[57] **ABSTRACT**

It is an object of the present invention to provide a linear bearing which is easy to manufacture and has sufficient mechanical strength, and its production method. A slider **1** guides a table or other movable bodies along a rail **2** and includes a thin ball plate **6** in which load ball channels **61** are formed to move balls **5** therein, and a thin mounting plate **7** adapted to secure the movable body. A molding material **8** such as resin or die cast alloy is molded to insert the ball plate **6** and the mounting plate **7** thereinto. The rail **2** is made of a metallic material **2** whose surface is hardened to a predetermined level when subjected to plastic deformation. During plastic deformation, the ball channels **23** are hardened to a predetermined level.

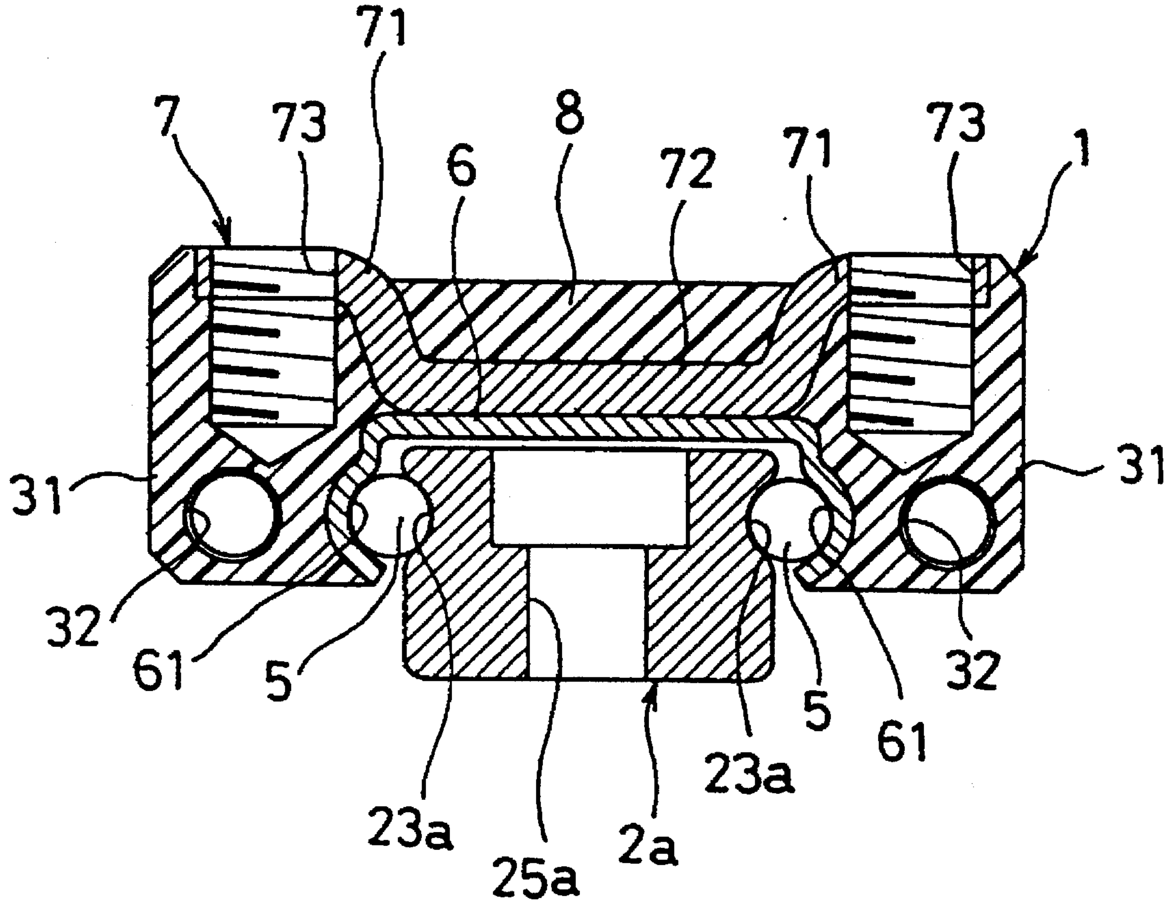
FIG. 17



PRODUCTION METHOD FOR A LINEAR BEARING

This is a divisional application of application Ser. No. 08/050,374, filed Jul. 16, 1993, now U.S. Pat. No. 5,380, 099.

TECHNICAL FIELD

The present invention relates to a linear bearing for guiding movable bodies such as tables for use in various machine tools or industrial robots along a straight bed or stationary element.

BACKGROUND ART

This kind of linear bearing comprises a rail having ball channels in which balls are moved and secured to a bed or stationary element, and a slider having load ball channels cooperating with the ball channels to sandwich a multiplicity of balls and adapted to guide a table or movable body along the rail.

The slider has a function such that the load of the movable body is applied directly thereto. Under the circumstances, if the slider is deformed, the movable body is displaced relative to the base to which the rail is mounted. This presents a problem that the movable body can not be guided accurately on a straight line. The slider body to which the movable body is secured must have high rigidity.

To thid end, the slider conventionally has a slider body formed from a metal block made, for example, of bearing steel. The slider body is made by first cutting a rectangular metal block to a predetermined shape, then, forming nonload ball bores and tapping bolt holes for securement of a movable body, and finally, carburizing a portion of the slider body and cutting and lapping that portion of the slider body to form load ball channels.

However, where a slider body is made from a metal block made, for example, of bearing steel, such a metal block must be machined in various ways. This production method is thus cumbersome.

It is necessary to accurately and smoothly cut the slider body at a predetermined angle to form load ball channels. However, it is difficult to accurately contact a grinder or other cutting tools when the slider body has a complicated shape. This deteriorates the accuracy of load ball channels.

There is proposed a slider body made from materials other than metal block. A thin metal plate has load ball channels and is molded, at its outer periphery, of epoxy concrete or synthetic resin (see Japanese utility model publication No. 48417/91).

According to this proposal, load ball channels can be readily and accurately formed by pressing or ball burnishing the thin metal plate. Also, the slider body can readily be machined to a complicated shape. This slider body can be more economically made than those formed by machining metal blocks.

However, the proposed slider body is less in rigidity than those made from metal blocks since it is like a metal plate with load ball channels attached to a block made of synthetic resin. The slider body is thus susceptible to deformation or breakage when substantial load is exerted from a movable body.

A slider must have a mounting portion for securement of a movable body. Movable bodies have various shapes and are, therefore, secured to the slider in various ways. The mounting portion may be in the form, for example, of a flange as an extension of the slider. Under the circumstances, linear bearing manufacturers are required to provide sliders with various mounting portions to meet user's need. Its manufacture is, however, rather cumbersome. Thus, there is a need for sliders which allow for ready securement of movable bodies in various ways and which are economical to manufacture.

Conventionally, a rail is formed by drawing a metal block to have a predetermined cross section, carburizing a portion of the metal block, and cutting or lapping that portion to form ball channels. This production method is as cumbersome as that of the slider. Another problem is that the surface of the rail where balls are moved is susceptible to crack.

There has recently been proposed a rail which includes a thin metal plate in which ball channels are formed by press, and synthetic resin inserted within the metal plate (see Japanese laid-open utility model publication No. 43521/90). However, to give ball channels predetermined hardness, it is necessary to treat the metal plate with TUFFTRIDE or thermally treat the metal plate such as quenching to harden the surfaces of the ball channels on which balls are moved. This treatment is also cumbersome and does not improve the fragility of the surfaces on which balls are moved.

DISCLOSURE OF THE INVENTION

In view of these problems, it is an object of the present invention to provide a linear bearing which is easy to manufacture and has high mechanical strength, and its production method.

In order to achieve the object, the present invention provides a slider for a linear bearing which comprises a thin ball plate having load ball channels, and a thin mounting plate having mounting portions to which a movable body is secured, characterized in that the ball plate and the mounting plate are integrated together by molding a molding material such as resin or die cast alloy.

According to such technical means, the slide can be formed by injection or extrusion molding synthetic resin within which the ball plate and mounting plate are inserted, or by die casting an alluminum or zinc alloy. This allows for ready production of the slider having various shapes such as an inclined C-shape or L-shape. The shape of the ball plate may thus be altered in response to the shapes of a slider. Also, the number and angle of load ball channels formed in the ball plate may be changed as necessary.

The mounting plate may take any shape so far as it has mounting portions to secure a table or other movable bodies. However, it is necessary for the mounting plate to have high rigidity according to its shape and material since the load of a movable body is applied locally to the mounting plate.

Further, nonload ball channels can be any means applicable to the existing linear bearings so far as it can bring balls up at ends of the load ball channels. In the present invention, for example, the slider includes nonload ball bores extending in parallel to the load ball channels. End caps may be attached to front and rear ends of the slider to provide a communication between the load ball channels and the nonload ball bores. Alternatively, ball tubes may be inserted in the slider to provide a communication between opposite ends of the load ball channels.

The present invention has for its purpose to reduce the number of production steps and the production cost. It is therefore preferable to form part of the nonload all channels during insert molding process.

The mounting plate is integrated in the slider by insert molding, but the molding material such as resin surrounds the mounting plate, only. The mounting may be separated from the slider when substantial load is exerted on the mounting plate. To more firmly integrate the mounting plate in the slider, an adhesive agent may be applied to the mounting plate prior to insert molding. Alternatively, the ball plate and the mounting plate may be projection welded or riveted together. However, the use of these means results in an increase in the number of production steps and is not preferable as the purpose of the present invention is to reduce the production cost.

Therefore, the mounting plate preferably has a fixed portion which is embedded in the molding material during insert molding. This results in a decrease in the number of production steps simply by changing the shape of the mounting plate. The fixed portion may be in the form of pawls provided at opposite ends of the mounting plate. Alernatively, recesses may be formed centrally in the mounting plate.

Where the mounting plate has a fixed portion, the fixed portion preferably has an axial length less than that of the ball plate or has through openings. This prevents separation of the molding material covering the fixed portion from the molding material surrounding the ball plate and thus ensures firm integration of the mounting plate with the ball plate.

The present invention also provides a rail for use in a linear bearing to achieve the foregoing object.

A first rail is made of a metallic material which has such a characteristic that its surface hardness is increased when subjected to plastic deformation. The ball channels have predetermined surface hardness when the rail is plastically deformed to a predetermined shape.

With these technical means, the rail is pressed or rolled to a predetermined shape where the rail is made from a thin metal plate. At that time, the surface of the ball channels is hardened to a predetermined level. The rail is drawn to a predetermined shape where the rail is made from a metal block. During drawing process, the surface of the ball channel is hardened to a predetermined level.

The surface hardness required for the ball channels may vary depending on the material of balls and the load to be exerted on the slider, but is normally at least H_RC35. With this production method, the greater the deformation during plastic deformation, the greater the hardness of the ball channel surface on which balls are moved. Thus, where the rail is made, for example, by drawing process, the surface hardness of the ball channels can be adjusted by changing the volume as drawn by a dice.

The same production method is applicable to the ball plate of the slider. The surface of the load ball channels can be hardened to a predetermined level simply by pressing or rolling a thin metal plate to a predetermined shape.

To achieve the foregoing object, a second rail is made from a metal rod and includes ball channels which is subjected to quenching and subzero (or deep freezing) treatment.

With these technical means, the fragile metallic system is improved during quenching process to effectively prevent crack which may occur in the ball channels upon repeated application of loads.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a perspective view of a linear bearing according to a first embodiment. FIG. 2 is a sectional view of the linear bearing according to the first embodiment. FIG. 3 is an exploded view, in perspective, of the linear bearing according to the first embodiment. FIG. 4 is a perspective view of the linear bearing according to the first embodiment, part of which is taken away to show the structure of a slider body. FIG. 5 is a front view of the slider body of the linear bearing according to the first embodiment. FIG. 6 is a bottom plan view of the slider body of the linear bearing according to the first embodiment. FIG. 7 is a top plan view of the slider body of the linear bearing according to the first embodiment. FIG. 8 is a side view of the slider body of the linear bearing according to the first embodiment. FIG. 9 is a bottom plan view of an end cap of the linear bearing according to the first embodiment. FIG. 10 is a rear view of the end cap of the linear bearing according to the first embodiment. FIG. 11 is a sectional view taken along the line XI—XI of FIG. 10. FIG. 12 is a front view of the end cap of the linear bearing according to the first embodiment. FIG. 13 is a sectional view taken along the line XIII—XIII of FIG. 10. FIG. 14 is a sectional view showing a modified form of the slider of the linear bearing according to the first embodiment. FIG. 15 is a perspective view of a linear bearing according to a second embodiment, part of which is taken away to show the structure of a slider. FIG. 16 is a sectional view of the linear bearing according to the second embodiment. FIG. 17 is a sectional view of the linear bearing according to the first embodiment, showing a modified form of a rail.

BEST MODE FOR CARRYING OUT THE INVENTION

A linear bearing and its production method of the present invention will now be described with reference to the accompanying drawings.

FIGS. 1 and 2 show a linear bearing according to a first embodiment of the present invention. The linear bearing generally includes a rail **2**, ad a slider **1** movable along the rail **2**. FIG. 3 is a disassembled view of the slider **1** which includes a slider body **3** having a substantially inclined C-shape and extending over the rail **2**, and a pair of end caps **4** coupled to front and rear ends of the slider body **3**. The slider **1** is mounted on the rail through balls **5** which endlessly circulate in the slider **1**.

As shown in FIG. 4, the slider body **3** includes a channel-like ball plate **6**, and a mounting plate **7** having mounting portions **71** for mounting a movable body (not shown). The ball plate **6** and the mounting plate **7** are integrally formed together by a synthetic resin **8** (for example, "TorayCA").

The ball plate **6** is made of stainless steel or other metal (for exmple, SUS430) and shaped by a press. Opposite inner surfaces of the ball plate **6** form load ball channels **61** which cooperate with ball channels **23** of the rail **2** to sandwich the balls **5**. Positioning projections **62** extend axially from opposite ends of the ball plate **6** to position the end caps. The load ball channels **61** are quenched and then, subzero treated. This treatment hardens the load ball channels **61** to increase its resistance to wear and stabilizes the metallic system of the load ball channels **61** to improve its fragility.

Alternatively, a metal sheet whose surface hardness can be increased when subjected to plastic deformation may be pressed or rolled to a predetermined shape. It is then plastically deformed to harden the surface of the load ball channels **61** to a predetermined level. Such a metal sheet which can be used in this process is, for example, austenite SUS304. The surface hardness of the load ball channels **61** is less than H_RC10 prior to pressing and increased to H_RC35 to 40 after it has been pressed. This method eliminates a need for heat treatment and results in lower production cost.

The mounting plate **7** is formed also by pressing a sheet metal made, for example, of stainless steel and having a thickness slightly greater than that used for the ball plate **6**. The mounting plate **7** includes a recess or fixed portion **72** embedded in the synthetic resin **8** and located between a pair of mounting portions **71**. The mounting portions **71** are tapped to form bolt holes **73** for threading engagement with bolts (not shown) of a movable body. The axial length of the mounting plate **7** is shorter than that of the ball plate.

The slider body **3** is formed by insert molding the ball plate **6** and the mounting plate **7**. FIGS. **5** to **8** show the slider body **3** after it is insert molded.

As is clear from these figures, the ball plate **6** is wrapped by synthetic resin and is not separated from the slider body **3** in any direction. The mounting portions **71** of the mounting plate **7** extend outwardly from the surface of the slider body **3**. The fixed portion **72** of the mounting plate **7** is embedded in the synthetic resin **8**. The mounting plate **7** is thus not separated from the slider body **3** in any direction. During insert molding, part of nonload ball bores is defined in the slider body **3** to provide a connection between ends of the load ball channels to circulate the balls **2** therethrough. Specifically, the slider body **3** has legs **31** in which ball bores **32** through which nonload balls are moved are defined in parallel relationship to the load ball channels **61**. Semicircular return guides **33** are formed in front and rear end surfaces of the slider body **3** to direct the balls **5** from the load ball channels **61** and the ball bores **32** and vice versa. Positioning holes **34** are defined during insert molding to receive projections **41** of the end caps **4**.

The slider body **3** is formed substantially during the insert molding process. Finally, the mounting portions **71** of the mounting plate **7** which extend outwardly from the surface of the slider body **3** is abraded to provide a reference surface.

The end caps **4** coupled to front and rear ends of the slider body **3** are injection molded of synthetic resin. Semicircular ball return channels **42** are formed in the inner sides of the end caps **4** and form part of the nonload ball channels. As shown in FIGS. **9** to **13**, the ball return channels **42** provide a connection between the load ball channels **61** of the slider body **3** and the ball bores **32**. Tongues **43** extend from ends of the end caps **4** to bring the balls **5** up from the load ball channels **61**. Also, seats **44** are provided centrally in the ball return channels **42** to receive return guides **33** of the slider body **3** when the end caps **4** are coupled to the slider body **3**. This facilitates guidance of the balls **5** through the ball return channels **42**.

The end caps **42** are adhesively attached to the slider body **3**. To ensure accurate attachment of the end caps **4** to the slider body **3**, the end caps **4** have recesses **4** to receive projections **62** of the ball plate **6**, and projections **41** to fit into the positioning holes **43** of the slider body **3**.

As shown in FIGS. **2** and **3**, the rail **2** includes a channel-like rail plate **21** made by pressing, and a synthetic resin **22** inserted in the rail plate **21** during molding process. A pair of ball channels **23** are formed in opposide outer sides of the rail plate **21** during pressing process. Also, through holes **24** are formed in the base along the length of the rail plate **21**. Bolt holes **25** are formed during insert molding process and correspond to the through holes **24**. In this embodiment, the slider **1** has no ball retainer. To avoid accidental removal of the slider **1** from the rail **2** and disengagement of the balls **5** from the load ball channels **61**, stoppers **9** are attached to opposite ends of the rail **2**.

The surface of the ball channels **23** are hardened to a predetermined level completely in the same manner as the load ball channels **61** of the ball plate **6**. After the rail has been pressed, the ball channels **23** are quenched and then, subzero treated. Alternatively, a metal sheet made of austenite SUS304 may be pressed or rolled to a predetermined shape to thereby increase the surface hardness of the ball channels **23** to a predetermined level.

When the slider **1** is in use, the balls **5** are placed in the nonload ball channels composed of the ball return channels **42** of the end caps **4** and the ball bores **32** of the slider body **3**. The balls **5** are also placed between the ball channels **23** of the rail **2** and the load ball channels **61** of the slider body **3**. A movable body is then secured to the mounting portions **71** which extend outwardly from the upper surface of the slider **1**.

A substantial part of the slider **1** is formed of synthetic resin **8**. However, part of the mounting plate **7** which has high regidity is embedded in the synthetic resin **8** to be integral with the slider body **3**. This mounting plate **7** serves as a reinforcing element for the slider body **3** to increase the rigidity of the slider body **3**. Thus, the slider body **3** is free from deformation or breakage if substantial load is exerted.

The mounting plate **7** and the slider body **3** are integrally formed during insert molding of the slider **3**. A change in shape of the mounting plate **7** results in a corresponding change in shape of the slider.

FIG. **14** shows a modification of the slider body **3** as insert molded. The slider body includes a mounting plate ***7a*** which has wider mounting portions than those of the mounting plate **7**, and bolt holes **76**.

According to this embodiment, while the ball plate **6** and other elements are commonly used, a variety of mounting plates **7** can be employed to provide a variety of sliders. Thus, various types of sliders can economically and readily be fabricated according to user's need.

In the foregoing embodiment, the axial length of the mounting plate **7** is less than that of the ball plate **6** so that the synthetic resin **8** which covers the fixed portion **72** of the mounting plate **7** are safely joined to the synthetic resin **8** which surrounds the ball plate **6**. As an alternative, the axial length of the mounting plate **6** may be identical to that of the slider body **3**. In such a case, slots or through openings **74** may be formed in the fixed portion **72** as shown in FIG. **15**.

FIG. **16** is a sectional view showing a second embodiment of the slider **1** wherein a mounting plate ***7b*** has the through openings **74**. As is clear from FIG. **16**, the synthetic resin **8** which covers the fixed portion **72** of the mounting plate **7** through the through openings **74** is safely joined to the synthetic resin **8** which surrounds the ball plate **6**. This embodiment also allows for firm integration of the mounting plate ***7b*** with the slider body **3**.

In this embodiment, the ball plate **6** is pressed, but the load ball channels **61** are not abraded. However, the load ball channels **61** may need be abraded when the plate **6** per se is made of a material which does not provide a smooth surface.

The rail **2** in which the slider **1** of this embodiment is assembled may be made by pressing a metal sheet. As shown in FIG. **17**, a matal block may be drawn to form a rail ***2a*** of a predetermined shape. In such a case, ball channels ***23a*** of the rail ***2a*** are quenched and then, subzero treated after it has been drawn so as to increase resistance to wear and improve the fragility of the ball channels ***23a***.

To reduce the cost of manufacturing the rail ***2a***, a block made of austenite SUS304 may be drawn to a predetermined shape. The rail ***2a*** is plastically deformed to thereby increase the surface hardness of the ball channels ***23a*** to a preetermined level.

INDUSTRIAL APPLICABILITY

As described above, according to a linear bearing and its production method of the present invention, a slider is formed by integrating a high rigid mounting plate with a ball plate by the use of molding material such as resin or die cast alloy. The slider thus made is highly rigid even if molding material is relatively flexible. It is therefore possible to provide a linear bearing which has high mechanical strength.

Also, according to a linear bearing and its production method of the present invention, a rail is plastically deformed to a predetermined shape to thereby harden a ball channels. This eliminates a need for heat treatment of the ball channels. It is therefore possible to provide a linear bearing which has high mechanical strength and is economical to manufacture.

Further, according to a linear bearing and its production method of the present invention, when a rail is quenched to harden ball channels, subzero treatment is subsequently effected to alter metallic system to improve the fragility of the rail. The ball channels are thus free from crack. It is therefore possible to provide a linear bearing which has high mechanical strength.

I claim:

1. A method of producing a linear bearing, said linear bearing comprising a rail having ball channels, and a slider having load ball channels cooperating with said ball channels to sandwich a multiplicity of balls and guiding a table or movable body secured to said slider along said rail, said method comprising the steps of

forming a thin ball plate having load ball channels, forming a thin mounting plate having mounting portions to which the movable body is secured, and integrally molding said ball plate and said mounting plate to provide said slider.

2. A method of producing a linear bearing according to claim 1, wherein part of nonload ball channels through which nonload balls are circulated are formed when said ball plate and said mounting plate are integrated together during insert molding process.

3. A method of producing a linear bearing according to claim 1, wherein said ball plate is made from a metal sheet whose surface hardness is increased when subjected to plastic deformation, and said load ball channels are hardened to a predetermined level while said ball plate is subjected to plastic deformation.

4. A method of producing a linear bearing, said linear bearing comprising a rail having ball channels, and a slider having load ball channels cooperating with said ball channels to sandwich a multiplicity of balls and guiding a table or movable body secured to said slider along said rail, said method comprising the steps of

providing a metallic material whose surface hardness is increased when subjected to plastic deformation, and plastically deforming said metallic material to form said rail and harden said ball channels to a predetermined level.

5. A method of producing a linear bearing, said linear bearing comprising a rail having ball channels, and a slider having load ball channels cooperating with said ball channels to sandwich a multiplicity of balls and guiding a table or movable body secured to said slider along said rail, said method comprising the steps of

forming ball channels in said rail, quenching said ball channels, and then, subzero treating (or deep freezing) said ball channels.

[57] ABSTRACT

A linear guide device which comprises a track bed having a substantially rectangular section opened at one side and is provided at its inner surfaces with rolling surfaces for rolling members; and a bearing block which has load rolling surfaces cooperating with the rolling surfaces to hold the rolling members therebetween and moves in a hollow portion of the track bed in accordance with rotation of a feed screw shaft engaging the bearing block. The bearing block is formed of a block body, rolling aperture forming plates and covers which are jointed together to entirely form ball circulation paths through which no-load balls circulate. Therefore, a long bearing block can be facilely manufactured, and thus a number of the rolling members can be increased for achieving the linear guide device having a large maximum allowable load and a compact configuration.

LINEAR GUIDE DEVICE

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a linear guide device used, for example, in a linear motion component of a machine tool or an industrial robot.

2. Description of the Related Art

A linear guide device of a type described above has been disclosed in Japanese Laid-Open Patent publication No. 62-200016. Specifically, as shown in FIG. 17, a bearing block (a) (which will be called merely a "block") is provided at its opposite side surfaces with load ball grooves (c) in which balls (b) rolls. A pair of track beds (d) is disposed with the block (a) therebetween. The beds (d) are provided with ball rolling grooves opposed to the load ball grooves (c). The balls (b) held between the load ball grooves (c) and the ball rolling grooves support the block (a) so that the block (a) may be movable along the track beds (d).

A screw shaft (f) of a feed screw mechanism is engaged with a central portion of the block (a), so that the screw shaft (f) may be rotated to move the block (a) along the track beds (d).

According to this linear guide device, since the bearing block for supporting a movable member such as the table is constructed integrally with the feed screw mechanism for applying a driving force for the linea motion to the movable member, a compact construction of the device can be achieved, and a height of the movable member can be minimized, which enables a stable motion.

However, with respect to the bearing block of the linear guide device described above, opposite ends of each load ball groove must be connected by a ball circulation path so as to guide or introduce the balls from a termination end of the load ball groove to a start end of the load ball groove again.

In the prior art, the ball circulation path is generally formed of a no-load ball rolling aperture, which is formed in the block to correspond to each load ball groove, and ball return paths, each of which connects an end of the ball load groove and an end of the no-load ball rolling aperture.

However, the no-load ball rolling aperture is a very small aperture having a diameter only slightly larger than that of the ball, and thus it is difficult to form a long no-load ball rolling aperture by drilling. Therefore, machining of the no-load rolling aperture restricts increase of a length of the block, and thus restricts the length of the load ball groove.

Generally, in a bearing which employs rolling members such as balls for bearing the motion between two objects, a maximum allowable load may be increased by 1 increasing sizes of the rolling members, or 2 increasing numbers of the rolling members which rolls on the load rolling groove. However, the latter can be hardly applied to practical products because the lengths of the load ball grooves are restricted due to the above described reason.

The present invention is devised in view of the above problems. It is an object of the invention to provide a linear guide devide, which allows easy formation of no-load rolling apertures for rolling members and has a large maximum allowable load and a small sizes.

SUMMARY OF THE INVENTION

In order to achieve the above objects, a linear guide device of the invention comprises: a track bed which has a substantially rectangular section opened at one side and is provided at its inner surfaces with rolling surfaces for rolling members; and a bearing block which has load rolling surfaces cooperating with said rolling surfaces to hold the rolling members therebetween and moves in a hollow portion of the track bed in accordance with a degree of rotation of a feed screw shaft engaging the bearing block, wherein said bearing block has a block body which includes a ball-nut portion engaging the feed screw shaft, a pair of bearing portions projected from the ball-nut portion and the load rolling surfaces formed at ends of the bearing portion, said bearing block further includes a rolling aperture forming plate which cooperates with the bearing portions to form the no-load rolling apertures for the rolling members, and covers which are engaged with front and rear end surfaces of the block body, and said covers form return paths for the rolling members which connect the load rolling surfaces and the no-load rolling apertures, respectively.

According to the embodiment of the invention described above, the load rolling surfaces formed on the bearing block may be appropriately varied with respect to its configurations including a number of the surfaces and a contact angle thereof to the rolling members, provided that the load rolling surfaces can bear the load applied to the block, and that the variation does not apply the load to the screw shaft engaging the block body.

In a construction in which the no-load rolling apertures are formed by the bearing portions of the block body and the rolling aperture forming plates engaging them, the apertures may be formed by no-load rolling grooves provided in the block body and closed or covered with the rolling aperture forming plates, or conversely, may be formed by the no-load rolling grooves provided in the rolling aperture forming plates engaging the block body.

Further, the rolling members used in the invention may be appropriately selected from balls, rollers and others.

According to the above embodiment, since the no-load rolling apertures in the bearing block are formed by attaching the rolling aperture forming plates to the block body, the no-load rolling apertures can be facilely manufactured by forming grooves for receiving the rolling members in one or both of the members, which facilitates manufacturing of the long bearing.

Since the bearing block is formed by attaching the rolling aperture forming plates and the covers to the block body, the block body may have a vertically and laterally symmetrical configuration which allows manufacturing of the long body by drawing.

Further, since the rolling aperture forming plate forms one side of the no-load rolling aperture, collision noises of the rolling members during rolling thereof in the no-load rolling apertures can be sufficiently prevented by employing plates made from resin.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a cross section illustrating a first embodiment of a linear guide device according to the invention;

FIG. 2 is a perspective view with a certain part cut away;

FIG. 3 is an exploded view illustrating components of a linear guide device according to the first embodiment;

FIGS. 4–7 are an elevation, a side view, a top view and a bottom view illustrating a block body, respectively;

FIG. 8 is a longitudinally sectional view illustrating a ball-nut portion of the block body;

FIGS. 9 and 10 are a front view and a rear view of a cover;

FIG. 11 is a view taken along an arrow A in FIG. 9;

FIGS. 12 and 13 are a rear view and a side view illustrating a rolling aperture forming plate;

FIG. 14 is a cross section taken along line XIV—XIV in FIG. 13;

FIGS. 15 and 16 are a side view and an elevation of a ball retainer; and

FIG. 17 is a cross section illustrating a linear guide device of the prior art.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

A linear guide device of the invention will be described in greater detail with reference to the accompanying drawings.

FIGS. 1 and 2 illustrate a first embodiment of the linear guide device of the invention, which is basically formed of a track base or bed 1 having a substantially rectangular section opening at one side and fixed to, e.g., a bed, a substantially rectangular bearing block B (will be also called as a "block") engaging a screw shaft 7 of a feed screw mechanism for moving in a concave portion of the track bed 1, and a plurality of balls 2 or rolling members which bear loads between the block B and the track bed 1 during rolling therebetween.

The block B is formed of, as shown in FIG. 3, a block body 3 engaging the feed screw shaft 7, covers 4 attached to front and rear end surfaces of the block body 3, rolling aperture forming plates 5 engaging four corners of the block body 3, and a pair of ball retainers 6 engaging side surfaces of the block body 3.

