with the movable block body **6** by inserting the same into a mold. The circulation passage forming member **30** may be formed as a product of resin molding or aluminium die casting.

According to the manner mentioned above, the connected portions between the non-loaded ball return passages **11, 11** and **11, 11** and the direction changing passage inner periphery guide portions **14*a*, 14*a*** and **14*a*, 14*a*** and between the direction changing passage inner periphery guide portions **14*a*, 14*a*** and **14*a*, 14*a*** and the loaded ball rolling grooves **10, 10** and **10, 10** can be formed so as to provide substantially continuous surfaces with no stepped portion, enabling the ball rows **3, 3** and **3, 3** to smoothly circulate. Furthermore, since the ball retainer members **23, 23** and **23, 23** can be exactly positioned, the ball rows **3, 3**, and **3, 3** can smoothly roll without contacting the ball retainer members **23, 23** and **23, 23** at the ball row moving time.

Still furthermore, according to the present embodiment, there are also formed chain guide portions **40, 40** for limiting deviation of the respective bilateral two ball rows **3, 3** and **3, 3** at a time when the ball rows are guided through the endless circulation passage by the connection members **21** of the plural ball row chains **20, 20**.

The chain guide portions **40, 40** are provided with a loaded area guide portion **41** formed between the bilateral loaded ball rolling grooves **10, 10** and **10, 10**; a direction changing area guide portion **42** formed between the direction changing inner periphery guide portions **14***a*, **14***a* and **14***a*, **14***a*; and a return area guide portion **43** formed between the ball return passages **11, 11** and **11, 11**, the chain guide portions being integrally formed with the circulation passage forming member **30**.

According to the structure mentioned above, since the plural ball row chains **20, 20** can be guided along the chain guide portions in the ball row circulation operation, the deviation or swinging of the ball row chains **20, 20** can be prevented and the ball circulation can be further smoothly performed.

Further, the direction changing passage guide portion forming portion **32, 32** is composed of the end plates **7** as end surface forming portions integrally formed to the end surfaces of the movable block body **6** inclusive of the direction changing passage inner periphery guide portions **14***a*, **14***a* and **14***a*, **14***a* and an area in the vicinity thereof. These end plates **7** are formed with recessed portions **34, 34** exposing the direction changing inner periphery guide portions **14***a*, **14***a* and **14***a*, **14***a*, and bilateral one deflectors **35, 35** respectively formed with the outer periphery guide portions **14***b*, **14***b* and **14***b*, **14***b* of the ball direction changing passages **14, 14** and **14, 14** are engaged with these recessed portions **34, 34**, whereby the rolling member rolling direction changing passages **14, 14** and **14, 14** are constituted by the inner periphery guide portions **14***a*, **14***a* and **14***a*, **14***a* and the outer periphery guide portions **14***b*, **14***b* and **14***b*, **14***b*. It will be preferred to form the deflectors **35, 35** by a resin having wearproof property, large attenuation and large specific gravity.

According to the structure described above, the deflectors **35, 35** are positioned by the recessed portions **34, 34** formed to the end plates **7, 7** integrally formed with the movable block body **6**, and moreover, the outer periphery guide portions **14***b*, **14***b* and **14***b*, **14***b* of the ball direction changing passages **14, 14** and **14, 14** can be also exactly positioned by means of the end plates **7**. Since the recessed portions **35, 35** are formed integrally with the movable block body **6**, the positional relationship between the recessed portions **35, 35** and the loaded ball rolling grooves **10, 10** and **10, 10** can be exactly set.

Furthermore, in the assembling working of the plural ball row chains **20, 20**, the chains can be easily inserted from the recessed portions **34, 34**, reducing the chain assembling working time. That is, by inserting the plural ball row chains **20, 20** preliminarily holding the necessary numbers of balls into the movable block **4** through the recessed portions **34, 34**, the necessary numbers of balls can be quickly inserted without falling off.

[Another Embodiment]

FIG. **3** represents another embodiment of the present invention. In the former embodiment described above, the contact angle lines S1, S2, S3 and S4 constitute outwardly opened structure inclined bilaterally symmetrically in directions narrowing the distance therebetween towards the track rail side with respect to the horizontal line H passing the central portion between the upper and lower ball rows. However, in this embodiment, there is adopted a structure in which the contact angle lines S1, S2, S3 and S4 constitute inwardly opened structure inclined bilaterally symmetrically in directions widening the distance therebetween towards the track rail side with respect to the horizontal line H passing the central portion between the upper and lower ball rows.

In this embodiment, the ball retainer member **24** is disposed between the two ball rows **3, 3**, and the maximum width C of the ball retainer member **24** is set to a value larger than the minimum width D of the two ball rows **3, 3** to thereby form a gap g between the retainer member **24** and the movable block **4** through which the connection member **21** of the plural ball chain **20** passes.

Accordingly, the two ball rows **3, 3** supported by the plural ball row chain **20** are held together with the plural ball row chain **20** by both the side edge portions of the ball retainer member **24** positioned inside the chain **20**.

Both the ends of the ball retainer member **24** may be fixed to the deflector **35**, and as shown in FIG. **3**(*b*), both may be connected at the central portions thereof through the engagement between an engaging projection **24***a* and an engaging hole **24***b*, and otherwise, may be connected to the deflector **35**, as shown in FIG. **3**(*c*), at the end portion of the ball retainer member **24**. Further, as the connection structure, there may be adopted a structure, for example, in which a projection **24***c* having a trapezoidal section, which is engaged with a dovetail groove **24***d* formed to the deflector **35**, is formed to the end portion of the ball retainer member **24**, and many other connection structures may be further adopted.

Since structures of this embodiment other than the above structures are substantially the same as those mentioned with reference to the former embodiment, the same reference numerals are added to members or portions corresponding to those in the former embodiment and the details thereof are not mentioned herein.

Further, in the case of the parallel contact angle lines of the above two ball rows, it may be possible to locate two ball retainer members **23, 23** outside the two ball rows **3, 3** as shown in FIG. **1** or to locate the ball retainer member **24** between the two ball rows **3, 3** as shown in FIG. **2**.

Furthermore, in the above embodiment, although there is described the case of the linear motion guide device provided with two sets of two ball rows, the present invention is of course applicable to a case of single set of two ball rows.

As mentioned hereinabove, according to the present invention, the falling-off of the balls can be prevented by the combined structure of the ball retainer member and the plural ball row chain, and the hanging-down of the end portion of the plural ball row chain can be also prevented, so that the assembling working can be done without paying specific attention to the falling-off of the balls, thus improving the assembling workability.

Furthermore, according to the present invention, the return passage forming portion constituting the non-loaded ball returning passage corresponding to the two ball rows, the direction changing inner periphery guide portion forming portion constituting the inner periphery guide portion of the ball direction changing passage, and the ball retainer forming portion constituting the two ball retainer members positioned outside the plural ball row chain are constituted by the circulation passage forming portion integrally formed by inserting the movable block body into the mold. Accordingly, the connected portions between these portions are made continuous with no stepped portion, thus realizing the smooth ball circulation.

Still furthermore, since the ball retainer portion can be exactly positioned, the balls never contact the retainer portion at the time of the ball rolling movement and the balls can be smoothly rolled.

Still furthermore, the recessed portion exposing the direction changing passage inner periphery guide portion corresponding to the two ball rows are formed to the end surface forming portion formed to the end surface of the movable block body and the recessed portion is engaged with the deflector to thereby constitute the rolling member rolling direction changing passage, so that the deflector can be positioned by the recessed portion formed to the end surface forming portion integrally formed with the movable block body, and the outer periphery guide portion of the ball rolling direction changing passage can be also exactly positioned through the end surface forming portion, so that the positional relationship to the loaded ball rolling groove can be also exactly set, thus further achieving the smooth ball circulation.

Furthermore, in the assembling working of the plural ball row chain, the chain can be easily inserted through the recessed portion, thus reducing the chain assembling working.

Field of Industrial Usage

As mentioned above, the linear motion guide device provided with the plural ball row chain according to the present invention is usable for linear motion guide mechanisms for machine tools, industrial robots, measuring devices, etc.

I claim:

1. A linear motion guide device, provided with a plural ball row chain, which comprises a track rail and a movable block mounted to the track rail to be movable through a number of balls, said movable block comprising a movable block body provided with a loaded ball rolling groove corresponding to a loaded ball rolling groove formed to the track rail and a non-loaded ball return passage disposed in parallel to the loaded ball rolling groove of the movable block body and also provided with a direction changing passage forming members formed at both ends of the movable block body and constituting ball direction changing passages forming an endless ball circulation passage communicating the loaded ball rolling groove and the rolling member return passage, said balls being composed of at least one set of two ball rows in parallel to each other with a predetermined space and said two ball rows being supported by a belt-shaped plural ball row chain enabling the balls to circulate the endless ball circulation passage, said plural ball row chain being composed of a flexible connection member disposed between the two ball rows and spacers disposed at both side edges of the connection member and adapted to be inserted into adjacent balls,

wherein a ball retainer portion is disposed to the movable block body so that the balls in respective ball rows along the loaded ball rolling groove are engaged at a time of removing the movable block from the track rail and the balls are prevented from falling off through an assembling of the ball retainer portion and the plural ball row chain.

2. A linear motion guide device provided with a plural ball row chain according to claim **1**, wherein said ball retainer portion includes two retainer members disposed to side edge portion opposing to the location of the connection member of the plural ball row chain and an opening width of the retainer member is set smaller than a maximum width between balls of the respective ball rows.

3. A linear motion guide device provided with a plural ball row chain according to claim **1**, wherein said ball retainer members are disposed between said two ball rows, a maximum width between the retainer members is set larger than a minimum width of two ball rows and a gap through which the connection member of the plural ball row chain passes is formed between the ball retainer portion and the movable block body.

4. A linear motion guide device provided with a plural ball row chain according to any one of claims **1** to **3**, wherein a return passage forming portion constituting the non-loaded ball returning passage corresponding to the two ball rows, a direction changing inner periphery guide portion forming portion constituting an inner periphery guide portion of the ball direction changing passage, and a ball retainer forming portion constituting ball retainer members are constituted by a circulation passage forming portion integrally formed by inserting the movable block body into a mold.

5. A linear motion guide device provided with a plural ball row chain according to claim **4**, wherein the direction changing passage inner periphery guide portion forming portion is composed of an end surface forming portion integrally formed with an end surface of the movable block body inclusive of the direction changing passage guide portion and an area in a vicinity thereof, a recessed portion exposing the direction changing passage inner periphery guide portion corresponding to ball rows is formed to said end surface forming portion, a deflector formed with an outer periphery guide portion of a rolling member rolling direction changing passage is engaged with the recessed portion, and the rolling member rolling direction changing passage is composed of said inner periphery guide portion and said outer periphery guide portion.

[57] **ABSTRACT**

The present invention concerns a slider of a rectilinear guide unit for guiding a movable body such as a work table of a machine tool, an industrial robot or the like by moving along a track rail arranged on a stationary section such as a bed or a column while bearing a load. Such type of slider is manufactured by injection-molding a synthetic resin over a metallic block main body having ball load rolling surfaces. Further, the block main body is provided on the outer side surfaces thereof with synthetic resin side surface molded portions with ball return holes formed by padding and on the front and rear end surfaces thereof with end surface molded portions with change direction paths for balls formed by padding. Further, simultaneously with the padding of the side surface molded portions and the end surface molded portions, there is formed by padding an upper surface molded portion on the upper surface of the block main body so as to connect the end surface molded portions formed on both end surfaces of the block main body, respectively.

SLIDER FOR LINEAR GUIDE UNIT

TECHNICAL FIELD

The present invention relates to a slider of a rectilinear guide unit adapted to guide a movable body such as a work table of a machine tool, an industrial robot and etc. and more particularly to an improvement in a slider which is formed by padding a synthetic resin over a metallic block main body.

BACKGROUND TECHNOLOGY

Conventionally, as a rectilinear guide unit of the above type, there is known the one that has a structure comprising a track rail arranged on a stationary portion such as a bed and having ball rolling surface and a slider fastened to the track rail through a number of balls and movable along the rail while supporting a movable body such as a table.

Further, the slider comprises a movable block having ball load rolling surfaces opposing to the ball rolling surfaces of the track rail through the balls and ball return holes parallel to the ball load rolling surfaces and capable of moving along the track rail following the rolling of the balls and a pair of covers having change-direction paths for establishing communication between the ball load rolling surfaces and the ball return holes, and by fixing the covers to both front and rear end surfaces of the movable block, respectively, the load rolling surfaces and the ends of the ball return holes are respectively connected by the change direction paths thereby completing in the slider an endless circulation path for the balls.

In the case of the slider of the conventional rectilinear guide unit having the above-described structure, the process of drilling the ball return holes and the fixing of the ball retainers to the movable block becomes necessary resulting in taking much time and labor for its manufacture so that the present applicant provided such slider by making use of extrusion molding of a synthetic resin (refer to Unexamined Published Japanese Patent Application No. 7-317762).

FIG. **12** shows one example of a slider of a rectilinear guide unit manufactured according to the above-described method wherein the slider **101** fastened to a track rail **100** also comprises a movable block **102** and a pair of covers **103**, **103** such that the movable block **102** comprises a metallic block main body **105** having load rolling surfaces **104** and padded with a synthetic resin by an injection-molding method and as shown in FIG. **13**, ball return holes **107** corresponding to the load rolling surfaces **104** are formed in a pair of side surface molded portions **106** padded to the outer lower side surfaces of the block main body **105**, respectively. Further, to simplify the shape of each of the covers **13**, there are padded to the front and rear end surfaces of the block main body **105** a pair of end surface molded portions **108** which are continuous with the side surface molded portions **106**, respectively, as shown in FIG. **14** and these molded portions **108** are provided with semicircular ball guide sections (not shown) for guiding the balls which have rolled the load rolling surfaces **104** to the ball return holes **107**.

According to such slider manufacturing method making use of the injection molding of synthetic resin material, it is possible to manufacture in a simple manner the movable block **102** of a complicated shape by merely padding a synthetic resin over the block main body **105** and to continuously form the ball return holes **107** and the change direction paths through which unloaded balls roll with the advantage that the circulation of the balls is smoothed and the noise level at the time of rolling of the balls is reduced.

Now, due to the fact that the synthetic resin mold produced by injection-molding contracts in the direction of the large thickness portion thereof, when the side surface molded portions **106** are padded to the outer side surfaces of the block main body **105** so as to form the above-mentioned ball return holes **107** in the side surface molded portions **106**, the portions **106** contract in the longitudinal direction thereof, that is, in a direction parallel to the ball return holes **107**.

However, since both end surfaces of the block main body **105** are also provided with the synthetic resin end surface molded portions **108** padded by injection-molding and formed integral with the side surface molded portions **106** respectively, when the molded portions **106** contract for the above-described reason, the forces of such contraction of the molded portions **106** act unevenly upon the end surface molded portions **108**.

Consequently, there has arisen a problem that as shown in FIG. **14**, after a little while from the completion of injection-molding, the end surface molded portions **108** are pulled by the side surface molded portions **106** to become deformed and float up from the end surfaces of the block main body **105** so that gaps are formed between the block main body **105** and the end surface molded portions **108**, respectively.

Further, there has also arisen a problem that although the covers **103** are respectively fixed to the end surface molded portions **108** to allow the slider **101** to have the change direction paths for the balls, when each of the end surface molded portions **18** deforms, the covers **103** can no more be fixed tightly to the end surface molded portions **108** failing to accurately form the change direction paths so that the balls rolled on the load rolling surface **104** can not be smoothly guided with respect to the ball return holes **107**.

DISCLOSURE OF THE INVENTION

The present invention has been made in view of the above-described problems and an object of the present invention is to provide a slider of a rectilinear guide unit provided with ball return holes and change direction paths for balls formed by padding a synthetic resin to a metallic block main body, which slider is capable of preventing the deformation of the end surface molded portions padded onto the front and rear end surfaces of the block main body so that the change direction paths are formed accurately to thereby realize a smooth circulation of balls.

In order to achieve the above-described object, the present invention provides the following two types of sliders of a rectilinear guide unit.

That is, a first aspect of the present invention is characterized by the provision of a slider of a rectilinear guide unit, which comprises: a metallic block main body substantially in the shape of a saddle in section including a horizontal section and a pair of skirts drooping from the horizontal section and having ball load rolling surfaces on the inner surfaces thereof, respectively; synthetic resin side surface molded portions padded to the outer side surfaces of each of the pair of skirts of the block main body by injection molding and having ball return holes corresponding to the load rolling surfaces, respectively; and synthetic resin end surface molded portions padded to both longitudinal end surfaces of the block main body, respectively, by injection-molding so as to become continuous with the side surface molded portions, respectively, and having circular arc-shaped ball guide sections for guiding balls rolled on the load rolling surfaces to the ball return holes and operating such that it comes into engagement with a track rail through the balls rolling on the load rolling surfaces and moves along the track rail, wherein the block main body is provided on an upper surface of the horizontal section thereof with a synthetic resin upper molded portion which is injection-molded simultaneously with the side surface molded portions and the end surface molded portions and adapted to connect the end surface molded portions on both end surfaces of the block main body.

Further, a second aspect of the present invention is characterized by the provision of a slider of a rectilinear guide unit, which comprises: a metallic block main body substantially in the shape of the letter "L" including a horizontal section and a skirt drooping from one end of the horizontal section and having ball load rolling surfaces on the lower surface of the horizontal section and on the inner surface of the skirt, respectively; synthetic resin side surface molded portions padded to the top end of the horizontal section and the outer side surface of the skirt of the block main body by injection-molding and having ball return holes corresponding to the load rolling surfaces; and synthetic resin end surface molded portions padded to both longitudinal end surfaces of the block main body by injection-molding so as to become continuous with the side surface molded portions, respectively, and having circular arc-shaped ball guide sections adapted to guide the balls rolled on the load rolling surfaces to ball return holes, and operating such that it comes into engagement with a track rail through the balls rolling on the load rolling surfaces and moves along the track rail, wherein the block main body is provided on the upper surface of the horizontal section thereof with a synthetic resin upper molded portion which is injection-molded simultaneously with the side surface molded portions and the end surface molded portions and adapted to connect the end surface molded portions formed on both end surfaces of the block main body.

According to these technical means, even when the side surface molded portions forming the ball return holes contract and the force of such contraction acts on the end surface molded portions on both end surfaces of the block main body, since the upper surface molded portion is padded to the upper surface of the horizontal section of the block main body by injection-molding so as to connect the pair of end surface molded portions on both end surfaces of the block main body, the upper surface molded portion pulls the end surface molded portions against the force of contraction of the side surface molded portions so that the end surface molded portions are closely adhered to the end surfaces of the block main body without floating up from the latter.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a perspective view of a linear guide unit with a slider according to a first embodiment of the present invention;

FIG. **2** is a front view (partly in section) of the linear guide unit shown in FIG. **1**;

FIG. **3** is a side view of a movable block according to the first embodiment of the present invention;

FIG. **4** is a front view (partly in section) of the movable block shown in FIG. **3**;

FIG. **5** is a rear view of a cover according to the first embodiment of the present invention;

FIG. **6** is a sectional view of an endless ball circulation path attached to the slider of the linear guide unit according to the first embodiment of the present invention;

FIG. **7** is an exploded sectional view showing how the cover and the movable block are brought into engagement with each other;

FIG. **8** is a front view of a block main body according to the first embodiment of the present invention;

FIG. **9** is a perspective view of a linear guide unit according to a second embodiment of the present invention;

FIG. **10** is a plan view of the linear guide unit shown in FIG. **1**;

FIG. **11** is a sectional view taken along the XI—XI line of FIG. **10**;

FIG. **12** is a perspective view of a conventional linear guide unit;

FIG. **13** is a sectional view of a slider of the conventional linear guide unit shown in FIG. **12**; and

FIG. **14** is a plan view and a side view showing how end surface molded portions of a slider of the conventional rectilinear guide unit are deformed.

DESCRIPTION OF REFERENCE SYMBOLS

1: Track rail **2**: Slider **40**: Block main body **48**: Side surface molded portion **49**: End surface molded portion **50**: Upper surface molded portion

BEST MODE FOR CARRYING OUT THE INVENTION

The slider of the linear guide unit according to the present invention will be described with reference to the accompanying drawings.

FIGS. **1** and **2** show a rectilinear guide unit comprising a combination of a slider and a track rail according to a first embodiment of the present invention.

In the figures, reference numeral **1** designates the track rail to be arranged in the stationary section such as a bed of a machine tool, reference numeral **2** designates a slider for guiding a movable body such as a table along the track rail **1** and reference numeral **3** designates balls which roll between the track rail **1** and the slider **2** while applying road on the rail and endlessly circulate in the slider **2**.

First, the track rail **1** is substantially rectangular in section and on both side surfaces thereof there are formed two lines of ball rolling surfaces **11** for allowing the balls **3** to roll thereon along the longitudinal direction (vertical direction in FIG. **2**). The track rail **1** is provided with bolt fitting holes **12** at suitable intervals in the longitudinal direction of the rail so that the track rail **1** is fixed to a stationary section by means of fixing bolts (not shown) to be inserted into the bolt fitting holes **12**.

Further, the slider **2** comprises a movable block **4** having fitting surfaces **41** for a movable body such as a table and tapped holes **42** into which fixing bolts of the movable body are screw-fitted and a pair of covers **5**, **5** to be fixed to the front and rear end surfaces of the movable block **4**. Thus, by fixing the covers **5**, **5** to the movable block **4**, an endless circulation path for the balls **3** is formed within the slider.

The movable block **4** is substantially in the shape of a saddle in section and is provided with a horizontal section **4***a* on which the movable body fitting surface **41** is formed and a pair of skirts **4***b*, **4***b* drooping from the horizontal section **4***a*. On the inner surface of each of the skirts **4***b* there is formed a load rolling surface **4** opposing to the ball rolling surface **11** of the track rail **1**. Further, each of the skirts **4***b* is provided with a ball return hole **44** corresponding to each of the load rolling surfaces **43** so that each of the balls **3** released from its load after having rolled on the load rolling surface **43** rolls in a direction reverse to the rolling direction of the balls on the load rolling surface **43**.

On both front and rear end surfaces of the movable block **4** there are provided semicircular ball guide sections **46**, respectively, as shown in FIGS. **3** and **4** so as to form change direction paths for the balls **3** together with U-shaped groove **51** of each of the covers **5** to be described later thereby guiding the balls **3** coming into, and leaving away from, the ball return holes **44**. Further, on both front and rear end surfaces of the movable block **4** there are provided positioning bosses **7**, respectively, for the covers **5**.

FIG. **5** shows a contact surface of each of the cover **5** coming into contact with the movable block **4**. This contact surface is provided with a pair of the above-mentioned U-shaped grooves **51** for forming the change direction paths for the balls **3** and each of the grooves **51** is provided at one end thereof with a projection **52** which scoops up each of the balls **3** which has rolled on the ball rolling surface **11** of the track rail **1**. Further, the cover **5** has positioning holes **53** into which positioning bosses **47** of the movable block **4** are fitted, respectively.

FIG. **6** is a sectional view of an endless ball circulation path attached to the slider **2**. As shown in FIG. **7**, this endless circulation path is completed by fixing the covers **5** to both end surfaces of the movable block **4**, respectively. That is, when each of the covers **5** is fixed to the movable block **4**, the ball guide section **46** of the movable block **4** fits in the U-shaped groove **51** to thereby complete the U-shaped change direction path **54** and by this change direction path **54** the load rolling surface **43** of the movable block **4** and the above-mentioned ball return hole **44** are connected together.

With the above structure, when each of the balls **3** which has been bearing a load between the ball rolling surface **11** of the track rail **1** and the load rolling surface **43** of the movable block **4** has finished rolling on the load rolling surface **43** with the movement of the slider **2**, it is released from its load to enter the change direction path **54** of one of the covers **5** and begins to roll through the ball return hole **44** of the movable block **4** toward a direction reverse to its rolling direction on the load rolling surface **43** under no load condition. Further, each of the balls **3** having finished rolling through the ball return hole **44** again enters between the track rail **1** and the movable block **4** through the change direction path **54** in the other cover **5** and rolls on the load rolling surface **43** as it bears a load.

In the linear guide unit according to the instant embodiment, the movable block **4** forming the slider **2** is manufactured by injection-molding a synthetic resin material. That is, the movable block **4** is so formed that a metallic block main body **40** produced by mechanical machining is padded with a synthetic resin by injection-molding in such a manner that the portions such as the above-mentioned movable body fixing surface **41** and the load rolling surface **43** for the balls **3** where a mechanical strength is required are formed on the block main body **40** while the portions such as the ball return holes **44**, the ball guide holes **46** and positioning bosses **47** where not so great mechanical strength is required are formed of a synthetic resin material thereby making the weight of the movable block as small as possible.

FIG. **8** shows the block main body **40** before it is padded with the synthetic resin material. Such block main body **40** is first drawn to have a horizontal section **4***a* and a pair of skirt sections **4***b*, **4***b* and in this case, the outer side surface of each of the skirt sections **4***b* is formed to have a concave portion **47** for padding a synthetic resin thereto later. Further, the block main body **40** formed to its predetermined shape by drawing is ground whereby the above-mentioned movable body fitting surface **41** and the load rolling surface **43** are formed with a predetermined accuracy.

The block main body **40** finished to the predetermined shape is padded with a synthetic resin by injection-molding and in the case of such injection-molding, side surface molded portions **48** are padded to the concave portions **47** formed on the skirts **4***b* while end surface molded portions **49** are padded to the front and rear end surfaces of the block main body **40** so that the side surface molded portions **48** provide the above-mentioned ball return holes **44**, respectively, while the end surface molded portions **49** provide the above-mentioned ball guide sections **46** and the positioning bosses **47**, respectively.

On the other hand, where the amount of contraction of the synthetic resin after the completion of the injection-molding is taken into consideration, in the instant embodiment, the amount of contraction of each of the side surface molded portions **48** padded along the longitudinal direction of the block main body **40** is considered larger than that of each of the end surface molded portions **49** padded along the cross direction of the block main body **40** so that if the movable block **4** manufactured by the above-mentioned injection-molding is left as it is, there is a possibility that the end surface molded portions **49** are pulled by the side surface molded portions **48** to become deformed as shown in FIG. **14**.

Therefore, in the instant embodiment, an upper surface molded portion **50** is padded between the pair of movable body fitting surfaces **41** simultaneously with the injection-molding of the above-mentioned end surface molded portions **49** and the side surface molded portions **48** so that the pair of end surface molded portions **49** located at both end surfaces of the block main body **40** are connected by the upper surface molded portion **50**.

Consequently, the deformation of the end surface molded portions **49** is prevented by the upper surface molded portion **50** so that the end surface molded portions **49** can adhere to the block main body **40** without leaving any gaps therebetween thereby effectively preventing the aging of the movable block **4** manufactured by injection-molding. Further, since the deformation of the end surface molded portions **49** can be prevented, the covers **5** can be tightly fixed to the end surface molded portions **49**, respectively, so that change direction paths **54** for the balls **3** which are completed by the fixation of the covers **5** thereto (refer to FIGS. **6** and **7**) are accurately formed thereby achieving a smooth endless circulation of the balls.