The block body 3 includes, as shown in FIGS. 4–7, a ball-nut portion 3*a* engaging the screw shaft 7 and a pair of bearing portions 3*b*, and thus has a section similar to a cross. Each bearing portion 3*b* is provided at corners or edges with a pair of load ball grooves 31*a* and 31*b*, or 31*c* and 31*d*, in which the balls 2 rolls. No-load ball grooves 32*a*–32*d* for circulating the balls which roll from ends of the load ball grooves 31*a*–31*d* are formed at corners between the bearing portions 3*b* and the ball-nut portion 3*a*. Each bearing portion 3*b* is provided with tapped bolt apertures 37 into which attaching bolts 55 are screwed for attaching the rolling aperture forming plates 5.

The ball-nut portion 3*a* engaging the screw shaft 7 is provided with, as shown in FIG. 8, a through aperture 33 having a diameter slightly larger than the screw shaft 7 and a rolling groove 34 which is formed at a portion of the through aperture 33 and corresponds to a spiral ball rolling groove on the screw shaft 7. Further, a return tube 36 is fixed to the ball-nut portion 3*a* by a holder member 35 to form a circulation path. Pre-loads are applied to balls (not shown) disposed between the screw shaft 7 and the block body 3 for increasing the accuracy of motion of the block B.

Since the block body 3 thus constructed has a vertically and laterally symmetrical configuration, it can be manufactured by drawing without utilizing conventional machining such as cutting. Specifically, the block body 3 can be manufactured in such a manner that the drawing is applied to a steel member to form the above sectional shape and then polishing for the load ball grooves 31*a*–31*d* and drilling for the through apertures 33 are applied to it. According to this manufacturing method, block bodies 3 having intended lengths can be facilely manufactured by appropriately cutting the drawn steel member into pieces.

The cover 4 has a sectional shape similar to a cross, as shown in FIGS. 9 and 10, and includes a base 4*a* and a pair of arms 4*b* projected therefrom. The cover 4 is formed by injection molding of synthetic resin. The base 4*a* is provided with a through aperture 41 into which the screw shaft 7 is inserted. Each projected arm 4*b* is provided at its opposite side surfaces with ball return grooves 42*a*–42*d* for connecting the load ball grooves 31*a*–31*d* on the block body 3 and the corresponding no-load ball grooves 32*a*–32*d* to each other (see FIG. 11). In FIG. 11, a numeral 43 indicates one of projections for scooping and guiding the balls 2, which roll from the load ball grooves 31*a*–31*d*, into the ball return grooves 42*a*–42*d*. A numeral 44 indicates one of positioning seats for bearing the guide projections 53 which will be described later and are provided in the rolling aperture forming plates 5.

The rolling aperture forming plates 5 are manufactured by injection molding of synthetic resin, similarly to the covers 4. As shown in FIGS. 12–14, the plates 5 each are provided at one surface with ball circulation grooves 51 corresponding to the no-load ball grooves 32*a*–32*d* on the block body 3 and the ball retrn grooves 42*a*–42*d* on the covers 4. Also, the plates 5 each are provided at one side edge with a ball retaining groove 52 which connects to the ball circulation groove 51 and corresponds to the load ball groove 31*a*–31*d* of the block body 3. Further, inside return portions 51*a* of the ball circulation paths 51, the guide pieces 53 are projected for positioning the plates 5 with respect to the block body 3 or the covers 4. In an assembly of the block B, each pair of the guide pieces 53 engage the front and rear end surfaces of the bearing portion 3*b* for positioning the block body 3, and rest on the positioning seats 44 of the covers 4 for positioning the covers 4. Numerals 54 indicate penetrated apertures through which attaching bolts 55 are inserted for attaching the plates 5 to the block body 3.

The ball retainer 6 is a rod-like member having a nearly trapezoid shape, as shown in FIGS. 15 and 16, and has a width so determined that a gap between the projected end 61 of the retainer 6 attached to the block body 3 and the ball retaining groove 52 on the rolling aperture forming plate **5** may be smaller than the diameter of the ball **2**, whereby the balls **2** are prevented from disengaging from the load ball grooves **31***a*–**31***d* when the block B is removed from the track bed **1**.

The track bed **1** has a nearly rectangular shape opened at one side and includes a fixing portion **1***a* fixed to a basic member such as a bed, and a pair of support portions **1***b* projected from the opposite ends of the fixing portion **1***a* for supporting the block body **3**. Each supporting portion **1***b* is provided at its inner surface with a groove **11**, and the grooves **11** are provided at their upper and lower corners with ball rolling grooves **12***a*–**12***d* opposed to the load ball grooves **31***a*–**31***d* of the block body **3**, respectively. A numeral **13** indicates one of bolt holes into which fixing bolts for fixing the track bed **1** are inserted.

In the construction described above, the bearing block B is assembled by attaching the covers **4** to the front and rear end surfaces of the block body **3** by screws (not shown), attching the four rolling aperture forming plates **5** to the bearing portions **3***b* of the block body **3** and attaching the ball retainers **6** to the side surfaces of the bearing portions **3***b* by screws (not shown).

Therefore, in the illustrated embodiment, the no-load ball rolling apertures corresponding to the load ball grooves **31***a*–**31***d* is formed of the no-load ball grooves **32***a*–**32***d* on the block body **3** and the ball circulation grooves **51** on the rolling aperture forming plates **5** opposed thereto. Further, the ball return paths which connect the no-load ball rolling apertures and the load ball grooves **31***a*–**31***d* are formed of the ball return grooves **42***a*–**42***d* on the covers **4** and the ball circulation grooves **51** on the plates **5** faced thereto.

In this construction, the no-load ball grooves **31***a*–**31***d* are facilely formed by applying milling to the block body **3** and the ball return grooves **42***a*–**42***d* and the ball circulation grooves **51** are facilely formed by the injection molding of the covers **4** and the rolling aperture forming plates **5**, respectively. Therefore, even in the long block B, the no-load ball rolling apertures can be facilely and accurately formed.

Since the balls **2** are covered with the plates or covers **4** made from the synthetic resin while they are rolling the ball circulation paths, noises which may be caused by circulation of the balls can be reduced.

According to the linear guide device of the invention, as described hereinabove, the no-load rolling apertures can be facilely formed by machining the grooves for receiving the rolling members in the block body and/or the rolling aperture forming plates, so that the long bearing block can be facilely manufactured, and thus the number of the load rolling members can be increased to obtain the linear guide device having an increased maximum allowable load and a compact configuration.

Since the block body having an intended length can be manufactured by cutting a drawn member, the productive efficiency can be increased and the costs can be reduced.

Further, owing to the rolling aperture forming plates made from resin, the collision noises of the rolling members during rolling in the no-load apertures can be minimized, and thus the linear guide device having a small operation noise can be obtained.

What is claimed is:

1. A linear guide device comprising:

a track bed having a substantially rectangular section open at one side and provided at its inner surfaces with rolling surfaces for rolling members; and

a bearing block having load rolling surfaces cooperating with said rolling surfaces to hold the rolling members therebetween and moving in a hollow portion of the track bed in accordance with a degree of rotation of a feed screw shaft engaging the bearing block, wherein

said bearing block has a block body which includes a ball-nut portion engaging the feed screw shaft, a pair of bearing portions projecting from both sides of the ball-nut portion and the load rolling surfaces formed at corners or edges of the bearing portion, and, thus constructed, having a vertically and laterally symmetrical configuration.

said bearing block further including four rolling aperture forming plates engaged with upper and lower sides of said bearing portions, and cooperating with the bearing portions to form no-load rolling apertures for the rolling members, and covers which are engaged with front and rear end surfaces of the block body, and

said covers forming return paths for the rolling members which connect the load rolling surfaces and the no load rolling apertures, respectively.

[57] **ABSTRACT**

A ball retainer to be used in a linear bearing of a ball bush, a ball spline or the like. The ball retainer is formed with endless ball guide races for guiding balls smoothly and can be easily assembled in a bearing outer cylinder. The ball retainer is constructed to comprise: a retainer body fitted in a hollow portion from one opening of the bearing outer cylinder which moves linearly around a bearing shaft; and an annular piece fitted in the hollow portion from the other opening. The ball retainer is characterized in that its outer shape is configured with the inner shape of the bearing outer cylinder when the annular piece is fixed on the leading end portion of the retainer body.

BALL RETAINER FOR LINEAR BEARINGS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a ball retainer adapted to be used in a linear bearing of a ball spline, a ball bush or the like for retaining and arraying balls held between a bearing outer cylinder and a bearing shaft and, more particularly, to an improvement in the shape of the ball retainer for circulating the balls smoothly.

2. Description of the Prior Art

The ball retainer of this kind generally known in the prior art is exemplified by a ball retainer **60** of a ball spline, as shown in FIG. **9**.

This ball retainer **60** is molded into a generally cylindrical thin shape having a hollow portion **61**, in which a spline shaft (although not shown) is loosely fitted. Specifically, the ball retainer **60** is formed in its outer circumference **62** with a plurality of endless ball guide races, each of which is composed of: elongated loaded ball guide races **64** for rolling loaded balls **63** held between a spline outer cylinder **70** and the spline shaft; unloaded ball guide races **66** for loading unloaded balls **65**; and ball turning races **67** for connecting the loaded ball guide races **64** and the unloaded ball guide races in communication. Moreover, this ball retainer **60** is fitted for use in the hollow portion of the spline outer cylinder **70** after its endless ball guide races have been arrayed with the loaded balls **63** and the unloaded balls **65**.

Considering the assembly efficiency of the ball spline, the ball retainer thus constructed and used is integrally injection-molded of a synthetic resin and is assembled with the spline outer cylinder **70** by inserting it into the hollow portion from one opening of the spline outer cylinder **70**.

Incidentially, this spline outer cylinder **70** has its inner circumference divided into: a loaded ball region for holding the loaded balls **63** together with the spline shaft; and a pair of ball scoop regions **68** positioned axially adjacent to the loaded ball region. The loaded ball region is formed axially of the spline outer cylinder **70** with a plurality of ridges **71** for holding the loaded balls **63** between themselves and the spline shaft. On the other hand, the aforementioned ball scoop regions **68** are formed to have such an equal internal diameter that the loaded balls **63** are released in the ball scoop regions **68** from the clearances between the aforementioned ridges **71** and the spline shaft.

In order to fit the integrally molded ball retainer **60** in the hollow portion of the spline outer cylinder **70**, therefore, the shape of the outer circumference of the ball retainer **60** has to be configured with the sectional shape of the loaded ball regions formed with the ridges **71**. For this reason, the ball retainer **60** is given an axially uniform sectional shape (as shown in FIG. **9**).

However, this sectional shape raises the following disadvantages. At first, if the ball retainer **60** has its sectional shape made identical to that of the load ball regions, the aforementioned ball turning races **67** are partially (as indicated at A in FIG. **9**) shallowed so much that the rolling runs of the unloaded balls **65** are liable to grow unstable. Since, moreover, the ball turning races **67** correspond to the ball scoop regions **68** of the spline outer cylinder **70**, clearances are established between the spline outer cylinder **70** and the ball retainer **60** in the ball scoop regions **68** to make unstable the rolling runs of the unloaded balls **65** in the aforementioned A portions.

As a result, at the time of the high-speed or vertical movements of the spline outer cylinder **70**, the unloaded balls **65** are liable to come out of the ball turning races **67** so that they interfere with each other, as shown in FIG. **10**, to clog the ball turning races **67**. Thus, there rises another problem that the balls cannot circulate any more.

SUMMARY OF THE INVENTION

The present invention has been conceived to solve such problems and has an object to provide a ball retainer which has endless ball guide races capable of guiding balls smoothly along predetermined tracks and which can be easily assembled with a bearing outer cylinder.

In order to achieve the above-specified object, according to the present invention, there is provided a ball retainer fitted in the hollow portion of a bearing outer cylinder, which can move linearly around a bearing shaft, for retaining and arraying balls held between the bearing outer cylinder and the bearing shaft, which retainer comprises: a retainer body including: a smaller-diameter portion adapted to be fitted in a loaded ball region of the bearing outer cylinder, which is formed with a plurality of axially extending ridges for holding said balls together with the bearing shaft; a larger-diameter portion formed at one end of the smaller-diameter portion and so fitted in a ball scoop region of the bearing outer cylinder adjacent to the loaded ball region that it is axially retained by the ridges; and a leading end portion formed at the other end of the smaller-diameter portion to have a diameter equal to or smaller than that of the smaller-diameter portion for forming a clearance with the inner circumference of the bearing outer cylinder in another ball scoop region of the bearing outer cylinder, the smaller-diameter portion being formed in its outer circumference with loaded ball guide races and unloaded ball guide races corresponding to loaded ball rolling faces and unloaded ball races, which are formed in the inner circumference of the bearing outer cylinder, the larger-diameter portion and the leading end portion being formed in its outer circumferences with ball turning races for connecting the loaded ball guide races and the unloaded ball guide races in communication; and an annular piece formed with semicircular cut portions corresponding to the ball turning races and fixed on the outer circumference of the leading end portion of the retainer body for occupying the clearance between the leading end portion and the inner circumference of the bearing outer cylinder.

BRIEF DESCRIPTION OF THE DRAWINGS

Other objects, advantages and features of the present invention will become apparent from the following description to be made with reference to the accompanying drawings, in which:

FIG. **1** is an exploded perspective view showing the state, in which a ball retainer according to a first embodiment of the present invention is assembled;

FIG. **2** is a section showing the assembled state of the ball retainer according to the first embodiment;

FIG. **3** is a side elevation showing the ball retainer according to the first embodiment;

FIG. **4** is a section taken along line IV—IV of FIG. **3**;

FIG. **5** is a section taken along line V—V of FIG. **3**;

FIG. 7 is a section showing the ball turning race in a seat of the retainer body;

FIG. 8 is an exploded perspective view showing an assembled state of a ball retainer according to a second embodiment of the present invention;

FIG. 9 is an exploded perspective view showing the assembled state of the ball retainer of the prior art;

FIG. 10 is an enlarged view for explaining the problems in the ball retainer of the prior art;

FIG. 11 is a section showing a ball contacting state in a ball bush, to which the ball retainer of the present invention can be applied; and

FIG. 12 is a section showing a ball contacting state in a ball spline, to which the ball retainer of the present invention can be applied.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

A ball retainer in a linear bearing in accordance with the present invention will be described in detail in the following with reference to the accompanying drawings.

FIG. **1** is an exploded perspective view showing a ball retainer of a ball spline, to which the present invention is applied. This ball retainer is constructed to include a retainer body **1** fitted in the hollow portion of a spline outer cylinder **3** (as will be shortly referred to as the "outer cylinder") from one opening of the same, and an annular piece **2** fitted in the hollow portion from the other opening of the outer cylinder **3**.

First of all, the retainer body **1** is composed of: a smaller-diameter portion **11** fitted in a loaded ball range of the outer cylinder **3**; a larger-diameter portion **12** formed to extend from one end of the smaller-diameter portion **11** and fitted in a ball scoop region **31** of the outer cylinder **3**; and a leading end portion **10** formed to extend from the other end of the smaller-diameter portion **11** and positioned in the ball scoop region **31** of the outer cylinder **3**. The retainer body **1** is injection-molded of a synthetic resin to have a substantially equal total length as that of the outer cylinder **3**.

FIG. **5** shows a section of the aforementioned smaller-diameter portion. This smaller-diameter portion **11** is formed with: loaded ball guide races **5** of elongated window shape for guiding loaded balls **4*a*** between the outer cylinder **3** and the spline shaft (although not shown); and unloaded ball guide races **6** for rolling unloaded balls **4*b***. These two guide races **5** and **6** are partitioned by islands **7**, and the unloaded ball guide races **6** are formed at their one sides with banks **8**, which face the islands **7** and extend from the larger-diameter portion **12**, for enclosing and guiding the unloaded balls **4*b*** rolling in the unloaded ball guide races **6**. As shown in FIG. **1**, moreover, those islands **7** and the banks **8** are fitted in unloaded ball races **33** which are formed between a plurality of ridges **32** of the outer cylinder **3**. Moreover, the loaded ball guide races **5** are formed at their two ends with tongues **14** for scooping the loaded balls **4*a*** having rolled in said races **5** up to ball turning races **9** and **13**.

As shown in FIG. **6**, on the other hand, the aforementioned larger-diameter portion **12** is formed with the deeper ball turning races **9** for wrapping and guiding the unloaded balls **4*b*** like the aforementioned unloaded ball guide races **6**. Each of the ball turning races **9** connects one end of the loaded ball guide race **5** and one end of the unloaded ball guide race **6** in communication.

Moreover, the aforementioned leading end portion provides a seat having its outer circumference fitting the aforementioned annular piece **2** therein. This leading end portion **10** is formed with the ball turning races **13** for connecting the loaded ball guide races **5** and the unloaded ball guide races **6** in communication.

On the other hand, the annular piece **2** is a ringshaped member having its internal diameter for fitting the outer circumference of the leading end portion **10** therein. The annular piece **2** is formed, as shown in FIG. **1**, with semicircular cut portions **21** which correspond to the ball turning races **13** formed in the leading end portion **10** of the retainer body **1**. The cut portions **21** are provided in the number corresponding to the ball tracks and arranged at an equal distance.

Moreover, the ball retainer thus constructed according to the present embodiment is assembled with the outer cylinder by fitting the retainer body in the hollow portion from one opening of the outer cylinder, by fitting the annular piece **2** in the hollow portion from the other opening, and by fixing the annular piece **2** on the leading end portion **10** of the retainer body **1**.

FIG. **6** shows the behavior, in which the unloaded ball **4*b*** is rolling in the ball turning race **9** formed in the larger-diameter portion **12**. The unloaded balls **4*b*** are completely sealed by both the ball turning races **9** formed in the retainer body **1** and the outer cylinder **3** so that they can roll smoothly in the ball turning races **9** without coming out of these races **9**. On the other hand, the ball turning races **13** formed in the leading end portion **10** are made deep and defined, as shown in FIGS. **4** and **7**, by the islands **7** of the retainer body **1** and the cut portions **21** of the annular piece to have sections identical to those of the ball turning races **9** shown in FIG. **6**. As a result, the unloaded balls **4*b*** to roll in the ball turning races **13** can roll smoothly in the ball turning races **13** without coming out these races **13**.

Thus, in the ball retainer of the present embodiment, the deep ball circulating tracks for connecting the two ends of the loaded ball guide races **5** in communication are completed, when the annular piece **2** is fixed in the retainer body **1**, so that the unloaded balls **4*b*** scooped up from the load ball guide races **5** can circulate smoothly.

Next, FIG. **8** shows a second embodiment of the present invention.

This embodiment takes a structure substantially similar to that of the foregoing first embodiment. Since the smaller-diameter portion **11** of the retainer body **1** is cut by a lathe, it has its center portion of the islands **7** and its banks **8** cut away.

As a result, the unloaded ball guide races **6** are made shallow, but the ball turning races **9** and **13** are made deep like the first embodiment so that the balls **4** can be arrayed in the predetermined tracks and smoothly guided from the loaded ball guide races **5** to the unloaded ball guide races **6**.

Here in FIG. **8**, the components similar to those of FIG. **1** are designated at the common reference numerals, and their descriptions will be omitted.

In the first and second embodiments thus far described, moreover, the description is directed to the case, in which the present invention is applied to the ball spline having three ball tracks, but the present invention can also be applied to any ball spline irrespective of the number of ball tracks.

Incidentally, the linear bearing, to which the present invention can be applied, is a bearing for bearing the relative linear movements between the cylindrical bearing outer cylinder and the bearing shaft by holding a plurality of balls circulating endlessly inbetween. This bearing is exemplified by: a ball bushing in which a ball **81** can bear a load while contacting in point-to-point relation with a loaded ball rolling face **83** formed on the inner circumference of a baring outer cylinder **82** and the outer circumference of a bearing shaft **84**, as shown in FIG. **11**; and a ball spline in which the ball **81** can bear the load while contacting in point-to-point relation with a bearing outer cylinder **85** and a shallow loaded ball rolling face **87** formed on a bearing shaft **86** and can transmit the rotational torque acting between the two members.

According to the structures thus far described, the ball retainer is assembled by fitting the retainer body in the hollow portion of the bearing outer cylinder from one opening of the same and by fitting the annular piece from the other opening, so that its shape can be completely contoured with the shape of the hollow portion of the bearing outer cylinder. As a result, the ball turning races connecting the loaded ball guide races and the unloaded ball guide races are made deep throughout their lengths so that the balls can roll smoothly in array within the ball turning races. As a result, the balls are prevented from coming out of the predetermined track in the ball turning races and from clogging the races so that their circulations can be smoothed to achieve the smooth sliding movements of the bearing outer cylinder.

What is claimed is:

1. A ball retainer fitted in the hollow portion of a bearing outer cylinder, which can move linearly around a bearing shaft, for retaining and arraying balls held between said bearing outer cylinder and said bearing shaft, comprising:

a retainer body including: a smaller-diameter portion adapted to be fitted in a loaded ball region of said bearing outer cylinder, which is formed with a plurality of axially extending ridges for holding said balls together with said bearing shaft; a larger-diameter portion formed at one end of said smaller-diameter portion and so fitted in a ball scoop region of said bearing outer cylinder adjacent to said loaded ball region that it is axially retained by said ridges; and a leading end portion formed at the other end of said smaller-diameter portion to have a diameter equal to or smaller than that of said smaller-diameter portion for forming a clearance with the inner circumference of said bearing outer cylinder in another ball scoop region of said bearing outer cylinder, said smaller-diameter portion being formed in its outer circumference with loaded ball guide races and unloaded ball guide races corresponding to loaded ball rolling faces and unloaded ball races, which are formed in the inner circumference of said bearing outer cylinder, said larger-diameter portion and said leading end portion being formed in its outer circumference with ball turning races for connecting said loaded ball guide races and said unloaded ball guide races in communication; and

an annular piece formed with semicircular cut portions corresponding to said ball turning races and fixed on the outer circumference of the leading end portion of said retainer body for occupying the clearance between said leading end portion and the inner circumference of said bearing outer cylinder.

2. A ball retainer according to claim **1**, wherein the loaded ball guide races of the smaller-diameter portion of said retainer body are formed at their two ends with tongues for scooping up the loaded balls having rolled therein to said ball turning races.

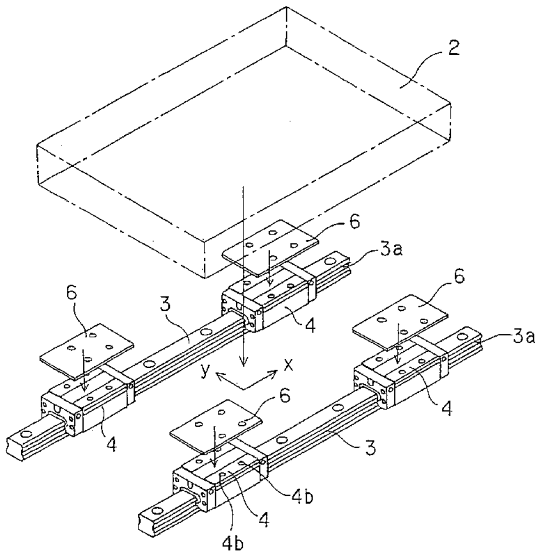
(54) Bezeichnung: **Dämpfungsstruktur und Bewegungsführungsvorrichtung, die in die Dämpfungsstruktur einbezogen ist**

(57) Hauptanspruch: Dämpfungsstruktur mit einer Mehrzahl von dünnen Metallschichten und einer Mehrzahl von dünnen Dämpfungsschichten mit jeweils einem Young-Modul, der sich von dem der Metallschicht unterscheidet, wobei die Metallschicht und die Dämpfungsschicht eine nach der anderen wechselweise derart laminiert sind, dass sie eine Gesamtdicke der Dämpfungsstruktur von nicht mehr als 1,0 mm schaffen.



Beschreibung

Gebiet der Erfindung

[0001] Die vorliegende Erfindung betrifft eine Dämpfungsstruktur, die eine Schwächungs- oder Dämpfungsfunktion hat, und insbesondere eine Dämpfungsstruktur für die Anwendung der Dämpfungsfunktion bei einem Führungssystem zum Führen einer Relativbewegung eines Tisches in Bezug auf eine Basis.

Stand der Technik

[0002] Es ist ein Führungssystem zum Führen eines Tisches in Bezug auf eine Basis bekannt. Ein solches Führungssystem weist eine Laufschiene, die an der Basis montiert ist, und einen bewegbaren Block auf, der an dem Tisch montiert ist, um entlang der Laufschiene verschiebbar zu sein. Um eine sanfte Gleitbewegung des bewegbaren Blocks in Bezug auf die Laufschiene sicherzustellen, sind Wälzkörper, wie Kugeln, Rollen oder dergleichen, die eine Wälzbewegung durchführen, zwischen der Laufschiene und dem bewegbaren Block angeordnet.

[0003] Wenn der Tisch nach der Bewegung des Tisches unter Verwendung eines Antriebsmechanismus, wie einer Kugelumlaufspindel, rapide gestoppt wird, wird der Tisch in dessen Vorlaufrichtung in Schwingungen oder Vibrationen versetzt. In einem Falle, wo ein Führungssystem in eine Werkzeugmaschine, eine Teilmontagemaschine, eine Halbleiter/Flüssigkristall-Herstellungsvorrichtung und so weiter eingebaut ist, muss eine Bedienperson mit der Durchführung einer Arbeit an dem Führungssystem warten, bis die Schwingung oder Vibration aufhört, und dementsprechend ist es notwendig, die Schwingung abzuschwächen oder zu dämpfen.

[0004] In einem herkömmlichen Führungssystem wird, um die Schwingung des Tisches zu dämpfen, ein Vorbelastungsverfahren angewendet, bei welchem eine innere Belastung auf einen Wälzkörper ausgeübt wird. Zum Beispiel sind Wälzkörper mit jeweils einem Außendurchmesser, der größer als ein Spalt zwischen einer in der Laufschiene ausgebildeten Wälzkörperlaufrille und einer Wälzkörperlaufrille des bewegbaren Blocks ist, zwischen der Laufschiene und dem bewegbaren Block angeordnet. wenn die innere Belastung auf den Wälzkörper ausgeübt wird, ist der Reibungswiderstand groß, der zu einem Zeitpunkt aufhört, wenn der Wälzkörper in der Wälzkörperlaufrille abrollt, und somit wird eine Bewegungsstabilität verbessert. Ferner kann die Schwingungs-(Vibrations-) Energie in Wärmeenergie umgewandelt werden, wodurch die Schwingung gedämpft wird.

Probleme, die mit der Erfindung zu lösen sind

[0005] Jedoch wird gemäß der oben genannten Struktur durch Ausüben der inneren Belastung auf den Wälzkörper ein Widerstand zu einem Zeitpunkt erhöht, wenn der bewegbare Block in Bezug auf die Laufschiene gleitet, und infolgedessen wird die nutzbare Lebensdauer des Wälzkörpers verkürzt.

[0006] Zwischenzeitlich ist auch als eine erdbebenfeste Struktur zum Schützen eines Gebäudes vor Erdbeben eine laminierte Gummistruktur bekannt, die zwischen dem Gebäude und dessen Grundstruktur angeordnet ist. Eine solche laminierte Gummistruktur ist aus Eisenplatten und Gummis gebildet, welche wechselweise laminiert sind, und die laminierte Gummistruktur hat eine hohe Steifigkeit gegen eine senkrechte Belastung und wird in horizontaler Richtung verformt, wodurch eine große Schwächungs-(Dämpfungs-) Funktion geschaffen wird.

[0007] Jedoch hat die herkömmliche laminierte Gummistruktur im Allgemeinen eine nicht so große Dicke (Höhe), zum Beispiel von 10 bis 20 mm, welche nicht für deren Montage in einem Führungssystem geeignet ist, das eine geringe Größe erfordert. Darüber hinaus ist entsprechend einer solchen Höhe das Verformungsmaß der laminierten Gummistruktur infolge der horizontalen Belastung (d.h. der Scherkraft) groß. Unter diesem Gesichtspunkt ist eine solche herkömmliche laminierte Gummistruktur nicht für das Führungssystem geeignet, bei welchem eine hohe Steifigkeit erforderlich ist.

[0008] Die vorliegende Erfindung bezweckt dann, eine kompakte Dämpfungsstruktur zu schaffen, die in der Lage ist, ein hohes Dämpfungsverhalten zu erreichen und eine hohe Steifigkeit zu schaffen.

Mittel zur Lösung des Problems

[0009] Nachstehend wird die vorliegende Erfindung beschrieben.

[0010] Um die obigen Probleme zu lösen, konzipierten die Erfinder der betreffenden Anmeldung die Laminierungsstruktur einer Mehrzahl von dünnen Metallschichten und einer Mehrzahl von dünnen Dämpfungsschichten mit jeweils einem Young-Modul, der sich von dem der Metallschicht unterscheidet, und legten die Gesamtdicke extrem dünn fest, was in einer herkömmlichen laminierten Gummistruktur nicht konzipiert wurde.

[0011] Das heißt, um das obige Problem zu lösen, schafft die Erfindung nach Anspruch 1 eine Dämpfungsstruktur mit einer Mehrzahl von dünnen Metallschichten und einer Mehrzahl von dünnen Dämpfungsschichten mit jeweils einem Young-Modul, der sich von dem der Metallschicht unterscheidet, wobei die Metallschichten und die Dämpfungsschichten eine nach der anderen wechselweise derart laminiert sind, dass sie eine Gesamtdicke der Dämpfungsstruktur von nicht mehr als 1,0 mm schaffen.

[0012] Unter einem Gesichtspunkt, dass ein hohes Dämpfungsverhalten erreicht werden kann und auch eine hohe Steifigkeit erreicht werden kann, ist es erwünscht, dass die Dämpfungsstruktur die Gesamtdicke von nicht mehr als 0,5 mm hat, und dass die Metallschicht eine Dicke von 20 bis 40 µm hat und die Dämpfungsschicht eine Dicke von 5 bis 10 µm hat.

[0013] In einer Ausführungsform, in welcher die Dämpfungsschicht aus einer Gummi- oder Harzschicht gebildet ist und auf der Metallschicht gedruckt ist, kann die Dicke der zu laminierenden Dämpfungsschicht dünn gestaltet sein.

[0014] In einer Ausführungsform, in welcher eine Grenzfläche zwischen der Metallschicht und der Dämpfungsschicht eine gewellte Form mit kontinuierlich wechselnden Spitzen und Tälern vorsieht, kann ein Bereich der Grenzfläche erhöht werden, so dass ein weiter verbessertes Dämpfungsverhalten erreicht wird.