Next, FIGS. **9** through **11** show a rectilinear guide unit according to a second embodiment of the present invention wherein a slider is combined with a track rail.

Like the above-described first embodiment, this rectilinear guide unit also comprises a track rail **6** and a slider **7** fastened to the track rail through balls **8** and adapted to guide a movable body along the track rail wherein the slider **7** comprises the movable block **9** having movable body fitting surfaces **71** and tapped holes **72** for receiving fitting bolts and a pair of covers **10** to be fixed to both front and rear end surfaces of the movable block **9**, respectively.

Further, like the above-described first embodiment of the present invention, on both side surfaces of the track rail **6** there are formed two ball rolling surfaces **61***a* and **61***b*, respectively, of which the ball rolling surface **61***a* is formed to face upward at an angle of 45° (with respect to the horizontal direction) while the ball rolling surface **61***b* is formed to face downward at an angle of 12.5° (with respect to the horizontal direction). Further, the track rail **6** is provided with bolt fitting holes **62** in spaced apart relationships with one another in the longitudinal direction thereof so that it is fixed to a stationary section by fixing bolts (not shown) to be inserted into these bolt fitting holes **62**.

The movable block **9** is substantially in the shape of L and comprises a horizontal section **9***a* provided with the above-mentioned movable body fitting surfaces **71** and a skirt **9***b* drooping from one end of the horizontal section **9***a* and into a concave portion formed by the horizontal section **9***a* and the skirt **9***b*, the upper half of the track rail **6** enters. On the side of the lower surface of the horizontal section **9***a* there is formed a load rolling surface **93***a* opposing to the upward facing ball rolling surface **61***a* of the track rail **6** and on the side of the inner surface of the skirt **9***b* there is a load rolling surface **93***b* opposing to the downward facing ball rolling surface **61***b* so that balls **8** supporting the slider **7** moving on the track rail **6** roll in the state of being sandwiched between the ball rolling surfaces **61***a*, **61***b* and the load rolling surfaces **93***a*, **93***b*.

Further, on both sides of the load rolling surfaces **93***a* and **93***b* of the movable block **9** there are formed retainers **92**, respectively, so that when the slider **7** is removed from the track rail **6**, the balls **8** on the load rolling surfaces **93***a* and **93***b* are prevented from falling down from the slider **7**.

Further, the horizontal section **9***a* and the skirt **9***b* are provided with ball return holes **94***a* and **94***b*, respectively, in correspondence to the above-mentioned load rolling surfaces **93***a* and **93***b* so that the balls **8** released from their loads after having rolled on the load rolling surfaces **93***a* and **93***b* roll in a direction reverse to the direction of rolling thereof on the load rolling surfaces **93***a* and **93***b*.

Further, also in this embodiment, on the front and rear end surfaces of the movable block **9**, there are provided semi-circular ball guide sections (not shown) for guiding the balls **8** from the load rolling surfaces **93***a* and **93***b* to the ball return holes **94***a* and **94***b* and by fixing the covers **10** to the movable block **9**, an endless circulation path for the balls **9** is completed as in the case of the first embodiment.

Also in the case of the rectilinear guide unit according to this embodiment having the above-described structure, the movable block **9** forming the slider **7** comprises a metallic block main body **90** with a synthetic resin pad formed by injection-molding. The injection-molding is performed such that side surface molded portions **98** are padded to the top end of the horizontal section and the side surface of the skirt **9***b* of the block main body **90**, respectively, with the formation of the above-mentioned ball return holes **94***a* and **94***b* and end surface molded portions **99** are padded to both front and rear end surfaces of the block main body **90**, respectively, with the formation of the above-mentioned ball guide sections.

Also, in the case of the movable block **9** according to this embodiment thus manufactured, when the contraction of the side surface molded portions **98** and that of the end surface molded portions **99** are taken into consideration after completion of injection-molding, since there is a possibility that each of the end surface molded portions **99** is pulled by the contraction of each of the side surface molded portions **98** to become deformed with the generation of a gap between the two portions, the same countermeasure is taken as in the case of the first embodiment.

That is, an upper molded portion **97** is padded between the pair of movable body fitting surfaces on the upper surface of the block main body **90** simultaneously with the injection-molding of the end surface molded portions **99** and the side surface molded portions **98** so that the pair of end surface molded portions **99** of the block main body **90** are connected by this upper molded portion **97**.

Consequently, also in the case of this embodiment, the upper surface molded portion **97** prevents the deformation of the end surface molded portions **99** so that the end surface molded portions **99** closely adhere to the block main body **90** without leaving any gap therebetween and since the end surface molded portions **99** are prevented from becoming deformed, it is possible to tightly fix the covers to these portions **99**, respectively.

INDUSTRIAL AVAILABILITY

As described above, according to the slider of the rectilinear guide unit of the present invention, where the slider is manufactured by padding a synthetic resin to the metallic block main body, the upper molded portion is padded on the horizontal section of the block main body so as to connect the pair of end surface molded portions padded to both end surfaces of the block main body so that the end surface molded portions are prevented from becoming deformed after their padding and can be tightly adhered to the end surfaces of the block main body.

Further, even when the endless ball circulation path is formed by fixing the covers to the end surface molded portions, the deformation of the end surface molded portions is controlled according to the present invention so that it is possible to tightly fix the covers to the end surface molded portions, respectively, thereby achieving a smooth endless circulation of balls.

What is claimed is:

1. A slider of a rectilinear guide unit, which comprises: a metallic block main body substantially in the shape of a saddle in section including a horizontal section and a pair of skirts drooping from the horizontal section and having ball load rolling surfaces on the inner surfaces thereof, respectively; synthetic resin side surface molded portions padded to outer side surfaces of each of said pair of skirts of said block main body by injection-molding and having ball return holes corresponding to said load rolling surfaces, respectively; and synthetic resin end surface molded portions padded to both longitudinal end surfaces of said block main body, respectively, by injection molding so as to become continuous with said side surface molded portions, respectively, and having circular arc-shaped ball guide sections for guiding each of balls rolled said load rolling surfaces to said ball return holes and operating such that it comes into engagement with a track rail through the balls rolling on said load rolling surfaces and moves along said track rail, wherein said block main body is provided on the upper surface of the horizontal section thereof with a synthetic resin upper molded portion injection-molded simultaneously with said side surface molded portions and said end surface molded portions and adapted to connect said end surface molded portions formed on both end faces of said block main body.

2. A slider of a rectilinear guide unit, which comprises: a metallic block main body substantially in the shape of the letter “L” including a horizontal section and a skirt drooping from one end of the horizontal section and having ball load rolling surfaces on the lower surface of the horizontal section and on the inner surface of said skirt, respectively; synthetic resin side surface molded portions padded to the top end of said horizontal section and the outer side surface of the skirt of said block main body by injection-molding and having ball return holes corresponding to said ball load rolling surfaces; and synthetic resin end surface molded portions padded to both longitudinal end surfaces of said block main body by injection-molding so as to become continuous with said side surface molded portions, respectively, and having circular arc-shaped ball guide sections adapted to guide the balls rolled on the load rolling surfaces to ball return holes, and operating such that it comes into engagement with a track rail through the balls rolling on said load rolling surfaces and moves along said track rail, wherein the block main body is provided on the upper surface of said horizontal section thereof with a synthetic resin upper molded portion which is injection-molded simultaneously with said side surface molded portions and said end surface molded portions and adapted to connect said end surface molded portions respectively formed on both end surfaces of said block main body.

[57] **ABSTRACT**

A rolling motion guide apparatus comprises a guide rail formed with a loaded rolling member rolling passage and a movable member disposed to be movable with respect to the guide rail through a number of rolling members, in which the rolling direction changing passage structure is composed of an end surface forming portion which is formed with a rolling direction changing passage inner periphery guide portion integrally formed with the movable member main body and an end plate which is formed with a rolling direction changing passage outer periphery guide portion separately formed from the end surface forming portion. The rolling direction changing passage outer periphery guide portion of the end plate and a rolling direction changing passage inner periphery guide portion thereof have peripheral portions respectively which are joined and welded so as to provide joining surfaces as a welding portion.

ROLLING MOTION GUIDE APPARATUS

BACKGROUND OF THE INVENTION

The present invention relates to a rolling motion guide apparatus, particularly having a rolling direction changing passage structure, adapted for such as linear motion guide apparatus, ball spline, ball bush, ball screw and the like, in which a movable member is assembled to a guide shaft to be movable through rolling members.

In a known art, there is provided a rolling motion guide apparatus of the kind mentioned above in which a movable member is assembled to a guide shaft to be movable through a plurality of rolling members. The movable member is composed of a movable member main body provided with a loaded rolling member rolling passage corresponding in position to a loaded rolling member rolling passage formed to the guide shaft and a rolling member returning passage for returning the rolling members from one end of the loaded rolling member rolling passage to another end thereof and also composed of a structure constituting a rolling direction changing passage disposed at both ends of the main body of the movable member and constituting rolling member rolling direction changing passages for scooping the rolling members from the loaded rolling member rolling passage and guiding the same to the rolling member returning passage.

In order to prevent a staged portion from occurring at the connection between the loaded rolling member rolling passage and the rolling member rolling direction changing passage to thereby smoothly roll the rolling members, in the known art, an inner peripheral guide portion of the rolling member direction changing passage is formed integrally with the main body of the movable member such as disclosed in the Japanese Patent Laid-open Publication No. HEI 7-317762.

Although there is provided an end plate, generally formed of resin, as a member constituting the rolling direction changing passage structure for constituting an outer periphery guide portion of the loaded rolling member rolling direction changing passage (herein called merely rolling direction changing passage), the end plate is formed of a different member from the main body of the movable member, and the end plate is positioned and then fastened to the movable member main body by means of bolt. The rolling direction changing passage is composed of such outer periphery guide portion of the end plate and the inner periphery portion integrally formed with the movable member main body.

In the above known structure, there is a problem of fastening the end plate to the movable member main body by means of bolt, involving a troublesome assembling working.

In the case of the bolt fastening, the fastening bolt is screwed into a tap hole formed to an end surface of the movable member main body through a bolt insertion hole formed to the end plate. However, in this assembling, there may cause an alignment error to the end plate assembling portion due to a working error in the tap hole formation or a play between the bolt insertion hole and the bolt inserted. The occurrence of such error will result in the formation of the staged portion between the direction changing passage outer periphery guide portion of the end plate and the end portion of the rolling member rolling passage in a loaded area, disturbing the smooth circulation of the rolling members.

Furthermore, even if such assembling working can be made accurately, the end plate formed of the resin material has contraction strain of the resin at the cooling and curing time of the end plate. Such contraction strain may cause the staged portion to occur between the end portion inside the direction changing passage outer periphery guide portion and the end portion of the rolling member rolling passage in the loaded area, thus also disturbing the smooth circulation of the rolling members.

Still furthermore, in a known structure, an oil groove for feeding a lubricant to the direction changing passage is formed between joining surfaces of the end plate and the movable member main body so as to tightly contact the joining surfaces by means of the fastening bolt to prevent the lubricant from leaking through the joined surface. However, as mentioned above, since the end plate has the contraction strain at the cooling time, the end plate cannot tightly contact the movable member main body and there is a fear of the leakage of the lubricant through the not-tightly contacting portion. Although the complete tight contacting can be achieved by strongly fastening the bolt, such strong fastening may damage or deform the end plate, resulting in the deformation of the direction changing passage outer periphery guide portion and further resulting in the deformation of the end position of the direction changing passage outer peripheral guide portion, causing the staged portion between it and the end portion of the loaded rolling member rolling passage and, hence, disturbing the smooth circulation of the rolling members.

SUMMARY OF THE INVENTION

An object of the present invention is to substantially eliminate defects or drawbacks encountered in the prior art described above and to provide a rolling motion guide apparatus having an improved mounting structure of an end plate of a movable member of the apparatus particularly for ensuring a stable and smooth circulation of rolling members with high reduced working process and with high assembling performance.

This and other objects can be achieved according to the present invention by providing a rolling motion guide apparatus which comprises a guide shaft formed with a loaded rolling member rolling passage and a movable member disposed to be movable with respect to the guide shaft through a number of rolling members, the movable member being composed of a movable member main body provided with a loaded rolling member rolling passage corresponding in position to the loaded rolling member rolling passage formed to the guide shaft and a rolling member returning passage for returning the rolling members from one end of the loaded rolling member rolling passage of the movable member main body to another end thereof and also composed of a rolling direction changing passage structure constituting a rolling member direction changing passage for guiding the rolling member scooped from the loaded rolling member rolling passage of the movable member main body to the rolling member returning passage, wherein the rolling direction changing passage structure is composed of an end surface forming portion which is formed with a rolling direction changing passage inner periphery guide portion integrally formed with the movable member main body and an end plate which is formed with a rolling direction changing passage outer periphery guide portion separately formed from the end surface forming portion, and wherein the rolling direction changing passage outer periphery guide portion of the end plate and a rolling direction changing passage inner periphery guide portion thereof have peripheral portions respectively which are joined and welded so as to provide joining surfaces as a welding portion.

In preferred examples of the present invention, the end surface forming portion of the movable member main body is formed of a resin material through an insertion molding process.

The guide shaft is a guide rail and the movable member is composed of a central horizontal portion and side portions extending downward in a mounted state from both end portions of the horizontal portion so that the guide rail is disposed between the side portions of the movable member.

The movable member main body is provided with axial forming portions which are integrally formed with the end surface forming portions formed at both ends of the movable member main body. Each of the axial forming portions is provided with at least either one of a return hole constituting member forming a non-loaded rolling member returning hole and a rolling member retainer member for preventing the rolling member from falling down at a time when the guide shaft is withdrawn from the movable member.

The rolling direction changing passage outer periphery guide portion and the rolling direction changing passage inner periphery guide portion of the rolling direction changing passage structure have peripheral portions respectively which are joined so as to provide joining surfaces, and a welding portion is continuously formed between the joining surfaces.

A lubricant groove is formed between the joining surfaces of the end surface forming portion and the end plate to communicate with the rolling direction changing passage structure and the welding portion is formed continuously so as to surround the rolling direction changing passage structure and the lubricant groove.

A recessed portion and a protruded portion, which is faucet fitted to the recessed portion, are formed to the peripheral portions of the rolling direction changing passage inner periphery guide portion of the end surface forming portion of the movable member main body and the rolling direction changing passage outer periphery guide portion of the end plate, the protruded and recessed portions having flat portions as joining surfaces to be joined together, and a welding width portion, which is fused at a welding time, is formed between the joining surfaces.

A projection is formed to the joining surface of the end surface forming portion of the movable member main body and the end plate is formed with a hole at the joining surface thereof through which the projection is inserted, and a front end portion of the projection penetrating over the hole is fused to a peripheral edge portion of the hole.

According to the characters and structures of the rolling motion guide apparatus of the present invention mentioned above, the following functions and/or effects will be attained.

The direction changing passage inner periphery guide portion of the end surface forming portion integrally formed with the end surface of the movable member main body through the insertion molding process is accurately formed to the predetermined position of the movable member main body with the predetermined shape. In the formation mold, the movable member main body is positioned by a support portion contacting the rolling member rolling passage, and the direction changing passage inner periphery guide portions can be accurately positioned with reference to the rolling member rolling passage and, after the positioning, the molding process is carried out.

The peripheral portions of the direction changing passage inner periphery guide portion and the direction changing passage outer periphery guide portion of the end plate and the movable member main body are fused and welded. Accordingly, even if the end plate is deformed, the rolling direction changing passage outer periphery guide portion is fixed with the corrected deformation along the rolling direction changing passage inner periphery guide portion of the end surface forming portion of the movable member main body molded with high performance, thereby forming the passage constituting the rolling direction changing passage with high accuracy. That is, in the rolling direction changing passage, the respective rolling members are changed in their rolling directions with pushing force being applied to each other and the rolling members collide repeatedly with the inner peripheral surface of the direction changing passage. In order to prevent the rolling members from irregularly circulating due to the collision, it is necessary to form uniform play passage. According to the structure of the direction changing passage of the present invention, this can be achieved.

Furthermore, the direction changing passage outer periphery guide portion of the end plate can be exactly positioned with respect to the movable member main body along the rolling direction changing passage inner periphery guide portion of the end surface forming portion of the movable member main body. Accordingly, there can be accurately achieved the positional alignment of both the end portions of the direction changing passage outer periphery guide portion with the rolling member rolling passage on the guide shaft side and with the end portion of the rolling member return passage.

Further, in the direction changing passage, although noise will be likely generated due to the mutual collision of the rolling members, such noise can be substantially eliminated by forming the rolling direction changing passage through the welding process.

Furthermore, the apparatus is formed with the return hole constituting member as the axial forming portion and the ball retainer member, and accordingly, the end surface forming portion of the movable member main body can be further firmly fixed to the end surface of the movable member main body due to the axial contraction of these portions, so that the positional accuracy of the direction changing passage inner periphery guide portion can be enhanced at the welding time of the end plate.

The most high positional accuracy is required for both the end portions of the direction changing passage inner periphery guide portion which are to be connected to the non-loaded ball returning hole and the ball retainer member. The position of the direction changing passage inner periphery guide portion can be accurately determined by providing the return hole constituting member as the axial forming portion and the ball retainer member through which the axial contraction force is applied to both the end portions of the direction changing passage inner periphery guide portion. Accordingly, both the end portions of the direction changing passage outer periphery guide portion of the end plate which is welded along such direction changing passage inner periphery guide portion can be also accurately positioned.

The welded portion is formed continuously along the entire length between the joining surfaces at the peripheral portions of the rolling direction changing passage inner periphery guide portion and the rolling direction changing passage outer periphery guide portion. Accordingly, the rolling direction changing passage outer periphery guide portion on the end plate side can be more precisely positioned with respect to the rolling direction changing passage inner periphery guide portion, so that the direction changing passage can be further accurately manufactured.

Furthermore, the portions between the joining surfaces at the peripheral portions of the direction changing passage inner periphery guide portion and the direction changing passage outer periphery guide portion can be substantially completely sealed, so that the leakage of the lubricant to be supplied to the direction changing passage can be substantially prevented and the noise suppressing function can also be enhanced.

Still furthermore, since the joining surfaces are formed respectively to the recessed portions of the end plate and the protruded portions which are to be faucet fitted to those recessed portions, the direction changing passage outer periphery guide portion of the end plate can be further accurately positioned with respect to the movable member main body. The fused resin is filled up in the gaps between the fitted surface portions of the protruded portions and the recessed portions as well as the portions of the joining surfaces mentioned above, thereby further increasing the fixing strength. The filling and fusing of the fused resin in the gap between the protruded portions and the recessed portions can further contribute the maintenance of the accurate performance. The welding performed from the faucet fitting portion to the direction changing passage peripheral portion can contributes to increase the welding strength and prevent the fused resin from entering into the direction changing passage and the lubricant groove.

Still furthermore, according to a further preferred example, the joining surfaces of the end surface forming portion of the movable member main body and the end plate are not directly welded, and the fitted portions of the projection and the hole are welded, so that although the continuous welding is not performed, and the end plate is firmly fixed at the peripheral portion of the direction changing passage inner periphery guide portion, whereby the direction changing passage outer periphery guide portion can be precisely fixed with respect to the direction changing passage inner periphery guide portion.

The nature and further characteristic features of the present invention will be made more clear from the following descriptions with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

In the accompanying drawings:

FIG. **1** represents a linear motion guide apparatus according to a first embodiment of the present invention, in which FIG. **1**A is a front view, left half being in section, of the apparatus from which an end plate is removed, FIG. **1**B is a side view thereof partially cut away, FIG. **1**C is a sectional view in an enlarged scale of a portion of a rolling direction changing passage of the apparatus, and FIGS. **1**D and **1**E are schematic views showing welding sequence applied to the apparatus;

FIG. **2** represents a movable block of the linear motion guide apparatus of FIG. **1**, in which FIG. **2**A is a disassembled side view of the apparatus having end plate shown in section, FIG. **2**B is a partial bottom view of the end plate and an end surface portion of the movable block body in a disassembled state, FIG. **2**C is a view showing an end surface of the end plate to be joined to the end surface of the movable block body, FIG. **2**D shows a welding overlap width portion, FIG. **2**E shows an end surface of the movable block body, and FIGS. **2**F to **2**I show deformed states (strains) of the end plate in an exaggerated manner; and

FIG. **3** represents a linear motion guide apparatus according to a second embodiment of the present invention, in which FIG. **3**A is a front view, left half being in section, of the apparatus from which an end plate is removed, FIG. **3**B is a partial sectional view in an enlarged scale of a portion of a rolling direction changing passage of the apparatus, FIG. **3**C is a side view of the apparatus partially cut away, FIG. **3**D is a half front view showing a state that the end plate is assembled, and FIG. **3**E is a view showing a state of engagement of a projection of the movable block body with an engaging hole of the end plate before welding.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention will be described hereunder by way of preferred embodiments with reference to the accompanying drawings.

[First Embodiment]

FIGS. **1** and **2** represents the first embodiment of a linear motion guide apparatus as a rolling motion guide apparatus according to the present invention.

Referring to FIGS. **1** and **2**, reference numeral **1** denotes an entire structure of the linear motion guide apparatus, which is provided with a guide (track) rail **2** as a guide shaft and a movable block **4** as a movable member mounted to the guide rail **2** to be movable through a number of balls **3** as rolling members.

The guide rail **2** is composed of a long member having a rectangular cross section, and the movable block **3** is guided at the lateral, left and right, side of the guide rail **2**, through four ball rows, two rows at each lateral side, **3**A, **3**A, **3**A, **3**A. The left and right side surfaces of the guide rail **2** is formed each with two, totally four, loaded ball rolling grooves **5**, **5**, **5**, **5** as loaded rolling member rolling passage corresponding in positions to the four ball rows **3**A, **3**A, **3**A, **3**A, respectively, along the entire longitudinal length of the guide rail **2**.

The movable block **3** is composed of a movable block body **6** as the main body of the movable member and rolling direction changing passage constituting members **10**, **10** disposed to both end sides of the movable block body **6**. The movable block body **6** is a member having a]-shaped section an d is provided with a horizontal portion **61** opposing to the upper surface of the guide rail **2** and a pair of support leg (skirt) portions **62**, **62** corresponding in positions to the left and right side surfaces of the guide rail **2**. Furthermore, two loaded ball rolling grooves **8**, **8**, as loaded rolling member rolling passages, are formed respectively to the inner side surfaces of the paired left and right support leg portions **62**, **62** of the movable block body **6**, and the loaded ball rolling grooves **8**, **8**, **8**, **8** correspond in position to the loaded ball rolling grooves **5**, **5**, **5**, **5**, respectively, formed to the left and right side surfaces of the guide rail **2**. Furthermore, the support leg portions **62**, **62** are also formed with ball returning passages **7**, **7**, **7**, **7** as the rolling member returning passages for returning the balls from one end of each loaded ball rolling groove **8** to another end thereof.

The each rolling direction changing passage constituting member **10** is composed of an end surface forming portion **11** made of resin and an end plate **12** also made of resin. The end surface forming portion **11** is formed with an inner periphery guide portion of the rolling member direction changing passages (herein called merely direction changing passage inner periphery guide portion) **9***a*, **9***a*, **9***a*, **9***a* integrally formed with the movable block body **6** through an insertion molding process in which the movable block body **6** is inserted into a formation mold to carry out the molding. The end plate **12** is formed with an outer periphery guide portion of the rolling member direction changing passages (herein merely called direction changing passage outer periphery guide portion) **9***b*, **9***b*, **9***b*, **9***b* independently formed from the end surface forming portion **11**. Joining surfaces of the peripheral portions of the direction changing passage inner periphery guide portion **11** and the direction changing passage outer periphery guide portion **12** are welded to thereby constitute a direction changing passage **9** having a curved U-shape.

The movable block body **6** is formed integrally with an axial forming portion, which is composed of a return hole constituting members **13** forming a non-loaded ball return holes **7** and connected to the end surface forming portions **11** at both the ends of the movable block body **6** and ball retainer members **14** preventing the balls **3** from falling down at the time when the guide rail **2** is withdrawn from the movable block body **6**.

Each of the end surface forming portions **11** is composed of first protruded portions **111**, each having substantially rectangular shape, formed to the end surfaces of the left and right leg (skirt) portions **62**, **62** of the movable block body **6** and second protruded portions **112** formed to the end surface of the horizontal portion **61** so as to connect the right and left first protruded portions **111** to each other. Each of the left and right first protruded portions **111** is formed with upper and lower rows of the direction changing passage inner periphery guide portions **9***a*, **9***a*, **9***a*, **9***a* projecting in half-moon shape.

The end plate **12** has left and right skirt (leg) portions, to which first recessed portions **121** into which the first protruded portions **111** of the end surface forming portion **11** are fitted in a faucet manner, and second recessed portions **122** into which the second protruded portions are fitted in a faucet manner. These first and second protruded portions **111** and **112** of the end surface forming portion **11** constitute a staged protruded portion according to the structure of the present invention.

The first recessed portion **121** is formed with the direction changing passage outer periphery guide portions **9***b*, **9***b*; **9***b*, **9***b* which are circularly recessed in correspondence to the half-moon shaped direction changing passage inner periphery guide portion and constitutes the rolling direction changing passages **9**, **9**; **9**, **9** in combination of the direction changing passage inner periphery guide portion **9***a*, **9***a*; **9***a*, **9***a*.

A second recessed portion **122**, into which the second protruded portion **112** is fitted, is formed to the horizontal portion of each of the end plate **12**, and the second recessed portion **122** has a bottom portion to which an oil groove **15** is formed so as to be communicate with the left and right direction changing passage outer periphery guide portion **9***b*, **9***b*; **9***b*, **9***b* from an oil supply port **123** opened at a central portion thereof. A grease nipple, not shown, is mounted to the oil supply port **123**.

Joining surfaces **16***a* to **16***e* and **17***a* to **17***e* are formed between a peripheral portion of the direction changing passage inner periphery guide portion **9***a* of the left and right first protruded portions **111** of the movable block body **6** and a peripheral portion of the direction changing passage outer periphery guide portion **9***b* of the first recessed portions **121** of the end plate **12**. These joining surfaces extend each with a predetermined width and are joined together, respectively. Joining surfaces **16***f*, **17***g* and **17***f*, **17***g*, which are joined together through the oil groove **15**, are formed between the second protruded portions **112** and the first recessed portions **121** of the end plate **12**. These joining surfaces **16***f*, **16***g* and

17*f*, **17***g* are formed with welding width portions **18** which are welded together in the fusing process. Although such welding width portions **18** may be formed either one of the joining surfaces **17***a* to **17***g* on the side of the end plate **12** and the joining surfaces **16***a* to **16***g* on the side of the first and second protruded portions **111** and **112** of the movable block body **6**, in the present embodiment, the welding width portions **18** are formed on the side of the joining surfaces **17***a* to **17***g* of the first and second recessed portions **121** and **122** of the end plate **12**.

Furthermore, the welding width portions **18** are formed continuously so as to surround the oil groove **15** as well as the bilateral direction changing passage outer periphery guide portions **9***b* of the end plate **12**. The joining surfaces **17***a*, **17***b* and **17***c*, which are positioned at upper edge, outside edge and lower edge portions of the first recessed portion **121** of the end plate **12**, are formed continuously so as to surround the two rows of upper and lower direction changing passage outer periphery guide portions **9***b*, **9***b*. The joining surface **17***d* constituting the boundary portion between the upper and lower direction changing passage outer periphery guide portion **9***b* and the joining surface **17***e* facing the end surface of the ball retainer portion **14** are formed at the intermediate portions therebetween.

The joining surface **17***b* of the outside edge portion of the first recessed portion **121** is formed to be flat, and the joining surfaces **17***a* and **17***c* of the upper and lower edge portions have partial flat portions at their outer end portions continuous to the outside edge portion and circular portions along the direction changing passage outer periphery guide portion **9***b*. The circular portions of the joining surfaces **17***a* and **17***c* may not be welded as occasion demands. Further, the joining surface **17***d* at the boundary portion between the upper and lower direction changing passage inner periphery guide portions **9***b*, **9***b* may not also be welded as occasion demands.

Furthermore, the joining surfaces **17***e* and **17***f* of the upper and lower edge portions of the second recessed portion **122** are continuously trimmed between the joining surfaces of the second protruded and recessed portions **112** and **122** surrounding the oil groove **15**.

The joining surfaces **17***a*, **17***b*, **17***c* of the upper, outside and lower edge portions of the first recessed portion **121** and the welding width portions **18** trimming the joining surfaces **17***f*, **17***g* of the upper and lower edge portions of the second recessed portion **122** are formed respectively at the corner portions of the first and second recessed portions **121** and **122** to make maximum the thickness of the corner portions, the thickened portions being reduced in their thicknesses towards the direction changing passage **9** and the oil groove **15** so as to each provide a triangular shape in section and extend continuously with uniform width. Although, the welding width portions **18** may be formed to intermediate portions of the respective joining surfaces **17***a*, **17***b*, **17***c*, **17***f*, **17***g*, it will be desired to form them at portions apart by a predetermined distance from the rolling direction changing passage **9** or the oil groove **15** for preventing the fused resin material from entering into the rolling direction changing passage **9** or the oil groove **15**.

In the described embodiment of the present invention, the direction changing passage inner periphery guide portion **9***a* of the end surface forming portion **11** integrally formed with the end surface of the movable block body **6** through the insertion molding process is accurately formed to the predetermined position of the movable block body **6** with the predetermined shape. In the formation mold, the movable block body **6** is positioned by a support portion contacting the loaded ball rolling grooves **8**, **8**, **8**, **8**, and the direction changing passage inner periphery guide portions **9***a*, **9***a*, **9***a*, **9***a* are accurately positioned with reference to the loaded ball rolling grooves **8**, **8**, **8**, **8**, and after the positioning, the molding process is carried out.

In the described embodiment, the peripheral portions of the direction changing passage inner periphery guide portion **9***a* and the direction changing passage outer periphery guide portion **9***b* of the end plate **12** and the movable block body **6** are fused and welded. Accordingly, even if the end plate is deformed as shown in FIGS. **2**F to **2**I in an exaggerative manner, the direction changing passage outer periphery guide portion **9***b* is fixed with the corrected deformation along the direction changing passage inner periphery guide portion **9***a* of the end surface forming portion **11** of the movable block body **6** molded with high performance, thereby forming the the passage constituting the rolling direction changing passage **9** with high accuracy. That is, in the rolling direction changing passage **9**, the respective balls **3** are changed in their rolling directions with pushing force being applied to each other and the balls **3** collide repeatedly with the inner peripheral surface of the direction changing passage **9**. In order to prevent the balls **3** from irregularly circulating due to the collision, it is necessary to form uniform play passage. According to the present invention, this can be achieved.

Furthermore, according to the embodiment of the present invention, the direction changing passage outer periphery guide portion **9***b* of the end plate **12** can be exactly positioned with respect to the movable block body **6** along the direction changing passage inner periphery guide portion **9***a* of the end surface forming portion **11** of the movable block body **6**. Accordingly, there can be accurately achieved the positional alignment of both the end portions of the direction changing passage outer periphery guide portion **9***b* with the loaded ball rolling groove **5** on the guide rail side and with the end portion of the rolling ball return passage **7**.

Further, in the direction changing passage **9**, although noise will be likely generated due to the mutual collision of the rolling balls **3**, such noise can be substantially eliminated by forming the direction. changing passage through the welding process.

Furthermore, in the present embodiment, the apparatus is formed with the return hole constituting member **13** as the axial forming portion and the ball retainer portion **14**, and accordingly, the end surface forming portion **11** of the movable block body **6** can be further firmly fixed to the end surface of the movable block body **6** due to the axial contraction of these portions **13** and **14**, so that the positional accuracy of the direction changing passage inner periphery guide portion **9***a* at the welding time of the end plate **12**.

The most high positional accuracy is required for both the end portions of the direction changing passage inner periphery guide portion **9***a* which are to be connected to the non-loaded ball returning hole **7** and the ball retainer portion **14**. The position of the direction changing passage inner periphery guide portion **9***a* can be accurately determined by providing the return hole constituting member **13** as the axial forming portion and the ball retainer portion **14** through which the axial contraction force is applied to both the end portions of the direction changing passage inner periphery guide portion **9***a*. Accordingly, both the end portions of the direction changing passage outer periphery guide portion **9***b* of the end plate **12** which is welded along such direction changing passage inner periphery guide portion **9***b* can be also accurately positioned.

The welded portion **19** is formed continuously along the entire length portions between the joining surfaces **16***a* to **16***g* and **17***a* to **17***g* at the peripheral portions of the direction changing passage inner periphery guide portion **9***a*, the direction changing passage outer periphery guide portion **9***b* and the oil groove **15**. Accordingly, the direction changing passage outer periphery guide portion **9***b* on the end plate side can be more precisely positioned with respect to the direction changing passage inner periphery guide portion **9***a*, so that the rolling direction changing passage **9** can be further accurately manufactured.

Furthermore, the portions between the joining surfaces **16***a* to **16***g* and **17***a* to **17***g* at the peripheral portions of the direction changing passage inner periphery guide portion **9***a*, the direction changing passage outer periphery guide portion **9***b* and the oil groove **15** can be substantially completely sealed, so that the leakage of the oil to be supplied to the rolling direction changing passage **9** can be completely prevented and the noise suppressing function can also be enhanced.

Particularly, since the joining surfaces **16***a*, **16***b*, **16***c*, **16***f*, **16***g* and **17***a*, **17***b*, **17***c*, **17***f*, **17***g* are formed respectively to the first and second recessed portions **121**, **122** of the end plate **12** and the first and second protruded portions **111**, **112** which are to be faucet fitted to those recessed portions, the direction changing passage outer periphery guide portion **9***b* of the end plate **12** can be further accurately positioned with respect to the movable block body **6**.

Still furthermore, the fused resin (welding portion) is filled up in the gaps **19** between the fitted surface portions of the first and second protruded portions **111**, **112** and the first and second recessed portions **121**, **122** as well as the portions of the joining surfaces mentioned above, thereby further increasing the fixing strength. The filling and welding of the fused resin in the gaps **19** between the first and second protruded portions **111**, **112** and the first and second recessed portions **121**, **122** can further contribute the maintenance of the accurate performance.

The welding process of the rolling motion guide apparatus of the structure mentioned above will be performed in the following manner.

At the first step, the end plates **12** are mounted to both the ends of the movable block body **6** in a manner that the first and second protruded portions **111**, **112** of the end surface forming portions **11** of the movable block body **6** are faucet fitting to the first and second recessed portions **121**, **122** of the end plates **12**, respectively.

In the next step, the movable block body **6** is supported by an ultrasonic plastic welder, not shown, while the back surface, to which the welding width portion **18** of the end plate **12** is formed, is uniformly pressed by a honing head, not shown, so that corner portions of the first and second protruded portions of the end surface forming portion **11** of the movable block body **6** abut against the welding width portion **18**. Under the state, ultrasonic vibration is applied to thereby fuse and weld the welding width portions by friction force caused between the joining surfaces of the welding width portions **18** and the corner portions of the first and second protruded portions **111**, **112**.

At the initial stage of the welding, the most front end portion of the corner portion of the welding width portion **18** is first fused and, in an intermediate stage thereof, fused resin flows into the gap between the fitting portions of the first and second protruded portions **111**, **112** and the first and second recessed portions **121**, **122** and the joining surfaces **16***a* to **16***g* and **17***a* to **17***g* therebetween. In the final stage, the fusing at the welding width portion **18** has been completed by the pressing of the welder, and the joining surfaces **16***a* to **16***g* and **17***a* to **17**g of the first and second protruded portions **111, 112** and the first and second recessed portions **121, 122** are contacted respectively and subjected to the pressing vibration. Thereafter, the fused resin is solidified, thus completing the welding process.

FIG. **3** represents a second embodiment of a linear motion guide apparatus as a rolling motion guide apparatus of the present invention.

Referring to FIG. **3**, reference numeral **21** denotes an entire structure of a linear motion guide apparatus **21** which is essentially composed of a guide rail **22** as a guide shaft and a movable block **24** as a movable member which is mounted to the guide rail **22** through a number of balls **23** as rolling members.

The guide (track) rail **22** of this embodiment is composed of a long member having a rectangular cross section, and the movable block **24** is guided at the lateral, left and right, side of the guide rail **2**, through two ball rows, one row at each lateral side, **23**A, **23**A. The left and right side surfaces of the guide rail **22** are formed with two loaded ball rolling grooves **25, 25** as loaded rolling member rolling passage corresponding in position to the two ball rows **23**A, **23**A, respectively, along the entire longitudinal length of the guide rail **22**.

The movable block **24** is composed of a movable block body **26** as the main body of the movable member and rolling direction changing passage constituting members **30** disposed to both end sides of the movable block body **26**. The movable block body **26** is a block member having a]-shaped section and is provided with a horizontal portion **261** opposing to the upper surface of the guide rail **22** and a pair of support leg (skirt) portions **262, 262** corresponding in positions, i.e. opposing, to the left and right side surfaces of the guide rail **22**. Furthermore, loaded ball rolling grooves **28, 28**, as loaded rolling member rolling passages, are formed respectively to the inner side surfaces of the paired left and right support leg portions **262, 262** of the movable block body **26**, the loaded ball rolling grooves **28, 28** corresponding in position to the loaded ball rolling grooves **25, 25**, respectively, formed to the left and right side surfaces of the guide rail **22**. Furthermore, the support leg portions **262, 262** are also formed with ball returning passages **27, 27** as the rolling member returning passages for returning the balls from one end of each loaded ball rolling groove **8** to another end thereof. Each of the respective balls **23** of the ball row **23**A has a diameter larger than a diameter of the loaded ball rolling groove **25** to thereby apply a preload to the balls **23**.

The rolling direction changing passage constituting member **30** is composed of an end surface forming portion **31** made of resin and an end plate **32** also made of resin. The end surface forming portion **31** is formed with a direction changing passage inner periphery guide portion **29***a*, **29***a* integrally formed with the movable block body **26** through an insertion molding process in which the movable block body **26** is inserted into a formation mold to carry out the molding. The end plate **32** is formed with a direction changing passage outer periphery guide portion **29***b*, **29***b* independently formed from the end surface forming portion **31**. Peripheral portions of the direction changing passage inner periphery guide portion **29***a* of the movable block body **26** and the direction changing passage outer periphery guide portion **29***b* of the end plate **32** are welded to thereby constitute a rolling direction changing passage **29** having a curved U-shape.

The movable block body **26** is formed integrally with an axial forming portion, which is composed of a return hole constituting member **33** forming a non-loaded ball return hole **27** and connected to the end surface forming portions **31** at both the ends of the movable block body **26**.

To the peripheral portions of the direction changing passage guide portion **29***a* of the end surface forming portion **31** of the movable block body **26** and the direction changing passage outer periphery guide portion **29***b* of the end plate **32**, there are formed a recessed portion **36** and a protruded portion **37** which is faucet fitted to the recessed portion **36**.

In the structure of the second embodiment, a projection **38** is formed to the joining surface at the peripheral portion of the direction changing passage **29** of the end surface forming portion **31** of the movable block body **26**, and the end plate **32** is formed at its joining surface with a hole **39** through which the projection **38** is inserted. The front end portion **40** of the projection **38** extending over the hole **38** is fused to thereby form an engaging portion **41** which is engageable with the peripheral edge portion of the hole **39**.

According to such structure, the joining surfaces of the end surface forming portion **31** of the movable member **26** and the end plate **32** are not directly welded and the fitted portions of the projection **38** and the hole **39** are welded. Accordingly, although the continuous welding is not carried out, the end plate **32** is firmly fixed at the peripheral portion of the direction changing passage inner periphery guide portion **29***a*, so that the direction changing passage outer periphery guide portion **29***b* can be precisely fixed with respect to the direction changing passage inner periphery guide portion **29***a*.

The welding process in this second embodiment will be performed in the following manner.

First, the front end portion **41** of the projection **38** of the movable block body **26** is pressed and crushed by a jig, not shown, under the application of the ultrasonic vibration to form the engaging portion **41** having a bevel shape having a diameter larger than that of the hole **39**.

In the initial stage of the welding, the projection **38** is fused first at its front end portion, and in the intermediate stage, a shank portion **38***a* of the projection **38** inserted into the hole **39** is swelled by the compressing force, whereby a gap between the shank portion **38***a* and the inner peripheral surface of the hole **39** vanishes.

In the final stage of the welding, the engaging portion **41** of the front end portion of the projection **38** is pressed by a plastic welder, not shown, to thereby provide a semi-circular shape such as head portion of a rivet, and the end plate **32** is fixed to the movable block body **26** upon the completion of the pressing and vibrating processes.

Through the processes mentioned above, the positional performance between the direction changing passage inner periphery guide portion **29***a* and outer periphery guide portion **29***b* can be ensured, the balls **23** are fitted into the direction changing passage **29** while maintaining a suitable gap therebetween, and hence, the balls **23** can be smoothly circulated.

Furthermore, the positional precision of the direction changing passage inner periphery guide portion **29***a* formed to the end surface of the movable block body **26** can be ensured by forming the movable block body **26** through the insertion molding process. That is, since the direction changing passage inner periphery guide portion **29***a* of the movable block body **26** having high rigidity and the peripheral portion thereof are further tightly fixed through the axial contraction of the non-loaded rolling member return hole **27**, the precision of the direction changing passage inner periphery guide portion **29***a* of the movable block body **26** can be ensured.

According to the present embodiment, since the positioning projection **38** is fused and then fixed at the peripheral portion of the direction changing passage **29**, the direction changing passage outer periphery guide portion **29***a* of the end plate **23** can be also fixed in accordance with the direction changing passage inner periphery guide portion **29***b* of the movable block body **26** formed precisely, and accordingly, the rolling direction changing passage **29** can be formed with high precision and performance.

It is further to be noted that the present invention is not limited to the embodiments described above and many other changes or modifications may be made without departing from the scope of the appended claims. For example, in the embodiments mentioned above, either one of the end plate and the end surface forming portion may be formed of a thermoplastic resin. Although it is described above that the plastic welding (fusing) process is performed by using ultrasonic welding method, the present invention is not limited thereto and a heat welding process may be applicable, and a laser welding process or other welding processes may be also applicable.

What is claimed is:

1. A rolling motion guide apparatus comprising:

a guide shaft formed with a loaded rolling member rolling passage; and

a movable member disposed to be movable with respect to the guide shaft through a number of rolling members, said movable member being composed of a movable member main body provided with a loaded rolling member rolling passage corresponding in position to the loaded rolling member rolling passage formed to the guide shaft and a rolling member returning passage for returning the rolling members from one end of the loaded rolling member rolling passage of the movable member main body to another end thereof and a pair of rolling direction changing passage structures respectively constituting a rolling member direction changing passage for guiding the rolling member scooped from the loaded rolling member rolling passage of the movable member main body to the rolling member returning passage,

wherein said each rolling direction changing passage structure is composed of an end surface forming portion which is formed with a rolling direction changing passage inner periphery guide portion integrally formed with the movable member main body and an end plate which is formed with a rolling direction changing passage outer periphery guide portion separately formed from the end surface forming portion, and

wherein the rolling direction changing passage outer periphery guide portion of the end plate and a rolling direction changing passage inner periphery guide portion thereof have peripheral portions respectively which are joined and welded.

2. A rolling motion guide apparatus according to claim **1**, the peripheral portions respectively is provided with the joining surfaces as a welding portion.

3. A rolling motion guide apparatus according to claim **1**, wherein the end surface forming portion of the movable member main body is formed of a resin material through an insertion molding process.

4. A rolling motion guide apparatus according to claim **1**, wherein said guide shaft is a guide rail and said movable member is composed of a central horizontal portion and side portions extending downward in a mounted state from both end portions of the horizontal portion, said guide rail being disposed between the side portions of the movable member.

5. A rolling motion guide apparatus according to claim **1**, wherein the movable member main body is provided with axial forming portions which are integrally formed with the end surface forming portions formed at both ends of the movable member main body.

6. A rolling motion guide apparatus according to claim **5**, wherein each of said axial forming portion is provided with at least either one of a return hole constituting member forming a non-loaded rolling member returning hole and a rolling member retainer member for preventing the rolling member from falling down at a time when the guide shaft is withdrawn from the movable member.

7. A rolling motion guide apparatus according to claim **1**, wherein the rolling direction changing passage outer periphery guide portion and the rolling direction changing passage inner periphery guide portion of the rolling direction changing passage structure have peripheral portions respectively which are joined so as to provide joining surfaces, and a welding portion is continuously formed between the joining surfaces.

8. A rolling motion guide apparatus according to claim **1**, wherein a lubricant groove is formed between joining surfaces of the end surface forming portion and the end plate to communicate with the rolling direction changing passage structure and the welding portion is formed continuously so as to surround the rolling direction changing passage structure and the lubricant groove.

9. A rolling motion guide apparatus according to claim **1**, wherein a recessed portion and a protruded portion which is faucet fitted to the recessed portion are formed to peripheral portions of the rolling direction changing passage inner periphery guide portion of the end surface forming portion of the movable member main body and the rolling direction changing passage outer periphery guide portion of the end plate, said protruded and recessed portions having flat portions as joining surfaces to be joined together and a welding width portion, which is fused at a welding time, is formed between the joining surfaces.

10. A rolling motion guide apparatus according to claim **1**, wherein a projection is formed to the joining surface of the end surface forming portion of the movable member main body and the end plate is formed with a hole at the joining surface thereof through which the projection is inserted and a front end portion of the projection penetrating over the hole is fused and welded to a peripheral edge portion of the hole.

[57] **ABSTRACT**

At least a ball escape hole (**10**) of a ball circulation passage (**7**) is formed of a molded body (**12**) and the molded body (**12**) is formed integrally with a block body (**13**) having high rigidity through an insert molding process, thereby eliminating a drilling working, possibly reducing assembling processes and reducing generation of noise.

It is preferred that the molded body (**12**) is provided with an inner peripheral portion of a direction changing passage (**11**) integrally connected with the ball escape hole (**10**) and joined with both end surfaces of the block body (**13**).

Furthermore, it is preferred that the molded body (**12**) is provided with a retainer (**17**) extending along a loaded ball passage (**8**) and integrally connected, at its both ends, with the inner peripheral portion of the direction changing passage (**11**), thereby providing a closed sectional shape surrounded by the ball escape hole portion (**10**), the direction changing portion (**11**) and the retainer portion (**17**).

ROLLING GUIDE APPARATUS AND METHOD OF MANUFACTURING MOVABLE BLOCK OF ROLLING GUIDE APPARATUS

This application is a continuation of application Ser. No. 08/569,125 filed Apr. 3, 1996, now abandoned; which is a 371 of PCT/JP95/00974 filed May 22, 1995.

TECHNICAL FIELD

The present invention relates to a rolling guide apparatus of contact-type for guiding a rolling member along a linear passage or the like, more particularly, to a structure of a rolling member circulation passage and also relates to a method of manufacturing a movable block of the rolling guide apparatus.

BACKGROUND ART

A conventional rolling guide apparatus of this type generally has a structure in which a movable block is supported to be movable along a guide rail through a number of rolling members, the movable block is provided with a circulation passage through which the rolling members are guided and circulated. The rolling member circulation passage is formed with a loaded rolling member rolling passage composed of loaded rolling member rolling grooves formed to opposing surfaces of the movable block and the guide rail, respectively, and is formed with a return passage formed to a non-loaded area and connected at their both end portions with the loaded rolling member rolling passage so that the rolling member circulates the loaded rolling member rolling passage and the return passage. The return passage is composed of a rolling member escape hole extending in parallel to the loaded rolling member rolling passage and a direction changing passage connecting both end portions of the rolling member escape hole to both ends of the loaded rolling member rolling passage to change the rolling direction of the rolling member.

In the conventional structure, however, the rolling member escape hole is formed through a drilling working to a block body so as to penetrate it vertically, which requires a troublesome working and involves a factor of cost increasing.

In order to obviate this defect, a conventional technology has provided a structure in which a rolling member escape hole in a non-loaded area is formed by cutting away a side surface of the block body and the cut-out portion is covered by a cover member formed of a resin material, for example. However, according to this conventional structure, it is difficult to assemble the rolling member circulation passage, and noise is generated due to an assembling error, thus providing a problem.

Furthermore, in the conventional rolling guide apparatus, it is attempted to construct the block body to have a sufficient rigidity so as not to be deformed even if a heavy load is applied to the guide apparatus. On the contrary, in a case where there causes a large misalignment between the guide rail and the movable block (for example, an error in degree of parallelism between a fixing surface of the guide rail and a fixing surface of a conveyer table fixed to the movable block), an unnatural force is applied to a contact surface between the rolling member and the rolling member rolling groove. This unnatural force obstructs smooth rolling of the rolling member and, hence, the rolling member and the rolling member rolling groove are easily worn, providing a problem.

In view of this point, in the case of the structure in which the rolling member escape hole is formed by cutting away the outside surface of the block body, the block body has a reduced thickness portion corresponding to the cut-away portion and hence the rigidity thereof is lowered correspondingly. However, in the type of this structure, the rolling member contacts the cutout portion of the block body and then is covered by the cover member. Therefore, the thickness of the block body is not reduced to a thickness more than that corresponding to a gap between the rolling member escape hole and the loaded rolling member rolling groove and the rigidity is also not reduced correspondingly. However, the gap between the rolling member escape hole and the rolling member rolling groove is not so much reduced because of the smooth rolling direction changing of the rolling member. Thus, there is a limit to reduce the thickness of the block body.

The rolling member circulates the circulation passage formed in the loaded and non-loaded areas, and as far as the positional relationship of the rolling member escape hole with respect to the loaded rolling member rolling groove is not accurately decided, the direction changing passage between the loaded rolling member passage and the rolling member escape hole is not also accurately positioned. Further, in a case where the loaded rolling member rolling passage is not smoothly and continuously connected with the direction changing passage, the rolling member is not smoothly rolled and circulated therein.

Furthermore, a retainer is also disposed to both sides of the loaded rolling member rolling passage for preventing the rolling member from falling off at a time when the movable block is disassembled from the guide rail. It is necessary to form a gap between the retainer and the rolling member rolling passage so that the rolling member does not interfere with the retainer at a time when the rolling member rolls in and along the rolling member rolling passage, and because of this reason, it is necessary to accurately position the retainer with respect to the loaded rolling member rolling passage and it is also required for the passage to have an accurate linearity.

Still furthermore, in the conventional structure, respective members or elements assembled with the movable block body made of steel are often fastened by insufficient fastening force, and because of this reason, these members or elements resonate and generate noises, thus also providing a problem at a time of the rolling circulation of the rolling member particularly in the non-loaded area at which the rolling member is rolled with no load.

The present invention was conceived to solve the above problems and aims to provide a rolling guide apparatus which does not require a drilling working for a rolling member escape hole by integrally molding a block body and at least the rolling member escape hole through a molding process, assembling process can be possibly reduced and generation of noise during the rolling of the rolling member is effectively reduced, and also provide a method of manufacturing the movable block.

In addition to the above object, it is aimed to change the rigidity of the block body without changing a gap between the rolling member escape hole and the loaded rolling member rolling groove.

Furthermore, in addition to the above objects, it is aimed to ensure smooth circulation of the rolling member by accurately positioning the rolling member circulation passage with respect to the rolling member rolling groove.

DISCLOSURE OF INVENTION

The present invention relates to a rolling guide apparatus in which a movable block is supported to be movable along a guide rail through a number of rolling members, a circulation passage for guiding circulation of the rolling members is formed to the movable block, the rolling member circulation passage being composed of a loaded rolling member rolling passage in a loaded area between loaded rolling member rolling grooves formed to opposing surfaces of the movable block and the guide rail and a non-loaded return passage for returning the rolling members in the loaded area from one end of the loaded rolling member rolling passage to another one end thereof, the return passage being composed of a rolling member escape hole extending in parallel to the loaded rolling member rolling passage and a direction changing passage having inner and outer peripheral portions connecting both ends of the rolling member escape hole to both ends of the loaded rolling member rolling passage, and the rolling guide apparatus being characterized in that at least one of the rolling member escape hole, the inner peripheral portion of the direction changing passage and a retainer extending along the loaded rolling member rolling passage is formed of a molded body and the molded body is integrally formed with a block body having high rigidity.

The molded body may be composed of only the rolling member escape hole, only the inner peripheral portion of the direction changing passage or only the retainer, or composed of integral combination thereof.

That is, the molded body may be provided with the rolling member escape hole and the inner peripheral portion of the direction changing passage integrally connected to the rolling member escape hole and joined with both end surfaces of the block body.

The molded body may be provided with the rolling member escape hole and the retainer extending along the loaded rolling member rolling passage.

The molded body may be provided with the inner peripheral portion of the direction changing passage joined with both end surfaces of the block body and the retainer extending along the loaded rolling member rolling passage and integrally connected at its both ends with the inner peripheral portion of the direction changing passage.

The molded body may be provided with the rolling member escape hole, the inner peripheral portion of the direction changing passage integrally connected to the rolling member escape hole and joined with both end surfaces of the block body and the retainer extending along the loaded rolling member rolling passage and integrally connected at its both ends with the inner peripheral portion of the direction changing passage, the molded body having a closed sectional shape surrounded by the rolling member escape hole, the direction changing passage and the retainer.

Furthermore, a recess-protrusion engaging portion is formed to joining surfaces of the molded body and the block body.

The molded body is formed of a resin material, and a portion between the loaded rolling member rolling groove and the rolling member escape hole of the movable block is formed as one portion of the resin molded body so as to define a reduced thickness in the block body having high rigidity to provide an elastic property.