[0015] Ferner schafft die vorliegende Erfindung eine Bewegungsführungsvorrichtung mit einer Laufschiene und einem bewegbaren Block, der angeordnet ist, um entlang der Laufschiene verschiebbar zu sein, wobei eine Mehrzahl von dünnen Metallschichten und eine Mehrzahl von dünnen Dämpfungsschichten mit jeweils einem Young-Modul, der sich von dem der Metallschicht unterscheidet, eine nach der anderen wechselweise derart laminiert sind, dass sie eine Gesamtdicke der Dämpfungsstruktur von nicht mehr als 1,0 mm schaffen.

[0016] Noch darüber hinaus schafft die vorliegende Erfindung ein Führungssystem mit einer Basis, einem Tisch und einer Bewegungsführungsvorrichtung, die zwischen der Basis und dem Tisch angeordnet ist, so dass der Tisch in Bezug auf die Basis relativ bewegbar ist, wobei die Bewegungsführungsvorrichtung eine Laufschiene, die an der Basis montiert ist, und einen bewegbaren Block aufweist, der an dem Tisch montiert ist, um entlang der Laufschiene verschiebbar zu sein, wobei eine Mehrzahl von dünnen Metallschichten und eine Mehrzahl von dünnen Dämpfungsschichten mit jeweils einem Young-Modul, der sich von dem der Metallschicht unterscheidet, eine nach der anderen wechselweise derart laminiert sind, dass sie eine Gesamtdicke der Dämpfungsstruktur von nicht mehr als 1,0 mm schaffen.

[0017] Gemäß der vorliegenden Erfindung der oben erwähnten Gestalt kann das Dämpfungsverhalten der Dämpfungsstruktur erhöht werden. Außerdem kann auch deren Steifigkeit erhöht werden. Das heißt, ein Maß der Verformung der Dämpfungsstruktur infolge von Scherkräften kann gering gestaltet sein, und eine auszuübende Kompressionsbelastung kann groß gestaltet sein.

[0018] Darüber hinaus kann die Dämpfungsstruktur ohne Durchführung einer Gestaltungsänderung des bewegbaren Blocks durch eine zusätzliche Bearbeitung, wie Schleifen, der oberen Fläche des bewegbaren Blocks montiert werden.

[0019] Noch darüber hinaus kann, da eine Mehrzahl von Dämpfungsschichten angeordnet sind, die an der Tischseite erzeugte Wärme von einer Übertragung auf eine Bewegungsführungsvorrichtung ferngehalten werden, was eine Wärmeisolierungswirkung schafft.

Kurzbeschreibung der Zeichnungen

[0020] Fig. 1 ist eine perspektivische Ansicht, die ein Führungssystem unter Einbeziehung eines Dämpfungskissens gemäß einer Ausführungsform der vorliegenden Erfindung zeigt.

[0021] Fig. 2 ist eine teilweise Schnittansicht des Führungssystems aus Fig. 1.

Bevorzugte Ausführungsform der Erfindung

[0026] Fig. 1 und Fig. 2 stellen ein Führungssystem unter Einbeziehung einer Dämpfungsstruktur gemäß einer Ausführungsform der vorliegenden Erfindung dar. Das Führungssystem wird für eine Werkzeugmaschine, wie ein Bearbeitungszentrum, eine Drehmaschine, Fräsmaschine oder dergleichen, eine Teilmontagemaschine, wie einen Roboter zur Montage von Teilen an eine elektrische Leiterplatte, und eine Halbleiter- oder Flüssigkristall-Herstellungsmaschine, wie Substratzerteiler oder Drahtbonder, oder dergleichen, verwendet, und das Führungssystem wird angewendet, um eine lineare Bewegung oder krummlinige Bewegung eines Tisches **2** in Bezug auf eine Basis **1** zu tragen.

[0027] Eine sich genau erstreckende Laufschiene **3** ist an der Basis **1** angebracht. Ein bewegbarer Block **4** des Spreiztyps ist an der Laufschiene **3** montiert, um entlang der Laufschiene **3** verschiebbar zu sein. Der Tisch **2** ist an der oberen Fläche des bewegbaren Blocks **4** angebracht. In dieser Ausführungsform können, obwohl zwei Laufschienen **3**, **3** und vier bewegbare Blöcke **4**, --- angeordnet sind, die Anzahl von Laufschienen **3** und bewegbaren Blöcken **4** entsprechend den zu verwendenden Maschinen geändert oder bestimmt werden.

[0028] Eine Anzahl von Kugeln **5**, --- sind als Wälzkörper zwischen der Laufschiene **3** und dem bewegbaren Block **4** angeordnet, so dass der bewegbare Block **4** leicht gleiten kann. Diese Kugeln **5**, --- wälzen und bewegen sich zwischen einer Kugellaufrille **3a**, die sich entlang der Laufschiene **3** genau erstreckt, und einer Kugellastlaufrille **4a**, die in dem bewegbaren Block **4** derart ausgebildet ist, dass sie der Kugellaufrille **3a** gegenüberliegt. Die Details der durch diese Laufschienen **3** und die bewegbaren Blöcke **4** gebildeten Bewegungsführungsvorrichtung werden später hierin beschrieben.

[0029] Dämpfungskissen **6**, --- als eine Dämpfungsstruktur haben jeweils eine geringe Dicke und rechteckige Form entsprechend der flachen Form des bewegbaren Blocks **4**. Der Tisch **2** wird zum Beispiel in einer X-Richtung in der Zeichnung durch einen nicht gezeigten Antriebsmechanismus, wie eine Kugelumlaufspindel oder dergleichen, linear bewegt. Wenn der Tisch **2** schnell gestoppt wird, schwingt (vibriert) der Tisch **2** in der X-Richtung. In einem Falle, wo ein solches Führungssystem in eine Werkzeugmaschine einbezogen ist, kann eine Bedienperson den nächsten Bearbeitungsschritt nicht ausführen, bis eine solche Schwingung aufhört, und andererseits kann in einem Falle, wo ein solches Führungssystem in eine Teilmontagemaschine einbezogen ist, eine Bedienperson keine Teile montieren, bis die Schwingung aufhört. Das Dämpfungskissen **6** gemäß dieser Ausführungsform kann die Schwingung des Tisches in jeder Richtung in der X-Y-Ebene abfangen und dämpfen, um dadurch die Schwingung schnell zu bündeln.

[0030] Das Dämpfungskissen **6** wird zwischen dem bewegbaren Block **4** und dem Tisch **2** in der folgenden Weise fixiert. Gewindelöcher **4b**, --- sind in einer oberen Fläche des bewegbaren Blocks **4** ausgebildet, Schraubenlöcher sind in dem Tisch **2** und dem Dämpfungskissen **6** zum Einsetzen von Schrauben ausgebildet, und der Tisch **2** und das Dämpfungskissen **6** werden mit Befestigungsmitteln, wie einer Schraube, an dem bewegbaren Block **4** fixiert. Bei diesem Fixierungsvorgang wird das Schraubenbefestigungsdrehmoment derart gesteuert, dass diese drei Teile nicht integriert werden und der Tisch **2** in Bezug auf den bewegbaren Block **3** leicht verformbar ist. In einer anderen Weise können der bewegbare Block **4** und das Dämpfungskissen **6** verklebt werden, oder das Dämpfungskissen **6** und der Tisch **2** können verklebt werden.

[0031] Fig. 3 zeigt die Schnittansicht des Dämpfungskissens **6**. Das Dämpfungskissen **6** wird durch wechselweises Laminieren einer Mehrzahl von dünnen Metallschichten und einer Mehrzahl von Dämpfungsschichten mit einem Young-Modul, der sich von dem der Metallschichten unterscheidet, gebildet. Insbesondere werden die Metallschichten **8**, --- aus einer Mehrzahl von dünnen flachplattenförmigen rostfreien oder Eisen-Metallschichten gebildet, und die Dämpfungsschichten **9** werden aus einer Mehrzahl von dünnen flachplattenförmigen Gummi- oder Leimschichten derart gebildet, dass diese Schichten **8** und **9** eine nach der anderen wechselweise laminiert werden. Das Dämpfungskissen **6** in dieser Ausführungsform wird aus einer Mehrzahl von laminierten Einheiten U gebildet, die jeweils aus der Metallschicht **8** bestehen, auf welche die aus Gummi hergestellte Dämpfungsschicht **9** gedruckt wird. Die Einheiten U, auf welche die Dämpfungsschichten **9** gedruckt werden, verbinden sich nicht miteinander. Die Dämpfungsschicht **9** wird in einer Weise gebildet, dass Gummi im flüssigen Zustand mit einer Dämpfungswirkung auf die gesamte Fläche der Metallschicht **8** siebgedruckt wird und der Gummi im flüssigen Zustand danach zum Beispiel durch einen Erwärmungsvorgang gehärtet wird. In den anderen Weisen kann ein Verfahren, bei welchem eine Gummifolie, die auf einer Metallplatte liegt, erwärmt und gepresst wird, oder ein Verfahren angewendet werden, bei welchem eine Gummischicht auf einer Metallplatte mittels eines Spritzgießvorgangs gebildet wird.

[0032] Ferner, um eine große Dämpfungskraft zu erreichen, ist es erwünscht, die Einheiten U nicht miteinander zu verbinden, aber es kann möglich sein, die Einheiten U unter Berücksichtigung ihrer leichten Handhabung zu verkleben. Die äußerste Schicht des Dämpfungskissens **6** kann mit der Metallschicht **8** oder der Dämpfungsschicht **9** gebildet werden. Andererseits kann die außen positionierte Metallschicht **8** verstemmt werden, um ein integriertes Dämpfungskissen zu schaffen.

[0033] Das charakteristische Merkmal des Dämpfungskissens **6** der vorliegenden Ausführungsform liegt in der Bildung der laminierten Schichtstrukturen der dünnen Metallschichten **8** und der Dämpfungsschichten **9** mittels einer Grenzfläche **10**, die zwischen jeweils benachbarten Schichten **8** und **9** angeordnet ist. Einer der Gründe, weshalb die Anordnung einer Mehrzahl von Grenzflächen **10** dazu dient, eine große Dämpfungskraft zu schaffen, ist wie folgt. Wenn eine Scherkraft auf das Dämpfungskissen **6** ausgeübt wird, wirkt eine Kraft, um eine Verschiebung an der Grenzfläche **10** zwischen der Metallschicht **8** und der Dämpfungsschicht **9** zu bewirken, und entsprechend einer solchen Verschiebung wird eine Reibungskraft an der Grenzfläche **10** verursacht, welche eine Schwingungsenergie in eine Wärmeenergie umwandelt, wodurch die Dämpfungskraft erzeugt wird. Daher bewirkt die Anordnung einer Mehrzahl solcher Grenzflächen **10** eine große Reibungskraft und erzeugt somit eine große Dämpfungskraft.

[0034] Bei einer speziellen Struktur hat die Metallschicht **8** eine Dicke von 20 bis 80 µm, und die Dämpfungsschicht **9** hat eine Dicke von 5 bis 10 µm. Die Gesamtdicke des Dämpfungskissens **6** wird auf weniger als 1 mm, und etwa 0,5 mm in dieser Ausführungsform festgelegt. In einem Falle der Metallschicht **8** und der Dämpfungsschicht **9** mit Dicken von mehr als denen der obigen, wird die Anzahl von zu laminierenden Schichten reduziert, und daher wird die Dämpfungskraft reduziert. Andererseits wird in einem Falle der Metallschicht **8** und der Dämpfungsschicht **9** mit Dicken von weniger als denen der obigen eine Kompressionsbelastung in der zu belastenden Dickenrichtung reduziert.

[0035] Der Grund, weshalb die Gesamtdicke des Dämpfungskissens weniger als (nicht mehr als) 1 mm, und etwa 0,5 mm in dieser Ausführungsform gestaltet ist, wird nachfolgend beschrieben.

[0036] Wenn der in Fig. 1 gezeigte Tisch **2** schnell gestoppt wird, wird die Scherkraft P auf das Dämpfungskissen **6** ausgeübt, wie in Fig. 4 gezeigt ist. Wenn die Scherkraft P ausgeübt wird, wird die obere Fläche um einen Betrag von λ in Bezug auf die untere Fläche verschoben. Dieses λ ist ein Betrag der Verschiebung, die durch die Scherkraft P verursacht wird. Angenommen, dass das Dämpfungskissen um einen Betrag von λ in Bezug auf die Dicke t verschoben wird, wird eine Scherung φ als $\varphi = \lambda/t$ ausgedrückt. Bei der Festigkeit von Materialien ist in dem Falle, dass die Scherkraft P konstant ist, die Scherung φ ebenfalls konstant, so dass, wenn die Dicke t groß ist, die Verschiebung λ ebenfalls groß ist. Dementsprechend kann durch extrem dünne Gestaltung der Gesamtdicke des Dämpfungskissens **6**, wie etwa 0,5 mm, die Verschiebung infolge der Scherkraft möglichst klein gestaltet werden. Andererseits wird für einen herkömmlichen Baulaminierungsgummi mit einer Dicke von etwa 20 mm die Verschiebung λ zu groß, und daher ist dieser für ein Führungssystem, bei welchem hohe Steifigkeit erforderlich ist, nicht geeignet.

[0037] Ein anderer Grund, weshalb die Dicke des Dämpfungskissens auf etwa 0,5 mm in dieser Ausführungsform festgelegt wird, liegt darin, dass das Dämpfungskissen **6** durch Ausführen einer zusätzlichen Bearbeitung, zum Beispiel Schleifen der oberen Fläche des bewegbaren Blocks **4**, ohne Änderung der Gestaltung des bestehenden bewegbaren Blocks **4** in den bewegbaren Block **4** einbezogen werden kann. Da es nicht notwendig ist, die Gestaltung des bestehenden bewegbaren Blocks **4** zu verändern, kann das Dämpfungskissen **6** nach der Montage in eine bestehende Werkzeugmaschine oder Teilmontagemaschine einbezogen werden.

[0038] Darüber hinaus wird, da das Dämpfungskissen **6** mit einer Mehrzahl von Dämpfungsschichten **9**, --- versehen ist, die an der Tischseite erzeugte Wärme von der Übertragung auf eine Bewegungsführungsvorrichtung ferngehalten, wodurch eine Wärmeisolierungswirkung erreicht wird.

[0039] Fig. 5 zeigt die Details der Bewegungsführungsvorrichtung. Diese Bewegungsführungsvorrichtung weist eine Laufschiene **3**, die sich als ein Spurteil linear erstreckt, und einen bewegbaren Block **4** auf, der an der Laufschiene **3** relativ zu dieser verschiebbar montiert ist. Eine Anzahl von Kugeln **5**, --- als Wälzkörper sind zwischen der Laufschiene **3** und dem bewegbaren Block **4** angeordnet.

[0040] Die Laufschiene **3** hat beiderseits seitliche Flächen, an welchen zwei Reihen von Kugellaufrillen **3a**, **3a** derart ausgebildet sind, dass sie sich parallel zueinander in der Längsrichtung der Laufschiene **3** erstrecken.

[0041] Der bewegbare Block **4** weist einen mittigen flachen Abschnitt **11**, welcher der oberen Fläche der Laufschiene **3** gegenüberliegt, und Seitenwandabschnitte **12** auf, die sich an beiderseits seitlichen Endabschnitten des mittigen Abschnitts **11** derart nach unten erstrecken, dass sie den Seitenflächen der Laufschiene **3** gegenüberliegen. Der bewegbare Block **4** ist auch mit einem Paar Endplatten **13**, **13** als Seitendeckel an beiden Längsenden (Bewegungsrichtungsende) des bewegbaren Blocks **4** versehen. Die Seitenwandabschnitte **12** des bewegbaren Blocks **4** sind mit zwei Reihen von Kugellastlaufrillen **4a**, **4a** versehen, die jeweils den Kugellaufrillen **3a**, **3a** der Laufschiene **3** gegenüberliegen. Zwei Kugellastlaufrillen **4a**, **4a** sind vertikal an jedem Seitenwandabschnitt **12** des bewegbaren Blocks **4** ausgebildet, und somit sind vier Kugellastlaufrillen **4a**, **4a** an den beiden Seitenwandabschnitten **12** parallel zueinander ausgebildet.

[0042] Der bewegbare Block **4** ist ferner an seinen Seitenwandabschnitten **12** mit zwei vertikalen Kugelrücklaufpassagen **14**, **14**, die parallel zueinander in einem vorbestimmten Abstand an Abschnitten von den beiden vertikalen Kugellastlaufrillen **4a** entfernt angeordnet sind, und mit U-förmigen Kugellastlauf-Richtungswechselpassagen für den Umlauf der Kugeln **5**, --- durch Verbinden des Endabschnitts der Kugellastlaufrille **4a** und der Kugelrücklaufpassage **14** versehen. Wie oben erwähnt, wird eine Kugelumlaufpassage in Kreislaufform durch die Kugellastlaufrille **4a**, die paarweisen Richtungswechselpassagen und die Kugelrücklaufpassage **14** gebildet.

[0043] Eine Anzahl von Kugeln **5**, --- sind in der Kugelumlaufpassage untergebracht und angeordnet. Die Kugeln **5**, --- können in Reihe mittels eines Kugelhalters oder Rückhalters gekuppelt sein.

[0044] Der Seitendeckel (Endplatte) **13** hat eine Querschnittsform entsprechend dem bewegbaren Block **4**. Jeder der Seitendeckel **13** ist mit einer Außenumfangsseite der Richtungswechselpassage versehen. Der Seitendeckel **13** ist auch mit einer Schmiermittelzuführpassage zum Zuführen eines Schmiermittels zu der Kugellastlaufrille des bewegbaren Blockkörpers versehen.

[0045] Wenn der bewegbare Block **4** in Bezug auf die Laufschiene **3** bewegt wird, wälzen und bewegen sich die Kugeln **5**, --- unter dem Lastzustand zwischen der Kugellaufrille **3a** der Laufschiene **3** und der Kugellaufrille **4a** des bewegbaren Blocks **4**. Die Kugeln **5**, ---, die zu dem einen Ende der Kugellastlaufrille **4a** des bewegbaren Blocks **4** bewegt werden, passieren die eine Richtungswechselpassage an der einen Seite, die Kugelrücklaufpassage **14** und die andere Richtungswechselpassage an der anderen Seite in dieser Reihenfolge, und wälzen danach wieder in der Kugellastlaufrille **4a** ab. Wie oben erwähnt, wird zu dem Zeitpunkt, wenn sich die Kugeln **5**, --- von dem nicht belasteten Bereich zu dem Lastbereich bewegen, eine leichte Schwingung oder Vibration erzeugt. Jedoch kann gemäß dem Dämpfungskissen **6** der vorliegenden Ausführungsform sogar eine solche Schwingung gedämpft werden, was somit wirksam ist.

[0046] Fig. 6 zeigt die Schnittansicht eines anderen Dämpfungskissens **21**. Dieses Dämpfungskissen **21** besteht auch aus einer Laminierungsstruktur einer Mehrzahl von dünnen Metallschichten **22** und einer Mehrzahl von Dämpfungsschichten **23** mit jeweils einem Young-Modul, der sich von dem der Metallschicht **22** unterscheidet, wobei die Metallschichten **22** und die Dämpfungsschichten **23** wechselweise laminiert sind. Das Dämpfungskissen **21** dieser Ausführungsform wird durch Pressen der Metallschichten **22** und dergleichen gebildet, um eine gewellte (Welle) Form zu schaffen. Die Dämpfungsschichten **23**, die jeweils aus einer Gummischicht gebildet sind, werden jeweils in Form einer Wellung auf die gewellten Metallschichten **22** gedruckt. Das Dämpfungskissen **21** wird durch Laminieren einer Mehrzahl von Platteneinheiten U gebildet, die jeweils aus der Metallschicht **22** bestehen, auf welche die Dämpfungsschicht **23** gedruckt wird, und die Einheiten U, in welchen die Dämpfungsschichten **23** gedruckt sind, werden nicht miteinander laminiert. Die Metallschicht ist mit einer Dicke von 20 bis 40 μm bestimmt, die Dämpfungsschicht ist mit einer Dicke von 5 bis 10 μm bestimmt, und die Gesamtdicke des Dämpfungskissens ist mit weniger als 1,0 mm, und etwa 0,5 mm in dieser Ausführungsform bestimmt.

[0047] Das charakteristische Merkmal dieses Dämpfungskissens **21** liegt darin, dass die Grenzfläche **24** zwischen der Metallschicht **22** und der Dämpfungsschicht **23** derart ausgebildet ist, dass sie eine gewellte Form schafft, welche abwechselnd Spitzen und Täler hat. Die gewellte Form der Grenzfläche **24** erhöht einen Bereich der Grenzfläche **24** mit einem konstanten Volumen, woraus sich die Vergrößerung eines Bereichs zum Umwandeln der Schwingungsenergie in die Wärmeenergie ergibt, so dass eine größere Dämpfungskraft erreicht wird.

[0048] Die Dämpfungsstruktur der vorliegenden Erfindung ist nicht auf die beschriebene Ausführungsform beschränkt, und viele Änderungen und Modifikationen können vorgenommen werden, ohne von dem Kern der vorliegenden Erfindung abzuweichen. Zum Beispiel kann die Dämpfungsstruktur der vorliegenden Erfindung an verschiedenen Abschnitten von Maschinen angeordnet sein, die eine Dämpfung der Schwingung oder Vibration erfordern, ohne Beschränkung auf eine Position zwischen dem Tisch und der Bewegungsführungsvorrichtung in einem Führungssystem wie bei der vorliegenden Erfindung. Darüber hinaus kann die Dämpfungsstruktur der vorliegenden Erfindung auch in eine Bewegungsführungsvorrichtung, wie eine Kugelkeilwelle, eine Kugelumlaufspindel oder dergleichen, einbezogen sein, ohne Beschränkung auf eine Bewegungsführungsvorrichtung, wie eine Linearbewegungsvorrichtung.

[0049] Darüber hinaus wird angemerkt, dass die verschiedenen Änderungen und Modifikationen der Ausführungsformen der vorliegenden Erfindung, die oben erwähnt sind, für die Ausführung der Erfindung verwendbar sind. Daher sind die Patentansprüche der vorliegenden Erfindung zum Definieren von Bereichen der Erfindung, und Strukturen und äquivalente Gegenstände, die in den Ansprüchen enthalten sind, sollten darin einbezogen sein.

[0050] Die gesamte Offenbarung der jeweiligen japanischen Patentanmeldung Nr. 2003-155351, eingereicht am 30. Mai 2003, und 2004-148908, eingereicht am 19. Mai 2004, einschließlich der Beschreibung, Ansprüche, Zeichnungen und Zusammenfassung, ist hierin durch Bezugnahme in deren Gesamtheit einbezogen.

ZUSAMMENFASSUNG

[0051] Eine Mehrzahl von dünnen Metallschichten **8** und eine Mehrzahl von dünnen Dämpfungsschichten **9** sind eine nach der anderen wechselweise laminiert. Die Gesamtdicke der laminierten Dämpfungsstruktur ist auf nicht mehr als 1,0 mm festgelegt. Gemäß dieser Struktur wird, da eine Mehrzahl von Grenzflächen zwischen den Metallschichten **8** und den Dämpfungsschichten existieren, wird Schwingungsenergie leicht in Reibungsenergie umgewandelt, wodurch eine große Dämpfungskraft geschaffen wird. Außerdem kann, da die Gesamtdicke auf nicht mehr als 1,0 mm festgelegt ist, das Verformungsmaß der Dämpfungsstruktur **6** infolge der Scherkraft gering gehalten werden, so dass die Steifigkeit der Dämpfungsstruktur **6** erhöht werden kann.

Patentansprüche

1. Dämpfungsstruktur mit einer Mehrzahl von dünnen Metallschichten und einer Mehrzahl von dünnen Dämpfungsschichten mit jeweils einem Young-Modul, der sich von dem der Metallschicht unterscheidet, wobei die Metallschicht und die Dämpfungsschicht eine nach der anderen wechselweise derart laminiert sind, dass sie eine Gesamtdicke der Dämpfungsstruktur von nicht mehr als 1,0 mm schaffen.

2. Dämpfungsstruktur nach Anspruch 1, wobei die Dämpfungsstruktur die Gesamtdicke von nicht mehr als 0,5 mm hat.

3. Dämpfungsstruktur nach Anspruch 1 oder 2, wobei die Metallschicht eine Dicke von 20 bis 40 µm hat und die Dämpfungsschicht eine Dicke von 5 bis 10 µm hat.

4. Dämpfungsstruktur nach Anspruch 1, wobei die Dämpfungsschicht aus einer Gummi- oder Harzschicht gebildet ist und auf der Metallschicht gedruckt ist.

5. Dämpfungsstruktur nach einem der Ansprüche 1 bis 4, wobei eine Grenzfläche zwischen der Metallschicht und der Dämpfungsschicht existiert, um eine gewellte Form mit kontinuierlich wechselnden Spitzen und Tälern zu schaffen.

6. Bewegungsführungsvorrichtung mit einer Laufschiene und einem bewegbaren Block, der angeordnet ist, um entlang der Laufschiene verschiebbar zu sein, wobei eine Mehrzahl von dünnen Metallschichten und eine Mehrzahl von dünnen Dämpfungsschichten mit jeweils einem Young-Modul, der sich von dem der Metallschicht unterscheidet, eine nach der anderen wechselweise derart laminiert sind, dass sie eine Gesamtdicke der Dämpfungsstruktur von nicht mehr als 1,0 mm schaffen.

7. Führungssystem mit einer Basis, einem Tisch und einer Bewegungsführungsvorrichtung, die zwischen der Basis und dem Tisch angeordnet ist, so dass der Tisch in Bezug auf die Basis relativ bewegbar ist, wobei die Bewegungsführungsvorrichtung eine Laufschiene, die an der Basis montiert ist, und einen bewegbaren Block aufweist, der an dem Tisch montiert ist, um entlang der Laufschiene verschiebbar zu sein, wobei eine Mehrzahl von dünnen Metallschichten und eine Mehrzahl von dünnen Dämpfungsschichten mit jeweils einem Young-Modul, der sich von dem der Metallschicht unterscheidet, eine nach der anderen wechselweise derart laminiert sind, dass sie eine Gesamtdicke der Dämpfungsstruktur von nicht mehr als 1,0 mm schaffen.

Beschreibung

(Gebiet der Erfindung)

[0001] Die vorliegende Erfindung betrifft eine Bewegungsführungsvorrichtung zum Führen einer linearen Bewegung oder einer bogenförmigen Bewegung eines zu führenden Gegenstandes, und insbesondere eine Bewegungsführungsvorrichtung des Wälztyps, bei welcher Rollen zum Führen einer Wälzbewegung zwischen einem Führungselement und einem bewegbaren Element relativ zu dem Führungselement bewegbar angeordnet sind.

(Stand der Technik)

[0002] Im Allgemeinen ist eine Bewegungsführungsvorrichtung mit einer Führungsschiene, einem bewegbaren Block, der entlang der Führungsschiene bewegbar angeordnet ist, und einer Mehrzahl von Rollen versehen, die zwischen der Führungsschiene und dem bewegbaren Block angeordnet sind. Fig. 4 zeigt eine herkömmliche Bewegungsführungsvorrichtung, die Rollen benötigt, um eine Bewegung eines bewegbaren Elements zu veranlassen. Wenn sich der bewegbare Block **21** relativ zu einer Führungsschiene **22** bewegt, werden Rollen **23**, die sich in einem Lastbereich zwischen Rollenwälzflächen **21a** und **22a** befinden, gezwungen, sich in einer Wälzbewegung derart zu bewegen, dass eine Relativbewegung des bewegbaren Blocks **21** ermöglicht wird.

[0003] Eine Kugel, welche eine Art des Wälzelements ist, ist üblicherweise zu einem Sphärenelement geformt, das eine unendliche Anzahl von Drehachsen aufweist und in der Lage ist, sich in allen Richtungen ohne irgendwelche Einschränkungen zu drehen. Im Gegensatz dazu ist jede der Rollen **23** zu einem zylindrischen Körper geformt, mit dem Ergebnis, dass jede Rolle **23** daran gebunden ist, nur eine Drehachse zu haben, wenn jede Rolle **23** eine Wälzbewegung einnimmt. In anderen Worten ist die Bewegungsrichtung jeder Rolle **23** auf nur eine Richtung beschränkt. Um zu ermöglichen, dass die Rollen **23** Wälzbewegungen ohne Schlupf ausführen, sollte Orthogonalität zwischen den Drehachsen der Rollen **23** und einer Fortbewegungsrichtung der Rollen **23** gehalten werden.

[0004] Bei der herkömmlichen Bewegungsführungsvorrichtung, welche die Rollen **23** anwendet, gibt es, wenn Parallelität zwischen der Rollenwälzfläche **21a** des bewegbaren Blocks **21** und der Rollenwälzfläche **22a** der Führungsschiene **22** verloren geht oder eine versetzte Belastung auf den bewegbaren Block **21** ausgeübt wird, einige Fälle, wo auch die Orthogonalität zwischen den Drehachsen der Rollen **23** und der Fortbewegungsrichtung der Rollen **23** verloren geht. Die Erscheinung, dass die Rollen **23** gegen deren normalen Drehachsen schräggestellt sind, wird „Schräglauf" genannt.

[0005] Um die Schräglauferscheinung zu verhindern, wendet die herkömmliche Bewegungsführungsvorrichtung eine Stufe **24** an, die an dem einen Rand der Rollenwälzfläche **21a** des bewegbaren Blocks **21** ausgebildet ist. Die Stufe **24** ist derart gestaltet, dass sie einen Verbindungsvorsprung **24a** aufweist, mit welchem die eine Endfläche jeder Rolle **23** in Kontakt gelangen kann, wobei die eine Endfläche orthogonal zu deren Drehachsenrichtung ist. Das Vorhandensein des Verbindungsvorsprungs **24a** verhindert, dass die Rollen **23** schräggestellt werden können (bezogen auf die japanische offengelegte (KOKAI) Patentveröffentlichung Nr. 2002-54633). Dieser Verbindungsvorsprung **24a** kann, wie in Fig. 4 dargestellt ist, an nur einerseitigen Endfläche der Rollenwälzfläche **21a** in deren Achslinienrichtung ausgebildet sein oder kann an deren beiderseitigen Endflächen ausgebildet sein. Alternativ ist die Stufe an nur einer Seite der Rollenwälzfläche ausgebildet, und eine Eisenplatte ist an der anderen Seite der Rollenwälzfläche derart angeordnet, dass sie jeder Rolle derart zugewandt ist und diese andrückt, dass ein Spalt zwischen den Rollen und der Rollenwälzfläche eingestellt wird.