It is effective that the rolling members rolling in the loaded rolling member rolling passage are scooped by a guide, each in two point contact state, extending in the loaded area of the direction changing passage from the loaded rolling member rolling groove to the direction changing passage in a manner of being separated gradually from each other.

It is further characterized that the movable block is provided with a pair of leg portions between which the guide rail is interposed and a connection portion connecting the leg portions, and the rolling member circulation passages are formed to the leg portions.

It is characterized that a covering portion is provided for covering at least one of upper and lower surfaces of the connection portion of the movable block and the covering portion is integrally formed with the inner peripheral portion of the direction changing passage joined with both the end surfaces of the block body.

The rolling member escape hole has a sectional shape having a rolling member passing section through which the rolling member passes and a lubrication agent storing section capable of storing a lubrication agent bled outward from the rolling member passing section.

In another aspect, the present invention relates to a method of manufacturing a movable block, which is supported to be movable with respect to a guide rail through a number of rolling members, of a rolling guide apparatus provided with loaded rolling member rolling grooves formed to opposing surfaces of the movable block and the guide rail, a rolling member escape hole extending in parallel to the loaded rolling member rolling grooves, and a direction changing passage having inner and outer peripheral portions connecting both ends of the rolling member escape hole with both ends of the loaded rolling member rolling passage, the manufacturing method being characterized in that the block body is placed in a mold, and at least one of the rolling member escape hole, the inner peripheral portion of the direction changing passage and a retainer extending along the loaded rolling member rolling passage is formed integrally with the block body through an insertion molding process.

The rolling member escape hole and the inner peripheral portion of the direction changing passage may be integrally formed together through the insertion molding process.

The rolling member escape hole and the retainer extending along the loaded rolling member rolling passage may be integrally formed together through the insertion molding process.

The inner peripheral portion of the direction changing passage and the retainer extending along the loaded rolling member rolling passage may be integrally formed together through the insertion molding process.

The rolling member escape hole, the inner peripheral portion of the direction changing passage, and the retainer extending along the loaded rolling member rolling passage may be integrally formed together through the insertion molding process.

The block body is positioned in the mold with reference to the rolling member rolling groove formed to the movable block.

According to the present invention, since the rolling member escape hole is integrally formed with the block body through the molding process, the drilling working can be eliminated to thereby easily form the structure.

Particularly, since the rolling member escape hole forming portion is integrally formed in the non-loaded area with the molded body, noise which will be caused by an insufficient fastening force can be prevented from generating.

The degree of integral formation can be increased by integrally forming the inner peripheral portion of the direction changing passage with the rolling member escape hole, making easy the assembling process.

Furthermore, by integrally forming the rolling member escape hole, the inner peripheral portion of the direction changing passage and the retainer, the tensile stress is applied, by the shrinkage of the molded portions, to the rolling member escape hole, so that the fastening force can be increased by the remaining tensile stress, thus remarkably reducing the generation of the noise.

Particularly, with respect to the retainer, the degree of straightness can be made high by the function of the remaining tensile stress, so that the retainer is made parallel and straight with respect to the loaded rolling member rolling passage, and as a result, when the loaded rolling member is rolled and moved, the retainer does not contact and interfere with the rolling member and the rolling member is hence rolled smoothly and the movable block is also smoothly moved along the guide rail.

Furthermore, since the retainer is firmly secured to the block body through the tensile stress, no resonance is caused by the rolling vibration of the rolling member, thus remarkably reducing the noise.

Further, the thickness of the block constituting material such as metal constituting the block body at its portion between the loaded rolling member rolling groove to the rolling member escape hole which affects on rigidity thereof can be made thin so as to provide an elastic property without changing the dimension between the rolling member rolling groove and the rolling member escape hole, in other words, with the dimension suitable for the smooth direction changing operation being maintained, by forming the rolling member escape hole by the molded resin body.

Accordingly, if an assembling error between the guide rail and the movable block (for example, misalignment such as assembling error due to an error in parallelism between the fixing surface of the guide rail and the fixing surface of a conveyer table to be fixed to the movable block) be caused, such error can be absorbed through the flexibility of the thin portions of the block body and the contact portion between the rolling member and the rolling member rolling groove is prevented from being applied with an excessive force.

The rolling member escape hole is formed so as to provide a sectional shape having a rolling member passing section along which the rolling members roll and a lubrication agent storing section capable of storing lubrication agent bled outward from the rolling member passing section, and according to such structure of the rolling member escape hole, since the lubrication agent can be retained without obstructing the circulating motion of the rolling member, the smooth circulating motion thereof can be surely maintained for the long time operation with no substantial maintenance. Furthermore, the escape hole having such complicated sectional shape can be easily formed through the molding process.

The positioning of the block body inserted into the mold is performed with reference to the rolling member rolling groove through the insertion molding process, and accordingly, since the position of the rolling member escape hole and the position of the retainer can be determined with reference to the rolling member rolling groove, the relative positional relationship among the loaded rolling member rolling passage, the direction changing passage and the escape hole constituting the rolling member circulation passage can be exactly determined. Accordingly, no staged portion is formed to the connection portion between the loaded rolling member rolling passage, the inner peripheral portion of the direction changing passage and the rolling member escape hole, thus smoothly circulating the rolling members.

Furthermore, when the position of the block body in the mold is determined, the contacting portion of the mold with the block body is minimally limited to the rolling member rolling groove by positioning it with reference to the rolling member rolling groove, and the other portions of the mold can be maintained with non-contact state, which requires no precise working, thus easily performing manufacturing process.

BRIEF DESCRIPTION OF DRAWINGS

FIGS. 1 through 5 shows a rolling guide apparatus according to one embodiment of the present invention, in which: FIG. 1(*a*) is a vertical sectional view and FIGS. 1(*b*) to 1(*d*) show structures of a ball circulation passage;

FIG. 2(*a*) is a perspective view of an outer appearance of the rolling guide apparatus of FIG. 1 and FIG. 2(*b*) is a disassembled perspective view of a movable block;

FIGS. 3A–3K show a disassembled perspective view of the block body and a molded body of the movable block of the rolling guide apparatus of FIG. 1;

FIGS. 4*a*–4*k* shows the movable block body of the rolling guide apparatus of FIG. 1, in which FIG. 4(*a*) is a front view, FIG. 4(*b*) is a side view, FIG. 4(*c*) is a sectional view taken along the line C—C of FIG. 4(*a*) and FIG. 4(*d*) is a sectional view taken along the line D—D of FIG. 4(*b*); and

FIG. 5 shows a side cover of the rolling guide apparatus of FIG. 1, in which FIG. 5(*a*) is a front view, FIG. 5(*b*) is a sectional view taken along the line B—B of FIG. 5(*a*), FIG. 5(*c*) is backside view, FIG. 5(*d*) is a sectional view taken along the line D—D of FIG. 5(*c*), FIG. 5(*e*) is a sectional view taken along the line E—E of FIG. 5(*c*) and FIG. 5(*f*) is a end view along the line F—F of FIG. 5(*b*).

FIGS. 6*a*–6*c* is a view showing a manufacturing process of the movable block of the rolling guide apparatus of the present invention.

FIG. 7 shows a rolling guide apparatus according to another embodiment of the present invention, in which FIG. 7(*a*) is a vertical sectional view, FIG. 7(*b*) is a view showing an endless type retainer and FIG. 7(*c*) is a plan view partially broken away.

FIG. 8 shows a structure of a further rolling guide apparatus utilizing the endless type retainer of FIG. 7, in which FIG. 8(*a*) is a vertical sectional view, FIG. 8(*b*) is a plan view and FIG. 8(*c*) is a view showing the retainer.

FIGS. 9(*a*) to (*g*) represent structures of various types of the rolling guide apparatus of the present invention.

BEST MODE FOR EMBODYING INVENTION

The present invention will be described hereunder by way of the embodiments shown in the accompanying drawings.

FIGS. 1 and 2 represent a rolling guide apparatus of one embodiment according to the present invention.

The rolling guide apparatus 1 has a structure in which a movable block 2 is supported, through a plurality of balls as rolling members, by a guide rail 4 to be movable therealong.

The movable block 2 has a]-shape in section and is provided with a pair of leg portions 5, 5 between which the guide rail 4 is interposed and a horizontal portion 6 to which the leg portions 5, 5 are rigidly connected.

Four ball circulation passages 7 for guiding a number of balls 3 are formed to the movable block 2. In the illustrated example, two pairs of upper and lower circulation passages 7 are formed to the bilateral leg portions 5, 5, respectively.

Each of the respective ball circulation passages 7 is composed of a loaded ball rolling passage 8 defined by loaded ball rolling grooves 8*a*, 8*b* respectively formed to the opposing surfaces of the movable block 2 and the guide rail 4 and a return passage 9, formed in a non-loaded area, for returning the balls 3 from one end of the loaded ball rolling passage 8 to the other one end thereof.

Contact lines showing directions of contact angles of the four rows of the loaded balls incline in directions to be closed with respect to horizontal line towards the center of the guide rail 4. In such structure, the contact line means a line connecting contact portions of the balls contacting to the ball rolling grooves of the movable block and the guide rail, and the term "contact line" used hereinafter means the same content.

The return passage 9 formed to the non-loaded area is composed of a ball escape hole 10 extending in parallel to the loaded ball rolling passage 8 and a ball rolling direction changing passage 11 connecting both ends of the ball escape hole 10 to both the ends of the loaded ball rolling passage 8. The direction changing passage 11 is composed of an end surface cover portion 16 integrally joined with the end surface of a high rigid movable block body 13, to which the loaded ball rolling passage is formed, and a side cover 14 as an outer periphery constituting member.

In the illustrated embodiment, an escape hole forming portion 15 to which the ball escape hole 10 of the ball circulation passage, the end surface cover portion 16 and a retainer 17 extending along the loaded ball rolling passage are formed with a resin molded body 12 integrally with the high rigid block body 13.

The escape hole forming portions 15 are joined integrally with cutouts 18, substantially rectangular in section, formed to the bilateral side surfaces of the metallic block body 13, and the two rows of the upper and lower ball escape holes 10 are independently formed with space. Each of the ball escape holes 10 is entirely peripherally surrounded by the escape hole forming portion 15. In the illustrated embodiment, an inside portion 10*a* of the ball escape hole 10 is formed in arc shape, and this inside portion 10*a* is integrally connected with the end surface cover portion 16 integrally joined to the end surface of the block body 13.

The most simple structure of the end surface cover portion 16 is shown in FIG. 1(*c*) and comprises only an inner peripheral portion 19 of each of the direction changing passages which is connected with the inside portion 10*a* of the ball escape hole 10, but in the present embodiment, a staged protruded portion 20 fitted to the side cover 14 is formed, and an inner periphery guide surface 11*a* of the direction changing passage is formed in shape of recess to the staged protruded portion 20. Further, a central staged protruded portion 21 is formed to the end surface of the horizontal portion 6 of the block body 13 so as to connect the bilateral staged protruded portions 20, 20.

Recess-protrusion engaging portions 23 are formed to surfaces to be joined of the bilateral staged protruded portions 20 and the end surface of the block body 13 for preventing the mold forming member and the block body from positionally shifting from each other through their recess-protrusion engagement. Each of these recess-protrusion engaging portions 23 is composed of a recess 23*a* formed to the end surface of the block body 13 and a protrusion 23*b* fitted to the recess 23*a*.

Screw tap holes 20*a* are formed to the end surfaces of the bilateral staged protruded portions 20 for fastening the side covers 14. These screw tap holes 20*a* are formed to the end surfaces of the molded body 12, and on the other hand, tap prepared holes each having a diameter smaller than that of the tap hole 20*a* are formed, through resin formation, to the end surfaces of the block body 13 to positions corresponding to the screw tap holes 20*a*, respectively, and screw tap holes 20*a* are also formed to these prepared holes. The side covers 14 are formed with bolt insertion holes 22*a* through which bolts 22 are inserted and screw engaged with the screw tap holes 20*a*, thereby fastening the side covers 14.

The staged protruded portions 20 and the central protruded portion 21 are both formed with positioning holes 25 at their end faces at portions near the ball rolling direction changing portions 11, and the side covers 14 are formed with positioning projections 24, at their end surfaces, at portions near the ball rolling direction changing portions 11 corresponding to the positioning holes 25. These positioning projections 24 and holes 25 are engaged with each other when these members are joined together, whereby the outer peripheral side of the ball rolling direction changing portion 11 on the side cover side and the inner peripheral side of the ball rolling direction changing portion 11 on the mold forming member side of the block body 13 can be surely positioned.

The inner periphery of the ball escape hole 10 may have a simple circular section having a diameter slightly larger than that of the rolling ball, but a guide projection 10*b* as shown in FIG. 3(*c*) will be provided for constituting three-point contact structure, or a spline shape guide projection 10*c* as shown in FIG. 3(*b*) may be provided. Since the position of the ball is determined by three point support structure, it is desired to provide the guide projections contacting the ball at more than three points and portions other than the projections 10*b* and 10*c* may be formed as escape. It is desired that the gap between the ball outer periphery and a virtual circle connecting the tip ends of the projections 10*b* and 10*c* is made small so as to be approximately equal to the diameter of the ball.

According to this structure, the balls 3 are guided by the tip ends of these projections, thus preventing meandering motion of the balls 3.

. Furthermore, a lubrication agent such as grease in the ball escape hole 10 stays in a portion between the guide projections 10*b* and 10*c*, and accordingly, resistance caused by the lubrication agent during the rolling motion of the balls 3 through the escape holes 10 can be made small, thus the balls 3 being smoothly rolled with less obstruction of the lubrication agent.

Still furthermore, as shown in FIG. 3(*d*), a structure in which parallel two rows of the ball escape holes 10, 10 are connected with each other to prevent the balls 3 from clogging due to the presence of the lubrication agent. In this arrangement, the connection groove 10*d* acts as lubrication agent stay position so that the lubrication agent staying in front of the balls does not obstruct the rolling of the balls 3.

The ball escape hole 10 is formed so as to provide other various shapes in its section such as shown in FIGS. 3(*h*), (*i*) and (*j*) showing triangular shape, square shape and grooved circular shape, respectively. That is, in other words, it will be said that it is desired for the ball escape hole to have a non-circular section provided with a virtual circular section 10A as a rolling member passing section for passing the ball 3 as rolling member and a lubrication agent staying section 10B capable of storing the lubrication agent bled out from the virtual circular section 10A.

In the conventional drilling technology, it is impossible to form the ball escape hole having such section as mentioned above and such drilling working can be realized by the integral molding method according to the present invention.

Further, in order to make large the rotation radius of the ball in the direction changing passage 11, the both end portions of the ball escape hole forming portion is cut away at the outer peripheral portion of the ball escape hole **10** by a predetermined length, and according to the ball escape hole forming portion **15** of the above structure provided for the side cover **14**, the cutout portion **27** is covered to thereby connect the end portion of the ball escape hole **10** with the end portion of the direction changing passage **11**. That is, since the balls **3** can be circulated more smoothly by making possibly large the rotation radius of the direction changing passage, it will be not desired to adopt the structure having a small curvature.

The escape hole outer periphery forming portion **26** of the side cover **14** is formed with positioning projections **28** and the end surfaces of the cutout portions **27** formed to both the ends of the escape hole forming portions **15** of the mold forming member **12** are formed with positioning holes **29**, which are engaged with the projections **28** with each other. According to this structure, the ball escape holes **10** and the ball direction changing passages **11** are surely positioned at their outer peripheral and inner peripheral sides, providing no staged portion at the joined portions. Since the connection portions between the ball escape holes **10** and the direction changing passages **11** are formed as continuous guide surfaces with no staged portion, the smooth circulation of the balls **3** can be ensured. Particularly, as shown in FIG. 3(*e*), it is desired for the ball escape hole **10** to have an annular tapered projection **10*e*** and desired for the direction changing passage **11** to have a taper received portion **11*e*** which is circumferentially entirely engaged with the tapered projection **10*e*** as a faucet joint engagement. The tapered projection **10*e*** and the taper receiving portion **11*e*** are formed at the connection portion of the ball escape hole **10** and the direction changing passage **11**. According to this structure, the ball escape hole **10** and the direction changing passage **11** can be substantially completely joined together.

The retainer **17** acts to hold the balls **3** to prevent the balls **3** from falling off from the movable block **2** when the guide rail **4** is drawn out from the movable block **2**, and in the assembling state of the guide rail **4** and the movable block **2**, the retainer **17** is designed in its dimension so that a gap is formed between the retainer **17** and the balls **3** so as not to obstruct the rolling motion of the balls rolling in the loaded ball passage **8**.

In the described embodiment, the retainer **17** is disposed between the upper and lower two rows of loaded balls **3** formed to the bilateral leg portions **5**, **5** and includes a first retainer section **30** for holding the lower edge portion of the ball **3** in the upper row of balls **3** and the upper edge portion of the ball **3** in the lower row of balls **3**, a second retainer section **31** for holding the upper edge portion of the ball **3** of the upper row of balls **3** and a third retainer section **32** for holding the lower edge portion of the ball **3** of the lower row of balls **3**. The upper ball row is held by the first and second retainer sections **30** and **31** and the lower ball row is held by the first and third retainer sections **30** and **32**. The portions of the balls **3** are exposed between these first to third retainer sections **30**, **31** and **32** and contact the ball rolling groove **8*b*** on the guide rail side to be capable of freely rolling.

These retainer sections **30**, **31** and **32** are integrally connected, at their both ends, with the end surface cover portion **16**, and in the illustrated embodiment, the third retainer section **32** is integrally connected with the ball escape hole forming portions **15** of the bilateral leg portions **5**, **5** of the block body **13** through the lower surface cover portion **33** covering the lower side surfaces of the leg portions **5**, **5**.

The connection between the ball direction changing passage **11** and the loaded ball passage **8** is done by the manner such that each of the balls **3** is scooped gradually at bilateral two points by a tongue piece **34** having a boat shape serving as a guide suitable for scooping the ball **3** by invading the loaded area, the tongue piece **34** being provided at the outer peripheral end portion of the direction changing passage of the side cover **14**, thereby smoothly transferring the balls **3** to the direction changing passage **11** from the loaded ball passage **8**. That is, as shown in FIG. 3(*f*), the tongue piece **34** is provided with a groove **34*a*** having a width gradually reduced towards both the end portions, and as shown in FIG. 3(*g*), the ball **3** is supported at two points and the loaded ball **3** then rolls apart from the ball rolling groove **8*b*** of the guide rail **4**.

Accordingly, the ball **3** circulates to the direction changing passage **11** from the non-loaded ball hole **10** through the tapered projection and receiving portions **10*e*** and **11*e***, then, to the loaded ball passage **8** in the loaded area through the boat shaped tongue piece **34**, to the direction changing passage **11** at the end portion of the tongue piece **34** and again to the ball escape hole **10** through the tapered projection and receiving portions **10*e*** and **11*e***, thus the balls **3** being circulated in a rolling state through this circulation route. Thus, the connection portions of these portions are not formed with no staged portion to thereby smoothly perform the circulation of the balls **3**.

According to this structure, in which, as shown in FIG. 3(*b*), the ball escape hole **10** has at least three point contact structure by providing the guide projections **10*b***, **10*c***, the balls **3** roll from the two point contact state in the scooping operation of the boat bottom shaped tongue piece **34** to the three point contact structure, and an ideal ball rolling route can be established throughout the entire ball circulation passage, so that the balls **3** can be smoothly rolled therealong, and hence, generation of noise caused by unbalanced rolling of the balls **3** can be also minimized. In addition, since the idle ball rolling is also reduced, the noise can be minimized.

The movable block **2** of the rolling guide apparatus according to the present invention of the structure described above will be manufactured in the following manner.

A loaded ball rolling groove **8*a*** is preliminarily formed to the block body **13**, and the block body **13** is inserted into the mold **40** to integrally form the rolling member escape hole **10** to the block body **13** through the insertion molding process.

FIG. **6** shows a structure of the mold, which is formed with a cavity **41** for forming ball escape hole forming portions **15** outside the leg portions **5**, **5**, a cavity **42** for forming the retainers **17** inside the leg portions **5**, **5** and a cavity **43** for forming the inner peripheral portions of the direction changing passages **19** at both longitudinal ends of the leg portions **5**, **5**. A stationary mold half **44** is provided with a protruded portion **45** to be fitted to the ball rolling groove **8*a*** to position the same and a movable mold half **46** is provided with a pin **47** for forming the ball escape hole **10**.

At the time of the insertion molding process, as shown in FIG. **6**(*c*), the positioning inside the mold **40** is made with reference to the ball rolling groove **8*a*** of the block body **13**. According to this manner, when the insertion molding process is performed with reference to the ball rolling groove **8*a***, since the positioning of the ball escape hole **10** and the retainer **17** can be done, relative positional relationship among the loaded ball rolling passage **8**, the direction changing passage **11** and the ball escape hole **10** can be accurately established.

In addition, at the time of the positioning in the mold **40** for the block body **13**, if the positioning is performed with reference to the ball rolling groove **8***a*, the contact point to the block body **13** is minimally made to the ball rolling groove **8***a* and the other portions of the mold **40** are allowed to take non-contact arrangement and an accurate working is hence not required to these portions of the mold **40**, resulting in easy manufacture thereof.

Furthermore, the inner peripheral portion **19** of the direction changing passage can be integrally formed with the block body **13** together with the ball escape hole **10** through the insertion molding process.

The retainer **17** can be also integrally formed with the block body **13** together with the ball escape hole formation portion **15** and the end surface covering portion **16** through the insertion molding process.

Thereafter, the direction changing passage **11** can be completed at both the end portions of the loaded ball rolling groove **8***a* by assembling the side covers **14**.

According to the rolling guide apparatus of the structure described above, the ball escape hole forming portion **15** is integrally formed with the block body **13** as the mold forming body **12** through the insertion molding process, so that the drilling working for the ball escape hole **10** can be eliminated, thus making simple the manufacturing process.

Furthermore, since the integral molding can be realized through the molding process, any assembling process can be eliminated, thus reducing the assembling working.

Still furthermore, according to the present embodiment, the ball escape hole forming portion **15**, the end surface covering portion **16** and the retainer **17** are integrally formed as the mold forming body **12**, thus making more simple the manufacturing process.

According to the structure for enclosing the outer periphery of the block body **13**, a tensile stress is applied, by the shrinkage of the mold forming body **12**, to the retainer **17**, the escape ball forming portion **15** and the end surface covering portion **16**, and hence, the ball escape hole forming portion **15** and the retainer **17** are formed with high degree of straightness. Particularly, the ball **3** and the respective retainer sections are not contacted by the application of the tensile stress to the thin retainer sections for the upper side loaded ball and the lower side loaded ball, thus realizing smooth circulation of the balls **3**.

However, in a case where the retainer **17** is formed of a resin material, there is a case of causing a shifting in position by temporary lowering of the tensile stress by a creeping phenomenon, and for such case, the joining surfaces of the first retainer section **30** of the retainer **17** and the block body **13** are formed with recesses and protrusions so as to be firmly joined together through the engagement of these recesses and protrusions. This engagement structure is composed of an engaging groove **35** formed to the joining surface of the block body **13** so as to extend entirely along the axial direction of the block body **13** and an engaging protrusion **36** fitted to the engaging groove **35**. This engaging protrusion **36** is formed by invading the forming material into the groove **35** at the molding time. It will be of course noted that substantially the same engagement is realized to the joining surfaces between the second and third retainer sections **31**, **32** and the block body **13**.

Furthermore, according to the present embodiment, the thickness of the block constituting material such as metal constituting the block body **13** at its portion between the loaded ball rolling groove **8***a* to the ball escape hole **10** which affects on rigidity thereof can be made thin so as to provide an elastic property without changing the dimension between the ball rolling groove **8a** and the ball escape hole **10**, in other words, with the dimension suitable for the smooth direction changing operation being maintained, by forming the ball escape hole **10** by the resin molded body **12**. The thin thickness of the block body will be performed by making large the thickness of the circular portion as shown with two-dot chain line a in FIG. **1**(*a*) or by performing a linear cutting as shown with two-dot chain line b in FIG. **1**(*a*).

Accordingly, if an assembling error between the guide rail **4** and the movable block **2** (for example, misalignment such as assembling error due to an error in parallelism between the fixing surface of the guide rail **4** and the fixing surface of a conveyer table to be fixed to the movable block **2**) will be caused, such error can be absorbed through the flexibility of the thin leg portions of the block body **13** and the contact portion between the ball **3** and the ball rolling groove **8***a* is prevented from being applied by an excessive force.

The ball escape hole may be formed to a structure in which half of the ball escape hole **10** is integrally formed as shown in FIG. **3**(*k*). In such case, an effect due to the thin thickness of the block body will be expected in comparison with the drilling working to the metal block though this effect may be small in comparison with the above embodiment.

FIG. **7** represents another embodiment according to the present invention, in which like reference characters are added to elements or portions corresponding to those of the first mentioned embodiment and explanations thereof are omitted hereunder.

In this embodiment, one ball row is formed to each of bilateral leg portions **5** of the movable block **2**, and the balls **3** are held by means of an endless retainer **50** as shown in FIG. **7**(*b*).

The endless retainer **50** is a flexible belt-shaped member formed of a resin or like material, and a number of ball retaining holes **50***a* are formed with predetermined space from each other. The ball **3** is held by the inner peripheral surface of the respective ball retaining holes **50***a* to be freely rollable and slidable to thereby guide the balls along the entire periphery of the ball circulation passage **7**. Spacers **50***b*, each having a recess of spherical crown shape corresponding to an outer spherical shape of the ball, are disposed between adjacent ball retaining holes **50***a* so as to squeeze the ball **3** from both axial sides of the retainer **50**.

Since the endless retainer **50** is vibrated during the rolling motion of the balls **3**, retainer support members **55** to **58** are disposed linearly along the loaded ball rolling passage **8** to suppress the vibration thereof, and a guide groove **60** is also formed to the ball escape hole **10** for guiding both side edges of the endless retainer **50**.

In this embodiment of FIG. **7**, the ball escape hole forming portion **15**, the end surface covering portion **16** and the retainer support members **55** to **58** are formed integrally as the molded body **12**. The contact line of the left side ball **3** is inclined downward towards the central portion of the guide rail **4** by a predetermined angle with respect to the horizontal line H, and the contact line of the right side ball **3** is inclined upward towards the central portion of the guide rail **4** by a predetermined angle with respect to the horizontal line H. Thus, these contact lines are substantially in parallel to each other. In an arrangement of a certain contact angle case, there may appear a case wherein each of the retainer support members has a portion having insufficient thickness, so that a reinforcing member **60** such as metal plate may be embedded to such portion as occasion demands. In the illustrated embodiment, the reinforcing members **60** such as metal plates are embedded in the right upper retainer support member 56 and the left lower retainer support member 57.