[0006] Jedoch wird, wenn die Rollen schräggestellt sind, eine den Verbindungsvorsprung andrückende Kraft infolge der Schrägstellung der Rollen extrem größer. Der herkömmliche Verbindungsvorsprung ist daher aus Metall hergestellt, dessen Festigkeit größer ist (zum Beispiel ein Metall aus demselben Material wie jenes, das zum Formen der Rollenwälzfläche des bewegbaren Blocks verwendet wird). Es war lange allgemeines Wissen, die Schrägläufe der Rollen durch einen Kontakt zwischen den Metallelementen zu verhindern.

[0007] Jedoch bewirkt der Kontakt zwischen den Metallelementen einen höheren Reibungsfaktor, wodurch sich der Gleitwiderstand erhöht, der auftritt, wenn der bewegbare Block entlang der Führungsschiene gleitet. Daher kann es schwierig sein, sanfte und stabile Bewegungen des bewegbaren Blocks zu erreichen.

[0008] Das Dokument EP 0 838 602 A offenbart eine lineare Rollenführungsvorrichtung mit einer Führungsschiene **202**, einem bewegbaren Block **204**, der an einer oberen Fläche der Führungsschiene **202** mittels vier Reihen von Rollen **203** bewegbar montiert ist, und einem Umlaufkanal für die Rollen **203**, der von dem Lastbereich zwischen den Rollenwälzflächen **206**, **207**, **205**, **208** des metallischen Blockkörpers **2040** des bewegbares Blocks **204** und entsprechend der Führungsschiene **202** durch den Richtungswechselkanal **210** und den Rollenrücklaufkanal **209** gebildet wird. Der Blockkörper **2040** ist mit Rücklaufkanälen **209** zum Umlaufen und Führen der Rollen **203** versehen. Der Rollenrücklaufkanal **209** erstreckt sich linear parallel zu den jeweiligen Rollenwälzflächen **205**, **206**, die an dem Blockkörper **2040** ausgebildet sind. Ferner offenbart das Dokument Rollen **203**, welche durch eine Rollenkette **218** miteinander verbunden sind, welche ein aus Harz geformtes Produkt ist und Abstandsstücke **218a** aufweist, welche zwischen den benachbarten Rollen **203** angeordnet sind und mit einem haltenden vertieften Abschnitt **218c** an den beiden Seitenflächen versehen sind, die eine der Fläche der Rollen **203** entsprechenden Form haben. Die Lastrollenendflächenführungswände **213** zum Führen beider Endflächen der Rolle **203** sind mit Führungsnuten **213a** versehen, mit welchen die Führungsvorsprungsabschnitte **2181** der Rollenkette **218** in Eingriff stehen. Um die Lastrollenendflächenführungswand **213** zu bilden, weist der Blockkörper **2040** eine erste bis dritte Flächenführungswand auf, die Elemente **2141–2143** bildet, die aus Harz bestehen.

[0009] Das Dokument US 6 287 005 A offenbart eine Rollenführungsvorrichtung **1** mit einer länglichen Laufschiene **2**, die eine Mehrzahl von daran ausgebildeten Rollenwälzflächen **5** aufweist, einem bewegbaren Körper **3**, der eine Mehrzahl von daran in Gegenüberstellung mit den entsprechenden Rollenwälzflächen **5** der Laufschiene **2** ausgebildeten Rollenwälzflächen **6** aufweist, und einer Vielzahl von Rollen **4**, die zwischen den entsprechenden Rollenwälzflächen **5**, **6** der Schiene **2** und dem bewegbaren Körper **3** angeordnet sind. Die Rollen **4** sind zu einer Mehrzahl von Zügen von Rollen geformt, wobei jeder Zug von Rollen mittels eines Rollenverbinders **20** in Position gehalten wird. Jeder der Rollenverbinder **20** weist einen gurtförmigen Körper oder Teil **26** mit einer Vielzahl von Aufnahmelöchern **24** zum Halten der Rollen **4**, die entlang dessen Länge in einem vorbestimmten Abstand mit einem zwischen benachbarten Löchern angeordneten Abstandsstück **25** ausgebildet sind, und ein Paar stirnflächige Halteplatten auf, die an den quer einander gegenüberliegenden Seitenrändern jedes Aufnahmeloches **24** in dem Gurtelement **2** vorgesehen sind. Die stirnflächigen Halteplatten **27** sind in deren Mitte mit Eingriffsvorsprüngen **28** versehen, welche in passendem Eingriff mit den Mittellöchern **4a** sind, die an den gegenüberliegenden Stirnflächen jeder Rolle **4** zur drehbaren Gleitbewegung ausgebildet sind. Die stirnflächigen Halteplatten **27** jedes Rollenverbinders **20** werden von einer Innenwand einer entsprechenden Rollenlaufnut **6** geführt. Der bewegbare Körper **3** weist ein Blockelement **10** mit einem passenden Blockkörper **7** und einem Paar Schenkel **8**, **8**, die sich von den quer einander gegenüberliegenden Enden des passenden Blockkörpers **7** nach unten erstrecken, und ein Paar Seitenabdeckungen **11**, **11** auf, die an den Axial- oder Längsenden des Blockelements **10** montiert sind. Der passende Blockkörper **7** und die gegenüberliegenden Schenkel **8**, **8** sind jeweils mit Rollenrücklaufkanälen **12** versehen, die sich parallel zu den Rollenwälzflächen **6** erstrecken, die an deren Innenfläche ausgebildet sind.

[0010] Die vorliegende Erfindung wurde in Anbetracht der obigen Dinge konzipiert, und ein Ziel der vorliegenden Erfindung ist es, in einer einfachen und kostengünstigen Weise eine Bewegungsführungsvorrichtung zu schaffen, die nicht nur zum Verhindern der Schrägläufe der Rollen geeignet ist, sondern auch zum Reduzieren des Gleitwiderstandes, der auftritt, wenn das bewegbare Element entlang des Führungselements gleitet.

Zusammenfassung der Erfindung

[0011] Um das obige Ziel zu erreichen, schafft die vorliegende Erfindung eine Bewegungsführungsvorrichtung, aufweisend ein Führungselement, das daran eine Rollenwälzfläche aufweist; ein bewegbares Element, das einen Rollenumlaufkanal mit einer Lastrollenwälzfläche aufweist, die sich gegenüber der Rollenwälzfläche befindet und an dem Führungselement relativ zu dem Führungselement bewegbar angeordnet ist; eine Mehrzahl von Rollen, die jeweils aus Metall hergestellt und in dem Rollenumlaufkanal mit einer Drehachse jeder der Rollen parallel zueinander angeordnet sind, um dadurch in Antwort auf eine Relativbewegung des bewegbaren Elements zu dem Führungselement zu zirkulieren; und einen Rollenhalter, um die Mehrzahl der Rollen drehbar und gleitend zu halten. Das bewegbare Element weist Verbindungsvorsprünge auf, die daran ausgebildet und nur aus Harz hergestellt sind, um dadurch den Verbindungsvorsprüngen zu ermöglichen, mit beiden Achslinienrichtungs-Endflächen jeder der Rollen in Kontakt zu gelangen, die entlang der Lastrollenwälzfläche rollen, wobei die Verbindungsvorsprünge nur an einer Außenseite relativ zu der Drehachse jeder Rolle angeordnet sind, die entlang der Lastrollenwälzfläche rollt.

[0012] Daher werden bei der vorliegenden Erfindung, selbst wenn die Rollen schräggestellt sind, der Verbindungsvorsprung, der gestaltet ist, um die Schrägläufe zu verhindern, und die Endfläche der Rollen durch Kollisionen zwischen dem Harz- und Metallwerkstoffen in Kontakt miteinander gebracht. Dementsprechend verringert sich ein Reibungsfaktor zwischen dem Verbindungsvorsprung und der Endfläche, wodurch der Gleitwiderstand sinkt, der verursacht wird, wenn das bewegbare Element entlang des Führungselements gleitet. Dadurch kann sich das bewegbare Element in einer sanften und stabilen Weise bewegen. Außerdem machen es die Verbindungen der Rollen mit dem Rollenhalter möglich, den Widerstand gegen das Auftreten von Schrägläufen zu verstärken. Somit sind die aus Harz hergestellten Verbindungsvorsprünge in der Lage, zu verhindern, dass die Rollen schräggestellt werden.

[0013] Vorzugsweise ist der Rollenhalter platziert, um zwischen zwei der Rollen einzugreifen, und ist mit einer Mehrzahl von Abstandselementen mit zwei vertieften Flächen an deren beiden Seiten, wobei jede der vertieften Flächen in einer Form mit einer Außenumfangsfläche der neben der jeweiligen Rolle angeordneten Rolle übereinstimmt, und einem Verbindungselement versehen, das platziert ist, um sich von einer Drehachsrichtungs-Endfläche jeder der Rollen nach außen zu erstrecken und die Abstandselemente miteinander zu verbinden.

[0014] Noch bevorzugt ist der Verbindungsvorsprung an einem Stützelement ausgebildet, um durch Herstellen einer Verbindung mit dem Verbindungselement des Rollenhalters zu verhindern, dass die Rollen von der Lastrollenwälzfläche weg gelangen, wenn das bewegbare Element von dem Führungselement entfernt wird.

[0015] Daher ist der Rollenhalter in der Lage, die beiden Funktionen des Verhinderns des Weggelangens der Rollen, wenn das bewegbare Element von dem Führungselement entfernt wird, und des Verhinderns des Schräglaufes der Rollen zu erfüllen.

Kurze Beschreibung der Zeichnungen

[0016] Andere Ziele und Aspekte der vorliegenden Erfindung werden aus der folgenden Beschreibung und den Ausführungsformen mit Bezug auf die begleitenden Zeichnungen deutlich, in welchen:

[0017] Fig. 1 ist eine demontierte perspektivische Ansicht, die eine lineare Bewegungsführungsvorrichtung gemäß einer Ausführungsform der vorliegenden Erfindung erläutert;

[0018] Fig. 2 ist eine perspektivische Ansicht, die Rollen zeigt, die von einem Rollenhalter gehalten werden;

[0019] Fig. 3A ist ein detaillierter teilweiser Schnitt, der eine Rollenstützstruktur gemäß der Ausführungsform zeigt, bei welcher eine Rolle zwischen einer Führungsschiene und einem bewegbaren Block rollt;

[0020] Fig. 3B ist ein detaillierter teilweiser Schnitt, der eine Rollenstützstruktur gemäß einem Vergleichsbeispiel zeigt, bei welcher eine Rolle zwischen einer Führungsschiene und einem bewegbaren Block rollt; und

[0021] Fig. 4 zeigt die Vorderansicht einer herkömmlichen Bewegungsführungsvorrichtung.

Ausführliche Beschreibung der bevorzugten Ausführungsform

[0022] Eine bevorzugte Ausführungsform der vorliegenden Erfindung wird nun zusammen mit den begleitenden Zeichnungen beschrieben.

[0023] Mit Bezug auf Fig. 1 bis Fig. 3A und Fig. 3B wird nun eine lineare Bewegungsführungsvorrichtung gemäß einer Ausführungsform der vorliegenden Erfindung beschrieben.

[0024] Eine lineare Bewegungsführungsvorrichtung ist mit einer linearen länglichen Führungsschiene **1**, die als ein Führungselement dient, und einem bewegbaren Block **2** versehen, welcher als ein bewegbares Element dient und mit der Führungsschiene **1** derart montiert ist, dass er entlang der Führungsschiene **1** relativ verschiebbar ist. Zwischen der Führungsschiene **1** und dem bewegbaren Block sind eine große Anzahl von Rollen **3** vorgesehen, welche als eine Mehrzahl von Wälzelementen dienen. Die Rollen **3** sind aus Metall hergestellt und derart ausgebildet, dass sie rollen.

[0025] Um genau zu sein, wird die Führungsschiene **1** mit einem annähernd rechteckigen Querschnitt orthogonal zu deren Längsrichtung produziert. An jeder der beiden seitlichen Seiten der Führungsschiene **1** ist eine Nut **1a**, die aus Wandflächen **1b** und **1b** und einer Bodenfläche **1c** gebildet ist, entlang der Längsrichtung ausgebildet.

[0026] In jeder Nut **1a** sind die beiden Wandflächen **1b** und **1b** in rechten Winkeln gekreuzt. Jede der oberen Wandfläche **1b** und der unteren Wandfläche **1b** bilden eine Rollenwälzfläche, die als ein Wälzkörperrollabschnitt dient, entlang welcher die Rollen **3** abrollen. Das heißt, an der rechten und linken Seite der Führungsschiene **1** sind insgesamt vier Rollenwälzflächen **1b** ausgebildet, d.h. obere und untere Wälzflächen (zwei Wälzflächen) an jeder Seite. Diese Rollenwälzflächen sind parallel zueinander ausgebildet, um sich entlang der Führungsschiene **1** zu erstrecken.

[0027] Der bewegbare Block **2** ist mit einem Mittelabschnitt **2a**, der einer oberen Fläche der Führungsschiene **1** zugewandt ist, und Seitenwandabschnitten **2b** und **2b** versehen, die sich jeweils von beiden Seitenenden des Mittelabschnitts **2a** nach unten erstrecken und den beiden seitlichen Seitenflächen der Führungsschiene **1** zugewandt sind.

[0028] Der Mittelabschnitt **2a** weist einen Hauptblock **4** aus Stahl, eine Umlaufkanalbildungsstruktur aus Harz, die in den Hauptblock **4** eingebaut ist, und ein Paar Seitendeckel **5** und **5** auf, die an beiden Seitenflächen des Hauptblocks **4** angeordnet sind, in welchem die Umlaufkanalbildungsstruktur aus Harz eingebaut ist, wobei die beiden Seitenflächen entlang einer Bewegungsrichtung des Hauptblocks **4** verlaufen.

[0029] An Seitenwandabschnitten **4b** und **4b** des Hauptblocks **4** sind Vorsprünge **4c** und **4c** ausgebildet, wobei die Form jedes Vorsprungs **4c** mit der Form jeder Nut **1a** übereinstimmt, die an jeder Seitenfläche der Führungsschiene **1** ausgebildet ist. An jedem der Vorsprünge **4c** und **4c** sind zwei Lastrollenwälzflächen **4d** und **4d** ausgebildet, die als Lastwälzkörperrollabschnitte dienen, wobei jede Lastrollenwälzfläche **4d** jeder Rollenwälzfläche **1b** zugewandt ist. In anderen Worten sind die Lastrollenwälzflächen **4d** aus insgesamt vier Wälzflächen aufgebaut, d.h. zwei Wälzflächen (obere und untere Wälzflächen) an jeder der beiden rechten und linken Seitenwandabschnitte **4b** und **4b** des Hauptblocks **4**. Diese Lastrollenwälzflächen **4d** erstrecken sich parallel zueinander in der Bewegungsrichtung, entlang welcher der bewegbare Block **2** bewegt wird.

[0030] In den Seitenwandabschnitten **2b** und **2b** des bewegbaren Blocks **2** sind obere und untere Rollenausweichkanäle **7** und **7**, welche insgesamt zwei an jeder Seite sind, und ein U-förmiger Wälzrichtungswechselkanal ausgebildet. In jedem Seitenwandabschnitt **2b** sind die Rollenausweichkanäle **7** und **7** parallel. zueinander ausgebildet und im vorbestimmten Abstand von den oberen bzw. unteren beiden Lastrollenwälzflächen **4d** und **4d a**ngeordnet.

[0031] Der Wälzrichtungswechselkanal ist ausgebildet, um jede der Lastrollenwälzflächen **4d** und **4d** und beide Enden jeder der Rollenausweichkanäle **7** und **7** miteinander zu verbinden, damit die Rollen **3** durch diese hindurch umlaufen. Diese Lastrollenwälzfläche **4d**, der Wälzrichtungswechselkanal und der Rollenausweichkanals **7** bilden einen Rollenumlaufkanal.

[0032] Von diesen Bauteilen werden die Rollenausweichkanäle **7** von insgesamt vier, d.h. zwei Rollenausweichkanälen **7** und **7** in vorbestimmten oberen und unteren Positionen in jedem der rechten und linken Seitenwandabschnitte **2b** und **2b** des bewegbaren Blocks **2** gebildet. An jeder Seite des bewegbaren Blocks **2** verbindet der Wälzrichtungswechselkanal sowohl die obere Lastrollenwälzfläche **4d** und den unteren Rollenausweichkanal **7** als auch die untere Lastrollenwälzfläche **4d** und den oberen Rollenausweichkanal **7**, so dass die beiden verbundenen Kanäle eine Überquerung miteinander bilden.

[0033] Die Rollenumlaufkanäle werden von insgesamt vier, d.h. zwei in bzw. an jedem der seitlichen Seitenwandabschnitte **2b** und **2b** gebildet. Es werden zwei Rollenumlaufkanäle produziert. Jeder Rollenumlaufkanal ist ausgebildet, um in derselben Ebene zu liegen, mit dem Ergebnis, dass die Rollen **3** zweidimensional entlang jedes Rollenumlaufkanals zirkulieren können. An jeder Seite des bewegbaren Blocks **2** kreuzen die beiden Ebenen, in welchen die beiden Rollenumlaufkanäle jeweils angeordnet sind, in rechten Winkeln miteinander, und der eine Rollenumlaufkanal ist in einer Innenposition in Bezug auf den übrigen Rollenumlaufkanal angeordnet.

[0034] Die mehreren Rollen **3** sind in jedem Rollenumlaufkanal angeordnet, wobei die Drehachsen der Rollen **3** parallel zueinander sind. Die Rollen **3** sind durch einen Rollenhalter **10** derart miteinander verbunden, dass eine Kette von Rollen **3** erzeugt wird. Die Rollen **3** werden durch den Rollenhalter **10** drehbar und gleitend gehalten und sind in der Lage, entlang jedes vorgegebenen Rollenumlaufkanals zu zirkulieren. Fig. 2 zeigt die Rollen **3**, die von dem Rollenhalter **10** gehalten werden.

[0035] Zwischen den Rollen **3** und **3** gibt es ein Abstandselement **10b**. Daher sind eine Mehrzahl von Abstandselementen **10b** in jedem Zug der Rollen **3** angeordnet. An jeder Seite jedes Abstandselements **10b** ist eine Vertiefung ausgebildet, deren Krümmung mit einer Außenkrümmung jeder benachbarten Rolle **3** übereinstimmt. Die Abstandselemente **10b** sind durch ein Paar Verbindungselemente **10d** und **10d** miteinander gekuppelt, die derart angeordnet sind, dass sie sich von jeder Endfläche in den Drehachsrichtungen der Rollen **3** erstrecken.

[0036] Wie in Fig. 1 gezeigt ist, ist die Umlaufkanalbildungsstruktur aus Harz mit Stützelementen **11** und **11**, Ausweichkanalbildungselementen **14** und Richtungswechselkanalbildungselementen **8** versehen.

[0037] Unter diesen Bauteilen sind die Stützelemente **11** und **11**, welche sich entlang der Seitenränder der beiden Lastrollenwälzflächen **4d** und **4d** erstrecken, angeordnet, um zu verhindern, dass die Rollen **3** von den Lastrollenwälzflächen **4d** und **4d** weg gelangen, wenn der bewegbare Block **2** von der Führungsschiene **1** entfernt wird. Die Ausweichkanalbildungselemente **14** sind platziert, um einen Rollenausweichkanal für die Rollen **3** zu bilden, während die Richtungswechselkanalbildungselemente **8** angeordnet sind, um einen Richtungswechselkanal für die Rollen **3** zu bilden.

[0038] Die Stützelemente **11** und **11**, Ausweichkanalbildungselemente **14** und Richtungswechselkanalbildungselemente **8** werden jeweils als unterschiedliche Elemente gebildet, die von dem Hauptblock **4** getrennt sind, und werden aus Harz hergestellt, und werden dann in den Hauptblock **4** eingebaut.

[0039] Jedes der Stützelemente **11** aus Harz weist erste, zweite und dritte Stützelemente **11a**, **11b** und **11c** auf, die jeweils zu einem dünnen und lang bemessenen Element aus einem Harzwerkstoff geformt sind, und wird durch Bilden der ersten bis dritten Elemente **11a** bis **11c** zu einer Einheit konstruiert. Das erste Stützelement **11a** ist unter den unteren Rollen **3** angeordnet, das zweite Stützelement **11b** ist zwischen den unteren Rollen **3** und den oberen Rollen **3** angeordnet, und das dritte Stützelement **11c** ist über den oberen Rollen **3** angeordnet. Jedes der Stützteile **11** und **11** ist zwischen dem Paar Seitendeckeln **5** und **5** oder den paarweisen Richtungswechselkanalbildungselementen **8** und **8** gesteckt, so dass jedes Stützteil **11** mit beiden Enden an dem bewegbaren Block **2** abgestützt und befestigt ist.

[0040] In Fällen, wo der bewegbare Block **2** von der Führungsschiene **1** entfernt wird, ist jedes Stützteil **11** in der Lage, sich mit dem Verbindungselement **10d** des Rollenhalters **10** zu verbinden, um zu verhindern, dass die Rolle von den Lastrollenwälzflächen **4d** weg gelangt. Wie später detailliert wird, weisen die ersten, zweiten und dritten Stützelemente **11a**, **11b** und **11c** Verbindungsabschnitte **16** und **16** auf, die in der Lage sind, mit Endflächen jeder der Rollen **3** in deren Achslinienrichtung (bezogen auf **Fig.** 3) in Kontakt zu gelangen.

[0041] Die Ausweichkanalbildungselemente **14** bestehen aus einem Paar Rohrhälften **14a** und **14b**, die durch Trennen eines Rohrmaterials in zwei Elemente in einer Richtung orthogonal zu einer Achslinienrichtung des Rohres hergestellt werden. Jede der Rohrhälften **14a** und **14b** ist mit einer Nut, deren Form mit der jeder Rolle **3** übereinstimmt, und verläuft entlang deren Längsrichtung, und einer Führungsnut versehen, um das Verbindungselement **10d** des Rollenhalter **10** zu führen.

[0042] Die Richtungswechselkanalbildungselemente **8** weisen die U-förmigen Richtungswechselkanäle auf, welche in den Elementen **8** ausgebildet sind, um in einer Überquerung einander zu kreuzen. In diesem Richtungswechselkanal ist die Führungsnut ausgebildet, um das Verbindungsteil **10d** des Rollenhalters **10** zu führen.

[0043] Jeder Seitendeckel **5**, welcher einen Querschnitt hat, der mit dem des Hauptblocks **4** übereinstimmt, weist einen Mittelabschnitt **5a** und Seitenwandabschnitte **5b** und **5b** auf. In jedem der Seitenwandabschnitte **5b** und **5b** ist ein Außenführungsabschnitt des außenseitigen Rollenumlaufkanals ausgebildet. In jedem der Seitenwandabschnitte **5b** und **5b** sind die Richtungswechselkanalbildungselemente **8** und **8** eingebaut. Die Seitendeckel **5** und **5** sind an beiden Bewegungsrichtungsseiten des Hauptblocks **4** befestigt. Schrauben sind in Schraubeneinsetzlöcher eingesetzt, die in den Seitendeckeln **5** und **5** ausgebildet sind, und die Schrauben sind in Schraubenlöcher eingesetzt, die in den Endflächen des Hauptblocks **4** ausgebildet sind, so dass die Seitendeckel **5** und **5** an dem Hauptblock **4** befestigt und fixiert werden können.

[0044] An einer Innenseite jedes der Seitendeckel **5** und **5** sind Schmiermittelzuführplatten **12** und **12** platziert, um den Lastrollenwälzflächen des Hauptblocks **4** Schmiermittel zuzuführen.

[0045] An einer Außenseite jedes der Seitendeckel **5** und **5** (d.h. entsprechend beiden Bewegungsrichtungsseitenflächen des bewegbaren Blocks) sind jeweils Endplatten **13** und **13** befestigt. Jede der Endplatten **13** und **13** stimmt in ihren Querschnitten mit dem Hauptblock **4** überein und weist einen Mittelabschnitt **13a** und Seitenwandabschnitte **13b** und **13b** auf. Die Endplatten **13** und **13** sind an den jeweiligen Seitendeckeln **5** und **5** mittels Schrauben fixiert. Ein Dichtungsabschnitt **13c** ist entlang eines Innenumfangsrandes jeder Endplatte **13** ausgebildet, wobei der Innenumfangsrand der Führungsschiene **1** gegenüberliegt.

[0046] Fig. 3A zeigt im Detail einen Schnitt, bei welchem die eine obere Rolle **3** zwischen der Führungsschiene **1** und dem bewegbaren Block **2** rollt, welches die vorliegende Ausführungsform betrifft. Im Gegensatz dazu zeigt Fig. 3B ein Vergleichsbeispiel zu der vorliegenden Ausführungsform.

[0047] An den Stützelementen **11b** und **11c** sind jeweils Verbindungsvorsprünge **16** und **16** ausgebildet. Jeder der Verbindungsvorsprünge **16** und **16** ist in der Lage, jeweils eine der beiden Achslinienrichtungs-Endflächen **3a** und **3a** jeder Rolle **3** zu kontaktieren, die an der Lastrollenwälzfläche **4d** rollt. Die Verbindungsvorsprünge **16** und **16** sind weiter als die Kreisbahn der Drehachse **3b** jeder Rolle **3**, die entlang der Lastrollenwälzfläche **4d** rollt, nach außen hin angeordnet und um denselben Abstand von der Lastrollenwälzfläche **4d** getrennt. Ein Abstand L + ΔL zwischen den Verbindungsvorsprüngen **16** und **16** ist derart bestimmt, dass der Abstand L + ΔL etwas größer als eine Länge L jeder Rolle **3** in deren Drehachsrichtung ist, um ein Spiel ΔL in der Drehachsrichtung zu erreichen. Der Kontakt der Endflächen **3a** und **3a** jeder Rolle **3** zu den Verbindungsvorsprüngen **16** und **16** verhindert, dass die Drehachse **3b** jeder Rolle **3** aus den rechten Winkeln (d.h. in eine Schräglage zu einer orthogonalen Richtung) zu der Bewegungsrichtung der Rollen **3** während der Wälzbewegung der Rollen **3** verschoben wird.

[0048] Bei der vorliegenden Ausführungsform sind die Verbindungsvorsprünge **16** und **16** nur aus einem Harz hergestellt; kein Metallbestandteil ist in den Werkstoffen der Vorsprünge **16** enthalten. Daher wird der Kontakt zwischen den Endflächen **3a** jeder Rolle **3** und den Verbindungsvorsprüngen **16** zur Verhinderung der Schrägläufe der Rollen **3** zwischen Harz- und Metallwerkstoffen durchgeführt. Wenn die Rollen in einer Wälzbewegung sind, verringert sich ein Reibungsfaktor zwischen den Endflächen **3a** und den Verbindungsabschnitten **16**. Somit kann auch der

Gleitwiderstand gesenkt werden, der verursacht wird, wenn sich der bewegbare Block **2** gleitend entlang der Führungsschiene **1** bewegt, so dass eine stabile Bewegung des bewegbaren Blocks **2** geschaffen wird.

[0049] Außerdem, da der Rollenhalter **10** die Rollen **3** in Reihe in einer vorbestimmten Lage formiert, ist es möglich, zu vermeiden, dass die Rollen **3** schräggestellt werden. Selbst wenn die Rollen **3** schräggestellt werden, ist eine federnde Rückstellkraft, die von dem Paar Verbindungselementen **10d** und **10d** bereitgestellt wird, in der Lage, diese von den Schrägläufen zu befreien, in dessen Folge die Rollen **3** in der Lage sind, deren Drehachse wieder in rechten Winkeln zu halten. Eine kombinierte Verwendung der Verbindungsvorsprünge **16** und **16** aus Harz und des Rollenhalters **10** verhindert zuverlässig, dass die Rollen **3** schräggestellt werden.

[0050] Fig. 3B veranschaulicht eine andere Struktur, bei welcher eine Stufe **17** an der Lastrollenwälzfläche **4d** ausgebildet ist, um eine metallische Kontaktfläche **17a** zu erzeugen, und diese Kontaktfläche **17a** ist positioniert, um mit der einen Endfläche **3a** jeder Rolle **3** in Kontakt zu gelangen. Diese Struktur ist ebenso in der Lage, die Schrägläufe der Rollen **3** zu verhindern.

[0051] Jedoch in diesem Falle, da die Schräglaufverhinderungskontaktfläche **17a** aus Metall hergestellt ist, wäre es nötig, dass die Fläche **17a** einer höhergenauen Schleifbearbeitung unterzogen wird und eine Ausweichnut **18** an dem Eckpunkt der Stufe **17** gebildet wird.

[0052] Wie oben beschrieben, verwendet die vorliegende Ausführungsform die Verbindungsvorsprünge **16** aus Harz, so dass es nicht erforderlich ist, verschiedene Arten der Bearbeitung, wie Schleifen, an den Verbindungsvorsprüngen **16** anzuwenden. Es ist daher möglich, die Bewegungsführungsvorrichtung in einer kostengünstigen Weise herzustellen.

[0053] Bei der vorliegenden Ausführungsform gibt es einen zusätzlichen Vorteil bei der Vermeidung von einseitigem Kontakt der Rollen **3**. Wenn die paarweisen Verbindungsvorsprünge **16** und **16** mit jeder Rolle **3** zwischen diesen in unterschiedlichen Abständen von der Rollenwälzfläche **4d** angeordnet sind, besteht eine Gefahr, dass die Rollen **3** mit dem Verbindungsvorsprung **16** an der einen Seite (d.h. einseitiger Kontakt) in Kontakt gebracht werden, wenn die Rollen **3** schräggestellt sind. Im Gegensatz dazu ist die Vorrichtung gemäß der vorliegenden Ausführungsform derart strukturiert, dass sie die paarweisen Verbindungsvorsprünge **16** und **16** in denselben Höhenpositionen angeordnet hat, so dass ein solcher einseitiger Kontakt verhindert wird.

[0054] Wie oben beschrieben, werden bei der vorliegenden Ausführungsform, selbst wenn die Rollen schräggestellt sind, die Verbindungsvorsprünge und die Endflächen der Rollen durch Kollisionen zwischen den Harz- und Metallwerkstoffen in Kontakt miteinander gebracht. Dementsprechend verringert sich ein Reibungsfaktor zwischen den Verbindungsvorsprüngen und den Endflächen, so dass der Gleitwiderstand sinkt, der verursacht wird, wenn das bewegbare Element entlang der Führungsschiene gleitet, wodurch sich das bewegbare Element in einer sanften und stabilen Weise bewegen kann. Außerdem machen es die Verbindungen der Rollen mit dem Rollenhalter möglich, den Widerstand gegen das Auftreten von Schrägläufen zu verstärken. Somit sind die Verbindungsvorsprünge aus Harz in der Lage, zu verhindern, dass die Rollen schräggestellt werden.