An upper surface covering portion 51 for covering the upper surface of the block body 13 and an inner peripheral surface covering portion 54 for covering the upper surface of the inner periphery of the central recessed portion 13a of the block body 13 are provided to the block body 13. These covering members 51 and 54 are formed integrally through the end surface covering portion 16 to thereby achieve the reinforcement of the block body 13 and the resin portion formed integrally with the block body 13. The inner peripheral surface covering portions 54 are formed integrally with the left upper retainer support member 55 and the right upper retainer support member 56. Lower surface covering portions 61 for covering the lower surfaces of the leg portions 5, 5 of the block body 13 are also integrally provided to the block body 13 and formed integrally with the left and right lower retainer support members 57 and 58.

The upper surface of the block body 13 has a low level surface portion 52 and a high level surface portion 53 having a surface level higher than that of the lower level surface portion 52, and the high level surface portion 53 is formed as a bearing surface formed with a bolt hole 54 through which a fixing bolt is inserted for clamping, whereby the upper surface covering portion 51 is covered over the lower level surface portion 52 to make equal the surface level to that of the high level surface portion 53, providing a flat surface of the block body 13. In this embodiment, two high level surface portions 53 are provided in correspondence to the left and right leg portions 5, 5 of the block body 13, and three low level surface portions 52 are provided at an intermediate portion between the two high level surface portions 53 and at bilateral both end portions of the block body 13.

FIG. 8 shows an example of a structure which utilizes the endless retainer 50 described above.

In this example, the levels in arrangements of the left and right balls 3 are made different in a manner such that one of the ball rows is arranged to the right side edge of the upper surface of the guide rail 4 and the other one of the ball rows is arranged to the intermediate portion of the left side surface of the guide rail 4. The block body 13 is formed to have substantially an L-shape in section having one leg portion 5, and one of the ball escape holes 10 is formed to the right side portion of the upper surface of the horizontal portion 6 of the block body 13 and the other one of the ball escape holes 10 is formed to the leg portion 5. That is, a cutout 62 is formed to the right edge portion of the upper surface of the horizontal portion 6 of the block body 13, and the ball escape hole forming portion 15 formed of the resin material is integrally joined with the cutout 62 and the other ball escape hole forming portion 15 is integrally joined with a cutout 63 formed to the lower surface of the leg portion 5 and the corner portion of the left side surface thereof.

The left side surface covering portion 64 of the leg portion 5 and the left upper retainer support member 55 disposed to the inner periphery of the leg portion 5 are formed integrally through the front and rear end surface covering portions 16 so as to surround the leg portion 5. The inner side edge portion of the lower surface covering portion 61 for covering the lower surface of the leg portion 5 is integrally joined with the retainer support member 57 at the left side ball lower side edge portion. The escape ball hole forming portion 15 formed to the horizontal portion 6 and the lower surface covering portion 65 of the horizontal portion 6 are integrally joined together through the front and rear end surface covering portions 16 so as to vertically surround the horizontal portion 6. The lower surface covering portion 65 and the ball escape hole forming portion 15 are integrally formed through the right side surface covering portion 65 of the block body 13, and the inner side edge portion of the lower surface covering portion 65 is joined with the retainer support member 58 for the right lower ball row.

As described above, with the structure of the block body 13, only the portions necessary for the positioning are exposed and portions not required to form with high precision are covered with resin materials, so that portions of the block body 13 requiring cut working or the like are reduced, thus reducing manufacturing cost.

FIG. 9 shows a further example of arrangement of the present invention, in which like reference numerals are added to elements or portions corresponding to those of the former examples and explanations thereof are omitted herein.

FIG. 9(a) shows a structural example of the linear motion guide apparatus provided with four rows of ball circulation passages 7 as like the above first embodiment, in which the ball escape hole 10, the inner peripheral portion of the direction changing passage and the retainer 17 are integrally formed. This example differs from the former one in that the contact angle lines to the bilateral upper and lower two ball rows are opened towards the guide rail 4 with respect to the horizontal line.

In the illustrated embodiment, one retainer 17 is disposed between each of bilateral upper and lower ball rows.

An example shown in FIG. 9(b) has a structure in which the left and right leg portions such as shown in the embodiment of FIG. 1 are independently separated and which is utilized for conveying and guiding a table 66 or the like by using a pair of linear motion guide apparatus. In this structure, the ball escape hole 10, the direction changing passage inner peripheral surface 19 and the retainer 17 are also integrally formed.

An example shown in FIG. 9(c) has a structure in which the left and right leg portions 5 of the linear motion guide apparatus such as shown in FIG. 9(b) are independently separated. In this structure, the ball escape hole 10, the direction changing passage inner peripheral portion 19 and the retainer 17 are also integrally formed.

An example shown in FIG. 9(d) represents a structure of a linear motion guide apparatus provided with four ball rows including two rows formed to the upper surface of the guide rail 4 and respective one row formed to left and right side surfaces thereof, and in this arrangement, the ball escape hole 10, the direction changing passage inner peripheral portion 19 and the retainer 17 are integrally formed together.

In this example, the ball escape hole forming portion 15 of the molded body 12 is fitted in a lower hole 67 formed through the block body 13.

In such arrangement, however, high precision is not basically required with respect to the lower hole 67 to be formed to the block body 13, thus easily forming the same.

FIG. 9(g) is an example employing the structure of the lower hole 67 to the left and right two ball rows, and particularly, in this example, no retainer is provided and an engaging portion 68 performing recess-protrusion engagement for preventing the positional shifting is formed to the end surface of the block body 13 at the direction changing passage inner peripheral portion.

FIGS. 9(e) and 9(f) show examples of arrangements of the linear motion guide apparatus in which rollers 3' are used instead of the balls 3, and FIG. 9(*e*) shows a linear motion guide apparatus provided with four roller rows and FIG. 9(*f*) shows a linear motion guide apparatus provided with two roller rows.

With respect to the above examples, it is to be noted that the present invention is described with reference to the linear motion guide apparatus, but it is of course applicable to a linear guide rail slidably assembled with a curved motion guide rail, and as the molded body, a die cast product, sintered metal or the like other than resin material may be utilized.

According to the present invention having the structures and functions mentioned hereinbefore, since the rolling member escape holes are integrally formed with the block body through the molding process, the drilling working can be eliminated to thereby easily form the structure.

In addition, since the integral structure can be provided through the molding process, the assembling process can be reduced.

The degree of integral formation can be increased by integrally forming the inner peripheral portion of the direction changing passage with the ball escape hole, making easy the assembling process.

By integrally forming the rolling member escape hole, the inner peripheral portion of the direction changing passage and the retainer to surround the periphery of the block body, the tensile stress is applied, by the shrinkage of the molded portions, to the rolling member escape hole, the inner peripheral portion of the direction changing passage and the retainer, so that the degree of straightness of the rolling member escape hole and the retainer can be made high, and the generation of resonance noise, at the time of rolling member circulation, to the respective parts of the guide apparatus by residual tensile stress can be prevented.

The low noise frequency due to the rolling member circulation can be prevented from causing by the increasing of vibration frequency including mass of the block body.

Furthermore, the thickness of the block constituting material such as metal constituting the block body at its portion between the loaded rolling member rolling groove to the rolling member escape hole which affects on rigidity thereof can be made thin so as to provide an elastic property without changing the dimension between the rolling member rolling groove and the rolling member escape hole, in other words, with the dimension suitable for the smooth direction changing operation being maintained, by forming the rolling member escape hole by the molded resin body. Accordingly, if an assembling error between the guide rail and the movable block (for example, misalignment such as assembling error due to an error in parallelism between the fixing surface of the guide rail and the fixing surface of a conveyer table to be fixed to the movable block) be caused, such error can be absorbed through the flexibility of the thin portions of the block body and the contact portion between the rolling member and the rolling member rolling groove is prevented from being applied with an excessive force.

The rolling member escape hole is formed so as to provide a sectional shape having a rolling member passing section along which the rolling members roll and a lubrication agent storing section capable of storing lubrication agent bled outward from the rolling member passing section, and according to such structure of the rolling member escape hole, since the lubrication agent can be retained without obstructing the circulating motion of the rolling member, the smooth circulating motion thereof can be surely maintained for the long time operation with no substantial maintenance. Furthermore, the escape hole having such complicated sectional shape can be easily formed through the molding process.

The positioning of the block body inserted into the mold is performed with reference to the rolling member rolling groove through the insertion molding process, and accordingly, since the position of the rolling member escape hole and the position of the retainer can be determined with reference to the rolling member rolling groove, the relative positional relationship among the loaded rolling member rolling passage, the direction changing passage and the escape hole constituting the rolling member circulation passage can be exactly determined. Accordingly, no staged portion is formed to the connection portion between the loaded rolling member rolling passage, the inner peripheral portion of the direction changing passage and the rolling member escape hole, thus smoothly circulating the rolling members.

Furthermore, when the position of the block body in the mold is determined, the contacting portion of the mold to the block body is minimally limited to the rolling member rolling groove by positioning it with reference to the rolling member rolling groove, and the other portions of the mold can be maintained with non-contact state, which requires no precise working, thus easily performing manufacturing process.

We claim:

1. A rolling guide apparatus in which a movable block is supported to be movable along a guide rail through a number of rolling members, a circulation passage for guiding circulation of the rolling members is formed to the movable block, said rolling member circulation passage being composed of a loaded rolling member rolling passage in a loaded area between loaded rolling member rolling grooves formed to opposing surfaces of the movable block and the guide rail and a non-loaded return passage for returning the rolling members in the loaded area from one end of the loaded rolling member rolling passage to another one end thereof, said return passage being composed of a rolling member escape hole extending in parallel to said loaded rolling member rolling passage and a direction changing passage having inner and outer peripheral portions connecting both ends of the rolling member escape hole to both ends of the loaded rolling member rolling passage,

said rolling guide apparatus being characterized in that at least one of said rolling member escape hole, said inner peripheral portion of the direction changing passage and a retainer extending along the loaded rolling member rolling passage is formed of a molded body and said molded body is integrally formed with a block body having high rigidity.

2. A rolling guide apparatus according to claim 1, wherein said molded body is provided with the rolling member escape hole and the inner peripheral portion of the direction changing passage integrally connected to the rolling member escape hole and joined with both end surfaces of the block body.

3. A rolling guide apparatus according to claim 1, wherein said molded body is provided with the rolling member escape hole and the retainer extending along the loaded rolling member rolling passage.

4. A rolling guide apparatus according to claim 1, wherein said molded body is provided with the inner peripheral portion of the direction changing passage joined with both end surfaces of the block body and the retainer extending along the loaded rolling member rolling passage and integrally connected at its both ends with the inner peripheral portion of the direction changing passage.

5. A rolling guide apparatus according to claim 1, wherein said molded body is provided with the rolling member escape hole, the inner peripheral portion of the direction changing passage integrally connected to the rolling member escape hole and joined with both end surfaces of the block body and the retainer extending along the loaded rolling member rolling passage and integrally connected at its both ends with the inner peripheral portion of the direction changing passage, said molded body having a closed sectional shape surrounded by said rolling member escape hole, said direction changing passage and said retainer.

6. A rolling guide apparatus according to any one of claims 1, 2, 3, 4 and 5, wherein recess-protrusion engaging portion is formed to joining surfaces of the molded body and the block body.

7. A rolling guide apparatus according to any one of claims 1, 2, 3, 4 and 5, wherein said molded body is formed of a resin material, and a portion between the loaded rolling member rolling groove and the rolling member escape hole of the movable block is formed as one portion of the resin molded body so as to define a reduced thickness in the high rigid block body to provide an elastic property.

8. A rolling guide apparatus according to any one of claims 1, 2, 3, 4 and 5, wherein the rolling members rolling in the loaded rolling member rolling passage are scooped by a guide, each in two point contact state, extending in the loaded area of the direction changing passage from the loaded rolling member rolling groove to the direction changing passage in a manner of being separated gradually apart from each other.

9. A rolling guide apparatus according to any one of claims 1, 2, 3, 4 and 5, wherein the movable block is provided with a pair of leg portions between which the guide rail is interposed and a connection portion connecting said leg portions, and the rolling member circulation passages are formed to said leg portions.

10. A rolling guide apparatus according to claim 9, wherein a covering portion is provided for covering at least one of upper and lower surfaces of the connection portion of the movable block and said covering portion is integrally formed with the inner peripheral portion of the direction changing passage joined with both the end surfaces of the block body.

11. A rolling guide apparatus according to any one of the preceding claims 1 to 5, wherein said rolling member escape hole has a sectional shape having a rolling member passing section through which the rolling member passes and a lubrication agent storing section capable of storing a lubrication agent bled outward from the rolling member passing section.

12. A method of manufacturing a movable block, which is supported to be movable with respect to a guide rail through a number of rolling members, of a rolling guide apparatus provided with loaded rolling member rolling grooves formed to opposing surfaces of the movable block and the guide rail, a rolling member escape hole extending in parallel to the loaded rolling member rolling grooves, and a direction changing passage having inner and outer peripheral portions connecting both ends of the rolling member escape hole to both ends of the loaded rolling member rolling passage,

said manufacturing method being characterized in that said block body is placed in a mold, and at least one of said rolling member escape hole, said inner peripheral portion of the direction changing passage and a retainer extending along the loaded rolling member rolling passage is formed integrally with the block body through an insertion molding process.

13. A movable block manufacturing method according to claim 12, wherein the rolling member escape hole and the inner peripheral portion of the direction changing passage are integrally formed together through the insertion molding process.

14. A movable block manufacturing method according to claim 12, wherein the rolling member escape hole and the retainer extending along the loaded rolling member rolling passage are integrally formed together through the insertion molding process.

15. A movable block manufacturing method according to claim 12, wherein the inner peripheral portion of the direction changing passage and the retainer extending along the loaded rolling member rolling passage are integrally formed together through the insertion molding process.

16. A movable block manufacturing method according to claim 12, wherein the rolling member escape hole, the inner peripheral portion of the direction changing passage, and the retainer extending along the loaded rolling member rolling passage are integrally formed together through the insertion molding process.

17. A movable block manufacturing method according to any one of claims 12 to 16, wherein said block body is positioned in the mold with reference to the rolling member rolling groove formed to the movable block.

[57] **ABSTRACT**

A rolling guide unit comprises a movable member provided with a pair of support portions extending from lateral end portions of a main body portion so as to provide a recessed portion between the main body portion and both the support portions, a guide rail disposed in the recessed portion of the movable member so that side surfaces of the guide rail face the inner surfaces of the support portions, respectively, and a number of rolling members disposed to be rollable between corresponding rolling member rolling grooves formed to the guide rail and the support portions of the movable member so that each of the rolling members contact the rolling member rolling grooves at two contact points and the the rolling members apply load to the rolling member rolling grooves, the movable member and the guide rail being relatively movable through the rolling of the rolling members. Each of the rolling member rolling grooves has an arcuate shape in section having radius of curvature larger than that of the rolling member and the contact points are displaceable along the arcuate shape of the rolling member rolling groove.

FIG. 21

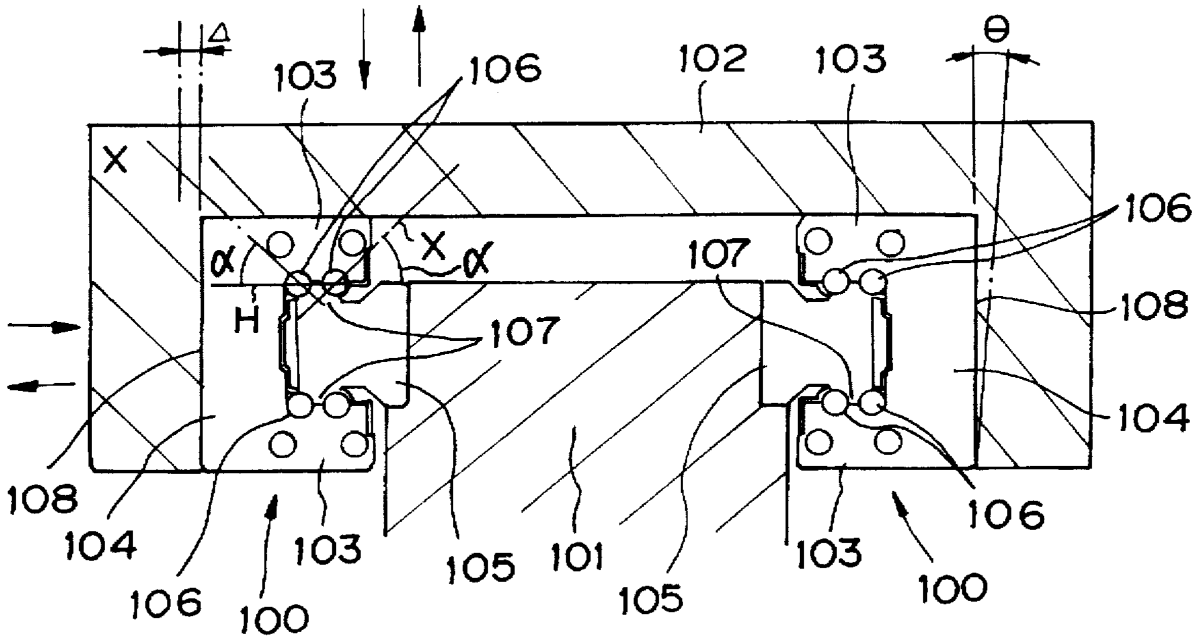

FIG. 22 PRIOR ART

ROLLING GUIDE UNIT

BACKGROUND OF THE INVENTION

The present invention relates to a rolling guide unit of rolling contact type linear or curved, such as circular, guide passage, particularly capable of being excellent in misalignment adjustment performance.

As a known example of such rolling guide unit, there is provided an example shown in FIG. 22 in which a rolling guide unit **100** is disposed so as to guide a table **102** with respect to a fixed base **101**.

The rolling guide unit **100** is assembled in a manner that a movable member **104** having a U-shape in cross section is provided with a pair of upper and lower support portions **103** extending in a lateral direction, i.e. longitudinal direction of the movable member, and upper and lower surfaces of a guide rail disposed in the U-shaped hollow portion of the movable member **104** are supported by the support portions through upper and lower two rows of balls **106**. In general, high rigidity is required for such rolling guide unit, and in the known art, the rigidity in every direction including vertical and horizontal directions is made high by applying a preload to the balls **106** and forming projecting ribs **107** to the upper and lower side surfaces of the guide rail **105** so as to project therefrom thereby to clamp the ribs **107** by the respective two rows of the balls **106** from the upper and lower directions thereof. Particularly, in the illustrated example, in order to equally support the load in every direction, a contact angle α of a line X connecting contacting points of the ball **106** to two ball rolling grooves with respect to a virtual horizontal line is set to 45°.

The known rolling guide unit of the type shown in FIG. 22, however, has high rigidity, and accordingly, when a working error, for example, an angular error θ and a dimensional error Δ in the horizontal direction, is caused to a mounting surface of the movable member **104**, a misalignment is caused between the guide rail **105** and the movable member **104** at the time of clamping and fixing the rolling guide unit between the table **102** and the fixed base **101**. Such misalignment constitutes a cause of an application of excessive force to the movable member **104**, resulting in the increasing of a sliding resistance and abrasion of the balls **106** and the ball rolling grooves, thus providing a problem.

Such misalignment will be avoided by increasing the working performance of the respective members of the rolling guide unit. However, the increasing of the working performance has a limit itself and involves cost increasing.

In the meantime, the misalignment will be somewhat reduced by making small the preload to be applied to the balls **106**, but the high rigidity of the rolling guide unit will be reduced by making small the preload to be applied. As mentioned above, the requirement of the high supporting rigidity is contrary to the reduction of the misalignment of the members, and hence, in the prior art construction, it is difficult to satisfy both the requirements for the realization of the high rigidity and the less misalignment.

SUMMARY OF THE INVENTION

An object of the present invention is to substantially eliminate defects or drawbacks encountered in the prior art described above and to provide a rolling guide unit capable of absorbing misalingment in a horizontal direction while maintaining vertical rigidity of the unit and also maintaining an allowable load bearing ability.

This and other objects can be achieved according to the present invention by providing a rolling guide unit comprising:

- a movable member provided with a main body portion and a pair of support portions extending from lateral end portions of the main body portion so as to provide a recessed portion between the central portion and both the support portions, the support portions having inner surfaces to which rolling member rolling grooves are formed;
- a guide rail disposed in the recessed portion of the movable member so that side surfaces of the guide rail face the inner surfaces of the support portions, respectively, the side surfaces of the guide rail being formed with rolling member rolling grooves at portions corresponding to the rolling member rolling grooves of the support portions, respectively; and
- a number of rolling members disposed to be rollable between the corresponding rolling member rolling grooves of the guide rail and the support portions of the movable member so that each of the rolling members contact the rolling member rolling grooves at two contact points and the the rolling members apply load to the rolling member rolling grooves, the movable member and the guide rail being relatively movable through the rolling of the rolling members,
- wherein each of the rolling member rolling grooves has an arcuate shape in section having radius of curvature larger than that of the rolling member and the contact points are displaceable along the arcuate shape of the rolling member rolling groove.

In preferred embodiments, the rolling member is a ball and each of the rolling member rolling grooves has a depth of approximately ¼ to ½ of a diameter of the ball.

A plurality of rolling member rolling grooves are formed at least one of the side surfaces of the guide rail and at least corresponding one inner surface of the support portion of the movable member.

An initial contact angle constituted by a line connecting the two contact points of the rolling members to the rolling member rolling grooves and a horizontal line passing a center of the rolling member is set substantially 90°.

A plurality of rolling member rolling grooves are formed at least one of the side surfaces of the guide rail and at least corresponding one inner surface of the support portion of the movable member, and an initial contact angle constituted by a line connecting the two contact points of the rolling members in at least one of the plurality of rolling member rolling grooves to this rolling member rolling groove and a horizontal line passing a center of the rolling member is set so as to have an inclination by a predetermined angle with respect to the angle of substantially 90°. All the rolling members disposed in the plurality of rolling member rolling grooves have contact angles inclined in the same direction or in directions reverse to each other.

A plurality of rolling member rolling grooves are formed at least one of the side surfaces of the guide rail and at least corresponding one inner surface of the support portion of the movable member, and the rolling members disposed in at least one of the plurality of rolling member rolling grooves are formed as tubular members and the rolling member rolling groove in which the tubular members are rolled is formed so as to provide a flat groove bottom. The rolling member rolling grooves for the tubular members are formed to the inner surfaces of the support portions so as to provide a groove bottom shape corresponding to an outer shape of the tubular member and the side surfaces of the guide rail for the tubular members are formed to be flat. Three rows of the rolling member grooves are formed and a central one is formed for the tubular members.

The guide rail has substantially rectangular cross section and is bent in a curved shape or has substantially linear shape.

Retainer means are disposed between the facing inner surfaces of the support portions of the movable member and the side surfaces of the rail guide.

The support portions are integrally formed with the main body portion of the movable member. The support portions may be independently formed with the main body portion of the movable member and the support portions are fixed to the main body portion of the movable member by means of bolts. The support portions have extending lengths different from each other and the numbers of rows of the rolling members of the respective support portions are different from each other.

According to the structures and characters of the rolling guide unit according to the present invention described above, the vertical load is born by the rolling members disposed between the upper and lower, as viewed in the illustrations of the drawings, support portions of the movable member and the guide rail. Particularly, in an arrangement in which the initial contact angle of the rolling member is set to approximately 90°, a vertical large load can be effectively born. When a horizontal load is applied, the contact points of the rolling member to the rolling member rolling groove are displaced to change the contact angle by the load balance between the vertical load and the horizontal, i.e. lateral, load, thereby to effectively bear both the loads.

With respect to the misalignment in the horizontal direction, the contact points of the rolling members are displaced along the arcuate shape of the rolling member rolling groove thereby to absorb the misalignment.

Since the rolling member rolling groove has an arcuate shape in section, the allowable load is represented by a sine function with a contact angle being variable. According to the present invention, the contact angle is set to a value near 90° about which the sine function shows a curve having a gentle variation, so that the allowable load varies small in amount even if the contact angle varies.

Since the depth of the rolling member rolling groove is set to a value approximately ¼ to ½ of the diameter of the rolling member such as ball, the ball does not contact the edge portions of the groove even if the contact points are displaced, and hence, the edge load is eliminated.

Furthermore, according to the present invention, the guide rail can be prevented from forming with a complicated cross section such as provided with projection ribs as in a conventional structure and the rolling member rolling grooves can be worked through a horizontal grinding working. Particularly, when the guide rail having a curved shape is formed, it can be formed so as to provide a simple rectangular shape, thus being uniformly bent.

In the case of contact angle of 90°, the contact points are displaced by the application of the horizontal load, and the variation of the contact points can be absorbed immediately by changing the initial contact angle in accordance with the load to be applied. The contact angle can be changed to an optional value by applying a horizontal load of predetermined amount, and for example, the horizontal load can be born by setting the contact angle to, for example, 30° or 45° in accordance with the load to be applied. In such case, since the contact points of the rolling member to the rolling member rolling groove can be displaceable, the misalignment can be effectively absorbed.

The nature and further characters of the present invention will be made more clear through the following descriptions made with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

In the accompanying drawings:

FIG. 1 represents one embodiment of a rolling guide unit according to the present invention, in which FIG. 1A is a cross-sectional view of the guide unit, FIG. 1B is a view showing a contacting condition of a ball to a ball rolling groove of FIG. 1A in an enlarged scale, and FIG. 1C is a view similar to FIG. 1B at a time when loads are applied to the ball in both horizontal and vertical directions as viewed;

FIG. 2 includes FIGS. 2A, 2B and 2C, in which FIG. 2A is a perspective view of a portion of a guide rail of the guide unit in FIG. 1A, FIG. 2B is a side view, partially broken away, of FIG. 2A, and FIG. 2C is a partial sectional view showing an assembled arrangement of a retainer;

FIG. 3 is an illustration of a support portion for a railway rolling stock to which the rolling guide unit of the present invention is applicable;

FIG. 4 includes FIGS. 4A and 4B, in which FIG. 4A is an illustration of an entire railway rolling stock to which the rolling guide unit of the present invention is applicable and FIG. 4B is an enlarged view of the rolling guide unit of FIG. 4A;

FIG. 5 includes FIGS. 5A, 5B and 5C, in which FIG. 5A is a view showing a condition of movement of a contacting point of the ball to the ball rolling groove, FIG. 5B is a sine function graph with the contact angle of the ball being variable, and FIG. 5C is a view in an enlarged scale at a point near the contact angle of 90° in FIG. 5B;

FIG. 6 includes FIGS. 6A to 6H for the explanatory of steps for absorption of misalignment by means of the rolling guide unit according to the present invention in this order;

FIG. 7 includes FIGS. 7A to 7C representing structures of other embodiments of the rolling guide unit according to the present invention;

FIG. 8 represents a further embodiment of the rolling guide unit according to the present invention, in which FIG. 8A is a side view thereof and FIGS. 8B to 8E show various types of rolling members;

FIG. 9 represents an embodiment of a rolling guide unit of linear guide type according to the present invention, in which FIG. 9A is a side view of the linear guide type rolling guide unit and FIG. 9B is a perspective view of a guide rail to which the guide unit of FIG. 9A is mountable;

FIG. 10 is a sectional view of a partial portion of another embodiment of the rolling guide unit in which a support structure is constructed as a separate member;

FIGS. 11A and 11B are schematic views showing the support structure of a movable member capable of increasing supporting rigidity both in the horizontal and vertical directions by utilizing the rolling guide unit according to the present invention;

FIG. 12 is a schematic view of the rolling guide unit representing one example of a tandem contact structure;

FIG. 13 is a schematic view, similar to that of FIG. 12, representing another example of the tandem contact structure;

FIG. 14 is a schematic view of the rolling guide unit representing one example of a DF type compound contact structure;

FIG. 15 is a schematic view representing another example of the DF type compound contact structure;

FIG. 16 is a schematic view of the rolling guide unit representing one example of a DB type compound contact structure;

FIG. 17 is a schematic view representing another example of the DB type compound contact structure;

FIG. 18 is a schematic view of the rolling guide unit representing one example of a compound contact structure of both the DF type and DB type;

FIG. 19 is a schematic view representing another example of the compound contact structure of both the DF type and DB type;

FIG. 20 is a schematic view showing a further example of the contact structure;

FIG. 21 is a schematic view showing a still further example of the contact structure; and

FIG. 22 is a cross sectional view of a table moving apparatus utilizing a rolling guide unit of conventional structure.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

It is first to be noted that the terms "upper" and "lower" used herein for the following respective embodiments or examples are made with reference to the corresponding illustrations of the accompanying drawings.