[0055] Die vorliegende Ausführungsform ist besonders in Fällen wirksam, wo der Durchmesser jeder Rolle so klein ist, dass eine mit den Endflächen der Rolle kontaktierende Kontaktfläche nicht sichergestellt werden kann. Obwohl die oben genannte Ausführungsform mit der Bewegungsführungsvorrichtung beschrieben wurde, die auf eine lineare Bewegungsführung gerichtet ist, ist die Bewegung nicht auf eine solche lineare Bewegung beschränkt. Die vorliegende Erfindung kann auch für eine Bewegungsführungsvorrichtung zur Führung einer bogenförmigen Bewegung angewendet werden. Ferner können die Stützelemente, Ausweichkanalbildungselemente und Richtungswechselkanalbildungselemente als eine Einheit mit dem Hauptblock durch die Verwendung von Umspritzen gebildet werden, was erfordert, dass der Hauptblock einzulegen ist.

[0056] Der Vollständigkeit halber sollte erwähnt werden, dass die Ausführungsform und Modifikationen, soweit erläutert, keine definitiven Aufzählungen von möglichen Ausführungsformen der vorliegenden Erfindung sind. Der Fachmann wird verstehen, dass es möglich ist, die verschiedenen konstruktiven Details zu kombinieren oder diese durch Maßnahmen zu ergänzen oder zu modifizieren, die aus dem Stand der Technik bekannt sind, ohne von dem grundlegenden Erfindungsgedanken abzuweichen, wie in den Ansprüchen definiert ist.

Patentansprüche

1. Eine Bewegungsführungsvorrichtung, aufweisend:
ein Führungselement (**1**), das eine Rollenwälzfläche (**1b**) darauf aufweist;
ein bewegbares Element (**2**), das einen Rollenumlaufkanal mit einer Lastrollenwälzfläche (**4d**) aufweist, die sich gegenüber der Rollenwälzfläche (**1b**) befindet und an dem Führungselement (**1**) relativ zu dem Führungselement (**1**) bewegbar angeordnet ist;

eine Mehrzahl von Rollen (**3**), die jeweils aus Metall hergestellt und in dem Rollenumlaufkanal mit einer Drehachse jeder der Rollen (**3**) parallel zueinander sind, um dadurch in Antwort auf eine Relativbewegung des bewegbaren Elements (**2**) zu dem Führungselement (**1**) zu zirkulieren; und
einen Rollenhalter (**10**), um die Mehrzahl der Rollen (**3**) drehbar und gleitend zu halten;
wobei das bewegbare Element (**2**) Verbindungsvorsprünge (**16**) aufweist, die daran ausgebildet und nur aus Harz hergestellt sind, um dadurch den Verbindungsvorsprüngen (**16**) zu erlauben, mit beiden Achslinienrichtungs-Endflächen jeder der Rollen (**3**) in Kontakt zu gelangen, die entlang der Lastrollenwälzfläche (**4d**) rollen, wobei die Verbindungsvorsprünge (**16**) nur an einer Außenseite relativ zu der Drehachse jeder Rolle (**3**) angeordnet sind, die entlang der Lastrollenwälzfläche (**4d**) rollt.

2. Die Bewegungsführungsvorrichtung nach Anspruch 1, wobei der Rollenhalter (**10**) platziert ist, um zwischen zwei der Rollen (**3**) einzugreifen, und mit einer Mehrzahl von Abstandselementen (**10b**) mit zwei vertieften Flächen an deren beiden Seiten, wobei jede der vertieften Flächen in einer Form mit einer Außenumfangsfläche der neben der jeweiligen Rolle angeordneten Rolle (**3**) übereinstimmt, und einem Verbindungselement (**10d**) versehen ist, das platziert ist, um sich von einer Drehachsrichtungs-Endfläche jeder der Rollen (**3**) nach außen zu erstrecken und die Abstandselemente (**10d**) miteinander zu verbinden.

3. Die Bewegungsführungsvorrichtung nach Anspruch 1 oder 2, wobei der Verbindungsvorsprung (**16**) an einem Stützelement (**11**) ausgebildet ist, um durch Herstellen einer Verbindung mit dem Verbindungselement (**10d**) des Rollenhalters (**10**) zu verhindern, dass die Rollen (**3**) von der Lastrollenwälzfläche (**4d**) weg gelangen, wenn das bewegbare Element (**2**) von dem Führungselement (**1**) entfernt wird.

(54) Bezeichnung: **Herstellungsverfahren von einer Wälzkörperkette**

Beschreibung

[0001] Die vorliegende Erfindung betrifft ein Verfahren zum Herstellen einer Wälzkörperkette, bei der eine Anzahl von Wälzkörpern in einer Reihe mit vorgeschriebenen Abständen ausgerichtet ist und wälzbar gehalten wird, und die verwendet wird, indem sie zum Beispiel in eine Geradführung zur endlosen Gleitbewegung eingebaut wird. Spezieller betrifft die Erfindung eine verbesserte Wälzkörperkette, deren Zug- und Biegefestigkeit erhöht ist.

[0002] Normalerweise ist die bekannte Geradführung, um einen beweglichen Körper wie einen Tisch längs des feststehenden Teils wie zum Beispiel ein Bett zu führen, von der Art, die einen Rollweg mit einer Kugellaufrille, ein Gleitstück mit einer der Kugellaufrille gegenüber liegenden belasteten Laufrille und einem lastfreien Rollweg, in dem die Kugel von einem Ende zum anderen Ende der belasteten Laufrille in Umlauf gebracht wird und sich längs des Rollweges bewegt, sowie eine Anzahl von Kugeln umfasst, die zwischen dem Gleitstück und dem Rollweg unter Belastungsbedingungen rollen und längs der endlosen Laufrille, die aus einer belasteten Laufrille und einem lastfreien Rollweg des Gleitstücks besteht, umlaufen.

[0003] In der normalen Geradführung neigen die benachbarten Kugeln in dieser Anordnung bei ihrem Umlauf längs der endlosen Laufrille, wenn sich das Gleitstück längs des Rollwegs bewegt, dazu, miteinander zu kollidieren oder gegeneinander zu reiben, da die endlose Laufrille des Gleitstücks mit Kugeln gefüllt ist, was zu einem früheren Verschleiß von Kugeln und einer kürzeren Betriebslebensdauer der Vorrichtung führt.

[0004] Um das oben beschriebene Problem zu lösen, wurde deshalb eine Geradführung vorgeschlagen, die eine Wälzkörperkette mit einer Vielzahl von Kugeln enthält, die in einer Reihe in der endlosen Laufrille ausgerichtet sind (siehe Japanische Offenlegungsschrift Nr. 5-52217 oder EP-A-890 754). Wie in den vorliegenden Fig. 17 und Fig. 18, die den Fig. 16 und Fig. 17 von EP-A-890 754 entsprechen, gezeigt ist, umfasst die Wälzkörperkette **100** die Kugelhalteelemente **102**, die zwischen den jeweiligen benachbarten Kugeln **101** eingelegt sind, und ist derart aufgebaut, dass die Kugeln aufeinander folgend verbunden sind, indem die jeweiligen Kugelhalteelemente **102** mit einem Paar von Lochkranzelementen **103**, die in Richtung der Ausrichtung der Kugeln **101** angeordnet sind, verbunden werden, und wird durch Spritzgießen eines elastischen Kunstharzes hergestellt, wobei die Kugeln **101** in einer Form als Kernstücke angeordnet sind.

[0005] Bei der in dieser Weise angeordneten normalen Wälzkörperkette **100**, die in die endlose Laufrille **105** eingebaut ist und längs der endlosen Laufrille gemäß der vorliegenden Fig. 19, die der Fig. 18 von EP-A-890 754 entspricht, umläuft, wird verhindert, dass Reibung oder Zusammenstoß zwischen Kugeln auftritt, und Reibungsverschleiß der Kugeln **101** soweit wie möglich vermieden werden kann, da die Kugelhalteelemente **102** zwischen den jeweiligen benachbarten Kugeln **101** eingelegt sind.

[0006] Da beim herkömmlichen Verfahren eine längliche Wälzkörperkette der Länge, die einer Kreisbahn der endlosen Laufrille entspricht, durch Spritzgießen hergestellt wird, gab es dadurch ein Problem, dass eine Anzahl von Zugängen vorgesehen werden muss, um geschmolzenes Kunstharz in einen Hohlraum in der Form einzuspritzen, damit sich das Lochkranzelement **103** zum Verbinden der jeweiligen Kugelhalteelemente **102** zu einer gleichmäßigen Dicke formen lässt, wodurch die Form komplex wird und sich die Kosten erhöhen.

[0007] Es gab ein anderes Problem darin, dass es in Anbetracht der weiteren Verkleinerung der Geradführung erforderlich ist, das dünnere Lochkranzelement für die Wälzkörperkette in die endlose Laufrille einzubauen und eine Abnahme der Zug- und Biegefestigkeit des Lochkranzelements, die mit dessen Verdünnen verbunden ist, einen Bruch der Wälzkörperkette in der endlosen Laufrille verursachen kann, wodurch die Fähigkeit der Wälzkörperkette, die Kugeln festzuhalten, nachteilig beeinflusst wird.

[0008] Es gab noch ein weiteres Problem darin, dass das von dem Zugang aus eingespritzte geschmolzene Kunstharz nicht den tiefsten Teil des Hohlraums in der Form erreichen kann, wenn das weitere Verdünnen des Lochkranzelements in Erwägung gezogen wird, was zu einer Anzahl von schadhaften Formteilen führt und somit Fertigungen reduziert.

[0009] Die vorliegende Erfindung ist auf die oben beschriebenen Probleme gerichtet und folglich ist es eine Aufgabe zumindest von bevorzugten Ausführungen, ein Verfahren zum Herstellen einer Wälzkörperkette bereitzustellen, durch welches eine weiter verkleinerte Wälzkörperkette mit geringen Kosten leicht hergestellt werden kann und durch das auch nach dem Verkleinern eine Wälzkörperkette mit ausgezeichneter Zugfestigkeit und Biegefestigkeit hergestellt werden kann.

[0010] EP-A-0 890 754 offenbart eine Wälzkörperkette mit einer Anzahl von Wälzelementen, wobei die Kette in einer Ausführung aus einem mit Durchgangslöchern ausgebildeten, streifenförmigen Feinblech aus rostfreiem Stahl gebildet ist, auf das Abstandsstücke aufgepolstert sind, die aus Kunstharz durch Spritzgießen mit den als Kernstücke verwendeten Kugelmatrizen oder den als Kernstücke verwendeten Wälzelementen gebildet sind.

[0011] Aus der Sicht von einer Ausführung stellt die vorliegende Erfindung ein Verfahren zum Herstellen einer Wälzkörperkette zur Verfügung, die eine Anzahl von Wälzelementen aufweist, die darin in vorgeschriebenen Abständen ausgerichtet sind und wälzbar gehalten werden, wobei das Verfahren umfasst:
Bilden eines flachen, bandförmigen Lochkranzelements;
Bilden von Käfiglöchern, um die Wälzelemente in einer Reihe auf dem Lochkranzelement lose aufzunehmen; und
Bilden von Abstandsbereichen durch Spritzgießen, um die Wälzelemente zwischen den benachbarten Käfiglöchern zu halten;
dadurch gekennzeichnet, dass das flache, bandförmige Lochkranzelement gebildet wird, indem ein längliches, flaches, bandförmiges Element aus einem Spritzwerkzeug durch Strangpressen eines Kunstharzes extrudiert wird, während ein verstärkendes Material eingebaut wird, und das flache, bandförmige Element zu einer vorgeschriebenen Länge geschnitten wird;
und dadurch, dass die Abstandsbereiche durch Ausrichten der Wälzelemente in den Käfiglöchern gebildet und die Abstandsbereiche mit den als Kernstücke verwendeten Wälzelementen spritzgegossen werden, so dass die Wälzelemente in den Käfiglöchern eingeschlossen sind.

[0012] So umfasst das Verfahren nach der ersten Ausführung einen ersten Schritt zum Bilden eines flachen, bandförmigen Lochkranzelements mit einem Kunstharz durch Strangpressen und Schneiden auf eine erforderliche Länge, einen zweiten Schritt zum Bilden von in einer Reihe ausgerichteten Käfiglöchern auf dem Lochkranzelement, um Wälzelemente lose aufzunehmen, und einen dritten Schritt zum Anordnen der Wälzelemente in den jeweiligen Käfiglöchern, Bilden von Abstandsbereichen zwischen den jeweiligen benachbarten Käfiglöchern, um die Wälzelemente darin festzuhalten, durch Spritzgießen mit diesen als Kernstücke verwendeten Wälzelementen und Einschließen der Wälzelemente in den Käfiglöchern. Da die Abstandsbereiche gebildet werden, nachdem das flache, bandförmige Lochkranzelement in dem ersten Schritt geformt ist und die Wälzelemente dann in den auf dem Lochkranzelement ausgebildeten Käfiglöchern eingeschlossen werden, kann das Lochkranzelement anschließend durch Strangpressen, nicht durch Spritzgießen, eines Kunstharzes in einem langen Streifen gebildet werden. Deshalb kann ein Lochkranzelement gleichmäßiger Dicke auch dann formfest gebildet werden, wenn die Dicke des Lochkranzelements in Verbindung mit einer Verkleinerung der Wälzkörperkette verringert ist.

[0013] Da das Lochkranzelement und die Abstandsbereiche getrennt geformt werden, kann das Lochkranzelement außerdem aus einem Kunstharzmaterial gebildet werden, das vollkommen anders als ein für die Abstandsbereiche verwendeter Formwerkstoff ist. Daher kann dadurch, dass das Lochkranzelement mit einem Kunstharz gebildet wird, dessen Zug- oder Biegefestigkeit durch Hinzufügen zum Beispiel von Kohlenstofffüller verbessert worden ist, eine Wälzkörperkette hoher Zugfestigkeit auch dann hergestellt werden, wenn die Dicke des Lochkranzteils reduziert ist. Andererseits kann, da die Abstandsbereiche in Gleitberührung mit den Wälzelementen gehalten werden sollen, das Material für die Abstandsbereiche so ausgewählt werden, dass es einen geringen Reibungskoeffizient wie zum Beispiel Ölharz aufweist, wodurch eine ruhige Drehung der Wälzelemente gewährleistet wird.

[0014] Der Einbau eines verstärkenden Materials wie zum Beispiel eine Kohlefaser oder eine Glasfaser in der Länge des Lochkranzelements, wenn dieses durch Strangpressen geformt wird, lässt dadurch eine Erhöhung der Zugfestigkeit des Lochkranzelements auch dann zu, wenn die Zug- oder Biegefestigkeit des das Lochkranzelement bildenden Kunstharzes gering ist.

[0015] Wie soweit beschrieben, kann nach dem Verfahren zum Herstellen der Wälzkörperkette nach der vorliegenden Erfindung das Band aufeinander folgend in einem langen Streifen durch Strangpressen, jedoch nicht durch Spritzgießen, gebildet werden, da die Abstandsbereiche zum Festhalten des Wälzelements innerhalb des Lochkranzelements durch Spritzgießen geformt werden, nachdem das Lochkranzelement zum Ausrichten der Wälzelemente geformt ist, wodurch ein Lochkranzelement gleichmäßiger Dicke bei niedrigen Kosten leicht gebildet werden kann, auch wenn die Dicke des Lochkranzelements in Verbindung mit einer Verkleinerung der Wälzkörperkette verringert wird.

[0016] Aus der Sicht einer anderen Ausführung stellt die vorliegende Erfindung ein Verfahren zum Herstellen einer Wälzkörperkette mit einer Anzahl von Wälzelementen bereit, die darin in vorgeschriebenen Abständen ausgerichtet sind und wälzbar gehalten werden, wobei das Verfahren umfasst:
Bilden eines flachen, bandförmigen Lochkranzelements;
Bilden von Käfiglöchern, um die Wälzelemente lose in einer Reihe auf dem Lochkranzelement aufzunehmen; und
Ausrichten von Wälzelementmodellen in den Käfiglöchern, wobei die Wälzelementlöcher im Durchmesser etwas größer sind als die Wälzelemente, und Bilden von Abstandsbereichen zum Halten der Wälzelemente zwischen den benachbarten Käfiglöchern durch Spritzgießen mit den als Kernstücke verwendeten Wälzelementmodellen und Ersetzen der Wälzelementmodelle durch die Wälzelemente, nachdem die Abstandsbereiche durch Spritzgießen geformt sind;

dadurch gekennzeichnet, dass das flache, bandförmige Lochkranzelement durch Strangpressen eines länglichen, flachen, bandförmigen Elements aus einem Spritzwerkzeug durch Strangpressen eines Kunstharzes geformt wird, während ein verstärkendes Material eingebaut wird, und Schneiden des flachen, bandförmigen Elements auf eine vorgeschriebene Länge.

[0017] Der dritte Schritt kann als das Ausrichten von Wälzelement-Kerneinrichtungen in den Käfiglöchern und das Bilden von Abstandsbereichen gesehen werden, um die Wälzelemente zwischen den benachbarten Käfiglöchern durch Spritzgießen mit den als Kernstücke verwendeten Wälzelement-Kerneinrichtungen zu halten. In der Erfindung aus Sicht der ersten Ausführung umfassen die Wälzelement-Kerneinrichtungen die Wälzelemente und werden innerhalb der Käfiglöcher durch das spritzgegossene Teil festgehalten. In der Erfindung aus Sicht der zweiten Ausführung sind die Wälzelement-Kerneinrichtungen Wälzelementmodelle, die einen etwas größeren Durchmesser als die Wälzelemente aufweisen, und werden durch die Wälzelemente ersetzt, nachdem die Abstandsbereiche gebildet sind.

[0018] Es werden jetzt mit Bezug auf die begleitenden Zeichnungen Ausführungen nach der Erfindung nur beispielhaft beschrieben, wobei

[0019] Fig. 1 ist eine Draufsicht, die eine erste Ausführung einer Wälzkörperkette darstellt, die nach einem Verfahren gemäß der vorliegenden Erfindung hergestellt wurde;

[0020] Fig. 2 ist eine die Wälzkörperkette von Fig. 1 darstellende Ansicht im Querschnitt, der längs der Linie II-II geführt ist;

[0034] Fig. 16 ist eine perspektivische Ansicht, die den Zustand zeigt, wie die Abstandsbereiche durch Spritzgießen auf dem Lochkranzelement mit darin ausgerichteten Walzen gebildet sind;

[0035] Fig. 17 ist eine Draufsicht, die die herkömmliche Wälzkörperkette darstellt;

[0036] Fig. 18 ist eine Vorderansicht, die die herkömmliche Wälzkörperkette darstellt; und

[0037] Fig. 19 ist eine Querschnittsansicht, die den Zustand zeigt, bei dem die Wälzkörperkette in den endlosen Laufring der Geradführung eingebaut ist.

[0038] Mit Bezug jetzt auf die Zeichnungen werden bevorzugte Ausführungen der vorliegenden Erfindung beschrieben.

[0039] Fig. 1 bis Fig. 3 zeigen eine erste Ausführung einer nach einem Verfahren der vorliegenden Erfindung hergestellten Wälzkörperkette. Die Wälzkörperkette **1** umfasst ein aus einem Kunstharz gebildetes Kettenband **2** und Kugeln **3** als Wälzkörper, die in einer Reihe in vorgeschriebenen Abständen ausgerichtet sind, wobei diese Kugeln **3** in dem Zustand, wo sie in dem Kettenband **2** festgehalten werden, wälzbar sind.

[0040] Das Kettenband **2** umfasst ein Lochkranzelement **21**, das in der flachen Bandform ausgebildet ist und Käfiglöcher **20** aufweist, um Kugeln **3** in vorgeschriebenen Abständen festzuhalten, und Abstandsbereiche **22**, die von beiden Flächen des Lochkranzelements **21** zwischen den entsprechenden benachbarten Käfiglöchern **20** hervorstehen, wobei die Kugeln **3** innerhalb der Käfiglöcher **20** des Lochkranzelements **21** durch die jeweiligen Abstandsbereiche **22** wälzbar eingeschlossen sind.

[0041] Das Verfahren zum Herstellen der Wälzkörperkette **1** wird jetzt schrittweise beschrieben.

[0042] Fig. 4 zeigt ein Lochkranzelement **21**, das in dem ersten Schritt gemäß der vorliegenden Erfindung gebildet wurde. Das Lochkranzelement **21** wird durch Spritzgießen eines Kunstharzes hergestellt. Das aus dem Spritzwerkzeug fortlaufend extrudierte Lochkranzelement **21** wird in einem Wassertank abgekühlt und anschließend durch eine Spule aufgewickelt. Im folgenden Schritt wird das auf die Spule aufgewickelte Lochkranzelement **21** auf eine vorgeschriebene Länge geschnitten und verwendet.

[0043] Weil das Lochkranzelement **21**, bevor daran die Abstandsbereiche **22** angebaut werden, über seine Länge einen gleichmäßigen Querschnitt aufweist, kann durch Strangpressen ein Lochkranzelement **21** von gleichmäßiger Dicke bei geringen Kosten leicht gebildet werden, auch wenn das Lochkranzelement **21** dünn ist.

[0044] Das auf diese Weise gebildete Lochkranzelement **21** wird auf eine Länge geschnitten, die einer Kreisbahn des endlosen Laufrings der Geradführung entspricht, und dann mit Käfiglöchern **20** ausgebildet, um die Kugeln **3** längs ihrer Länge in vorgeschriebenen Abständen festzuhalten. Jedes Käfigloch **20** ist derart geformt, dass dessen Innendurchmesser etwas größer ist als der Durchmesser der Kugel **3**, so dass die Kugel **3** ohne Reibung eingelegt und herausgenommen werden kann. Das Spritzgießen der Abstandsbereiche **22** wird mit den innerhalb dieser Käfiglöcher **20** ausgerichteten Kugeln **3** durchgeführt.

[0045] Das Spritzgießen wird in dem Zustand durchgeführt, wo das zu einer vorgeschriebenen Länge geschnittene Lochkranzelement **21** bei einer vorgeschriebenen Position in die Form gesetzt wird und die Kugeln **3** in den jeweiligen, auf dem Lochkranzelement **21** ausgebildeten Käfiglöchern **20** angeordnet werden, wobei dieses Lochkranzelement **21** und die Kugeln **3** als Kernstücke verwendet werden. Die Abstandsbereiche **22** sind zwischen den jeweiligen benachbarten Käfiglöchern **20** auf dem Lochkranzelement **21** aufgebaut, damit sie einen Teil der Flächen der Kugeln **3** bedecken, wobei die teilweise bedeckten Kugeln **3** innerhalb der Käfiglöcher **20** des Lochkranzelements **21** eingeschlossen sind. Dementsprechend ist gemäß Fig. 6 ein Kettenband **2** fertig, das auf dem Lochkranzelement **21** in vorgeschriebenen Abständen ausgerichtete und festgehaltene Kugeln **3** aufweist. Beim Spritzgießen der Abstandsbereiche **22** wird wie im Fall der Formung des Lochkranzelements **21** ein Kunstharz wie zum Beispiel Polyamid-Elastomer oder Polyester-Elastomer verwendet. Durch Bildung der Abstandsbereiche **22** durch Spritzgießen unter Verwendung des gleichen Kunstharzes wie das Lochkranzelement **21**, werden die Abstandsbereiche **22** an das Lochkranzelement **21** geschweißt, wenn es geformt ist, und als Folge werden das Abstandsteil **22** und das Lochkranzelement **21** fest eingebaut.

[0046] Wenn die Abstandsbereiche **22** durch Spritzgießen mit den Kugeln **3** als Kernstücke gebildet sind, kommen die Abstandsbereiche **22** mit den Flächen der Kugeln **3** in engen Kontakt, wodurch verhindert wird, dass die Kugel ruhig läuft. Deshalb wird bei Beendigung dieses Spritzgießens das Lochkranzelement **21** einen bestimmten Zeitraum lang in Öl eingetaucht. Da das aus einem Kunstharz gebildete Kettenband **2** Öl aufnimmt und somit anschwillt, werden zwischen den Abstandsbereichen **22** und den Kugeln **3** kleine Spalte gebildet, nachdem ein vorgeschriebener Zeitraum verstrichen ist, wodurch ungehindertes Rollen der Kugeln **3** ermöglicht wird, ohne dass sie aus den Käfiglöchern **20** herausfallen. Die Wälzkörperkette **1** ist damit fertig.

[0047] Andererseits ist es auch möglich, die Abstandsbereiche **22** zu formen, indem Kugelmodelle (Wälzkörpermodell), die im Durchmesser etwas größer sind als die Kugeln **3**, in den Käfiglöchern **20** des Lochkranzelements **21** ausgerichtet werden und mit den Kugelmodellen und dem Lochkranzelement **21**, die als Kernstücke verwendet werden, zu formen. Wenn die Kugeln **3** als Kernstücke verwendet werden, ist der Schritt zum Bilden von Spalten zwischen den jeweiligen Kugeln **3** und Abstandsbereichen **22** nach Beendigung der Formung der Abstandsbereiche **22** wie oben beschrieben erforderlich. Andererseits werden die Abstandsbereiche **22** in dem Fall, wo die Kugelmodelle als Kernstücke verwendet werden, entsprechend kleiner, weil die Kugelmodelle etwas größer sind als die Kugeln **3**. Deshalb können die Kugeln **3** dadurch, dass die Kugelmodelle aus dem Kettenband **2** gedrückt und anschließend stattdessen Kugeln **3** eingesetzt werden, wenn die Formung der Abstandsbereiche **22** beendet ist, in den Käfiglöchern **20** ungehindert rollen, ohne den Zeit raubenden Schritt, das Kettenband **2** einen vorgeschriebenen Zeitraum lang in Öl zu tauchen.

[0048] Nach dem Verfahren zum Herstellen der wie oben beschriebenen Wälzelementkette **1** ist die Bildung einer länglichen Wälzelementkette in einer Form durch Spritzgießen wie auf die herkömmliche Art und Weise nicht mehr notwendig, und die ein dünnes Lochkranzelement **21** umfassende Wälzelementkette **1** kann einfach mit geringen Kosten und dauerhaft hergestellt werden.

[0049] Nach dem Verfahren zum Herstellen der soweit beschriebenen Wälzkörperkette **1** wird für das Lochkranzelement **21** das gleiche Material wie für das Abstandsteil **22** verwendet und ein verstärkendes Material (nicht dargestellt) innerhalb des Lochkranzelements **21** eingebaut, um die Zugfestigkeit und die Biegefestigkeit des Lochkranzelements **21** zu erhöhen. Es ist jedoch außerdem möglich, die Zugfestigkeit und die Biegefestigkeit des Lochkranzelements **21** zu erhöhen, indem Kohlenstofffüller oder dergleichen zu dem Material für das Lochkranzelement **21** selbst zugegeben werden, um eine Verschlechterung der Zugfestigkeit und der Biegefestigkeit des Lochkranzelements **21** verbunden mit der Verringerung seiner Dicke zu kompensieren.

[0050] Fig. 7 bis Fig. 9 stellen eine zweite Ausführung einer Wälzkörperkette dar, die nach dem Verfahren der vorliegenden Erfindung hergestellt wurde.

[0051] Die Wälzkörperkette **1A** besitzt fast den gleichen Aufbau wie die Wälzkörperkette **1** nach der ersten Ausführung. Jedoch enthält das Lochkranzelement **21** wie es in Querschnitten von Fig. 8 und Fig. 9 dargestellt ist, ein verstärkendes Material wie zum Beispiel eine Glasfaser, eine Kohlefaser oder eine keramische Faser, die in beiden Kantenbereichen entlang ihrer Länge eingebaut sind. Deshalb wird, wenn die Zugkraft entlang der Länge des Kettenbandes **2** aufgebracht wird, das verstärkende Material **23** durch die Zugkraft belastet, wodurch der Bruch des Kettenbandes **2** wirksamer als in der ersten Ausführung verhindert werden kann. Mit den gleichen Bezugszahlen werden Komponenten, die der ersten Ausführung gleich sind, bezeichnet und eine ausführliche Beschreibung wird weggelassen.

[0052] Das Verfahren zum Herstellen der Wälzelementkette **1A** wird jetzt schrittweise beschrieben.

[0053] Fig. 10 zeigt ein in dem ersten Schritt nach der vorliegenden Erfindung gebildetes Lochkranzelement **21**. Das Lochkranzelement **21** ist durch Strangpressen eines Kunstharzes hergestellt, und ein oben beschriebenes verstärkendes Material **23** wird während des Strangpressens darin eingebaut.

[0054] Fig. 11 ist eine schematische Darstellung, die den Schritt der Ausführung von Strangpressen des Lochkranzelementes **21** zeigt, während ein verstärkendes Material eingebaut wird. Das verstärkende Material **23** ist auf einer Spule **4** mit großem Durchmesser aufgewickelt. Das von der Spule **4** abgewickelte verstärkende Material **23** wird durch die Vorwärmeinrichtung **5** vorgewärmt, anschließend durch den Ziehdorn **7** der Kreuzkopfmatrize **6** hindurch gelassen und aus dem Spritzwerkzeug **8** herausgezogen. Geschmolzenes Kunstharz wie zum Beispiel Polyamid-Elastomer oder Polyester-Elastomer wird in die Kreuzkopfmatrize **6** durch eine nicht gezeigte Schnecke gedrückt und um das verstärkende Material **23** herum aufgebaut, wenn es aus dem Spritzwerkzeug **8** extrudiert wird, wodurch ein längliches Lochkranzelement **21** aufeinanderfolgend aus der Kreuzkopfmatrize **6** extrudiert wird. Das extrudierte Lochkranzelement **21** wird in dem Wassertank **9** abgekühlt und anschließend durch die Spule **10** aufgewickelt, wobei es zu einer vorgeschriebenen Länge geschnitten und in einem anschließenden Schritt verwendet wird.