FIGS. 1 and 2 represent one embodiment of the present invention, and this embodiment will be preferably described hereunder with reference to an example of a rolling guide unit for guiding on a curved line a pendulum type vehicle such as railway rolling stock such as shown in FIGS. 3 and 4.

As shown in FIGS. 3 and 4, the rolling guide unit **1** is one usable for the curve guide for a vehicle body such as railway rolling stock, and a pair of such rolling guide units **1**, **1** are oppositely arranged for supporting the vehicle body **3** swingably on a bogie **2**. Each of the rolling guide unit **1** comprises as shown in FIGS. 1 and 2, a guide rail **4** and a movable member **6** assembled with the guide rail **4** so that the movable member **6** is movable along the guide rail **4** through rolling members **5** having a spherical outer shape such as balls.

The guide rail **4** has, as shown in FIG. 2A, rectangular section and is bent in an arcuate shape so as to provide a predetermined radius of curvature. The guide rail **4** has upper and lower (as viewed) side surfaces to which ball rolling grooves **7** are formed entirely therealong. The ball rolling grooves **7** are formed in three rows in the illustrated example on the upper and lower sides as shown in FIG. 2A. One row, two rows or more than three rows of the ball rolling grooves may be formed. The invention is not limited to the illustrated three-row arrangement.

Each of the ball rolling grooves **7** has an arcuate cross section having a radius of curvature larger than that of the ball **5** and has a depth of about ¼ to ½ of the diameter of the ball **5**.

The movable member **6** is formed of a block member provided with a pair of supporting portions **61** and **62** which extend sideway substantially perpendicularly from a central portion thereof so as to entirely provide a]-shaped cross section, and as shown in FIG. 2A, the movable member **6** is assembled with the guide rail **4** so that the supporting portions **61** and **62** are positioned on both the upper and lower sides of the guide rail **4** to be movable therealong. Each of the supporting portions **61** and **62** are formed with ball rolling grooves **8** corresponding to the ball rolling grooves **7** formed to the guide rail **4** in their positions and numbers. Each of the ball rolling grooves **8** also has an arcuate cross section having a radius of curvature larger than that of the ball **5** and has a depth of about ¼ to ½ of the diameter of the ball **5**.

When assembled, the balls **5** are disposed between these ball rolling grooves **7** and **8** each so as to contact at two points CP, in FIG. 1B or 1C, near groove bottoms thereof, and an angle α constituted by a line connecting these two contact points CP and a virtual horizontal line is set to approximately 90°. Accordingly, the contact points CP of the ball **5** is bilaterally displaceable with the position of contact angle α of 90° being the center of this displacement.

As shown in FIG. 2B, the movable member **6** comprises a main body **10** of the movable member **6**, having the supporting portions **61** and **62**, and side covers **12** mounted to front and rear end portions of the main body **10**. The movable member main body **10** is provided with return passages **9** in an unloaded region for circulating the balls **5** in addition to the ball rolling grooves **8**, **8**, and each of the side covers **12** is formed with a ball turning passage **11** for changing the ball rolling direction.

The left side, as viewed in FIG. 1A, surface of the movable member **6** is formed as a mounting surface **13** to which tap holes **14** for fixing bolts **13** are formed. The right side, as viewed in FIG. 1A, surface of the guide rail **4** is formed as a mounting surface **16** which is fixed by means of bolts, not shown. Seal members **15** are disposed to the gaps between the inside surfaces of the upper and lower supporting portions **61** and **62** of the movable member **6** and the upper and lower side surfaces of the guide rail **4**, and retainers **24** for holding the balls **5** are also disposed between these gaps as shown in FIG. 2C.

Preload is applied to the balls **5** by a suitable means.

In the rolling guide unit of the structure described above, load Fa applied in a vertical direction, as viewed in FIG. 1C, is born by three row of balls **5** having the initial contact angle of 90°. On the other hand, when a load Fb from the horizontal direction is born by the balls **5** having the displaced contact angle of α' at which the line X' connecting the contact points CP of the balls **5** to the ball rolling grooves **7** and **8** substantially accords with a direction of composite vector F of the vertical load Fa and the horizontal load Fb. In the thus manner, the vertical and horizontal loads are applied to the balls **5** at the displaced contact angle α'.

In this embodiment, since the ball rolling grooves **7** and **8** are formed so as to provide the arcuate cross sections and the ball contact angle α is set to approximately 90°, variation of allowable load is small even if the contact angle α be changed.

That is, the allowable load will be expressed as follows.

$$Co=f(Da \cdot z \cdot i \cdot \sin \alpha)$$

Da: diameter of ball

z: number of balls

i: number of ball rows

α: contact angle (90° in the perpendicular case)

As shown in FIG. 5B, the allowable load is expressed as sine function. A sine curve varies gently, as shown in FIG. 5C, at a portion near 90°, and the sine function value is 1 at the contact angle α of 90°; 0.998 of 87°; 0.996 of 85°; and 0.992 even of 83°. This means that even if the contact angle varies in the range of 90°±7°, the reduction ratio of the allowable load is less than 1%, being very small, and of course, the displacement of the allowable contact angle can be properly selected.

In addition, since the depth h of the ball rolling grooves 7 and 8 are made deep as mentioned hereinbefore, the ball 5 does not contact the edge E of the ball rolling groove 7 as shown in FIG. 5A even if the contact points CP are displaced, thus preventing the edge load from occurring. The depth h of the groove is determined in consideration of the edge load, but it is preferred to set the depth h to approximately ¼ to ½ of the diameter of the ball 5.

The misalignment absorbed according to the present invention basically corresponds to displacement of the guide rail and the movable member in the horizontal direction, and it is possible to absorb the following misalignments as shown in FIG. 6: (1) a misalignment in the rotating direction about the central axis of the guide rail 4 (MC direction in FIG. 6A); a misalignment in the rotating direction reversely changing the front and rear end portions of the movable member 6 (MA direction in FIG. 6C); and a misalignment in the direction displacing the movable member 6 in the horizontal direction (Z direction in FIG. B) .

The above misalignements are caused by, for example, a working error of the mounting surface of the movable member 6 as shown in FIG. 3 and an error caused by an angular error θ or dimensional error Δ in the horizontal direction. In addition, an error in degree of parallelism of the bilateral guide rails 4, 4 and an excessive clamping of the fastening bolt may also cause the misalignments.

FIGS. 6D to 6H represent the change of the contact angles in the absorption of the misalignments. FIG. 6D represents a position at which the initial contact angle α of 90° being the reference value preliminarily set, FIGS. 6E and 6F represent a position at which the misalignment in the MC direction is absorbed and the contact angle is displaced in a direction reverse to the rotating direction, and FIGS. 6G and 6H represent a position at which the misalignment in the Z direction is absorbed and the contact angle is displaced in a direction reverse to the first displaced direction.

In the meantime, when the misalignment in the MC direction is absorbed, the front and rear end portions of the movable member 6 are displaced in the horizontal direction reverse to each other, and the contact angle of the ball 5 positioned at the front and rear end portions of the movable member 6 are displaced in directions reverse to each other as shown in FIGS. 6G and 6H.

As discussed above, since the contact angle is initially set to approximately 90°, it is not necessary as in the conventional technology for the guide rail to be formed with complicated structure having a projection, and since the ball rolling groove 7 can be ground by a horizontal grinding technique, the guide rail can be easily manufactured. In the case where a plurality of ball rolling grooves 7 are formed, they can be formed with high performance of a pitch between adjacent ones. Furthermore, since the grinding allowance is constant along the entire length of the guide rail 4 and hence is easily measured, the ball rolling grooves 7 can be worked so as to provide a smooth finishing surface with high performance.

Particularly, when the guide rail 4 is formed to provide a curved line shape, since it is not necessary to form the guide rail with the projected rib 107, and the guide rail is formed so as to provide a simple rectangular shape, a plastical deformation in a bending working can uniformly progress with substantially no camber, thus being easily manufactured, and accordingly, the grinding allowance in the finishing working can be minimally suppressed, thus being effective in production.

FIG. 7 represents other embodiments of the present invention.

FIG. 7A shows an embodiment, in which the upper end surface 17 of the movable member 6 and the lower end surface 18 of the guide rail 4 are formed as mounting surfaces of the movable member 6 and the guide rail 4, respectively, and these members are fastened each by means of single fixing bolt 19 in the vertical direction as viewed. In the structure of FIG. 7B, two fixing bolts 19 are utilized respectively for the movable member 6 and the guide rail 4, respectively. In the embodiment of FIG. 7C, two fixing bolts 19 are utilized for the movable member 6 and single fixing bolt 19 is utilized for the guide rail 4. The numbers of rows of the balls 5 are different between the upper side surface and the lower side surface of the guide rail, and in the illustrated embodiment, three ball rows are formed on the upper side surface of the guide rail 4 and two ball rows are formed on the lower side surface thereof.

FIG. 8 represents a further embodiment of the present invention, which has a basic structure essentially identical to that of the embodiment shown in FIG. 1 and only has a different point that the balls rolling along the central ball rolling groove 7 in FIG. 1 are substituted with cylindrical rollers 20 rolling along a rolling groove 21.

In accordance with this structural difference, the roller rolling groove 21 for the rollers 20 formed to the inside surfaces of the supporting portions 61 and 62 of the movable member 6 is formed so as to provide a rectangular cross section so as to accord with the shape or the cylindrical roller 20. The bottom of the groove 21 is made flat accordingly. On the other hand, any roller rolling groove for the rollers 20 is not formed to the upper and lower side surfaces of the guide rail 4 and the upper and lower surfaces thereof are directly utilized for the roller rolling surface as they are.

According to this structure of the embodiment of FIG. 8, the rollers 20 can move in the horizontal direction along the upper and lower side surfaces of the guide rail 4, and hence, the misalignment in the horizontal direction can be absorbed by the embodiment of FIG. 1. In addition, according to this embodiment of FIG. 8, a larger load in the vertical direction can be born in comparison with the structure of the embodiment of FIG. 1, thus being more advantageous.

Furthermore, the misalignments in the horizontal (Z) direction and the MA direction of the kind shown in FIGS. 6B and 6C can be absorbed in the same manner as described with reference to the embodiment of FIG. 1, and the misalignment in the MC direction shown in FIG. 6A does not constitutes a problem since the rollers 20 are positioned at the central portion of the guide rail side surface and the displacement of the roller 20 is hence small in comparison with the bilateral side ones.

However, since there may be a slight fear of causing the edge load at the end portion of the roller 20, a crowning treatment will be effected to the edge portion 21 as shown in FIG. 8C, or barrel shaped roller having a central portion swelled in section such as shown in FIG. 8D may be utilized, as occasion demands. In the case where the barrel shaped rollers 20 are utilized, it is necessary to form the roller rolling groove so as to provide an arcuate cross section having a radius of curvature larger than that of the barrel roller 20.

In a modification, the barrel shaped rollers 20 or spherical, partially cut away, rollers 23 shown in FIG. 8E may be utilized in substitution for the ball rollers 5.

In the forgoing description, the embodiments of the curved line guiding structure were provided, the present invention is not limited to such curved line guiding structure and it can be applied as it is to the rolling guide units 1A for the linear guiding structure as shown in FIG. 9. That is, in comparison with the curved line guiding structure, the curved guide rail 4 is constructed to a linear guide rail 4A and the respective ball rolling grooves are formed linearly so as to accord with the linear guide rail 4A, and the other structure is the same as that of the former embodiment.

Furthermore, in the first described embodiment, the supporting portions 61 and 62 are formed integrally to the central portion of the movable member 6, but these portions may be independently formed as shown in FIG. 10, for example. That is, the supporting portion 61 is fixed to the main body 63 (FIG. 10) of the movable member 6 by a fastening means 64 such as bolt. Both these portions or either one of these portions may be independently formed from the main body 63 of the movable member 6.

In the present invention, the horizontal gap is formed between the ball and the ball rolling grooves for absorbing the misalignment of the ball. However, this gap may be eliminated by applying a horizontal preload, and in such arrangement, the horizontal supporting rigidity will be increased.

FIG. 11 shows an example increasing the horizontal supporting rigidity.

Referring to the example of FIG. 11, a movable table 31 is movably supported by a fixed table 30 through a pair of opposing rolling guide units 1, 1, and the movable table 31 is formed with skirt portions 32 and 33, as supporting portions, extending downward, as viewed, from both the bilateral ends thereof. The paired rolling guide units 1, 1 are mounted between the inner surfaces of the skirt portions 32 and 33 and the outer side surfaces of the fixed table 30.

In order to apply a preload to the structure shown in FIG. 11A, in one example, a preload adjusting bolt 34 may be screwed to one of the skirt portion 32, for example, thereby to push the side surface of one of the rolling guide unit 1 against the guide rail 4 fixed to the fixed table 30, whereby the horizontal gap between the balls 5 and the ball rolling grooves 7 and 8 is eliminated, thus applying the horizontal preload in a state shown in FIG. 11B. In a modification, a tapered wedge member, for example, not shown, may be inserted forcibly into the gap between the facing surfaces of the skirt portion 32 and the movable member 6 of the rolling guide unit 1, thus also applying the horizontal preload.

That is, when one of the movable members 6 of the rolling guide unit 1 is pressed through one 32 of the skirt portions of the movable table 31 by, for example, the preload adjusting bolt 34, a reaction force of the pressing force is transferred to the other one 33 of the skirt portions through the movable table 31, and then, the other movable member 6 of the other rolling guiding unit 1 is pressed against the guide rail 4, fixed to the fixed table 30 through the other skirt portion 33. Through this preload applying process, in the illustration of FIG. 11A, the contact angles a of the upper and lower balls in the right rolling guide unit 1 are displaced such that the upper ball 5R1 is rotated clockwisely from the initial contact angle 90° position and the lower ball 5R2 is rotated counterclockwisely therefrom. On the other hand, the contact angles α of the upper and lower balls in the left rolling guide unit 1 are also displaced such that the upper ball 5L1 is rotated counterclockwisely from the initial contact angle 90° position and the lower ball 5L2 is rotated clockwisely therefrom. In the thus manner, the horizontal gap between the respective balls 5 can be eliminated.

In the assumption that lines connecting the contact points of the respective balls 5R1, 5R2 5L1 and 5L2 and the ball rolling grooves 7 and 8 into which theses balls disposed constitute contact angle lines XR1, XR2, XL1 and XL2, upper and lower these contact angle lines in the right and left

rolling guide units 1, 1 are inclined outward of the guide units as shown in FIG. 11A.

According to the arrangement of the ball contact angles, the supporting rigidity in the vertical direction can be improved as well as that in the horizontal direction.

Therefore, according to the rolling guide unit of the present invention, the supporting structure having improved load bearing performance in the vertical and horizontal directions, i.e. every direction, can be realized as well as achieving the misalignment absorbing performance.

FIGS. 12 to 21 represent various examples each having such a contact angle structure as mentioned above of a plurality of ball rows, typically through examples of the upper and lower three ball rows.

FIG. 12 shows an example of tandem type, which has the respective upper and lower three rows, total six rows, of balls and the contact angles in the same directions as in the example of FIG. 11.

That is, as like in FIG. 3, a vehicle body 203 is movably supported by a bogie 202 through a pair of rolling guide units 201, 201. The paired rolling guide units 201, 201 have guide rails 204, 204 opposing to each other on the inner side, vehicle body side, thereof and movable members 206, 206 opposing to each other on the outer side thereof such that the inner side surfaces of the guide rails 204, 204 are fixed to the mounting surface of the vehicle body 203 and the outer side surfaces and the lower surfaces of the movable members 206, 206 are fixed to stepped mounting portions 202A, 202A formed to the bogie 202.

Each of the stepped portions 202A, 202A has an L-shaped cross section having a horizontal mounting surface 218 to which the lower side surface of the movable member 206 is fixed and a perpendicular mounting surface 213 to which the outer side surface of the movable member 206 is fixed.

Each of the movable members 206, 206 has substantially a]-shaped cross section having a pair of upper and lower supporting portions 261 and 262 extending in a horizontal direction as viewed in FIG. 12, and each of the guide rails 204, 204 having substantially rectangular cross section is fitted into a]-shaped recessed portion of the corresponding movable member 206 from the horizontal direction.

The balls as rolling members in respectively three rows are rollably disposed between the facing surfaces of the upper and lower supporting portions 261 and 262 and the guide rails 204, 204. Supposing that the upper and lower respectively three rows of balls are referred to as upper first, second and third balls 5A1, 5A2 and 5A3 and lower first, second and third balls 5B1, 5B2 and 5B3 from the inner side to the outer side as in the illustration of FIG. 12, these upper and lower balls have the same diameters and are arranged linearly symmetrically respectively with respect to a horizontal axis H passing the center of the guide rails 204, 204.

The upper first, second and third balls 5A1, 5A2 and 5A3 and the lower first, second and third balls 5B1, 5B2 and 5B3 are rollablY disposed between upper first, second and third ball rolling grooves 207A1, 208A1; 207A2, 208A2; 207A3, 208A3, and the lower first, second and third ball rolling grooves 207B1, 208B1; 207B2, 208B2; 207B3, 208B3 of the upper and lower supporting portions 261, 262 of the movable member 206 and the corresponding upper and lower side surfaces of the guide rails 204.

In such example of tandem type structure, the upper first, second and third ball rolling grooves 207A1, 208A1; 207A2, 208A2; 207A3, 208A3 formed to the upper supporting portion 261 and the upper side surface of the guide rail 204 are formed so as to provide the same phases and pitches as those of the lower first, second and third ball rolling grooves

207B1, 208B1; 207B2, 208B2; 207B3, 208B3 formed to the lower supporting portion 262 and the lower side surface of the guide rail 204. In a free arrangement of the balls, the initial contact angles of the upper first, second and third balls 5A1, 5A2 and 5A3 and lower first, second and third balls 5B1, 5B2 and 5B3 are made to substantially 90°.

In the illustrated example, the outer side surface of the movable member 206 of one of the rolling guide units 201 is pressed against the guide rail 204 mounted to the vehicle body side by means of a preload adjusting bolt such as shown in FIG. 6 or by using a tapered wedge member thereby to eliminate the horizontal gap between the balls 5A1 . . . , 5B1 . . . and the ball rolling grooves 207A1, 208A1; 207B1, 208B1 . . . , whereby a horizontal preload is applied, thereby inclining the balls by a predetermined angle with respect to the initial contact angle 90° to the ball rolling grooves.

That is, the ball contact angles α of the upper first, second and third balls 5A1, 5A2 and 5A3 of the right side rolling guide unit 201 are displaced clockwisely in the illustration from the initial contact angle 90°, and the ball contact angles α of the lower first, second and third balls 5B1, 5B2 and 5B3 of the right side rolling guide unit 201 are displaced counterclockwiselY in the illustration from the initial contact angle 90°. On the contrary, with respect to the upper and lower balls 5 of the left side rolling guide unit 201, the contact angles have linear symmetric arrangement with respect to the central perpendicular line between the right and left side rolling guide units 201, 201, and the contact angles of the upper first, second and third balls 5A1, 5A2 and 5A3 are displaced in the counterclockwisely in the illustration and the contact angles of the lower first, second and third balls 5B1, 5B2 and 5B3 are displaced clockwisely. In thus manner, the horizontal gaps of the respective balls can be eliminated, and the contact angle lines XR1, XR2, XR3 and XL1, XL2, XL3 of the upper and lower balls of the right and and left side rolling guide units 201 are inclined to be opened outward.

As described above, the example of FIG. 12 represents the tandem type structure which has the respectively upper and lower three rows, total six rows, of balls having the contact angles in the same direction. In a modified example, as shown in FIG. 13, the inclination of the contact angle lines may be set in directions reverse to those of FIG. 12.

That is, referring to FIG. 13, the contact angle lines XR1, XR2, XR3 and XL1, XL2, XL3 of the upper and lower balls of the right and and left side rolling guide units 201 are inclined to be opened inward. A structure having such contact angle arrangement will be easily realized by applying a force in the direction to outwardly draw out the movable member from the guide rail 204.

The basic structure of such tandem type example is identical to that shown in FIG. 6 in which the single row of balls are disposed at each of upper and lower sides, and accordingly, a moment load caused by the mounting error and eccentric load are not born, so that any inner load is not caused by such moment, thus being advantageous. That is, when the moment load MC acts, the movable member is moved in an inclined state in the direction of an arrow in FIG. 13.

Furthermore, according to this example, even in a case where the degree of parallelism between two axes of the respective guide rails are out of order, only the ball contact point varies and no forcible force acts on the balls, thus absorbing a geometric distortion of the parallelism between the axes of the guide rails.

Loads in the vertical and horizontal directions may be easily uniformly born.

According to the arrangement of the ball contact angles described above, the supporting rigidity in the horizontal direction can be improved as well as in the vertical direction. Accordingly, the rolling guide unit of these examples, the misalignment of the balls can be absorbed as well as realizing the support structure having high load bearing ability in the horizontal and vertical, i.e. every, directions in its use.

FIGS. 14 to 19 represent other examples of compound contact type structure in which the ball contact structure of respectively upper and lower three rows of balls is adapted such that at least one pair of balls of the upper or lower side rows have contact angles inclined reversely to each other. In such a compound contact type structure, the moment load caused by the mounting error or eccentric load can be born by one movable member.

As the basic structures of these examples are substantially identical to that of FIG. 12, the same reference numerals are added to members or portions corresponding to those of FIG. 12 and the descriptions thereof are omitted herein, and only the direction of the contact angle is referred to hereunder.

Elastic members 250 and 251 made of such as rubber material are interposed between the horizontal mounting surface 218 of the mounting stepped portion of the bogie and the lower side surface of the movable member 206, that is, between the perpendicular mounting surface 213 and the outer side surface of the movable member 206 for the purpose of absorbing the mounting error or the like. Of course, these mounting surfaces may be directly secured without interposing such elastic members 250 and 251.

In the example of FIG. 14, the contact angle lines are symmetrically inclined by predetermined angles with respect to the initial angle 90° so that the contact angle lines XA1 and XA2 of the upper first and second balls 5A1 and 5A2 are opened upward in the illustration and the contact angle lines XB1 and XB2 of the lower first and second balls 5B1 and 5B2 are opened downward. The contact angle line XA3 of the upper third ball 5A3 and the contact line XB3 of the lower third ball 5B3 are set in parallel to the contact angle lines XA2 and XB2 of the upper and lower second balls 5A2 and 5B2, respectively.

Such ball contact structure will be realized, for example, by setting a pitch P1 between the upper and lower first ball rolling grooves 207A1 and 207B1 and the upper and lower second ball rolling grooves, 207A2 and 207B2 of the upper and lower supporting portions 261 and 262 to be smaller than a pitch P2 between the upper and lower first ball rolling grooves 208A1 and 208B1 and the upper and lower second ball rolling grooves 208A2 and 208B2 of the guide rails 204, and also setting a pitch between the upper and lower second ball rolling grooves 207A2 and 207B2 and the upper and lower third ball rolling grooves 207A3 and 207B3 of the upper and lower supporting portions 261 and 262 to be equal to a pitch between the upper and lower second ball rolling grooves 207A2 and 207B2 and the upper and lower third ball rolling grooves 207A3 and 207B3 of the guide rails 204.

As described above, by adopting the ball contact structure of a pair of angular contact arrangement, the gap can be adjusted and the initial contact angle is made stable at the time of assembling the guide rail 204 and the movable member 206.

FIG. 15 shows an example in which an angle between the upper and lower contact angle lines are opened outward, in which an angle of the contact angle lines XA2 and XA3 of the upper second and third balls 5A2 and 5A3 and an angle of the contact angle lines XB2 and XB3 of the lower second and third balls 5B2 and 5B3 are opened outward.

In the example of FIG. 16, the contact angle lines are symmetrically inclined by predetermined angles with respect to the contact angle of 90° so that an angle between the contact angle line XA1 and XA2 of the upper first and second balls **5A1** and **5A2** is opened inward toward the inner guide rail **204**, and an angle between the contact angle line XB1 and XB2 of the lower first and second balls **5B1** and **5B2** is opened inward toward the inner guide rail **204**. On the other hand, the contact angle lines XA3 and XB3 of the upper and lower third balls **5A3** and **5B3** are set to be substantially parallel to the contact angle lines XA2 and XB2 of the upper and lower second balls **5A2** and **5B2**, respectively.

Such ball contact structure will be realized, for example, by setting a pitch P1 between the upper and lower ball rolling grooves **207A1** and **207B1** and the lower second ball rolling grooves **207A2** and **207B2** of the upper and lower supporting portions **261** and **262** to be larger than a pitch P2 between the upper and lower first ball rolling grooves **208A1** and **208B1** and the upper and lower second ball rolling grooves **208A2** and **208B2** of the guide rails **204**, and also setting a pitch between the upper and lower second ball rolling grooves **207A2** and **207B2** and the upper and lower third ball rolling grooves **207A3** and **207B3** of the upper and lower supporting portions **261** and **262** to be equal to a pitch between the upper and lower second ball rolling grooves **207A2** and **207B2** and the upper and lower third ball rolling grooves **207A3** and **207B3** of the guide rails **204**.

FIG. 17 shows an example in which an angle between the upper and lower contact angle lines are opened inward, in which an angle of the contact angle lines XA2 and XA3 of the upper second and third balls **5A2** and **5A3** and an angle of the contact angle lines XB2 and XB3 of the lower second and third balls **5B2** and **5B3** are opened inward.

Examples of FIGS. 18 and 19 shows an arrangement in which angles between respectively adjacent contact angle lines XA1, XA2, XA3, XB1, XB2 and XB3 are opened alternately outward and inward.