[0055] Das verstärkende Material **23** braucht nicht zwangsläufig selbst eine Glasfaser zu sein, sondern kann eine Kunstfaser sein, deren Zugfestigkeit oder Biegefestigkeit durch das Hinzugeben von Kohlenstofffüller oder dergleichen verbessert worden ist. In diesem Fall kann doppelschichtiges Strangpressen eingesetzt werden, um das Lochkranzelement **21** der in Fig. 10 gezeigten Form zu bilden. Gemäß Fig. 12 werden zwei Extruder **11**, **12** bei diesem doppelschichtigen Extrudieren verwendet. Nach dem Erstarren eines Kunstharzes zum Bilden eines verstärkenden Materials im Trichter **13** der Schneckenpresse **11** und eines Kunstharzes zum Überziehen des verstärkendes Material im Trichter **14** der anderen Schneckenpresse **12** werden diese Kunstharze aus der gemeinsamen Düse **15** extrudiert. Anschließend wird, wie in Fig. 11, das extrudierte Lochkranzelement **21** in dem Wassertank abgekühlt und durch die Spule gewickelt, und es kann ein längliches Lochkranzelement **21** einschließlich eines Kunstharzes von hoher Zugfestigkeit und Biegefestigkeit als ein verstärkendes Material **23**, das mit einer anderen Art von Kunstharz überzogen ist, erzielt werden.

[0056] Auf diese Weise besitzt das Lochkranzelement **21**, auch wenn ein verstärkendes Material **23** innerhalb des Lochkranzelements **21** eingebaut ist, einen gleichmäßigen Querschnitt entlang seiner Länge, bevor das Abstandsteil **22** darauf aufgebaut ist, wobei das Lochkranzelement **21** gleichmäßiger Dicke mit geringen Kosten wie im Fall der ersten Ausführung einfach gebildet werden kann.

[0057] Anschließend wird das Formen des Abstandsteils **22** in der gleichen Art und Weise wie bei der Wälzkörperkette **1** nach der ersten Ausführung durchgeführt.

[0058] Mit anderen Worten, das Lochkranzelement **21**, das in die einer Kreisbahn des Laufrings der endlosen Geradführung entsprechende Länge geschnitten ist, wird mit Käfiglöchern **20** ausgebildet, um die Kugeln **3** entlang ihrer Länge in vorgeschriebenen Abständen gemäß Fig. 13 festzuhalten, wobei Spritzgießen der Abstandsbereiche **22** mit den in diesen Käfiglöchern **20** ausgerichteten Kugeln **3** durchgeführt wird. Das Kettenband **2** wird, nachdem das Formen des Abstandsteils **22** beendet ist, einen bestimmten Zeitraum lang in Öl eingetaucht, wodurch Spalte zwischen den Abstandsbereichen **22** und den Kugeln **3** gebildet werden, die das Rollen der Kugeln **3** ermöglichen. Im Ergebnis ist, wie in Fig. 14 gezeigt wird, die Wälzkörperkette **1A** nach der zweiten Ausführung mit einem darin eingebauten verstärkenden Material **23** fertig.

[0059] In den Ausführungen werden, wie es soweit beschrieben ist, Kugeln als in dem Lochkranzelement auszurichtende Wälzelemente verwendet. Jedoch kann diese Erfindung auf den Fall angewandt werden, wo als Wälzelemente Walzen eingesetzt werden. Spezieller wird gemäß Fig. 15, nachdem Käfiglöcher **31** für Walzen **30** auf dem Lochkranzelement **21** entlang seiner Länge in vorgeschriebenen Abständen geformt sind, gemäß Fig. 16 mit den in diesen Käfiglöchern **31** ausgerichteten Walzen **30** Spritzgießen durchgeführt. Folglich sind die Walzen **30** innerhalb der Käfiglöcher **31** des Lochkranzelements **21** eingeschlossen und, wie es in dem Fall ist, wo die Kugeln **3** als Wälzelemente eingesetzt sind, kann das Kettenband **2** mit den in dem Lochkranzelement **21** in vorgeschriebenen Abständen ausgerichteten und festgehaltenen Walzen **30** fertig gestellt werden.

Patentansprüche

1. Verfahren zum Herstellen einer Wälzkörperkette (**1**; **1A**) mit einer Anzahl von Wälzkörpern (**3**; **30**), die darin in vorgeschriebenen Abständen ausgerichtet sind und wälzbar gehalten werden, wobei das Verfahren umfasst
Bilden eines flachen, bandförmigen Lochkranzelements (**21**);
Bilden von Käfiglöchern (**20**; **31**), um die Wälzelemente (**3**; **30**) in einer Reihe auf dem Lochkranzelement (**21**) locker aufzunehmen; und
Bilden von Abstandsbereichen (**22**, **32**) zum Festhalten der Wälzelemente (**3**; **30**) zwischen den benachbarten Käfiglöchern (**20**; **31**) durch Spritzgießen;
dadurch gekennzeichnet, dass das flache, bandförmige Lochkranzelement (**21**) durch Strangpressen eines länglichen, flachen, bandförmigen Elements aus einem Spritzwerkzeug gebildet wird, indem ein Kunstharz extrudiert wird, während ein verstärkendes Material (**23**) eingebaut wird; und Schneiden des flachen, bandförmigen Elements auf eine vorgeschriebene Länge,
und dadurch, dass die Abstandsbereiche (**22**; **32**) durch Ausrichten der Wälzelemente (**3**; **30**) in den Käfiglöchern (**20**; **31**) und Spritzgießen der Abstandsbereiche (**22**; **32**) mit den als Kernstücke verwendeten Wälzelementen (**3**; **30**) gebildet sind, so dass die Wälzelemente (**3**; **30**) in den Käfiglöcher (**20**; **31**) aufgenommen werden.

2. Verfahren zum Herstellen einer Wälzkörperkette (**1**; **1A**) nach Anspruch 1, dadurch gekennzeichnet, dass das Lochkranzelement (**21**) aus einem Kunstharz geformt ist, das eine ausgezeichnete Zugfestigkeit oder Biegefestigkeit gegenüber einem Kunstharz, das zum Formen der Abstandsbereiche (**22**; **32**) durch Spritzgießen verwendet wird, aufweist.

3. Verfahren zum Herstellen einer Wälzkörperkette (**1**; **1A**) mit einer Anzahl von Wälzelementen (**3**; **30**), die darin in vorgeschriebenen Abständen ausgerichtet sind und wälzbar gehalten werden, wobei das Verfahren umfasst
Formen eines flachen, bandförmigen Lochkranzelements (**21**);
Formen von Käfiglöchern (**20**; **31**), um die Wälzelemente (**3**; **30**) in einer Reihe auf dem Lochkranzelement (**21**) locker aufzunehmen; und
Ausrichten von Wälzelementmustern in den Käfiglöchern (**20**; **31**), wobei die Wälzelementmuster im Durchmesser etwas größer als die Wälzelemente (**3**; **30**) sind; und
Bilden von Abstandsbereichen (**22**; **32**) zum Festhalten der Wälzelemente (**3**; **30**) zwischen den benachbarten Käfiglöchern (**20**; **31**) durch Spritzgießen mit den als Kernstücke verwendeten Wälzelementmustern, und
Ersetzen der Wälzelementmuster durch die Wälzelemente (**3**; **30**), nachdem die Abstandsbereiche (**22**; **32**) durch Spritzgießen geformt sind;
dadurch gekennzeichnet, dass das flache, bandförmige Lochkranzelement (**21**) durch Extrudieren eines länglichen, flachen, bandförmigen Elements aus einem Spritzwerkzeug durch Strangpressen eines Kunstharzes gebildet wird, während ein Verstärkungsmaterial (**23**) eingebaut wird; und Schneiden des flachen, bandförmigen Elements auf eine vorgeschriebene Länge.

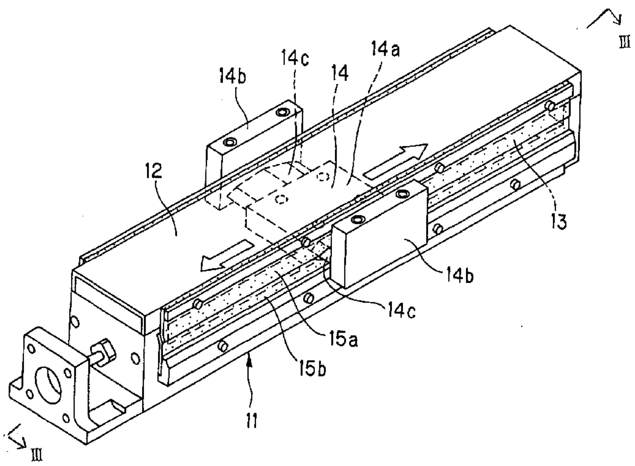
(54) Führungsvorrichtung mit einer staubdichten Struktur

(57) Die Erfindung betrifft eine Führungsvorrichtung mit einer staubdichten Struktur, umfassend eine lineare Führungsvorrichtung (11), eine Außenabdeckung (12, 50), die an der linearen Führungsvorrichtung befestigt ist, um die Führungsvorrichtung zu schützen, und die mit einer Öffnung (13) versehen ist, wobei die lineare Führungsvorrichtung ein bewegliches Glied (14, 40) mit einem nach außen durch die von der Außenabdeckung gebildete Öffnung hervorragenden Teil umfasst, und das bewegliche Glied entlang der Öffnung (13) bewegt werden kann; und eine Abdichtstruktur mit einer Mehrzahl Dichtungsglieder (15a, 15b; 51a, 51b), von denen jedes die Form eines Streifens hat und flexibel ist. Die Dichtungsglieder sind an Randabschnitten der Öffnung (13) der Außenabdeckung (12, 50) angeordnet, um sich so gegenseitig zu überlappen, wodurch ein im Wesentlichen abgedichteter Zustand innerhalb der linearen Führungsvorrichtung erhalten wird. Die Dichtungsglieder werden durch eine an dem beweglichen Glied ausgebildete Führungsstruktur getrennt und auf die Seite gedrückt, wenn das bewegliche Glied bewegt wird, wobei der abgedichtete Zustand innerhalb der linearen Führungsvorrichtung im Wesentlichen erhalten bleibt.



DE 100 05 765 A 1

Beschreibung

Die vorliegende Erfindung betrifft eine Führungsvorrichtung mit einer staubdichten Struktur (nachfolgend auch als "staubdichte Führungsvorrichtung" bezeichnet) zum Führen einer beweglichen Plattform oder dergleichen und insbesondere eine staubdichte Führungsvorrichtung, die mit einer äußeren (Panzer-) Abdeckung versehen ist.

Fig. 10 zeigt ein Beispiel einer herkömmlich bekannten staubdichten Führungsvorrichtung unter Verwendung einer Kugelgewindespindel. Die in **Fig.** 10 gezeigte staubdichte Führungsvorrichtung umfasst eine ausschließlich drehbar gelagerte Gewindewelle **1**, ein auf die Gewindewelle **1** geschraubtes Schraubenmutternglied **2** und eine die Gewindewelle **1** und das Mutternglied **2** schützende Außenabdekkung **3**. Die Außenabdeckung **3** ist mit einer oberen Öffnung **4** ausgebildet, die sich gemäß der Darstellung parallel zur Gewindewelle **1** erstreckt. Das Mutternglied **2** ist mit einem beweglichen Glied **5** einteilig ausgebildet, das an ein zu führendes Glied befestigt ist, so dass das bewegliche Glied **5** gemäß der Drehung der Gewindewelle **1** entlang der Öffnung geradlinig bewegt wird. Die Öffnung **4** der Außenabdeckung **3** ist durch ein Dichtungsglied **6** aus Gummi verdeckt und das Dichtungsglied **6** ist mit einem linearen Schnitt (Schnittlinie) **6**a entlang der Gewindewelle **1** ausgebildet. Das bewegliche Glied **5** biegt das Dichtungsglied **6** zwangsweise entlang der Schnittlinie **6**a nach außen, um durch eine Öffnung O nach außen vorzuragen, die durch die erzwungene Biegung des Dichtungsgliedes **6** gebildet wird. Das bewegliche Glied **5** führt entlang der Schnittlinie **6**a eine lineare richtungswechselnde Bewegung aus, wobei beide Seiten der Schnittlinie **6**a des Dichtungsgliedes **6** aufgeweitet werden. Gemäß dieser Struktur kann der durch die Kugelgewindespindel erzeugte Staub oder dergleichen durch Abdecken der Gewindewelle **1** und des Muttergliedes **2** durch die Außenabdeckung **3** und das Dichtungsglied **6** nicht nach außen gelangen.

In der in **Fig.** 10 gezeigten Struktur der staubdichten Führungsvorrichtung, in der der lineare Schnitt **6**a an dem Dichtungsglied **6**a ausgebildet ist, tritt jedoch ein Spalt mit einer geringen Breite zwischen den Abschnitten **6**b und **6**c des Dichtungsgliedes **6** auf, die einander entlang der Schnittlinie 6a zugewandt sind, und die Breite dieses Spaltes wird graduell größer, wenn das bewegliche Glied **5** wiederholt hin und herbewegt wird, was zu dem Problem führt, dass Staub oder dergleichen durch einen derart aufgeweiteten Spalt von der Außenabdeckung **3** nach außen gelangt. Demzufolge ist es gemäß der Struktur herkömmlicher staubdichter Führungsvorrichtungen wie der in **Fig.** 10 gezeigten schwierig, eine gute Staubabdichtung zu erhalten.

Aufgabe der vorliegenden Erfindung ist es, die zum Stand der Technik oben genannten Mängel oder Nachteile im Wesentlichen zu eleminieren und eine Führungsvorrichtung mit einer staubdichten Struktur vorzusehen, mit der eine hohe Staubabdichtung realisiert werden kann.

Diese Aufgabe wird gemäß der vorliegenden Erfindung gelöst, indem eine Führungsvorrichtung mit einer staubdichten Struktur vorgesehen ist, umfassend:
eine lineare Führungsvorrichtung;
eine an der linearen Führungsvorrichtung befestigte Außenabdeckung, um die lineare Führungsvorrichtung zu schützen, die mit einer Öffnung versehen ist, wobei die lineare Führungsvorrichtung ein bewegliches Glied mit einem durch die an der Außenabdeckung gebildete Öffnung nach außen hervorragenden Teil enthält und das bewegliche Glied entlang der Öffnung bewegt werden kann; und
eine Abdichtstruktur mit einer Mehrzahl Dichtungsglieder, von denen jedes die Form eines Riemenstreifens besitzt und flexibel ist, wobei die Dichtungsglieder an Randabschnitten der Öffnung der Außenabdeckung angeordnet sind, um sich so gegenseitig zu überlappen, wodurch im Wesentlichen ein abgedichteter Zustand innerhalb der linearen Führungsvorrichtung erhalten wird.

In bevorzugten Ausführungen der Erfindung besitzt das bewegliche Glied eine Führungsstruktur, die mit einem scharfkantigen Endabschnitt versehen ist, um die überlappten Dichtungsglieder gemäß einer Vorwärtsbewegung des beweglichen Gliedes zu trennen und seitwärts zu drücken, wobei die Führungsstruktur mit einem Seitenteil versehen ist, das in einer zur Bewegungsrichtung des beweglichen Gliedes entgegengesetzten Richtung graduell nach außen verbreitert ist.

Die Führungsstruktur ist vorteilhafterweise mit dem beweglichen Glied einteilig oder als ein von dem beweglichen Glied unabhängiges Glied ausgebildet.

Das bewegliche Glied ist vorteilhafterweise mit einem Verschlußglied zum Schließen der Öffnung der Dichtungsglieder versehen.

Eine Gleitfläche ist vorteilhafterweise zwischen der Führungsstruktur und der Abdichtstruktur mit einem sich in deren Längsrichtung kontinuierlich erstreckenden Vorsprung ausgebildet.

Neben der oben genannten Aufgabe werden durch die Strukturen der vorliegenden Erfindung folgende vorteilhafte Resultate oder Funktionen erzielt.

Da die Dichtungsglieder sich überlappende Endabschnitte besitzen, entsteht zwischen den jeweiligen Dichtungsgliedern kein Spalt, wodurch der Innenraum der Außenabdeckung, d. h. die lineare Führungsvorrichtung, vollständig verschlossen bleibt. Das bewegliche Glied wird bewegt, wodurch die Dichtungsglieder zwangsweise zur Seite gedrückt und geöffnet werden, und die Dichtungsglieder kehren dann aufgrund ihres eigenen flexiblen oder elastischen Vermögens in ihre ursprünglichen Formen zurück. Das bedeutet, dass die Dichtungsglieder gemäß der Struktur der erfindungsgemäßen Führungsvorrichtung nur an den Abschnitten geöffnet sind, die das bewegliche Glied passiert, und andere Abschnitte der Dichtungsglieder während der Vorwärtsbewegung des beweglichen Gliedes vollständig geschlossen sind, wodurch die Führungsvorrichtung mit einer hohen staubabdichtenden Struktur realisiert ist.

Desweiteren werden die Dichtungsglieder gemäß der bevorzugten Ausführungen während der Umkehrbewegung des beweglichen Gliedes sanft durch die Führungsstruktur deformiert und nach dem Passieren des beweglichen Gliedes werden die Dichtungsglieder in den ursprünglichen Schließzustand zurückgeführt, wodurch eine Spaltbildung zwischen der Führungsstruktur und den Dichtungsgliedern sicher verhindert wird.

Durch eine getrennte, d. h. unabhängige Bildung der Führungsstruktur kann eine relativ komplizierte Führungsstruktur leicht hergestellt werden, was zu einer einfachen Herstellung des beweglichen Gliedes selbst führt.

Wenn das bewegliche Glied die wiederholten Umkehrbewegungen ausführt, kann es passieren, dass die Dichtungsglieder die gebogenen Formen beibehalten und nicht vollständig in ihre ursprünglichen Formen zurückkehren. Gemäß der vorliegenden Erfindung werden derartig gebogene Abschnitte der Dichtungsglieder durch ein Verschlußglied, wie beispielsweise stabförmige Stifte, zwangsweise nach innen gedrückt, wodurch die Dichtungsglieder nach dem Passieren des beweglichen Gliedes sicherer geschlossen werden können.

Darüber hinaus kann die Anordnung der kontinuierlichen Vorsprünge der Gleitfläche den Reibungswiderstand zwischen der Führungsstruktur und der Abdichtstruktur reduzieren, wodurch die Linearbewegung des beweglichen Gliedes leicht ausgeführt wird.

Gemäß eines weiteren Aspekts der vorliegenden Erfindung ist eine Führungsvorrichtung mit einer staubdichten Struktur vorgesehen, umfassend:

eine lineare Führungsvorrichtung mit einem im Wesentlichen D-förmigen Querschnitt mit einer Öffnung;

eine Außenabdeckung, die an der linearen Führungsvorrichtung befestigt ist, um die Öffnung der D-förmigen Führungsvorrichtung zu überdecken, und die mit einer Öffnung versehen ist, wobei die lineare Führungsvorrichtung ein bewegliches Glied und ein lineares Glied umfasst, entlang dem das bewegliche Glied hin und herbewegt wird, wobei das bewegliche Glied einen nach außen durch eine zwischen der Außenabdeckung und der linearen Führungsvorrichtung gebildete Öffnung hervorragenden Teil umfasst, um entlang der zwischen der Außenabdeckung und der linearen Führungsvorrichtung gebildeten Öffnung bewegt werden zu können; und

eine Abdichtstruktur mit einer Mehrzahl Dichtungsglieder, von denen jedes die Form eines Streifens hat und flexibel ist, wobei die Dichtungsglieder an Randabschnitten der zwischen der Außenabdeckung und der linearen Führungsvorrichtung gebildeten Öffnung angeordnet sind, um sich gegenseitig zu überlappen, und die Öffnung zwischen der Außenabdeckung und der linearen Führungsvorrichtung abzudecken und im Wesentlichen einen abgedichteten Zustand innerhalb der linearen Führungsvorrichtung zu erhalten.

In bevorzugten Ausführungen der Erfindung umfasst das bewegliche Glied einen beweglichen Körper, Seitenteile, die als Vorsprünge auf beiden Seiten des beweglichen Gliedes vorgesehen sind, und Kupplungsteile, durch die der bewegliche Körper und die Seitenteile miteinander verbunden sind, wobei die Kupplungsteile in einem Niveau entsprechend der sich überlappenden Abschnitte der Dichtungsglieder angeordnet sind.

Die Kupplungsteile besitzen in der Bewegungsrichtung des beweglichen Gliedes scharfkantige Endabschnitte.

Die Kupplungsteile können an deren beiden Endabschnitten entlang der Bewegungsrichtung des beweglichen Gliedes mit Führungsteilen ausgebildet sein, wobei die Führungsteile jeweils einen scharfkantigen Endabschnitt in der Bewegungsrichtung des beweglichen Gliedes besitzen, um die sich überlappenden Dichtungsglieder gemäß einer Vorwärtsbewegung des beweglichen Gliedes zu trennen und seitwärts zu drücken, wobei das Führungsteil mit einem Seitenteil versehen ist, das in einer zur Vorwärtsrichtung des beweglichen Gliedes entgegengesetzten Richtung graduell nach außen verbreitert ist. Die Führungsteile können mit dem Kupplungsteil des beweglichen Gliedes einteilig oder von den Kupplungsteilen des beweglichen Gliedes unabhängig ausgebildet sein.

Das bewegliche Glied ist mit einem Verschlußglied versehen, das zwei Paare von stabförmigen Stiften umfasst, die an den Seitenteilen des beweglichen Gliedes befestigt sind, um in einer sich gegenüberstehenden Weise auf beiden Seiten des beweglichen Gliedes in seiner Bewegungsrichtung nach innen vorstehen, wobei die Stifte stirnseitige Enden haben, die sich im Wesentlichen an die sich überlappenden Abschnitte der Dichtungsglieder erstrecken.

Die Dichtungsglieder sind aus Gummi oder flexiblem synthetischen Harzmaterial hergestellt.

Die Dichtungsglieder sind an Seitenteilen der Außenabdeckung mittels eines Haftmittels angeordnet und jedes dieser Dichtungsglieder läuft an ein Vorderende spitz zu. Die Außenabdeckung kann mit Schwalbenschwanznuten ausgebildet sein und die Dichtungsglieder haben verbreiterte Endabschnitte, die in die Schwalbenschwanznuten der Außenabdeckung passen.

Gemäß dieses Ausführungsteils der vorliegenden Erfindung werden im Wesentlichen die gleichen Funktionen und Resultate erzielt, wie sie oben mit Bezug auf die erste Ausführung der vorliegenden Erfindung erwähnt wurden.

Der Gegenstand und weitere kennzeichnende Merkmale der vorliegenden Erfindung werden durch die folgende Beschreibung mit Bezug auf die beigefügte Zeichnung dargestellt.

In der beigefügten Zeichnung zeigt:

Fig. 1 eine perspektivische Ansicht einer erfindungsgemäßen Führungsvorrichtung mit staubdichter Struktur;

Fig. 2 eine perspektivische Explosionsansicht der Führungsvorrichtung von **Fig.** 1;

Fig. 3 einen Längsschnitt entlang der Schnittlinie III-III aus **Fig.** 1;

Fig. 4 einen Querschnitt entlang der Linie IV-IV aus **Fig.** 3;

Fig. 5 eine perspektivische Ansicht eines anderen Beispiels eines beweglichen Gliedes der Führungsvorrichtung;

Fig. 6 ein Führungsteil einschließlich der **Fig.** 6A, die eine perspektivische Ansicht des Führungsteils ist, und **Fig.** 6B, die dessen Draufsicht zeigt, und **Fig.** 6C mit dessen Seitenansicht;

Fig. 7 eine perspektivische Ansicht, die einen Zustand zeigt, in dem das Führungsteil ein Dichtungsglied der Führungsvorrichtung trennt und seitwärts drückt;

Fig. 8 einen Querschnitt eines anderen Beispiels einer Außenabdeckung der Führungsvorrichtung;

Fig. 9 einen Querschnitt eines weiteren Beispiels der Außenabdeckung der Führungsvorrichtung; und

Fig. 10 eine perspektivische Ansicht einer herkömmlichen staubdichten Führungsvorrichtung.

Mit Bezug auf die **Fig.** 1 und 2, die eine Führungsvorrichtung mit staubdichter Struktur gemäß der vorliegenden Erfindung zeigen (nachfolgend auch als "staubdichte Führungsvorrichtung oder lediglich als "Führungsvorrichtung", bezeichnet), umfasst die staubdichte Führungsvorrichtung zunächst eine lineare Führungsvorrichtung **11**, die ein Objekt wie beispielsweise eine Plattform auf einem befestigten Teil, wie beispielsweise einem Bett oder einem Sattel, führt, und eine äußere (Panzer-) Abdeckung **12**, die an einem oberen Abschnitt der linearen Führungsvorrichtung **11** befestigt ist.

Ein Öffnungspaar **13** ist zwischen den Seitenflächen der Außenabdeckung **12** und den Seitenflächen der linearen Führungsvorrichtung **11** ausgebildet. Das an dem Objekt befestigte bewegliche Glied **14** besitzt Teile, die durch diese Öffnungen **13** nach außen hervorragen, und während dieses Zustands bewegt sich das bewegliche Glied **14** entlang der Öffnungen **13** linear in der Längsrichtung der Führungsvorrichtung **11**. Die Öffnungen **13** werden durch ein Paar Dichtungsglieder **15**a und **15**b verschlossen oder abgedeckt, welche an oberen und unteren Randabschnitten der Öffnungen **13** befestigt sind.

Wie das in **Fig.** 2 gezeigt ist, umfasst die lineare Führungsvorrichtung **11** eine auf dem befestigten Teil angeordnete Führungsschiene **21**, ein Schlittenglied **22** in der Form eines Blocks, der entlang der Führungsschiene **21** linear geführt wird, das auf einer oberen Fläche des Schlittengliedes **22** befestigte bewegliche Glied **14**, und eine Kugelgewindespindel **23** als ein Zugspindelglied zum Antreiben des Schlittengliedes **22**.

Die Führungsschiene **21** besitzt gemäß der Darstellung einen zförmigen Abschnitt mit einer oberen Öffnung. Das heißt, dass sich die Führungsschiene **21** aus einem flachen Bodenteil und einem Paar gegenüberliegender Vorsprünge **24**a und **24**b zusammensetzt, die sich einander parallel an beiden längsseitigen Randabschnitten des flachen Bodenteiles erstrecken, um so den D-förmigen Abschnitt zu bilden. Der Bodenabschnitt ist zur Befestigung mit Schraubenlöchern versehen. Die innenseitige Oberfläche der jeweiligen Vorsprünge **24**a und **24**b ist mit vertieften Nuten **25** und einer jeweils großen Breite über die Längsrichtungen der Vorsprünge ausgebildet. An den Ober- und Unterabschnitten der Eckteile der vertieften Nuten **25** sind jeweils zwei Kugelrollnuten ausgebildet. So sind insgesamt vier Kugelrollnuten vorgesehen. Beide längsseitigen Endabschnitte der n-förmigen Führungsschiene sind jeweils durch Gehäuse **26**a und **26**b geschlossen, deren Höhe jeweils die Höhe der Vorsprünge **24**a und **24**b übersteigt, und deren Breite im Wesentlichen der der Führungsschiene **21** selbst entspricht.

Das Schlittenglied **22** ist aus einem Blockkörper **22**a und Endplatten **22**b zusammengesetzt, die an beiden längsseitigen Endabschnitten des Blockkörpers **22**a befestigt sind. Das Schlittenglied **22** ist in dem vertieften oberen Abschnitt der D-förmigen Führungsschiene eingepaßt und unterstützt, um durch als Rollglieder fungierende Kugeln **27** zwischen beiden Vorsprüngen **24**a und **24**b gleiten zu können.

Der Blockkörper **22**a des Schlittengliedes **22** besitzt beide Seitenflächen, an denen vier belastbare Kugelrollnuten ausgebildet sind, um den an der Führungsschiene **21** ausgebildeten Kugelrollnuten zu entsprechen, und eine Anzahl Kugeln **27** ist zwischen sich gegenüberliegenden Kugelrollnuten der Führungsschiene **21** und den an dem Blockkörper **22**a vorgesehenen belastbaren Kugelrollnuten jeweils rollbar angeordnet.

Der Blockkörper **22**a ist in seinem Zentralabschnitt mit einem Kugelgewindeloch **28** ausgebildet, das sich hierdurch in der Längsrichtung erstreckt, und eine Kugelgewindewelle **23** ist mit diesem Gewindeloch **28** verschraubt. Das Kugelgewindeloch **28** ist mit einer spiralförmig belastbaren Kugelrollnut ausgebildet, um einer spiralförmigen Kugelrollnut zu entsprechen, die in dem Außenumfangsbereich der Kugelgewindewelle **23** ausgebildet ist, und eine Anzahl Kugeln **29** ist zwischen der spiralförmigen belastbaren Kugelrollnut der Kugelgewindewelle **23** und der spiralförmigen Kugelrollnut des Kugelgewindeloches **28** rollbar angeordnet.

An der oberen Oberfläche des Blockkörpers **22**a sind Schraubenlöcher ausgebildet, um das bewegliche Glied **14** mittels Schrauben oder dergleichen zu befestigen.

Zwei Reihen Kugelsenklöcher sind auf jeder Seite des Kugelgewindeloches **28** ausgebildet, d. h. insgesamt vier Löcher, entsprechend den jeweiligen belasteten Kugelrollnuten des Blockkörpers **22**a, um die Kugeln in dem Lastbereich aufzunehmen. Das den Zentralabschnitt des Blockkörpers **22**a durchdringende Kugelgewindeloch **28** ist in seinem circa halben Längenbereich in der Längsrichtung mit einer Gewindenut ausgebildet, und ein Rückweg ist durch einen Rückführtunnel gebildet.

Jede der Endplatten **22**b ist ein Glied mit einer im Wesentlichen rechteckigen Form, ähnlich der der Endstirnseite des Blockkörpers **22**a, und ein Einsatzloch zum Einsetzen der Kugelgewindewelle **23** ist in seinem Zentralabschnitt ausgebildet, und Schraubenlöcher sind beidseitig auf beiden Seiten des Einsatzloches ausgebildet. Die Endplatten **22**b sind an dem Blockkörper **22**a mittels Schrauben befestigt, die in diese Schraubenlöcher eingesetzt sind. An den Endplatten **22**b sind vier Rückführgänge ausgebildet, um die Kugeln **27** in dem Lastbereich zwischen dem Blockkörper **22**a und der Führungsschiene **21** aufzunehmen und dann die Kugeln **27** wieder in den Lastbereich zurückzuführen.

Die Gewindewelle **23** ist an ihren beiden Endabschnitten durch Gehäuse **26**a, **26**b so unterstützt, dass sie sich nur drehen kann, und sie ist an ihrer Außenumfangsfläche mit einer spiralförmigen Kugelrollnut ausgebildet, entlang der die Kugeln **29** rollen. Wie das in **Fig.** 3 gezeigt ist, ist eine Kupplung **30** an einem Ende der Gewindewelle **23** befestigt, und die Kupplung **30** ist funktional an eine Abtriebswelle eines Motors angeschlossen, die an einem Zwischenflansch **31** befestigt ist, der sich von dem Gehäuse **26**a (oder **26**b) erstreckt.

Mit Bezug auf **Fig.** 2 ist das bewegliche Glied **14** mit einem beweglichen Körper **14**a und einem Paar Vorsprünge (Seitenteile) **14**b versehen, die an den Seitenabschnitten des beweglichen Körpers **14**a durch Kupplungsteile **14**c angeschlossen sind. Der bewegliche Körper **14**a ist mit Schraubeneinsatzlöchern versehen, um das bewegliche Glied **14** an dem Schlittenglied **22** mittels Schrauben zu befestigen. In einem dargestellten, d. h. eingebauten Zustand des beweglichen Gliedes **14**, sind Schraubenlöcher an der oberen Oberfläche der Seitenteile **14**b ausgebildet, und ein zu führendes Glied oder eine zu führende Einheit ist an den Seitenteilen **14**b des beweglichen Gliedes **14** durch Einsetzen von Schrauben oder dergleichen in diese Schraubenlöcher befestigt. Wie das in **Fig.** 3 gezeigt ist, besitzt das Kupplungsteil **14**c in einer Schnittebene, die die an dem beweglichen Glied **14** ausgebildeten Dichtungsglieder **15**a enthält, eine im Wesentlichen beidseitige symmetrische Stromlinienform. Das heißt, dass die beiden beidseitigen Enden des Kupplungsteiles **14**c jeweils eine scharfkantige hervorragende Form besitzen, und die den scharfkantigen Vorsprung bildenden gegenüberliegenden Seiten sind einmal im Zwischenabschnitt in Richtung des Zentralabschnittes des Kupplungsstückes **14**c gekrümmt, um dessen Kurvenneigung zu glätten.

Die Außenabdeckung **12** ist gemäß **Fig.** 2 aus einem im Wesentlichen langförmigen, rechteckigen, dünnen Plattenglied und durch Biegen seiner längsseitigen Seitenränder gebildet, und ein Paar Abstandshalter **32** ist an seiner unteren Oberfläche an den längsseitigen Enden befestigt. Die Außenabdeckung **12** ist an der linearen Führungsvorrichtung **11** durch Befestigen der Abstandshalter an den Gehäusen **26**a, **26**b der Führungsvorrichtung **11** befestigt. In der Form, in der die Außenabdeckung **12** an der linearen Führungsvorrichtung **11** befestigt ist, ist eine Stufe (stufiger Abschnitt) zwischen dem Gehäuse **26**b und den hervorragenden Seitenabschnitten **24**a, **24**b der Führungsschiene **21** gebildet, wodurch ein Öffnungspaar **13** in einer jeweils rechteckigen Form zwischen den Seitenflächen der Außenabdeckung **12** und den hervorragenden Seitenteilen **24**a, **24**b gebildet ist, wie das in **Fig.** 1 gezeigt ist. Die Kupplungsstücke **14**c des beweglichen Gliedes **14** erstrecken sich durch diese Öffnungen **13** nach außen, womit die Seitenteile (Vorsprünge) **14**b, **14**b, an die ein zu führendes Glied oder eine zu führende Einheit befestigt ist, des beweglichen Gliedes **14** nach außen freigesetzt werden.

Das streifenförmige obere Dichtungsglied **15**a ist an der Seitenfläche der Außenabdeckung **12**, d. h. an dem oberen Abschnitt des die Öffnung **13** bildenden Randes befestigt, wodurch es sich über die gesamte Längsseite der Öffnung **13** erstreckt. Das obere Dichtungsglied **15**a ist aus einem Gummi oder einem synthetischen Harz in einer langen, rechteckigen Form gebildet und an der Seitenfläche der Außenabdeckung **12** durch eine Pressdichtung **32** unter Verwendung einer Schraube oder dergleichen befestigt. Das untere Dichtungsglied ist in der Form eines Streifens/Riemens am unteren Abschnitt des die Öffnung **13** bildenden Randes befestigt, wodurch es sich über die gesamte Längsseite der Öffnung **13** erstreckt. Das untere Dichtungsglied ist ebenso durch eine Pressdichtung **33** befestigt.

Gemäß **Fig.** 4 überlappen sich die unteren Endabschnitte der oberen Dichtungsglieder **15**a und die oberen Endabschnitte der unteren Dichtungsglieder **15**b gegenseitig, wobei das obere Dichtungsglied **15**a außen angeordnet ist, wie das mit den gestrichelten Linien gezeigt ist, um so die Öffnungen **13** vollständig abzudecken. Da die Kupplungsteile **14**c des beweglichen Gliedes **14** durch die Öffnungen **13** nach außen hervorragen, sind diese oberen und unteren Dichtungsglieder **15**a und **15**b in den Formen entlang der oberen und unteren Oberflächen **14**c gebogen, wenn die Kupplungsstücke **14**c, d. h. das bewegliche Glied **14**, bewegt wird.

Mit der linearen Führungsvorrichtung **11** der oben erwähnten Struktur wird die mit der Drehwelle des Motors durch ein Anschlußstück verbundene Kugelgewindewelle **23** gedreht, wenn der Motor angetrieben wird, wobei dessen Drehbewegung auf das Schlittenglied **22** mittels der Kugelgewindespindel auf das Schlittenglied **22** übertragen wird und dieses daher entlang der Führungsschiene **21** linear bewegt wird.

Wie das in **Fig.** 1 gezeigt ist, wird das an dem Schlittenglied **22** befestigte bewegliche Glied **14** gemäß dieser Bewegung ebenso linear bewegt, und die Kupplungsstücke **14c** werden dadurch entlang den Längsrichtungen der Öffnungen **13** linear bewegt. Da die Öffnungen **13** durch die oberen und unteren sich gegenseitig überlappenden Dichtungsglieder **15**a und **15**b während dieser Bewegung abgedeckt sind, sind die innenseitigen Abschnitte der Außenabdeckung **12** und die lineare Führungsvorrichtung **11** selbst während der Linearbewegung des beweglichen Gliedes **14** im Wesentlichen vollständig abgedichtet. Die Kupplungsteile **14**c des beweglichen Gliedes **14** öffnen zwangsweise die oberen und unteren Dichtungsglieder **15**a und **15**b und drücken die Dichtungsglieder durch die Bewegung zur Seite. Nach dem Passieren der Kupplungsteile **14**c kehren die oberen und unteren Dichtungsglieder **15**a und **15**b aufgrund ihrer eigenen Elastizität oder Flexibilität in ihre ursprüngliche Form zurück, um somit wiederum die inneren Abschnitte der Außenabdeckung **12** und der linearen Führungsvorrichtung **11** abzudichten. Das bedeutet, dass die oberen und unteren Dichtungsglieder **15**a und **15**b nur in Abschnitten geöffnet sind, die das bewegliche Glied **14** während seiner Hin und Herbewegung durchfährt.

Fig. 5 ist eine perspektivische Ansicht, die ein anderes Beispiel des beweglichen Gliedes als bewegliches Glied **40** zeigt. Das bewegliche Glied **40** ist mit einem beweglichen Körper **40**a und einem Paar an Vorsprüngen (Seitenteilen) **40**b versehen, die an beiden Seitenteilen des beweglichen Gliedes **40** befestigt sind. Der bewegliche Körper **40**a besitzt breiter reduzierte Abschnitte, die als Kupplungsteile **40**c ausgebildet sind, durch welche die Seitenteile **40**b befestigt sind. Die Kupplungsteile **40**c haben jeweils eine in der Länge der Bewegungsrichtung des beweglichen Gliedes reduzierte Abmessung, und Führungsteile **41**a und **41**b sind an den breiten, reduzierten Abschnitten an deren beiden Enden in der Bewegungsrichtung des beweglichen Gliedes befestigt und haben scharfkantige Endformen, die zum Zur-seitedrücken der Dichtungsglieder geeignet sind, wie das nachfolgend im Detail erläutert wird. Das bedeutet, dass die Führungsteile **41**a und **41**b an vier Eckabschnitten vorgesehen sind, die durch den beweglichen Körper **40**a und die Kupplungsteile **40**c gebildet sind.

Die **Fig.** 6A bis 6C zeigen ein derartiges Führungsteil in vergrößertem Maßstab.

Gemäß **Fig.** 6B besitzt das Führungsteil **41**a einen Abschnitt, der in einer zur Bewegungsrichtung (Richtung **1**) entgegengesetzten Richtung nach außen graduell verbreitert ist, und gemäß **Fig.** 6C besitzt die Seitenfläche des Führungsteiles **41** eine sich in Richtung **1** zugespitzte Form. Darüber hinaus hat die Querschnittsform des Führungsteiles einen Vorsprung in Richtung **2** senkrecht auf die Bewegungsrichtung **1**, um eine im Wesentlichen fünfeckige Form zu schaffen, wie das durch die Schraffur in **Fig.** 6A gezeigt ist. Darüber hinaus besitzt das Führungsteil **41**b im Wesentlichen dieselbe Form wie das Führungsteil **41**a und ist an einem Eckabschnitt des beweglichen Gliedes **40** auf dessen Rückseite befestigt, um in die entgegengesetzte Richtung zum Führungsteil **41**a zu zeigen. Darüber hinaus ist zu beachten, dass sobald das bewegliche Glied **40** eine rückwärtige Bewegung ausführt, die Bewegungsrichtung des Führungsteiles **41**b zur Bewegungsrichtung des Führungsteils **41**a entgegengesetzt ist.

Mit Bezug auf **Fig.** 5 sind Paare stabförmiger Verschlußstifte **42**a und **42**b an beiden längsseitigen Endabschnitten eines jeden Seitenteiles (Vorsprünge) **40**b des beweglichen Gliedes **40** befestigt. Diese Verschlußstifte **42**a und **42**b sind an Abschnitten auf beiden Seiten der stirnseitigen Enden der Führungsteile **41**a und **41**b in einem hohen Niveau entsprechend der Stelle eines zentralen Schlitzabschnittes **42** angeordnet, der auf der Seitenfläche des Führungsteiles **41**a (**41**b) gebildet ist, um sich innenseitig horizontal an Positionen nahe der Stelle der Dichtungsglieder **15**a und **15**b zu erstrecken. Darüber hinaus sind die an den Seitenteilen **40**b und **40**b befestigten Verschlußstifte **42**a und **42**b symmetrisch zueinander angeordnet.

Fig. 7 zeigt eine Ausführung, in der die oberen und unteren Dichtungsglieder **15**a und **15**b durch das Führungsteil **41**a, gemäß der Vorwärtsbewegung des beweglichen Gliedes **40** getrennt und zur Seite gedrückt sind. Das heißt, dass sich unter Annahme einer Bewegung des beweglichen Gliedes **40** in Richtung A in **Fig.** 7 die oberen und unteren Dichtungsglieder **15**a und **15**b, die die Öffnungen O an beiden Seiten der linearen Führungsvorrichtung **11** schließen, gemäß der Vorwärtsbewegung der Führungsteile **41**a in die Richtung **1** seitwärts gedrückt werden und sich allmählich öffnen. In dieser Vorwärtsbewegung werden die oberen und unteren Dichtungsglieder **15**a und **15**b sanft deformiert und geöffnet, da die Führungsteile **41**a die scharfkantigen stirnseitigen Enden in der Bewegungsrichtung und die nach außen aufgeweiteten Seitenteile in der zur Bewegungsrichtung entgegengesetzten Richtung haben. Aus diesem Grund kann die Abdichtung zwischen den Dichtungsgliedern **15**a und **15**b und den Führungsteilen **41**a sorgfältig realisiert werden und die Bildung eines dazwischenliegenden Spalts kann sicher verhindert werden. Die deformierten Dichtungsglieder **15**a und **15**b werden letztendlich in einem Winkel von 90° an den oberen und unteren Oberflächen der Kupplungsteile **40**c gebogen.

Ausgehend von einer Bewegung des beweglichen Gliedes **40** in der Richtung B, werden gemäß **Fig.** 7 nachfolgend die geöffneten Dichtungsglieder **15**a und **15**b während der Vorwärtsbewegung des beweglichen Gliedes **40** allmählich deformiert und dann in ihre ursprüngliche geschlossenen Positionen aufgrund ihres eigenen elastischen Vermögens gemäß deren Rückwärtsbewegung zurückgeführt, wobei die Abdichtung gut realisiert wird und die Bildung eines dazwischenliegenden Spaltes sicher vermieden werden kann.

Darüber hinaus ist es einfach zu erkennen, dass die Dichtungsglieder **15**a und **15**b an dem gegenüberliegenden Seitenteil des beweglichen Gliedes **40** durch die Führungsteile **41**b verschlossen werden, wenn das bewegliche Glied **40** in der Richtung A bewegt wird, und im Gegensatz dazu die Dichtungsglieder **15**a und **15**b an dieser Seite durch die Führungsteile **41**b geöffnet werden, wenn das bewegliche Glied **40** in der Richtung B bewegt wird.

Darüber hinaus kann es besser sein, auf den Gleitflächen kontinuierliche Vorsprünge zwischen den Dichtungsgliedern **15**a und **15**b und den Führungsteilen **41**a und **41**b in deren Längsrichtung zu auszubilden. Die Ausbildung derartiger Vorsprünge reduziert Kontaktflächen, d. h. Reibungsflächen der Führungsteile **15**a und **15**b und der Führungsteile **41**a und **41**b, wodurch der während der Linearbewegung des beweglichen Gliedes **40** entstehende Reibungswiderstand reduziert wird.

Währenddessen kann in einem Fall, wo das bewegliche Glied **40** wiederholt die Umkehrbewegung ausführt, auftreten, dass die Dichtungsglieder **15**a und **15**b nicht vollständig in ihre ursprünglichen Formen (Positionen) zurückkehren und ihre gebogenen Zustände beibehalten, und daher die Öffnungen O nicht vollständig schließen. Selbst in einem derartigen Fall, werden gemäß der beschriebenen Ausführung der vorliegenden Erfindung die gebogenen Abschnitte der Dichtungsglieder **15**a und **15**b zwangsweise durch die Verschlußstifte **42**a und **42**b nach innen gebogen, wenn diese Stifte die Öffnungen O durchfahren, da die Verschlußstifte **42**a und **42**b an beiden Seiten der Führungsteile **41**a und **41**b angeordnet sind. Demgemäß werden selbst dann, wenn die Öffnungen O nicht vollständig geschlossen sind, die Dichtungsglieder **15**a und **15**b zwangsweise in ihre ursprünglichen Positionen zurückgeführt, wodurch die Öffnungen O vollständig verschlossen werden.

Fig. 8 zeigt ein anderes Beispiel der Außenabdeckung, wobei in diesem Beispiel an der Außenabdeckung **50** Dichtungsglieder **51**a an die unteren Endabschnitte der Seitenflächen der Außenabdeckung **50** angefügt sind. Jedes Dichtungsglied **51**a ist im Querschnitt zu einem Vorderende abgeschrägt, um dadurch leicht gebogen werden zu können und den Reibungswiderstand während der Linearbewegung des beweglichen Gliedes **14** zu reduzieren. Ein geeignetes Haftmittel oder Material ist gemäß dem die Dichtungsglieder **51**a und die Außenabdeckung **50** bildenden Materials frei wählbar. Gemäß dieses Beispiels kann die Anzahl der Glieder oder Elemente, wie beispielsweise Befestigungsglieder reduziert werden, da die Außenabdeckung **50** und die Dichtungsglieder **51**a einteilig ausgebildet sind, und daher kann das Gesamtgewicht der Außenabdeckung **50** und der Dichtungsglieder **51**a ebenso reduziert sein. Darüber hinaus werden diese Glieder mittels eines Haftmittels ohne Verwendung einer mechanischen Vorrichtung, wie beispielsweise Schrauben, zusammengefügt, wobei verhindert wird, dass die Dichtungsglieder **51**a an der Außenabdekkung **50** beispielsweise in geneigtem Zustand befestigt sind.

Fig. 9 zeigt ein anderes Beispiel der Außenabdeckung, und in diesem Beispiel ist die Außenabdeckung **50** mit Schwalbenschwanznuten **62** an beiden längsseitigen Endabschnitten ausgebildet und Dichtungsglieder **61**a sind mit verbreiterten oder vorstehenden Abschnitten **63** an ihren Oberteilen ausgebildet, deren Form zum Einpassen in die jeweilige Schwalbenschwanznut **62** bestimmt ist. Daher sind die Dichtungsglieder **61**a und die Außenabdeckung **60** einteilig durch jeweiliges Eingreifen der verbreiterten Abschnitte **63** mit den Schwalbenschwanznuten **62** ausgebildet. Darüber hinaus sind die anderen Dichtungsglieder **61**b ebenso an ihren unteren Endabschnitten mit verbreiterten oder vorstehenden Abschnitten **64** ausgebildet, die in die Dichtungsgliedaufnehmer **65** in der Form von Schwalbenschwanznuten eingreifen, die an den Seitenflächen der linearen Führungsvorrichtung **11** ausgebildet sind.

Gemäß dieses Beispiels, können verschlechterte Dichtungsglieder leicht mit neuen ausgetauscht werden, da, wie das oben erwähnt wurde, die Dichtungsglieder an der Außenabdeckung und der Führungsvorrichtung unter Verwendung verbreiterter Abschnitte befestigt sind, die in die Schwalbenschwanznuten eingreifen.

Es wird betont, dass die vorliegende Erfindung nicht auf die beschriebenen Ausführungen begrenzt ist und Modifikationen möglich sind, ohne sich vom Umfang der beigefügten Ansprüche zu entfernen.

Patentansprüche

1. Führungsvorrichtung mit einer staubdichten Struktur, umfassend:
eine lineare Führungsvorrichtung (**11**);
eine Außenabdeckung (**12**, **50**), die an der linearen Führungsvorrichtung befestigt ist, um die lineare Führungsvorrichtung zu schützen, und die mit einer Öffnung (**13**) versehen ist, wobei die lineare Führungsvorrichtung ein bewegliches Glied (**14**, **40**) mit einem nach außen durch die an der Außenabdeckung (**12**, **50**) gebildete Öffnung (**13**) hervorragenden Teil umfasst, wobei das bewegliche Glied (**14**, **40**) entlang der an der Außenabdeckung gebildeten Öffnung bewegt werden kann; und
eine Abdichtstruktur mit einer Mehrzahl Dichtungsglieder (**15**a, **15**b; **51**a, **51**b), von denen jedes die Form eines Streifens/Riemens hat und flexibel ist, wobei die Dichtungsglieder an Randabschnitten der Öffnung (**13**) der Außenabdeckung (**12**, **50**) angeordnet sind, um sich so gegenseitig zu überlappen, wodurch ein im Wesentlichen abgedichteter Zustand innerhalb der linearen Führungsvorrichtung erhalten wird.

2. Führungsvorrichtung (**11**) mit einer staubdichten Struktur nach Anspruch 1, bei der das bewegliche Glied (**14**, **40**) eine Führungsstruktur besitzt, die mit einem scharfkantigen Endabschnitt versehen ist, um die sich überlappenden Dichtungsglieder (**15**a, **15**b; **51**a, **51**b) gemäß einer Vorwärtsbewegung des beweglichen Gliedes zu trennen und seitwärts zu drücken, wobei die Führungsstruktur mit einem Seitenteil (**14**b, **40**b) versehen ist, das in der zur Bewegungsrichtung des beweglichen Gliedes (**14**, **40**) entgegengesetzten Richtung graduell nach außen verbreitert ist.

3. Führungsvorrichtung mit einer staubdichten Struktur nach Anspruch 2, bei der die Führungsstruktur mit dem beweglichen Glied (**14**, **40**) als ein Teil hergestellt ist.

4. Führungsvorrichtung mit einer staubdichten Struktur nach Anspruch 2, bei der die Führungsstruktur als ein von dem beweglichen Glied (**14**, **40**) unabhängiges Glied ausgebildet ist.

5. Führungsvorrichtung mit einer staubdichten Struktur nach Anspruch 2, bei der das bewegliche Glied (**14**, **40**) mit einem Verschlußglied (**42**a, **42**b) versehen ist, um die Öffnung der Dichtungsglieder zu schließen.

6. Führungsvorrichtung mit einer staubdichten Struktur nach Anspruch 2, bei der eine Gleitfläche zwischen der Führungsstruktur und der Abdichtstruktur mit einem sich in ihrer Längsrichtung kontinuierlich erstrekkenden Vorsprung vorgesehen ist.

7. Führungsvorrichtung mit einer staubdichten Struktur, umfassend:
eine lineare Führungsvorrichtung mit einem ⊐-förmigen Querschnitt mit einer Öffnung;
eine Außenabdeckung (**12**, **50**), die an der linearen Führungsvorrichtung (**11**) befestigt ist, um die Öffnung der ⊐-förmigen Führungsvorrichtung abzudecken, und die mit einer Öffnung versehen ist, wobei die lineare Führungsvorrichtung ein bewegliches Glied (**14**, **40**) und ein lineares Glied umfasst, entlang dem das bewegliche Glied wechselseitig bewegt wird, wobei das bewegliche Glied (**14**, **40**) einen durch eine zwischen der Außenabdeckung (**12**, **50**) und der linearen Führungsvorrichtung gebildete Öffnung (**13**) nach außen hervorragenden Teil umfasst, um entlang der zwischen

der Außenabdeckung und der linearen Führungsvorrichtung gebildeten Öffnung bewegt werden zu können;
eine Abdichtstruktur mit einer Mehrzahl Dichtungsglieder (**15**a, **15**b; **51**a, **51**b), von denen jedes die Form eines Streifens/Riemens hat und flexibel ist, wobei die Dichtungsglieder an Randabschnitten der zwischen der Außenabdeckung und der linearen Führungsvorrichtung gebildeten Öffnung (**13**) angeordnet sind, um sich gegenseitig zu überlappen, wodurch die Öffnung zwischen der Außenabdeckung (**12**, **50**) und der linearen Führungsvorrichtung abgedeckt und ein im Wesentlichen abgedichteter Zustand innerhalb der linearen Führungsvorrichtung erhalten wird.

8. Führungsvorrichtung mit einer staubdichten Struktur nach Anspruch 7, bei der das bewegliche Glied (**14**, **960**) einen beweglichen Körper (**14**a, **40**a) umfasst, Seitenteile (**14**b, **40**b) die als die Vorsprünge auf beiden Seiten des beweglichen Gliedes ausgebildet sind, und Kupplungsteile (**14**c, **40**c), durch die der bewegliche Körper und die Seitenteile miteinander verbunden sind, wobei die Kupplungsteile in einem Niveau entsprechend der sich überlappenden Abschnitte der Dichtungsglieder (**15**a, **15**b; **51**a, **51**b) angeordnet sind.

9. Führungsvorrichtung mit einer staubdichten Struktur nach Anspruch 8, bei der die Kupplungsteile (**14**c, **40**c) in der Bewegungsrichtung des beweglichen Gliedes (**14**, **40**) scharfkantige Endabschnitte besitzen.

10. Führungsvorrichtung mit einer staubdichten Struktur nach Anspruch 8, bei der die Kupplungsteile (**14**c, **40**c) an deren beiden Endabschnitten entlang der Bewegungsrichtung des beweglichen Gliedes (**14**, **40**) mit Führungsteilen (**41**a, **41**b) versehen sind, wobei die Führungsteile jeweils einen scharfkantigen Endabschnitt in der Bewegungsrichtung des beweglichen Gliedes besitzen, um die sich überlappenden Dichtungsglieder gemäß einer Vorwärtsbewegung des beweglichen Gliedes seitwärts zu drücken und zu trennen, wobei das Führungsteil (**41**a, **41**b) mit einem Seitenteil versehen ist, das in einer zur Bewegungsrichtung des beweglichen Gliedes entgegengesetzten Richtung graduell nach außen verbreitert ist.

11. Führungsvorrichtung mit einer staubdichten Struktur nach Anspruch 10, bei der die Führungsteile (**41**a, **41**b) mit dem Kupplungsteil (**14**c, **40**c) des beweglichen Gliedes (**14**, **40**) als ein Teil hergestellt sind.

12. Führungsvorrichtung mit einer staubdichten Struktur nach Anspruch 10, bei der die Führungsteile (**41**a, **41**b) als Glieder ausgebildet sind, die von den Kupplungsteilen (**14**c, **40**c) des beweglichen Gliedes (**14**, **40**) unabhängig sind.

13. Führungsvorrichtung mit einer staubdichten Struktur nach Anspruch 8, bei der das bewegliche Glied (**14**, **40**) mit einem Verschlußglied (**42**a, **42**b) versehen ist, welches Verschlußglied zwei Paare stabförmiger Stifte umfasst, die an den Seitenteilen (**14**b, **40**b) des beweglichen Gliedes befestigt sind, um in einer sich gegenüberstehenden Weise auf beiden Seiten des beweglichen Gliedes in seiner Bewegungsrichtung nach innen vorzuragen, wobei die Stifte vordere Enden haben, die sich im Wesentlichen an die sich überlappenden Abschnitte der Dichtungsglieder (**15**a, **15**b; **51**a, **51**b) erstrecken.

14. Führungsvorrichtung mit einer staubdichten Struktur nach Anspruch 7, bei der die Dichtungsglieder (**15**a, **15**b; **51**a, **51**b) aus flexiblem Gummi hergestellt sind.

15. Führungsvorrichtung mit einer staubdichten Struktur nach Anspruch 7, bei der die Dichtungsglieder (**15**a, **15**b; **51**a, **51**b) aus flexiblem, synthetischem Harz hergestellt sind.

16. Führungsvorrichtung nach Anspruch 7, bei der die Dichtungsglieder (**15**a, **15**b; **51**a, **51**b) mittels eines Haftmittels an Seitenteilen der Außenabdeckung (**12**, **50**) angeordnet sind und jedes der Dichtungsglieder an ein vorderes Ende spitz zuläuft.

17. Führungsvorrichtung nach Anspruch 7, bei der die Außenabdeckung (**12**, **50**) mit Schwalbenschwanznuten (**62**) ausgebildet ist und die Dichtungsglieder (**15**a, **15**b; **51**a, **51**b) verbreiterte Endabschnitte besitzen, die in die Schwalbenschwanznuten der Außenabdeckung eingepaßt sind.

(57) **ABSTRACT**

There is provided a condition detection apparatus for detecting a present operating condition of a linear rolling motion guide apparatus, and the condition detection apparatus includes an AE sensor **1** for detecting a waveform elastically generated at least due to rolling of balls included in the linear rolling motion guide apparatus and mutual collision of the balls and generating an electric detection signal corresponding the detected waveform, a waveform shaping unit **2**, an A/D converter **3**, and a signal processing unit **4** judging a content of the operation condition in response to the generated detected signal Sae.

CONDITION-DETECTING DEVICE, METHOD, AND PROGRAM, AND INFORMATION-RECORDING MEDIUM

FIELD OF THE INVENTION

[0001] The present invention relates to a technical field of condition detection apparatus, condition detection method, condition detection program, and information recording medium, and more specifically, to a technical filed concerning condition detection apparatus and method for detecting a state in operation of a linear rolling motion guide apparatus when being driven and a condition detection program for detecting the operating condition thereof, and also to a technical field concerning an information recording medium recorded to be readable by a computer.

BACKGROUND ART

[0002] In the known art, there has been widely utilized a linear rolling motion guide apparatus including a rail, a movable block moving longitudinally on the rail, and a plurality of balls (rolling members) disposed between the rail and movable block for moving the movable block at a high accuracy while being rotating and circulating (revolving) itself. More specifically, such linear rolling motion guide apparatus has been utilized for a support member supporting three-dimensional motion of a work-table of a machine tool or supporting a pendulum motion of a pendulum electric car, or for an aseismatic structure of a building or like.

[0003] According to the widening of such usable fields of the linear rolling motion guide apparatus, there is an increased request for prevention of faults or like of the linear rolling motion guide apparatus from causing, and therefore, it has been required to provide a method of diagnosing an operation or operating condition thereof at a high accuracy.

[0004] Incidentally, general diagnostic methods of operating conditions of conventionally general machine systems, excluding the linear rolling motion guide apparatus, (for example, rotational rolling bearing including ball bearings and like) include: a vibration detecting method of diagnosing the operating condition by monitoring a vibration generating condition in the machine system; an oil evaluation method of diagnosing the operating condition by evaluating a quality of a lubrication oil used in the machine system; an electric resistance method of diagnosing the operating condition by measuring an electric resistance between members driven through the lubrication oil in the machine system; or a temperature measuring method of diagnosing the operating condition by measuring the temperature driven through the lubrication oil in the machine system by utilizing a thermocouple.

[0005] However, in a case where these diagnostic methods are applied to the linear rolling motion guide apparatus, the following problems have been raised.

[0006] That is, in the case of the vibration detecting method, when used for a linear rolling motion guide apparatus in which the balls as rolling members revolves in a circulation path while being rotated itself, so that many vibration generating sources exist other than an abnormal vibration generating source, and hence, the vibration which should be naturally detected cannot be accurately detected, thus providing a problem.

[0007] Further, in the case of the oil evaluation method, it is necessary to take out, for inspection, a lubrication oil before use in the linear rolling motion guide apparatus and a lubrication oil after the use therein, respectively, from the linear rolling motion guide apparatus as a target apparatus to be diagnosed, which requires much time for obtaining the diagnosed result, and it is also necessary to take out the lubrication oil by once stopping the operation of the linear rolling motion guide apparatus, thus reducing the working efficiency, also providing a problem.

[0008] Furthermore, the cases of the electric resistance method and the temperature measuring method are both not suitable to electric noises, and in addition, in a case where the movable block is moved at a low speed, the measurement itself is difficult, thus also providing a problem.

[0009] Accordingly, as mentioned above, in the conventional methods, it is difficult to accurately diagnose the operation or operating conditions of the linear rolling motion guide apparatus in a real time.