That is, FIG. 18 shows an example in which angles between the contact angle lines XA1 and XA2 of the upper first and second balls **5A1** and **5A2** and between the contact angle lines XB1 and XB2 of the lower first and second balls **5B1** and **5B2** are opened inward, and angles between the contact angle lines XA2 and XA3 of the upper second and third balls **5A2** and **5A3** and between the contact angle lines XB2 and XB3 of the lower second and third balls **5B2** and **5B3** are opened outward.

FIG. 19 shows an example in which angles between the contact angle lines XA1 and XA2 of the upper first and second balls **5A1** and **5A2** and between the contact angle lines XB1 and XB2 of the lower first and second balls **5B1** and **5B2** are opened outward, and angles between the contact angle lines XA2 and XA3 of the upper second and third balls **5A2** and **5A3** and between the contact angle lines XB2 and XB3 of the lower second and third balls **5B2** and **5B3** are opened inward.

In these examples, the numbers of ball rows, the numbers of the balls in each ball row, and the ball diameter are optionally selected in accordance with a load to be applied. For example, regarding the numbers of the ball rows, as shown in FIG. 20, two ball rolling grooves corresponding to the upper and lower first and third balls **5A1**, **5A3** and **5B1**, **5B3**.

Furthermore, the contact structure of the respective balls of the upper and lower supporting portions **261** and **262** are made linearly symmetrical with respect to the horizontal axis, it is not always necessary to adapt the linear symmetric structure, and as shown in FIG. 21, in accordance with the load to be applied, an arrangement different in ball rows may be adapted such that two rows of the second and third balls **5A2** and **5A3** are formed on the upper side and three rows of the first, second and third balls **5B1**, **5B2** and **5B3** are formed on the lower side.

Further, it is to be noted that, in the above respective embodiments or examples, the rolling guide units are referred to for the guide support mechanism of a railway rolling stock, but the present invention is not limited to such specific utilization and many other applications may be adapted for guide mechanisms of, for example, various industrial robots or the like.

What is claimed is:

1. A rolling guide unit comprising:

a movable member provided with a main body portion and a pair of upper and lower support portions extending from lateral end portions of the main body portion so as to provide a recessed portion between the main body portion and both the support portions, said support portions having inner surfaces to which rolling member rolling grooves are formed;

a guide rail disposed in the recessed portion of the movable member so that upper and lower side surfaces of the guide rail face the inner surfaces of the support portions, respectively, the upper and lower side surfaces of said guide rail being formed with rolling member rolling grooves at portions corresponding to the rolling member rolling grooves of the upper and lower support portions, respectively, and

a number of rolling members disposed to be rollable between the corresponding rolling member rolling grooves of said guide rail and said upper and lower portions of the movable member so that each of the rolling members contact the rolling member rolling grooves at two contact points and the rolling members apply load to the rolling member rolling grooves, said movable member and the guide rail being relatively movable through the rolling of the rolling members,

wherein each of said rolling member rolling grooves has an arcuate shape cross section having radius of curvature larger than that of the rolling member and the contact points are displaceable along the arcuate shape of the rolling member rolling groove; and

wherein a plurality of rolling member rolling grooves are formed in at least one of the upper and lower side surfaces of the guide rail and at least one corresponding inner surface of the support portions of the movable member, and at least one pair of said plurality of rolling members have contact angles inclined in directions reverse to each other with respect to an initial contact angle of 90°.

2. A rolling guide unit assembly which comprises a first member and a second member disposed in an opposing arrangement to the first member to be relatively movable along the first member through a pair of rolling guide units arranged to bilateral side surfaces of said first member,

said pair of rolling guide units comprising:

guide rails respectively secured to both side surfaces of said first member;

a movable member secured to said second member disposed so as to oppose bilateral side surfaces of said guide rails and having a pair of upper and lower support portions extending along lateral side portions thereof by which the guide rails are clamped at upper and lower side surfaces thereof; and a number of rolling members disposed rollably in rolling member rolling grooves formed in the upper and lower side surfaces of the guide rails and opposing surfaces of the upper and lower support portions of the movable member in a manner facing correspondingly,

wherein each of said rolling member rolling grooves has a circular section having a curvature larger than a radius of each of the rolling members so that the rolling members are movable along the circular shape of the rolling member rolling grooves, a plurality of rolling member rolling grooves are formed at least one of the upper and lower side surfaces of the guide rail, and the contact angles of a plurality of rolling members disposed on the upper side surface or the lower side surface are bilaterally symmetrical and have at least a pair of inclinations reversely inclined to each other with respect to the rolling guide units, respectively.

3. A rolling guide unit comprising:

a movable member provided with a main body portion and a pair of upper and lower support portions extending from lateral end portions of the main body portion so as to provide a recessed portion between the main body portion and both the support portions, said support portions having inner surfaces to which rolling member rolling grooves are formed;

a guide rail disposed in the recessed portion of the movable member so that upper and lower side surfaces of the guide rail face the inner surfaces of the support portions, respectively, the upper and lower side surfaces of said guide rail being formed with rolling member rolling grooves at portions corresponding to the rolling member rolling grooves of the upper and lower support portions, respectively; and

a number of rolling members disposed to be rollable between the corresponding rolling member rolling grooves in said guide rail and said upper and lower support portions of the movable member so that each of the rolling members contact the rolling member rolling grooves at two contact points and the rolling members apply load to the rolling member rolling grooves, said movable member and the guide rail being relatively movable through the rolling of the rolling members,

wherein each of said rolling member rolling grooves has an arcuate shape cross section having a radius of curvature larger than that of the rolling member and the contact points are displaceable along the arcuate shape of the rolling member rolling groove;

wherein an initial contact angle formed between a line connecting the two contact points on the rolling members to the rolling member rolling grooves and a horizontal line passing through a center of the rolling member is set to substantially 90°;

wherein a plurality of rolling member rolling grooves are formed at least on one of the upper and lower side surfaces of the guide rail and at least one corresponding inner surface of the support portions of the movable member, and the rolling members disposed in at least one of the plurality of rolling member rolling grooves are formed as cylindrical members and the rolling member rolling groove in which the cylindrical members are rolled is formed so as to provide a flat groove bottom; and

wherein three rows of the rolling member grooves are formed and a central one is formed for the cylindrical members.

4. A rolling guide unit assembly which comprises a first member and a second member disposed in an opposing arrangement to the first member to be relatively movable along the first member through a pair of rolling guide units arranged to bilateral side surfaces of said first member,

said pair of rolling guide units comprising:

guide rails respectively secured to both side surfaces of said first member;

a movable member secured to said second member disposed so as to oppose to bilateral side surfaces of said guide rails and having a pair of upper and lower support portions extending along lateral side portions thereof by which the guide rails are clamped at upper and lower side surfaces thereof; and

a number of rolling members disposed rollably in rolling member rolling grooves formed in the upper and lower side surfaces of the guide rails and opposing surfaces of the upper and lower support portions of the movable member in a manner facing correspondingly,

wherein each of said rolling member rolling grooves has a circular section having a curvature larger than a radius of each of the rolling members so that the rolling members are movable along the circular shape of the rolling member rolling grooves, and

wherein each of the guide rails of the paired rolling guide units has a cross section substantially rectangular and bent to provide an arcuate portion and said guide rails support the first member relatively swingable with respect to the second member.

5. A rolling guide unit assembly which comprises a first member and a second member disposed in an opposing arrangement to the first member to be relatively movable along the first member through a pair of rolling guide units arranged to bilateral side surfaces of said first member,

said pair of rolling guide units comprising:

guide rails respectively secured to both side surfaces of said first member;

a movable member secured to said second member disposed so as to oppose to bilateral side surfaces of said guide rails and having a pair of upper and lower support portions extending along lateral side portions thereof by which the guide rails are clamped at upper and lower side surfaces thereof; and

a number of rolling members disposed rollably in rolling member rolling grooves formed in the upper and lower side surfaces of the guide rails and opposing surfaces of the upper and lower support portions of the movable member in a manner facing correspondingly,

wherein each of said rolling member rolling grooves has a circular section having a curvature larger than a radius of each of the rolling members so that the rolling members are movable along the circular shape of the rolling member rolling grooves,

wherein each of the guide rails of the paired rolling guide units has a cross section substantially rectangular and bent to provide an arcuate portion and said guide rails support the first member relatively swingable with respect to the second member, and

wherein said first member is a pendulum type vehicle and said second member is a railway rolling stock which is swingably supported by the vehicle.

6. A rolling guide unit assembly which comprises a first member and a second member disposed in an opposing arrangement to the first member to be relatively movable along the first member through a pair of rolling guide units arranged to bilateral side surfaces of said first member,

said pair of rolling guide units comprising:

guide rails respectively secured to both side surfaces of said first member;

a movable member secured to said second member disposed so as to oppose to bilateral side surfaces of said guide rails and having a pair of upper and lower support portions extending along lateral side portions thereof by which the guide rails are clamped at upper and lower side surfaces thereof; and

a number of rolling members disposed rollably in rolling member rolling grooves formed in the upper and lower side surfaces of the guide rails and opposing surfaces of the upper and lower support portions of the movable member in a manner facing correspondingly,

wherein each of said rolling member rolling grooves has a circular section having a curvature larger than a radius of each of the rolling members so that the rolling members are movable along the circular shape of the rolling member rolling grooves,

wherein each of the guide rails of the paired rolling guide units has a cross section substantially rectangular and bent to provide an arcuate portion and said guide rails support the first member relatively swingable with respect to the second member; and

wherein said first member is fixed to a pendulum type vehicle and said second member is fixed to a pantograph.

[57] **ABSTRACT**

In a linear motion slide unit, it is usable under a heavy load with high precision, or in a light load, an over-stroke amount can be made large. The linear motion slide unit comprises an elongated inner rail having high rigidity, a pair of outer rails attached to be reciprocally movable in an axial direction of the inner rail, and linear motion guides of endless track type structure disposed to be slidable with respect to the inner rail and fixed to the outer rails. A bearing body of the linear motion guide has also high rigidity, and accordingly, the balls mounted inside the endless track is applied with a large preload.

SLIDE UNIT FOR LINEAR MOTION

This application is a continuation of application Ser. No. 07/961,721 filed as PCT/JP92/00610, May 13, 1992, now abandoned.

TECHNICAL FIELD

This invention relates to a slide unit for a linear motion to be used for a slide portion such as a drawer, and more particularly to a linear motion slide unit with high performance for a heavy load.

BACKGROUND TECHNOLOGY

In office tables, peripheral devices for computers, copying machines, measuring instruments, telecommunication equipments, medical instruments, various office equipments, and the like, slide portions are utilized by over-stroking them over entire lengths of rails.

A slide unit for linear motion is utilized as a mechanical element for smoothly and precisely performing such sliding operation of the slide portion.

FIG. 4 represents a typical one example of a slide unit **50** for the linear motion of a conventional structure.

The linear motion slide unit **50** is generally composed of a pair of inner rails **60**, **60** secured back to back to each other, a pair of outer rails **70**, **70** attached to the inner rails **60**, **60** respectively to be axially reciprocal, a number of balls **80** interposed between corresponding inner and outer rails **60** and **70** in rolling contact to the rails, and a retainer **90** for holding the balls **80** in a predetermined positional relationship.

The inner and outer rails **60** and **70** are formed of steel plates subjected to a precise roll-forming process, and these rails **60** and **70** are formed with ball rolling grooves **61**, **61** and **71**, **71** on upper and lower surfaces thereof so as to oppose to each other.

The retainer **90** is formed with a number of holes **91** corresponding in numbers to the balls **80** and, hence, since the balls **80** are arranged with equal spaces with each other always, respectively, the balls **80** are free from the mutual friction, thus obtaining a smooth sliding mechanism.

Then, a case where such linear motion slide unit **50** is applied to a slide portion of a drawer of, for example, an office table will be described hereunder.

One of the paired outer rails **70** is fastened to a body **110** of the office table by means of bolt or the like and the other one of the rails **70** is fastened to a side surface of the drawer **100** of the office table by means of bolt or the like. A possible extending length of the drawer **100** is determined to be equal to an over-stroke amount of the other one of the outer rails **70** with respect to one of the outer rails **70**. As shown in FIG. **5**(*a*), it is assumed that the linear motion slide unit **50** be composed of a portion X_1 in which a number of balls **80** are disposed and both side slidable portions X_2. As shown in FIG. **5**(*b*), when the drawer is fully drawn out, the front end of the other one of the outer rails **70** can be drawn out from the front end of one of the outer rails **70** by an amount four times of the length of the portion X_2. Accordingly, the over-stroke amount of the linear motion slide unit **50** is made long as the length of the portion X_2 is possibly extended, and in other words, as the length of the portion X_1, is possibly made short.

In the slide unit **50** for the linear motion, since the balls **80** are held always with equal space between adjacent ones by the retainer **90** formed by a precise pressing operation, the balls are free from the mutual friction and can be rolled smoothly.

However, in recent years, there has been required to utilize such kind of linear motion slide unit for a sliding portion on which a heavy load is applied. The described linear motion slide unit **50** is not suitable for the heavy load, and therefore, development of a linear motion slide unit capable of withstanding the heavy-load has been required.

In the case of requiring an increased over-stroke amount, as described above, the length of the portion X_1, will be shorten. However, in the conventional linear motion slide unit, less number of balls **80** are utilized or less amount of a preload is applied in the present technology in this art, so that there is a limit for making short the length of the portion X_1.

DISCLOSURE OF THE INVENTION

This invention aims to solve the problems of the prior art described above and to provide a slide unit for linear motion capable of withstanding a heavy load with high precision.

This invention is characterized by comprising an elongated inner rail, a pair of outer rails attached to be reciprocally movable in an axial direction of the inner rail and linear motion guides supported slidable with respect to the inner rail through a number of rolling members and secured to the paired outer rails, the linear motion guides being formed with endless tracks in which the rolling members are endlessly circulated.

The linear motion guides comprise a bearing body provided with rolling member rolling grooves opposing to rolling member rolling grooves formed to the inner rail and return passages for non-loaded rolling members and a pair of side covers secured to both end surfaces of the bearing body and provided with rolling member returning grooves connecting the opposing rolling member rolling grooves of the bearing body and the return passages for the non-loaded rolling members to thereby constitute endless tracks.

It is preferred that the bearing body is a block member having a U-shaped cross section having a central recessed portion into which the inner rail is inserted, and rolling member rolling grooves are formed to the bilateral inner side surfaces of the central recessed portion so as to oppose to those formed to the opposing surfaces of the inner rail.

In addition, it is preferred that the inner rail and the bearing body are formed of a material having high rigidity and a preload is applied to the rolling members.

Furthermore, it is preferred that each of the linear motion guides is provided with a preload adjustment mechanism for adjusting the preload to be applied to the rolling members.

Still furthermore, each of the preload adjusting mechanisms provided for the linear motion guide is characterized by comprising a recessed portion for adjustment formed to the central portion of a surface to which the outer rail of the bearing body is fixed and an adjustment bolt screwed in a screw hole bored to the bottom surface of the preload adjustment recessed portion through a through hole formed to the outer rail, and in that the adjustment recessed portion is pulled towards the outer rails by fastening the adjustment bolt, a moment is caused to the bearing body by this pulling force in a direction narrowing a gap between bilateral inner side surfaces of the central recessed portion to thereby apply the preload to the rolling members, and an amount of the preload of the rolling members is made adjustable in accordance with the fastening force of the adjustment bolt.

Since the endless track is formed, it is possible to increase in number the rolling members withstanding the load, thus withstanding the heavy load. Furthermore, the rigidity of the linear motion guide can be improved by applying the preload to the rolling members mounted in the endless track, and accordingly, the rigidity of the slide unit for the linear motion can be improved.

Since the linear motion guide having such endless track is utilized, the load withstanding ability to the heavy load can be increased, and in the case of the over-stroke under the heavy load, the slide unit can be utilized without causing a gap between the respective members, and that is, in the case of the heavy load, precise and smooth sliding motion can be achieved.

Furthermore, in the case of the light load, the effective length of the linear motion guide can be shortened, and accordingly, the amount of the over-stroke can be made large.

Particularly, by applying the preload to the rolling members, the load withstanding ability against the heavy load can be improved, so that a more large preload can be applied by constituting the inner rail and the bearing body by a member having high rigidity.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. **1** and **2** represent a linear motion slide unit according to one embodiment of this invention, in which righthand half of the linear motion slide unit of FIG. **1** is a view taken along the line A—A of FIG. **2** and a lefthand half thereof is a view taken along the line B—B in FIG. 2, and FIG. **2** is a front view, partially eliminated, of the linear motion slide unit.

FIG. **3** is an illustration for the explanatory of the preload adjustment.

FIG. **4** is a perspective view of a conventional linear motion slide unit, partially omitted.

FIG. **5** is a view for the explanatory of an over-stroke amount of the linear motion slide unit.

BEST MODE FOR EMBODYING THE INVENTION

The details of the linear motion slide unit according to this invention will be described hereunder with reference to the accompanying drawings.

With reference to FIGS. **1** and **2**, one embodiment of the linear motion slide unit of this invention is shown.

As shown in these figures, a linear motion slide unit **1** of this invention generally comprises an elongaged inner rail **10** having high rigidity, a pair of outer rails **20** attached to be reciprocally movable in an axial direction of the inner rail **10**, and linear motion guides **30** secured fixedly to the outer rails **20** and slidably to the inner rail **10**.

The inner rail **10** is manufactured by cold-drawing a steel material. The inner rail **10** is formed with two rows of ball rolling grooves **11** on its upper and lower surfaces. The ball rolling grooves **11** are subjected to hardening treatment to apply sufficient hardness.

Each of the outer rails **20** has substantially a U-shaped cross section and has a longitudinal length slightly larger than that of the inner rail **10**. Each of the outer rails **10** is formed with a plurality of holes **21** for attachment and the outer rail **20** is secured to an office table body or a side surface of a drawer, for example, by means of bolts. The central portion of the outer rail **20** is formed with a through hole **22** provided with a back facing through which an adjustment bolt **40** for adjusting the preload amount to the balls, as described hereinlater.

Linear motion guides **30** disposed between the inner rail **10** and the respective outer rails **20** are of endless track type structure having high rigidity. In the illustrated embodiment, two linear motion guides **30** are mounted with respect to one outer rail **20** as shown in FIG. **2**.

The linear motion guide **30** is itself known in this art field and comprises a bearing body **31** made of iron steel, a pair of side covers **32**, **32** mounted in abutment to both end surfaces of the bearing body **31** and a number of balls **33** as rolling members.

The bearing body **31** is manufactured by cold-drawing a steel material. A recessed portion **31*a*** for receiving the inner rail **10** is formed to a central inside portion of the bearing body **31**. Ball rolling grooves **31*c*** opposing to the ball rolling grooves **11** of the inner rail **10** are formed to an inclining surface **31*b*** adjacent to the recessed portion **31*a***. These ball rolling grooves **31*c*** are also subjected to the hardening treatment to thereby apply sufficient hardness thereto.

Furthermore, return holes **31*d*** for the non-loaded balls are formed to the bearing body **31** so as to penetrate it in its axial direction.

In the illustrated preferred embodiment, a central outside portion of the bearing body **31** is formed as a shallow recessed portion **31*e*** for adjustment and a female screw hole **31*f***, which is screw engaged with a male screw of the adjustment bolt **40**, is bored at the central portion of the recessed portion **31*e***. Each of the preload adjustment mechanisms is composed of this recessed portion **31e** for adjustment and the adjustment bolt **40**.

The side covers **32** may be cheaply formed of a dicast alloy or synthetic resin because large load is not applied to these side covers **32**. The side covers **32** connect the corresponding ball rolling grooves **31*c*** and the non-loaded ball return holes **31*d***, thus being provided with ball returning grooves **32*a*** as endless tracks, respectively.

A number of balls **33** mounted in the respective endless tracks can apply a large preload for the reason that the inner rail **10** and the bearing body **31** transferring the load are made themselves of a material having high rigidity and the ball rolling grooves **11** and **31*c*** holding the loaded balls are hardened. Accordingly, in the over-stroke use under the heavy load any gap is not substantially caused between the respective members. In the light load use, the effective length of the linear motion guide **30**, corresponding to the portion X_1, in FIG. **5**, can be shortened, thus making large the over-stroke amount, corresponding to the four portions X_2 in FIG. **5**.

The adjustment bolts **40** are screw engaged with the female screw holes **31*f*** of the bearing body **31** through the through holes **22** of the outer rails **20**. As described before, since the shallow recessed portions **31*e*** are formed between the outer rails **20** and the bearing body **31** to provide spaces therebetween, the inclining surfaces **31*b***, i.e. the ball rolling grooves **31*c***, are minutely moved by fastening the adjustment bolts **40** so as to approach the inner rail **10**, thus adjusting the preload amount to the balls **33**.

FIG. **3** is an illustration showing this preload adjusting condition. That is, when the recessed portions **31*e*** of the bearing body **31** for adjustment are pulled by the fastening of the adjustment bolts **40** towards the outer rails **20** with fastening forces P, the pulling forces P and resisting forces N acting on the fixed surfaces constitute couple of forces, which causes to the bearing body **31**, moments M for narrowing the bilateral inner side surfaces of the central recessed portions **31***a*. According to the moments

the preload is applied to the balls **33** and the amount of the preload to be applied to the balls can be adjusted in accordance with the fastening amount of the adjustment bolts **40**.

A method of using the linear motion slide unit of this invention is identical to that of the conventional technology, so that the details thereof are omitted herein.

POSSIBILITY OF INDUSTRIAL USAGE

As described hereinabove, in the linear motion slide unit according to this invention, it is usable for the sliding portions of office tables, computer peripheral devices copying machines, measuring instruments, telecommunication equipments, medical instruments, various kinds of office equipments, and the like, and particularly, it is preferable for the use in which a heavy load can be supported by drawing out the sliding portion so as to extend over the entire length of the rail, that is, in the over-stroke condition.

I claim:

1. A linear motion slide unit comprising:

an elongated inner rail;

said elongated inner rail having at least one first side rolling member groove extending along the length of said inner guide rail on a first side of a width of said inner guide rail;

said elongated inner guide rail having at least one second side rolling member groove extending along the length of said inner guide rail on a second side, opposite to said first side, of the width of said inner guide rail;

a first outer rail attached to said first side of said elongated inner rail and reciprocally movable in an axial direction of said inner rail along said first side thereof;

a second outer rail attached to said second side of said elongated inner rail and reciprocally movable in the axial direction of said inner rail along said second side thereof;

at least one first side linear motion guide fixedly secured to said first outer rail and supported slidable with respect to the inner rail through a number of rolling members, said first side linear motion guide being formed with endless tracks in which the rolling members are endlessly circulated, said rolling members being supported along said first side rolling member groove;

at least one second side linear motion guide fixedly secured to said second outer rail and supported slidable with respect to the inner rail through a number of rolling members, said second side linear motion guide being formed with endless tracks in which the rolling members are endlessly circulated, said rolling members being supported along said second side rolling member groove; and

whereby said first side linear motion guide and said second side linear motion guide each are located on opposite sides of said inner guide rail from one another.

2. A linear motion slide unit according to claim **1**, wherein said linear motion guides each include a bearing body provided with rolling member rolling grooves opposing to the rolling member rolling grooves formed in the inner rail and return passages for non-loaded rolling members, and a pair of side covers secured to both end surfaces of the bearing body and provided with rolling member returning grooves connecting the opposing rolling member rolling grooves of the bearing body and the return passages for the non-loaded rolling members to thereby constitute endless tracks.

3. A linear motion slide unit according to claim **2**, wherein said bearing body is composed of a block member having substantially a U-shaped cross section having a central recessed portion into which the inner rail is inserted and rolling member rolling grooves are formed to the bilateral inner side surfaces of the central recessed portions so as to oppose to those formed to the opposing surfaces of the inner rail.

4. A linear motion slide unit according to claim **3**, wherein said inner rail and said bearing body are formed of a material having high rigidity and a preload is applied to the rolling members.

5. A linear motion slide unit according to claim **4**, wherein said linear motion guides are provided with preload adjustment mechanisms for adjusting the preload to be applied to the rolling members.

6. A linear motion slide unit according to claim **3**, wherein each of said preload adjustment mechanisms provided for said linear motion guides is characterized by comprising a recessed portion for adjustment formed to the central portion of a surface to which the outer rail of the bearing body is fixed and an adjustment bolt screwed in a screw hole bored to a bottom surface of the preload adjustment recessed portion through a through hole formed to the outer rail, and in that the adjustment recessed portion is pulled towards the outer rails by fastening the adjustment bolt, a moment is caused to the bearing body by this pulling force in a direction narrowing a gap between bilateral inner side surfaces of the central recessed portion to thereby apply the preload to the rolling members, and an amount of the preload to the rolling members is made adjustable in accordance with the fastening force of the adjustment bolt.

7. A linear motion slide unit, comprising:

an elongated inner rail, said inner rail having a pair of first side rolling grooves extending along a length of the elongated inner rail on a first side of a width thereof and having a pair of second rolling grooves extending along the length of the elongated inner rail on a second side of a width thereof;

a pair of first and second bearing bodies which are arranged on opposite sides of the elongated inner rail and which are reciprocally movable along the elongated inner rail, said first bearing body having a pair of first side rolling grooves opposing to the first side of the elongated inner rail and being reciprocally movable in an axial direction of the elongated inner rail along the first side thereof, said second bearing body having a pair of second side rolling grooves opposing to the second side of the elongated inner rail and being reciprocally movable in an axial direction of said elongated inner rail along the second side thereof, said first bearing body having a pair of endless tracks in which first side rolling members are endlessly circulated and the second bearing body having a pair of endless tracks in which second side rolling members are endlessly circulated; and

a pair of first and second outer rails, said first outer rail being fixedly secured to the first bearing body opposing to the elongated inner rail and including means for applying a preload to the first side rolling members cooperating with the first bearing body, and the second outer rail being fixedly secured to the second bearing body opposing to the inner rail and including means for applying a preload to the second side rolling members cooperating with the second bearing body;

whereby said elongated inner rail and the bearing bodies to which the outer rail are secured being relatively movable to each other.

8. A linear motion slide unit according to claim **7**, further comprising a pair of first and second preload adjustment members, said first preload adjustment member being arranged in said first bearing body and the first outer rail for adjusting an amount of preload to be applied to the first side rolling members and said second preload adjustment member being arranged in said second bearing body and the second outer rail for adjusting an amount of preload to be applied to the second side rolling members.

9. A linear motion slide unit according to claim **7**, wherein said inner rail is relatively movable by a movable stroke thereof in a single longitudinal direction with respect to said first outer rail through said first bearing body and said second outer rail is relatively movable by a movable stroke thereof in the same said single longitudinal direction with respect to said inner rail through said second bearing body.

10. A linear motion slide unit comprising:

a first outer rail;

an elongated inner rail attached to said first outer rail and reciprocally movable in an axial direction of the first outer rail, said elongated inner rail having at least one first side rolling member groove extending along the length of the inner rail on a first side of a width of the inner rail, said elongated inner rail having at least one

second side rolling member groove extending along the length of the inner rail on a second side opposite to said first side, of the width of said inner rail;

a second outer rail attached to said second side of the elongated inner rail and reciprocally movable in the axial direction of the inner rail along said second side thereof, wherein said outer rail is movable with respect to said first outer rail by a distance corresponding to a movable stroke of the inner rail with respect to the first outer rail and a movable stroke of the second outer rail with respect to the inner rail;

at least one first side linear motion guide fixedly secured to the first outer rail and supported slidable with respect to the inner rail through a number of rolling members, said first side linear motion guide being formed with endless tracks in which the rolling members are endlessly circulated, said rolling members being supported along said first side rolling member groove;

at least one second side linear motion guide fixedly secured to said second outer rail and supported slidable with respect to the second outer rail through a number of rolling members, said second side linear motion guide being formed with endless tracks in which the rolling members are endlessly circulated, said rolling members being supported along said second side rolling member groove.

[57] **ABSTRACT**

It is an object of the present invention to provide a linear bearing which is easy to manufacture and has sufficient mechanical strength, and its production method. A slider **1** guides a table or other movable bodies along a rail **2** and includes a thin ball plate **6** in which load ball channels **61** are formed to move balls **5** therein, and a thin mounting plate **7** adapted to secure the movable body. A molding material **8** such as resin or die cast alloy is molded to insert the ball plate **6** and the mounting plate **7** thereinto. The rail **2** is made of a metallic material **2** whose surface is hardened to a predetermined level when subjected to plastic deformation. During plastic deformation, the ball channels **23** are hardened to a predetermined level.

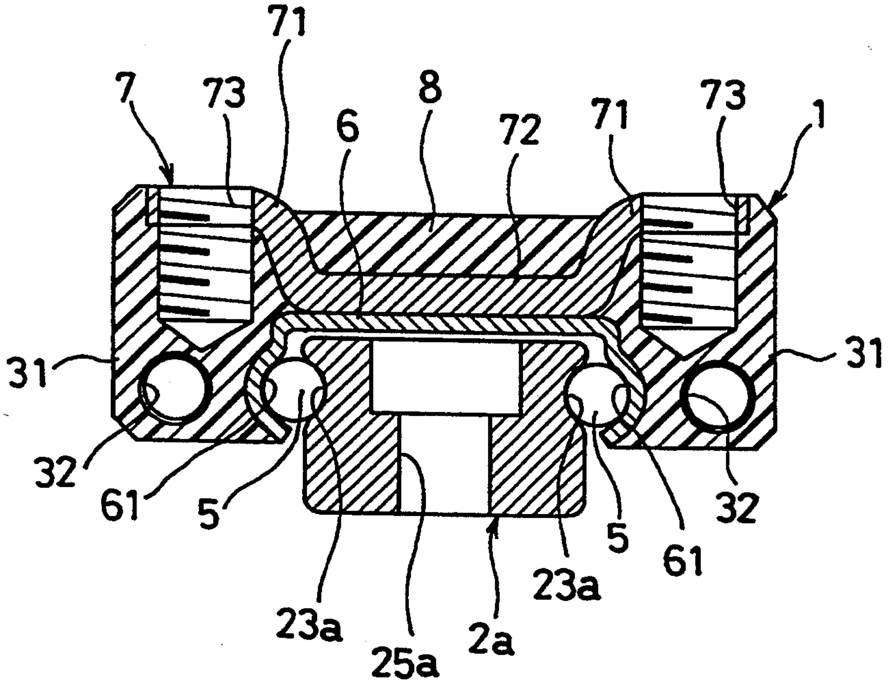
FIG. 17



LINEAR BEARING AND ITS PRODUCTION METHOD

TECHNICAL FIELD

The present invention relates to a linear bearing for guiding movable bodies such as tables for use in various machine tools or industrial robots along a straight bed or stationary element.

BACKGROUND ART

This kind of linear bearing comprises a rail having ball channels in which balls are moved and secured to a bed or stationary element, and a slider having load ball channels cooperating with the ball channels to sandwich a multiplicity of balls and adapted to guide a table or movable body along the rail.

The slider has a function such that the load of the movable body is applied directly thereto. Under the circumstances, if the slider is deformed, the movable body is displaced relative to the base to which the rail is mounted. This presents a problem that the movable body can not be guided accurately on a straight line. The slider body to which the movable body is secured must have high rigidity.

To this end, the slider conventionally has a slider body formed from a metal block made, for example, of bearing steel. The slider body is made by first cutting a rectangular metal block to a predetermined shape, then, forming nonload ball bores and tapping bolt holes for securement of a movable body, and finally, carburizing a portion of the slider body and cutting and lapping that portion of the slider body to form load ball channels.

However, where a slider body is made from a metal block made, for example, of bearing steel, such a metal block must be machined in various ways. This production method is thus cumbersome.

It is necessary to accurately and smoothly cut the slider body at a predetermined angle to form load ball channels. However, it is difficult to accurately contact a grinder or other cutting tools when the slider body has a complicated shape. This deteriorates the accuracy of load ball channels.

There is proposed a slider body made from materials other than metal block. A thin metal plate has load ball channels and is molded, at its outer periphery, of epoxy concrete or synthetic resin (see Japanese utility model publication No. 48417/91)

According to this proposal, load ball channels can be readily and accurately formed by pressing or ball burnishing the thin metal plate. Also, the slider body can readily be machined to a complicated shape. This slider body can be more economically made than those formed by machining metal blocks.

However, the proposed slider body is less in rigidity than those made from metal blocks since it is like a metal plate with load ball channels attached to a block made of synthetic resin. The slider body is thus susceptible to deformation or breakage when substantial load is exerted from a movable body.

A slider must have a mounting portion for securement of a movable body. Movable bodies have various shapes and are, therefore, secured to the slider in various ways. The mounting portion may be in the form, for example, of a flange as an extension of the slider. Under the circumstances, linear bearing manufacturers are required to provide sliders with various mounting portions to meet a user's need. Its manufacture is, however, rather cumbersome. Thus, there is a need for sliders which allow for ready securement of movable bodies in various ways and which are economical to manufacture.

Conventionally, a rail is formed by drawing a metal block to have a predetermined cross section, carburizing a portion of the metal block, and cutting or lapping that portion to form ball channels. This production method is as cumbersome as that of the slider. Another problem is that the surface of the rail where balls are moved is susceptible to cracking.

There has recently been proposed a rail which includes a thin metal plate in which ball channels are formed by press, and synthetic resin inserted within the metal plate (see Japanese laid-open utility model publication No. 43521/90). However, to give ball channels predetermined hardness, it is necessary to treat the metal plate with TUFFTRIDE or thermally treat the metal plate such as quenching to harden the surfaces of the ball channels on which balls are moved. This treatment is also cumbersome and does not improve the fragility of the surfaces on which balls are moved.

DISCLOSURE OF THE INVENTION

In view of these problems, it is an object of the present invention to provide a linear bearing which is easy to manufacture and has high mechanical strength, and its production method.

In order to achieve the object, the present invention provides a slider for a linear bearing which comprises a thin ball plate having load ball channels, and a thin mounting plate having mounting portions to which a movable body is secured, characterized in that the ball plate and the mounting plate are integrated together by molding a molding material such as resin or die cast alloy.

According to such technical means, the slider can be formed by injection or extrusion molding synthetic resin within which the ball plate and mounting plate are inserted, or by die casting an alluminum or zink alloy. This allows for ready production of the slider having various shapes such as an inclined C-shape or L-shape. The shape of the ball plate may thus be altered in response to the shapes of a slider. Also, the number and angle of load ball channels formed in the ball plate may be changed as necessary.

The mounting plate may take any shape so far as it has mounting portions to secure a table or other movable bodies. However, it is necessary for the mounting plate to have high rigidity according to its shape and material since the load of a movable body is applied locally to the mounting plate.

Further, nonload ball channels can be any means applicable to the existing linear bearings so far as it can bring balls up at ends of the load ball channels. In the present invention, for example, the slider includes nonload ball bores extending in parallel to the load ball channels. End caps may be attached to front and rear ends of the slider to provide a communication between the load ball channels and the nonload ball bores. Alternatively, ball tubes may be inserted in the slider to provide a communication between opposite ends of the load ball channels.

The present invention has for its purpose to reduce the number of production steps and the production cost. It is therefore preferable to form part of the nonload all channels during insert molding process.

The mounting plate is integrated in the slider by insert molding, but the molding material such as resin surrounds the mounting plate, only. The mounting may be separated from the slider when substantial load is exerted on the mounting plate. To more firmly integrate the mounting plate in the slider, an adhesive agent may be applied to the mounting plate prior to insert molding. Alternatively, the ball plate and the mounting plate may be projection welded or riveted together. However, the use of these means results in an increase in the number of production steps and is not preferable as the purpose of the present invention is to reduce the production cost.

Therefore, the mounting plate preferably has a fixed portion which is embedded in the molding material during insert molding. This results in a decrease in the number of production steps simply by changing the shape of the mounting plate. The fixed portion may be in the form of pawls provided at opposite ends of the mounting plate. Alernatively, recesses may be formed centrally in the mounting plate.

Where the mounting plate has a fixed portion, the fixed portion preferably has an axial length less than that of the ball plate or has through openings. This prevents separation of the molding material covering the fixed portion from the molding material surrounding the ball plate and thus ensures firm integration of the mounting plate with the ball plate.

The present invention also provides a rail for use in a linear bearing to achieve the foregoing object.

A first rail is made of a metallic material which has such a characteristic that its surface hardness is increased when subjected to plastic deformation. The ball channels have predetermined surface hardness when the rail is plastically deformed to a predetermined shape.

With these technical means, the rail is pressed or rolled to a predetermined shape where the rail is made from a thin metal plate. At that time, the surface of the ball channels is hardened to a predetermined level. The rail is drawn to a predetermined shape where the rail is made from a metal block. During drawing process, the surface of the ball channel is hardened to a predetermined level.

The surface hardness required for the ball channels may vary depending on the material of balls and the load to be exerted on the slider, but is normally at least H_RC35. With this production method, the greater the deformation during plastic deformation, the greater the hardness of the ball channel surface on which balls are moved. Thus, where the rail is made, for example, by drawing process, the surface hardness of the ball channels can be adjusted by changing the volume as drawn by a die.

The same production method is applicable to the ball plate of the slider. The surface of the load ball channels can be hardened to a predetermined level simply by pressing or rolling a thin metal plate to a predetermined shape.

To achieve the foregoing object, a second rail is made from a metal rod and includes ball channels which is subjected to quenching and subzero (or deep freezing) treatment.

With these technical means, the fragile metallic system is improved during quenching process to effectively prevent crack which may occur in the ball channels upon repeated application of loads.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a perspective view of a linear bearing according to a first embodiment.

FIG. **2** is a sectional view of the linear bearing according to the first embodiment.

FIG. **3** is an exploded view, in perspective, of the linear bearing according to the first embodiment.

FIG. **4** is a perspective view of the linear bearing according to the first embodiment, part of which is taken away to show the structure of a slider body.

FIG. **5** is a front view of the slider body of the linear bearing according to the first embodiment.

FIG. **6** is a bottom plan view of the slider body of the linear bearing according to the first embodiment.

FIG. **7** is a top plan view of the slider body of the linear bearing according to the first embodiment.

FIG. **8** is a side view of the slider body of the linear bearing according to the first embodiment.

FIG. **9** is a bottom plan view of an end cap of the linear bearing according to the first embodiment.

FIG. **10** is a rear view of the end cap of the linear bearing according to the first embodiment.

FIG. **11** is a sectional view taken along the line XI—XI of FIG. **10**. FIG.

12 is a front view of the end cap of the linear bearing according to the first embodiment.

FIG. **13** is a sectional view taken along the line XIII—XIII of FIG. **10**.

FIG. **14** is a sectional view showing a modified form of the slider of the linear bearing according to the first embodiment.

FIG. **15** is a perspective view of a linear bearing according to a second embodiment, part of which is taken away to show the structure of a slider.

FIG. **16** is a sectional view of the linear bearing according to the second embodiment.

FIG. **17** is a sectional view of the linear bearing according to the first embodiment, showing a modified form of a rail.

BEST MODE FOR CARRYING OUT THE INVENTION

A linear bearing and its production method of the present invention will now be described with reference to the accompanying drawings.

FIGS. **1** and **2** show a linear bearing according to a first embodiment of the present invention. The linear bearing generally includes a rail **2**, and a slider **1** movable along the rail **2**. FIG. **3** is a disassembled view of the slider **1** which includes a slider body **3** having a substantially inclined C-shape and extending over the rail **2**, and a pair of end caps **4** coupled to front and rear ends of the slider body **3**. The slider **1** is mounted on the rail through balls **5** which endlessly circulate in the slider **1**.

As shown in FIG. **4**, the slider body **3** includes a channel-like ball plate **6**, and a mounting plate **7** having mounting portions **71** for mounting a movable body (not shown). The ball plate **6** and the mounting plate **7** are integrally formed together by a synthetic resin **8** (for example, TORAYCA).

The ball plate **6** is made of stainless steel or other metal (for exmple, SUS430) and shaped by a press. Opposite inner surfaces of the ball plate **6** form load ball channels **61** which cooperate with ball channels **23** of the rail **2** to sandwich the balls **5**. Positioning projections **62** extend axially from opposite ends of the ball plate 6 to position the end caps. The load ball channels **61** are quenched and then, subzero treated. This treatment hardens the load ball channels **61** to increase its resistance to wear and stabilizes the metallic system of the load ball channels **61** to improve its fragility.

Alternatively, a metal sheet whose surface hardness can be increased when subjected to plastic deformation may be pressed or rolled to a predetermined shape. It is then plastically deformed to harden the surface of the load ball channels **61** to a predetermined level. Such a metal sheet which can be used in this process is, for example, austenite SUS304. The surface hardness of the load ball channels **61** is less than H_RC10 prior to pressing and increased to H_RC35 to 40 after it has been pressed. This method eliminates a need for heat treatment and results in lower production cost.

The mounting plate **7** is formed also by pressing a sheet metal made, for example, of stainless steel and having a thickness slightly greater than that used for the ball plate **6**. The mounting plate **7** includes a recess or fixed portion **72** embedded in the synthetic resin **8** and located between a pair of mounting portions **71**. The mounting portions **71** are tapped to form bolt holes **73** for threading engagement with bolts (not shown) of a movable body. The axial length of the mounting plate **7** is shorter than that of the ball plate.

The slider body **3** is formed by insert molding the ball plate **6** and the mounting plate **7**. FIGS. **5** to **8** show the slider body **3** after it is insert molded.

As is clear from these figures, the ball plate **6** is wrapped by synthetic resin and is not separated from the slider body **3** in any direction. The mounting portions **71** of the mounting plate **7** extend outwardly from the surface of the slider body **3**. The fixed portion **72** of the mounting plate **7** is embedded in the synthetic resin **8**. The mounting plate **7** is thus not separated from the slider body **3** in any direction. During insert molding, part of nonload ball bores is defined in the slider body **3** to provide a connection between ends of the load ball channels to circulate the balls **2** therethrough. Specifically, the slider body **3** has legs **31** in which ball bores **32** through which nonload balls are moved are defined in parallel relationship to the load ball channels **61**. Semicircular return guides **33** are formed in front and rear end surfaces of the slider body **3** to direct the balls **5** from the load ball channels **61** and the ball bores **32** and vice versa. Positioning holes **34** are defined during insert molding to receive projections **41** of the end caps **4**.

The slider body **3** is formed substantially during the insert molding process. Finally, the mounting portions **71** of the mounting plate **7** which extend outwardly from the surface of the slider body **3** is abraded to provide a reference surface.

The end caps **4** coupled to front and rear ends of the slider body **3** are injection molded of synthetic resin. Semi-circular ball return channels **42** are formed in the inner sides of the end caps **4** and form part of the nonload ball channels. As shown in FIGS. **9** to **13**, the ball return channels **42** provide a connection between the load ball channels **61** of the slider body **3** and the ball bores **32**. Tongues **43** extend from ends of the end caps **4** to bring the balls **5** up from the load ball channels **61**. Also, seats **44** are provided centrally in the ball return channels **42** to receive return guides **33** of the slider body **3** when the end caps **4** are coupled to the slider body **3**. This facilitates guidance of the balls **5** through the ball return channels **42**.

The end caps **42** are adhesively attached to the slider body **3**. To ensure accurate attachment of the end caps **4** to the slider body **3**, the end caps **4** have recesses **4** to receive projections **62** of the ball plate **6**, and projections **41** to fit into the positioning holes **43** of the slider body **3**.

As shown in FIGS. **2** and **3**, the rail **2** includes a channel-like rail plate **21** made by pressing, and a synthetic resin **22** inserted in the rail plate **21** during molding process. A pair of ball channels **23** are formed in opposide outer sides of the rail plate **21** during pressing process. Also, through holes **24** are formed in the base along the length of the rail plate **21**. Bolt holes **25** are formed during insert molding process and correspond to the through holes **24**. In this embodiment, the slider **1** has no ball retainer. To avoid accidental removal of the slider **1** from the rail **2** and disengagement of the balls **5** from the load ball channels **61**, stoppers **9** are attached to opposite ends of the rail **2**.

The surface of the ball channels **23** are hardened to a predetermined level completely in the same manner as the load ball channels **61** of the ball plate **6**. After the rail has been pressed, the ball channels **23** are quenched and then, subzero treated. Alternatively, a metal sheet made of austenite SUS304 may be pressed or rolled to a predetermined shape to thereby increase the surface hardness of the ball channels **23** to a predetermined level.

When the slider **1** is in use, the balls **5** are placed in the nonload ball channels composed of the ball return channels **42** of the end caps **4** and the ball bores **32** of the slider body **3**. The balls **5** are also placed between the ball channels **23** of the rail **2** and the load ball channels **61** of the slider body **3**. A movable body is then secured to the mounting portions **71** which extend outwardly from the upper surface of the slider **1**.

A substantial part of the slider **1** is formed of synthetic resin **8**. However, part of the mounting plate **7** which has high regidity is embedded in the synthetic resin **8** to be integral with the slider body **3**. This mounting plate **7** serves as a reinforcing element for the slider body **3** to increase the rigidity of the slider body **3**. Thus, the slider body **3** is free from deformation or breakage if substantial load is exerted.

The mounting plate **7** and the slider body **3** are integrally formed during insert molding of the slider **3**. A change in shape of the mounting plate **7** results in a corresponding change in shape of the slider.

FIG. **14** shows a modification of the slider body **3** as insert molded. The slider body includes a mounting plate **7a** which has wider mounting portions than those of the mounting plate **7**, and bolt holes **76**.

According to this embodiment, while the ball plate **6** and other elements are commonly used, a variety of mounting plates **7** can be employed to provide a variety of sliders. Thus, various types of sliders can economically and readily be fabricated according to user's need.

In the foregoing embodiment, the axial length of the mounting plate **7** is less than that of the ball plate **6** so that the synthetic resin **8** which covers the fixed portion **72** of the mounting plate **7** are safely joined to the synthetic resin **8** which surrounds the ball plate **6**. As an alternative, the axial length of the mounting plate **6** may be identical to that of the slider body **3**. In such a case, slots or through openings **74** may be formed in the fixed portion **72** as shown in FIG. **15**.

FIG. **16** is a sectional view showing a second embodiment of the slider **1** wherein a mounting plate **7b** has the through openings **74**. As is clear from FIG. **16**, the synthetic resin **8** which covers the fixed portion **72** of the mounting plate **7** through the through openings **74** is safely joined to the synthetic resin **8** which surrounds the ball plate **6**. This embodiment also allows for firm integration of the mounting plate *7b* with the slider body **3**.

In this embodiment, the ball plate **6** is pressed, but the load ball channels **61** are not abraded. However, the load ball channels **61** may need be abraded when the plate **6** per se is made of a material which does not provide a smooth surface.

The rail **2** in which the slider **1** of this embodiment is assembled may be made by pressing a metal sheet. As shown in FIG. **17**, a metal block may be drawn to form a rail *2a* of a predetermined shape. In such a case, ball channels *23a* of the rail *2a* are quenched and then, subzero treated after it has been drawn so as to increase resistance to wear and improve the fragility of the ball channels *23a*.

To reduce the cost of manufacturing the rail *2a*, a block made of austenite SUS304 may be drawn to a predetermined shape. The rail *2a* is plastically deformed to thereby increase the surface hardness of the ball channels *23a* to a preetermined level.

INDUSTRIAL APPLICABILITY

As described above, according to a linear bearing and its production method of the present invention, a slider is formed by integrating a high rigid mounting plate with a ball plate by the use of molding material such as resin or die cast alloy. The slider thus made is highly rigid even if molding material is relatively flexible. It is therefore possible to provide a linear bearing which has high mechanical strength.

Also, according to a linear bearing and its production method of the present invention, a rail is plastically deformed to a predetermined shape to thereby harden a ball channels. This eliminates a need for heat treatment of the ball channels. It is therefore possible to provide a linear bearing which has high mechanical strength and is economical to manufacture.

Further, according to a linear bearing and its production method of the present invention, when a rail is quenched to harden ball channels, subzero treatment is subsequently effected to alter metallic system to improve the fragility of the rail. The ball channels are thus free from crack. It is therefore possible to provide a linear bearing which has high mechanical strength.

What is claimed is:

1. A linear bearing, comprising:

a rail having ball channels; and

a slider having load ball channels cooperating with said ball channels of said rail to sandwich a plurality of balls therebetween, in order to guide a movable body secured to said slider along a path of said rail, said slider including,

(a) a ball plate in which said load ball channels are formed,

(b) a mounting plate having mounting portions for supporting the movable body and a fixed portion connected to said mounting portions, and

(c) a resin molding material at least partially surrounding said ball plate and said mounting plate, wherein said fixed portion of said mounting plate is embedded in said resin molding material.

2. A linear bearing according to claim **1**, wherein said mounting plate has an axial length less than that of said ball plate.

3. A linear bearing according to claim **1**, wherein said ball plate is made from a metal plate whose surface hardness is increased when subjected to plastic deformation, and said load ball channels are hardened to a predetermined level when said ball plate is plastically deformed to a predetermined shape.

4. A slider for a linear bearing, wherein the linear bearing includes a rail having ball channels, and a slider having load ball channels cooperating with the ball channels of the rail and to sandwich a plurality of balls therebetween, in order to guide a movable body secured to said slider along a path of the rail, said slider comprising:

(a) a ball plate in which said load ball channels are formed,

(b) a mounting plate having mounting portions for supporting the movable body and a fixed portion connected to said mounting portions, and

(c) a resin molding material at least partially surrounding said ball plate and said mounting plate, wherein said fixed portion of said mounting plate is embedded in said resin molding material.

[57] **ABSTRACT**

A linear motion slide unit comprises a slider axially movably mounted on a guide rail by a number of rolling members. A sealing device comprises a pair of end plates mounted at both ends of the slider and a connection plate, connecting the pair of end plates, with the connection plate disposed between the slider and the guide rail in the axial direction. First sealing members are disposed on the end plates where the end plates face the guide rail. Second sealing members extend along the axial direction of the connection plate.

PRIOR ART

LINEAR MOTION SLIDE UNIT

TECHNICAL FIELD

This invention relates to a sealing device of a linealy movable mechanism and a method of manufacturing the sealing device.

BACKGROUND ART

FIG. **4** shows a conventional linearly movable mechanism, in which first rolling member rolling grooves **102** are provided to both side surfaces **101** of a guide rail **100** and second rolling member rolling grooves **104** facing the first rolling grooves **101** are formed to a slider **103**. The slider **103** is slidable on the guide rail **100** in the axial direction thereof through rolling members **105** disposed between the first and second rolling grooves **102** and **104**.

A pair of end plates **103***a* are attached to both the axial ends of the slider **103**, and end seals (first seal members) **106** are secured to end plates **110** disposed at the end faces of the end plates **103***a*. The end plates **103***a* and the end plates **110** are fastened fixedly to the slider **103** by means of screws **114**. The end seals **106** are provided with sealing projections **107** slidably contacting the first rolling grooves **102**. Upper seals (second sealing members) **111** extending axially are fixedly fastened to the slider **103** by means of screws **115** at portions corresponding to the upper surface **108** of the guide rail **100**, and the upper seals **111** are constructed as members independent from the end seals **106**.

In the conventional linearly movable mechanism of the structure described above, the rolling members **105** are rolled to thereby axially move the slider **103** on and along the guide rail **100**. The sealing projections **107** prevent external cut chips or spatters from invading into the first and second rolling grooves **102** and **104**. In addition, the upper seals **111** prevent foreign materials from invading into the first and second rolling grooves **102** and **104** through the upper surface **108** of the guide rail **100**. However, in the conventional technology, the end seals **106** and the upper seals **111** are attached to the slider **103** independently with each other, thus performing less workability and reducing productionability.

DISCLOSURE OF INVENTION

The present invention is directed to a linear motion slide unit comprising:

a guide rail in which a first rolling member rolling groove extending in an axial direction is formed;

a slider in which a second rolling member rolling groove facing the first rolling member rolling groove is formed;

a number of rolling members disposed between the first and second rolling member rolling grooves to thereby axially movably support the slider on the guide rail; and

a sealing device comprising a pair of end plates axially disposed at both ends of the slider, a connection plate disposed between the slider and the guide rail in the axial direction thereof and integrally connected to the paired end plates, first sealing members disposed at positions at which the end plates face the guide rail and second sealing members extending along the axial direction of the connection plate.

The slider has preferably substantially a]-shape in cross section and the end plates each secured to the end portion of the slider has also a]-shape in cross section. The respective recessed portions of the end plates can be integrally connected with each other through the connection plate.

The first seal members are formed in a shape conforming with the outer peripheral shape of the guide rail.

Furthermore, the connection plate comprises a base portion and bent portions formed by bending both side edges of the base portion, and the second seal members are secured to the outer side surfaces of the bent portions.

Still furthermore, in a preferred embodiment, the second seal members are composed of lip portions inclining towards the centeral side of the guide rail.

The present invention further provides a method of manufacturing a sealing device of a linearly movable mechanism comprising the steps of forming a pair of end plates integrally with a plate-like body having a connection plate connected in an axial direction to the paired end plates, joining first seal members to the paired end plates, joining second seal members to the connection plate, and thereafter bending connected portions between the end plates and the connection plate in a widthwise direction, wherein the end plates and the connection plate is integrally formed, so that the first and second seal members are secured to the slider together in one assembling process.

Further, the sealing device can be constructed by the steps of forming a pair of end plates integrally with a plate-like body having a connection plate to which the paired end plates are axially connected, joining first seal members to the paired end plates and second seal members to the connection plate along the axial direction, and thereafter bending connected portions between the end plates and the connection plate in a widthwise direction.

As described above, according to the present invention, the first and second seal members are secured to the slider together by one assembling process, thus improving the assembling workability, and hence, improving the production efficiency of the linearly movable mechanisms.

BRIEF DESCRIPTION OF THE DRAWINGS