[0010] Then, present invention was therefore conceived in consideration of the above circumstances, and an object of the present invention is to provide a condition-detecting device and a condition-detecting method capable of foreseeing generation of fault in a linear rolling motion guide apparatus by accurately detecting an operation condition in a real time in the linear rolling motion guide apparatus, improving maneuverability, for user, of the linear rolling motion guide apparatus, elongating a usable life time and contributing to the quality improvement of devices or machineries incorporated with the linear rolling motion guide apparatus, to provide a program for the condition detection, and to provide an information recording medium in which the condition detection program is recorded to be readable by a computer.

DISCLOSURE OF THE INVENTION

[0011] In order to achieve the above object, the invention recited in claim **1** is a condition detection apparatus for detecting a present operation condition in a linear rolling motion guide apparatus comprising: detection means, such as AE (Acoustic Emission) sensor, for detecting a wave motion elastically generated on the basis of at least either one of contact or collision of a movable member or a track member to a rolling member contained in the linear rolling motion guide apparatus, contact or collision of a rolling surface to the rolling member contained in the linear rolling motion guide apparatus, or mutual contact or collision of the rolling members themselves, at a time when a plurality of rolling members contained in the linear rolling motion guide apparatus revolve in a circulation section therein, and generating an electric detection signal in accordance with the detected wave motion; and judgment means, such as signal processing unit, for judging a content of the present operation condition in response to the generated detection signal.

[0012] Accordingly, since the wave motion elastically generated by the operation of the linear rolling motion guide apparatus is detected to thereby detect the present operating condition thereof, the operating condition of the linear rolling motion guide apparatus can be detected in a real time without disassembling the apparatus while excluding influence of vibration caused by the operation of the apparatus.

[0013] In order to achieve the above object, the invention of claim **2** is the condition detection apparatus of claim **1**, in which the judgment means comprises: periodicity judgment means, such as signal processing unit, for judging presence or absence of a periodicity in the generated detection signal; maximum value detection means, such as signal processing unit, for detecting a maximum value in the generated detection signal at a time when it is judged that the periodicity is present; maximum value judgment means, such as signal processing unit, for judging whether or not the detected maximum value is not less than a preliminarily set threshold value of the maximum value; and condition judgment means, such as signal processing unit, for judging that, when the detected maximum value is not less than the threshold value of the maximum value, the linear rolling motion guide apparatus falls in a lubrication fault condition and then announcing that fact.

[0014] Accordingly, in the case when the generated detected signal has the periodicity and the maximum value at the detected signal is not less than the threshold value of the maximum value, it is judged that the linear rolling motion guide apparatus falls in a lubrication fault condition and that fact is then announced, so that the generation of the lubrication fault in the linear rolling motion guide apparatus can be easily and precisely detected in a real time during the operation of the apparatus.

[0015] In order to achieve the above object, the invention of claim **3** is the condition detection apparatus of claim **1**, in which the judgment means comprises: periodicity judgment means, such as signal processing unit, for judging presence or absence of a periodicity of the generated detection signal; maximum value detection means, such as signal processing unit, for detecting a maximum value in the generated detection signal at a time when it is judged that the periodicity is present; maximum value judgment means, such as signal processing unit, for judging whether or not the detected maximum value is not less than a preliminarily set threshold value of the maximum value; event ratio detection means, such as signal processing unit, for detecting an event ratio in the generated detection signal at a time when the detected maximum value is less than a threshold value of the maximum value; event ratio judgment means, such as signal processing unit, for judging whether or not the detected event ratio is not less than a preliminarily set threshold value of the event ratio; and condition judgment means, such as signal processing unit, for judging that, when the detected event ratio is less than the threshold value of the event value, the linear rolling motion guide apparatus is in a possibility of falling in a lubrication fault condition and then announcing that fact.

[0016] Accordingly, when the generated detected signal has the periodicity, the maximum value in the detected signal is less than the threshold value of the maximum value and the detected event ratio is less than the threshold value of the event value, it is judged that the linear rolling motion guide apparatus is in a possibility of falling in a lubrication fault condition and that fact is then announced, so that the possibility of the generation of the lubrication fault in the linear rolling motion guide apparatus can be detected easily and precisely in a real time during the operation of the apparatus.

[0017] In order to achieve the above object, the invention of claim **4** is the condition detection apparatus of claim **1**, in which the judgment means comprises: periodicity judgment means, such as signal processing unit, for judging presence or absence of a periodicity of the generated detection signal; maximum value detection means, such as signal processing unit, for detecting a maximum value in the generated detection signal at a time when it is judged that the periodicity is present; maximum value judgment means, such as signal processing unit, for judging whether or not the detected maximum value is not less than a preliminarily set threshold value of the maximum value; event ratio detection means, such as signal processing unit, for detecting an event ratio in the generated detection signal at a time when the detected maximum value is less than a threshold value of the maximum value; event ratio judgment means, such as signal processing unit, for judging whether or not the detected event ratio is not less than a preliminarily set threshold value of the event ratio; and condition judgment means, such as signal processing unit, for judging that, when the detected event ratio is not less than the threshold value of the event value, a flaking is generated in the linear rolling motion guide apparatus and then announcing that fact.

[0018] Accordingly, when the generated detected signal has the periodicity, the maximum value in the detected signal is less than the threshold value of the maximum value and the detected event ratio is not less than the threshold value of the event value, it is judged that a flaking is generated in the linear rolling motion guide apparatus and that fact is then announced, so that the generation of the flaking in the linear rolling motion guide apparatus can be detected easily and precisely in a real time during the operation of the apparatus.

[0019] In order to achieve the above object, the invention of claim **5** is the condition detection apparatus of claim **1**, in which the judgment means comprises: periodicity judgment means, such as signal processing unit, for judging presence or absence of a periodicity of the detected detection signal; effective value detection means, such as signal processing unit, for detecting an effective value of the detected detection signal at a time when it is judged that the periodicity is absent; effective value judgment means, such as signal processing unit, for judging whether or not the detected effective value is not less than a preliminarily set threshold value of the effective value; and condition judgment means, such as signal processing unit, for judging that, when the detected effective value is not less than the threshold value of the effective value, a foreign material invades in the linear rolling motion guide apparatus and then announcing that fact.

[0020] Accordingly, when the generated detected signal has no periodicity, and the effective value in the detected signal is not less than the threshold value of the effective value, it is judged that a foreign material is invaded in the linear rolling motion guide apparatus and that fact is then announced, so that the generation of the case of the invasion of the foreign material in the linear rolling motion guide apparatus can be detected easily and precisely in a real time during the operation of the apparatus.

[0021] In order to achieve the above object, the invention of claim **6** is the condition detection apparatus of claim **1**, in which the judgment means comprises: periodicity judgment means, such as signal processing unit, for judging presence or absence of a periodicity of the detected detection signal;

effective value detection means, such as signal processing unit, for detecting an effective value of the detected detection signal at a time when it is judged that the periodicity is absent; effective value judgment means, such as signal processing unit, for judging whether or not the detected effective value is not less than a preliminarily set threshold value of the effective value; and condition judgment means, such as signal processing unit, for judging that, when the detected effective value is less than the threshold value of the effective value, a present operation condition is normal, and then announcing that fact.

[0022] Accordingly, when the generated detected signal has no periodicity and the effective value in the detected signal is less than the threshold value of the effective value, it is judged that the present operating condition is normal and that fact is then announced, so that it can be detected easily and precisely in a real time whether or not the operating condition in the linear rolling motion guide apparatus is normal.

[0023] In order to achieve the above object, the invention of claim **7** is the condition detection method for detecting the present operating condition in the linear rolling motion guide apparatus, comprising: a detection step for detecting a wave motion elastically generated on the basis of at least either one of contact or collision of a movable member or a track member to a rolling member contained in the linear rolling motion guide apparatus, contact or collision of a rolling surface to the rolling member contained in the linear rolling motion guide apparatus, or mutual contact or collision of the rolling members themselves, at a time when a plurality of rolling members contained in the linear rolling motion guide apparatus revolve in a circulation section therein, and generating an electric detection signal in accordance with the detected wave motion; and a judgment step for judging a content of the present operation condition in response to the generated detection signal.

[0024] Accordingly, since the wave motion elastically generated by the operation of the linear rolling motion guide apparatus is detected to thereby detect the present operating condition thereof, the operating condition of the linear rolling motion guide apparatus can be detected in a real time without disassembling the apparatus while excluding influence of vibration caused by the operation of the apparatus.

[0025] In order to achieve the above object, the invention of claim **8** is the condition detection method of claim **7**, in which the judgment step comprises: a periodicity judgment step for judging presence or absence of a periodicity in the generated detection signal; a maximum value detection step for detecting a maximum value in the generated detection signal at a time when it is judged that the periodicity is present; a maximum value judgment step for judging whether or not the detected maximum value is not less than a preliminarily set threshold value of the maximum value; and a condition judgment step for judging that, when the detected maximum value is not less than the threshold value of the maximum value, the linear rolling motion guide apparatus falls in a lubrication fault condition and then announcing that fact.

[0026] Accordingly, in the case when the generated detected signal has the periodicity and the maximum value at the detected signal is not less than the threshold value of the maximum value, it is judged that the linear rolling motion guide apparatus falls in a lubrication fault condition and that fact is then announced, so that the generation of the lubrication fault in the linear rolling motion guide apparatus can be easily and precisely detected in a real time during the operation of the apparatus.

[0027] In order to achieve the above object, the invention of claim **9** is the condition detection method of claim **7**, in which the judgment means step comprises: a periodicity judgment step for judging presence or absence of a periodicity of the generated detection signal; a maximum value detection step for detecting a maximum value in the generated detection signal at a time when it is judged that the periodicity is present; a maximum value judgment step for judging whether or not the detected maximum value is not less than a preliminarily set threshold value of the maximum value; an event ratio detection step for detecting an event ratio in the generated detection signal at a time when the detected maximum value is less than a threshold value of the maximum value; an event ratio judgment step for judging whether or not the detected event ratio is not less than a preliminarily set threshold value of the event ratio; and a condition judgment step for judging that, when the detected event ratio is less than the threshold value of the event value, the linear rolling motion guide apparatus is in a possibility of falling in a lubrication fault condition and then announcing that fact.

[0028] Accordingly, when the generated detected signal has the periodicity, the maximum value in the detected signal is less than the threshold value of the maximum value and the detected event ratio is less than the threshold value of the event value, it is judged that the linear rolling motion guide apparatus is in a possibility of falling in a lubrication fault condition and that fact is then announced, so that the possibility of the generation of the lubrication fault in the linear rolling motion guide apparatus can be detected easily and precisely in a real time during the operation of the apparatus.

[0029] In order to achieve the above object, the invention of claim **10** is the condition detection method of claim **7**, in which the judgment step comprises: a periodicity judgment step for judging presence or absence of a periodicity of the generated detection signal; a maximum value detection step for detecting a maximum value in the generated detection signal at a time when it is judged that the periodicity is present; a maximum value judgment step for judging whether or not the detected maximum value is not less than a preliminarily set threshold value of the maximum value; an event ratio detection step for detecting an event ratio in the generated detection signal at a time when the detected maximum value is less than a threshold value of the maximum value; an event ratio judgment step for judging whether or not the detected event ratio is not less than a preliminarily set threshold value of the event ratio; and a condition judgment step for judging that, when the detected event ratio is not less than the threshold value of the event value, a flaking is generated in the linear rolling motion guide apparatus and then announcing that fact.

[0030] Accordingly, when the generated detected signal has the periodicity, the maximum value in the detected signal is less than the threshold value of the maximum value and the detected event ratio is not less than the threshold value of the event value, it is judged that a flaking is generated in the linear rolling motion guide apparatus and that fact is then announced, so that the generation of the flaking in the linear rolling motion guide apparatus can be detected easily and precisely in a real time during the operation of the apparatus.

[0031] In order to achieve the above object, the invention of claim **11** is the condition detection method of claim **7**, in which the judgment step comprises: a periodicity judgment step for judging presence or absence of a periodicity of the detected detection signal; an effective value detection step for detecting an effective value of the detected detection signal at a time when it is judged that the periodicity is absent; an effective value judgment step for judging whether or not the detected effective value is not less than a preliminarily set threshold value of the effective value; and a condition judgement step for judging that, when the detected effective value is not less than the threshold value of the effective value, a foreign material invades in the linear rolling motion guide apparatus and then announcing that fact.

[0032] Accordingly, when the generated detected signal has no periodicity, and the effective value in the detected signal is not less than the threshold value of the effective value, it is judged that a foreign material is invaded in the linear rolling motion guide apparatus and that fact is then announced, so that the generation of the case of the invasion of the foreign material in the linear rolling motion guide apparatus can be detected easily and precisely in a real time during the operation of the apparatus.

[0033] In order to achieve the above object, the invention of claim **12** is the condition detection method of claim **7**, in which the judgment step comprises: a periodicity judgment step for judging presence or absence of a periodicity of the detected detection signal; an effective value detection step for detecting an effective value of the detected detection signal at a time when it is judged that the periodicity is absent; an effective value judgment step for judging whether or not the detected effective value is not less than a preliminarily set threshold value of the effective value; and a condition judgement step for judging that, when the detected effective value is less than the threshold value of the effective value, a present operation condition is normal and then announcing that fact.

[0034] Accordingly, when the generated detected signal has no periodicity and the effective value in the detected signal is less than the threshold value of the effective value, it is judged that the present operating condition is normal and that fact is then announced, so that it can be detected easily and precisely in a real time whether or not the operating condition in the linear rolling motion guide apparatus is normal.

[0035] In order to achieve the above object, the invention of claim **13** is a condition detection program, wherein a condition detection apparatus for detecting a present operation condition in a linear rolling motion guide apparatus, which includes detection means for detecting a wave motion elastically generated on the basis of at least either one of contact or collision of a movable member or a track member to a rolling member contained in the linear rolling motion guide apparatus, contact or collision of a rolling surface to the rolling member contained in the linear rolling motion guide apparatus, or mutual contact or collision of the rolling members themselves, at a time when a plurality of rolling members contained in the linear rolling motion guide apparatus revolve in a circulation section therein, and generating an electric detection signal in accordance with the detected wave motion, includes a computer which is operated as judgment means for judging a content of the operation condition in response to the generated detected signal.

[0036] Accordingly, since the computer functions so as to detect the wave motion elastically generated by the operation of the linear rolling motion guide apparatus and to thereby detect the present operating condition thereof, the operating condition of the linear rolling motion guide apparatus can be detected in a real time without disassembling the apparatus while excluding influence of vibration caused by the operation of the apparatus.

[0037] In order to achieve the above object, the invention of claim **14** is an information recording medium, wherein the condition detection program as claimed in claim **13** is recorded to be readable by the computer.

[0038] Accordingly, at the time of reading out and executing the program for the condition detection by utilizing the computer, since the computer functions so as to detect the wave motion elastically generated by the operation of the linear rolling motion guide apparatus and to thereby detect the present operating condition thereof, the operating condition of the linear rolling motion guide apparatus can be detected in a real time without disassembling the apparatus while excluding influence of vibration caused by the operation of the apparatus.

BRIEF DESCRIPTION OF THE DRAWINGS

[0039] **FIG. 1** is one for explaining the principle of the present invention, in which (a) and (b) are views showing generation of en extended AE wave according to an embodiment of the present invention and (c) is one example of envelope detection wave-shape corresponding to the extended AE wave.

[0040] **FIG. 2** is a block diagram showing a structure of the condition detection apparatus according to the embodiment of the present invention.

[0041] **FIG. 3** is a elevational section of an AE sensor according to the embodiment of the present invention.

[0042] **FIG. 4** is one (I) representing an installation example of the AE sensor according to the embodiment of the present invention, in which (a) is a perspective view of an outer appearance showing a structure of an LM system including a movable block, (b) is a perspective view showing an inner structure thereof, and (c) is a side view of an outer appearance of one example of a position in a case where the AE sensor is set to the LM system.

[0043] **FIG. 5** is a side view of the LM system including the movable block according to the embodiment of the present invention.

[0044] **FIG. 6** is one (II) representing an installation example of the AE sensor according to the embodiment of the present invention, in which (a) is a perspective view of an outer appearance showing a structure of an LM system including a ball screw and (b) is a side view of an outer appearance of one example of a position in a case where the AE sensor is set to the LM system.

[0045] **FIG. 7** shows a flowchart representing an operating condition detection procedure.

BEST MODE FOR EMBODYING THE INVENTION

[0046] Hereunder, a preferred embodiment of the present invention will be described with reference to the accompanying drawings.

[0047] Further, embodiments described hereinafter are ones in which the present invention is applied to detection and diagnosis of an operational (or operating) condition in a linear rolling motion guide apparatus (hereinafter, merely called LM "Linear Motion" System, more specifically, including a linear motion system such as so-called an LM guide, ball spline and the like).

[0048] (I) Principle of the Invention

[0049] First, in advance of the concrete explanation of the embodiment of the present invention, the principle of the present invention will be described with reference to **FIG. 1**.

[0050] In a study of a diagnosis method of operating condition of an LM system of the type mentioned above, the inventor of the subject application was found that so-called an AE phenomenon could be utilized for the diagnosis of the operating condition of the LM system utilized for the diagnosis of fault of a conventional rolling roller bearing device.

[0051] That is, the inventor of the present invention was found through experiments that mutually different AE waves were caused in a case where the AE phenomena of different modes are caused with respect to various abnormal operating conditions (specifically, generation of lubrication defect and flaking (that is, peeling phenomenon on a ball surface as rolling member included in the LM system, or a guide surface as a track member to which the ball contacts), or mixing of foreign material), and according to such causing, various abnormal operating conditions were caused.

[0052] Here, such AE phenomena or phenomenon was defined in a conventional technology, as "phenomenon generating acoustic emission wave (AE wave) by releasing an elastic energy in accordance with destroy or deformation of a solid material" or "phenomenon generating an elastic wave following plastic deformation or crack generation inside a material". The inventor of the subject application, however, confirmed in addition thereto that the AE wave is also generated only by mutual collision of balls caused by the normal operation of the LM system through any plastic deformation or crack is not generated on the ball or guide surface.

[0053] More specifically, in the case of the LM system utilizing the movable block, as shown in **FIG. 1**(*a*), the ball B revolves, while rotating, in the rolling path formed in the movable block C, it was confirmed by the inventor that the AE wave is generated in each of the cases when the balls B collide with each other at the contact point P**1**, when the ball B and the movable block C collide at the contact point P**2**, and when the ball B and the rolling surface G collide at the contact point P**3**.

[0054] Further, as shown in **FIG. 1**(*b*), with respect to the case of the LM system utilizing the movable block, even in the case where not only the ball B but also so-called a retainer R is disposed in the rolling path, if the ball B revolves, while rotating, in the rolling path formed in the movable block C, it was confirmed by the inventor that the AE wave is generated in each of the cases when the ball B and the movable block C collide with each other at the contact point P**5** and when the ball B and the rolling surface G collide with each other at the contact point P**4**.

[0055] The inventor then found that the generation modes of such AE waves were different from each other in accordance with kinds or types of the abnormal operating conditions mentioned hereinabove.

[0056] Further, as mentioned above, in the present invention, the generation of the AE phenomenon in a range wider than that of the AE phenomenon according to the conventional definition is promised, so that, in the following description, the AE phenomenon applied to the present invention is referred to as extended AE phenomenon, and the AE wave generated based on this extended AE phenomenon is referred to as extended AE wave.

[0057] Further, an electric signal corresponding to the extended AE wave has a frequency higher than a vibration or oscillation generally generated at an operating period of the LM system, and accordingly, for example, as shown in **FIG. 1**(*c*), it is possible to detect it separately from that vibration by the so-called envelope detection wave method, and it is thereby possible to detect the operating condition in real time during the operation of the LM system.

[0058] (II) Exemplary Embodiment

[0059] Hereunder, the exemplary embodiment of the present invention based on the above principle will be specifically explained with reference to FIGS. **2** to **7**.

[0060] Herein, **FIG. 2** is a block diagram showing a general structure of a condition diagnosis apparatus according to the embodiment of the present invention, **FIG. 3** is an elevational section showing a general structure of an AE sensor detecting the extended AE wave according to the embodiment of the present invention, FIGS. **4** to **6** are views for explaining the LM system to which the present invention is applied, and **FIG. 7** shows a flowchart representing an operating condition detection procedure executed by the condition diagnosis apparatus according to the present embodiment.

[0061] As shown in **FIG. 2**, a condition diagnosis apparatus S according to the present embodiment comprises an AE sensor **1**, a waveform shaping unit **2** including a BPF (Band Pass Filter) **2**A and an envelope detection section **2**B, an A/D (analog-to-digital) converter **3**, a signal processing unit **4** serving as periodicity judging means, maximum value detecting means, maximum value judging means, condition judging means, event detection means, event judging means, effective value detecting means and effective value judging means, and a display unit **5** including a liquid crystal display and the like.

[0062] Next, operation of the embodiment will be described.

[0063] First, the AE sensor **1** is disposed at an optional position of the LM system which is an object to be diagnosed, for example, an end position of a rail or a position on a movable block as a movable member. The AE sensor **1** detects the extended AE wave generated by the operation of the LM system and outputs the detected AE wave to the waveform shaping unit **2** after the conversion into a detection signal Sae as analog signal.

[0064] Next, the BPF **2**A in the waveform shaping unit **2** serves to remove a frequency component other than the extended AE wave from the detection signal Sae and generate it to the envelope detection section **2**B. Herein, it is desirable to use an BPR, for example as a concrete example of this BPF **2**A, capable of passing the frequency component more than 100 kHz and less than 1 MHz as pass frequency band area with respect to the detection signal Sae in this BPF **2**A.

[0065] The envelope detection section **2**B serves to extract the envelope component based on the detection signal Sae and create an envelope signal Sw, which is then sent to the A/D converter **3**.

[0066] Next, the A/D converter **3** serves to digitalize the envelope signal Sw as analog signal and create a digital envelope signal Sdw, which is then sent to the signal processing unit **4**.

[0067] The signal processing unit **4** serves to judge the present operation (operating) condition in the LM system as the object to be diagnosed by the operation condition detection processing shown in **FIG. 7**, described hereinlater, based on the digital envelope signal Sdw, and a resulting judgment signal Sdp is created, which is then outputted to the display unit **5**.

[0068] According to the operations mentioned above, the display unit **5** serves to display its content based on the judgment signal Sdp, thereby making it possible to grasp the operating condition of the LM system by a user thereof.

[0069] Next, the structure of the AE sensor **1** and its setting mode to the LM system as the object to be diagnosed will be explained hereunder with reference to FIGS. **3** to **6**.

[0070] An inside structure of the AE sensor **1** will be first described with reference to **FIG. 3**.

[0071] As shown in **FIG. 3**, the AE sensor **1** has a circular cylindrical shape in its entire structure, and more specifically, is composed of a contact portion **10** arranged so as to contact a rail LM or like in the LM system, a casing **11**, a piezoelectric element **13**, silver evaporated thin films **12** and **14** deposited on upper and lower surfaces of the piezoelectric element **13**, and an external line **15** through which the detection signal Sae, mentioned above, is outputted to the waveform shaping unit **2**.

[0072] When the extended AE wave generated inside the LM system is transferred to the piezoelectric element **13** via the contact portion **10** and the silver thin film **14**, the shape of the piezoelectric element **13** is minutely deformed by the extended AE wave, and hence, an electric potential difference is caused between the silver thin films **12** and **14**, thus generating the detection signal Sae on the external line **15**.

[0073] The AE sensor **1** having the structure mentioned above is installed to the LM system in the following manner with reference to FIGS. **4** to **6**. Further, **FIG. 4** and **FIG. 5** are views representing examples at a time of installing the AE sensor **1** to the LM system using the movable block as an object to be diagnosed, and **FIG. 6** is a view representing an example at a time of installing the AE sensor **1** to the LM system using the ball screw as an object to be diagnosed.

[0074] First, the case where the AE sensor **1** is mounted to the LM sensor utilizing the movable block will be explained with reference to **FIGS. 4 and 5**.

[0075] The LM system shown in FIGS. **4**(*a*) and (*b*) is composed of a rail **20** provided with ball rolling grooves **20***a* and **20***b* along which balls **22** roll in the longitudinal direction as mentioned later, a movable block **21** engaged with the rail **20** through the number of balls **22** and provided, in its inside, with an endless circulation passage of the balls **22**, and seal members **23** applied to both end surfaces of the movable block **21** in its moving direction so as to seal the upper and both side surfaces of the rail **20**, and according to the circulation of the balls **22**, the movable block **21** is reciprocally moved on the rail **20**.

[0076] As shown in these figures, the rail **20** has substantially a rectangular shape in section and formed with attachment holes **24** for inserting fastening bolts, the holes being formed through out the rail **20** in its longitudinal direction at an appropriate interval between adjacent ones. In addition, two rows of ball rolling grooves **20***a* are formed on the upper surface of the rail **20** so as to sandwich the attachment holes **24** therebetween, and on the other hand, further two rows of ball rolling grooves **20***b* are formed to the side surfaces of the rail **20**, respectively. These four rows of ball rolling grooves are formed with a radius of curvature slightly larger than the radius of curvature of the spherical surface of the ball **22** so as to provide a relatively deep grope shape.

[0077] On the other hand, the movable block **21** is composed of a block body **26** provided with a mount surface **25** to which a movable member such as table **30**, mentioned hereinlater, is mounted, and a pair of end plates **27**, **27** fixed to both longitudinal end surface portions of the block body **26**, and the lower side of the movable block **21** has a straddle shape, in section, having a recessed portion in its lower side into which the rail **20** is idly fitted.

[0078] Then, as shown **FIG. 5**, the block body **26** has a pair of skirt portions extending downward from a base, to which the mount surface **25** mentioned before is formed, or both the end portions of the base so as to provide a saddle shape in section, and four rows of loaded rolling grooves **28** are formed to the inside surfaces of the skirt portions and the lower surface of the rail **20** so as to correspond respectively to the ball rolling grooves **20***a* and **20***b* formed thereto. The balls **20** roll between the loaded rolling grooves **28** and the ball rolling grooves **20***a* and **20***b* while being loaded, whereby the movable block **21** is moved on the rail **20**.

[0079] Now, back to FIGS. **4**(*a*) and (*b*), the base and the skirt portions of the block body **26** are pierced as ball return bores **29** corresponding to the loaded rolling grooves **28**, respectively, and these ball return bores **29** are coupled and communicated with the loaded rolling grooves **28**, respectively, through direction changing passages having substantially U-shape, not shown, formed to the end plates **27**, **27**. That is, the direction changing passages scoop up balls **22** which have rolled on the loaded rolling grooves **28** of the block body **26** and feed the balls **22** to the ball return bores **29**, and on the other hand, the direction changing passages also serve to feed the balls **22** from the ball return bores **29** again to the loaded rolling grooves **28**. Accordingly, by fastening the end plates **27**, **27** to the block body **26** by means of fastening bolts **21***a*, **21***a*, the endless circulation passage for the balls **22** is formed to the movable block **21**.

[**0080**] Further, when the AE sensor **1** of the present embodiment is set to the LM system shown in FIGS. **4**(*a*) and (*b*), as shown in **FIG. 4**(*c*) as an outer appearance side view, for example, in the case where the table **30** is set on a plurality of movable blocks **21** which linearly move on the track rail **20**, the AE sensor **1** is placed on a position of the rail **20** outside the moving range of the movable block **21**.

[**0081**] Next, the case where the AE sensor **1** is set to the LM system utilizing the ball screw will be explained with reference to **FIG. 6**.

[**0082**] As shown in **FIG. 6**(*a*), a ball screw **40** is provided with a screw shaft **41** having an outer peripheral surface in which a spiral ball rolling groove **41***a* is formed, a nut member **42** having an inner peripheral surface in which a spiral loaded rolling groove **42***a* is formed so as to correspond to the spiral ball rolling groove **41***a*, and a number of balls **43**, **43**, rolling between the ball rolling groove **41***a* and the loaded rolling groove **42***a*. A loaded rolling passage is formed by and between he ball rolling groove **41***a* of the screw shaft **41** and the loaded rolling groove **42***a* of the nut member **42**. The nut member **42** is mounted with two return pipes **44** as circulation members. The return pipes **44** connect one and the other ends of the loaded rolling passage so as to constitute a non-loaded return passage. The return pipes **44** has substantially gate-shaped arrangement having a central portion **44***a* and a pair of leg portions **44***b*, **44***b* on both sides of the central portion **44***a*. The paired leg portions **44***b*, **44***b* are inserted into the loaded rolling passage at a several-pitch interval. The return pipes **44** are fixed to the nut member **42** by coupling means such as bolts **45**.

[**0083**] The spiral ball rolling groove **41***a* of the screw shaft **41** is formed, through a grinding working, rolling working or like working, in the outer peripheral surface thereof so as to provide a semi-circular cross section with a constant lead. The nut member **42** has substantially a cylindrical shape and is provided with a flanged portion **46** at one end for mounting the ball screw **40** to a machine or like. The loaded rolling groove **42***a* having a semi-circular sectional shape corresponding to the ball rolling groove **41***a* of the screw shaft **41** is formed to the inner peripheral surface of the nut member **42**. The nut member **42** is provided with a flat surface portion **47** partially of an upper surface. A plurality of return pipe fitting holes, into which the leg portions **44***b*, **44***b* of the return pipes **44** are inserted, are formed to the flat surface portion **47** of the nut member **42**.

[**0084**] Then, when the AE sensor **1** of the present embodiment is set to the LM system shown in **FIG. 6**(*a*), in the case where the ball screw **41** driven by a motor **48** is rotatably supported by a table **49**, for example, as shown in **FIG. 6**(*b*) as an outer appearance view, and a table **51** is fixed to the ball screw **40** through a bracket **50**, the AE sensor **1** is mounted to a surface of the flanged portion **46** perpendicular to the central axis of the ball screw **40**.

[**0085**] In the followings, the operating condition detection processing according to the embodiment executed mainly by the signal processing unit **4** will be explained with reference to **FIGS. 1, 2** and **7**.

[**0086**] As shown in **FIG. 7**, in the case when the operating condition detection processing according to the embodiment of the present invention is executed during the operation of the LM guide being the object to be diagnosed, a required initial setting processing is first carried out. Next, the extended AE wave generated in accordance with the extended AE phenomenon during the LM system operation is detected by the AE sensor **1** (step S**1**), the detection signal Sae generated in response to the detected AE wave is subjected to the waveform shaping in the waveform shaping unit **2** (step S**2**), and the envelope signal Sw is created and sent as digital envelope signal Sdw, through the A/D converter **3**, to the signal processing unit **4**. Thereafter, the extended AE wave detection procedure (step S**1**) and the waveform shaping procedure (step S**2**) are repeated by required inspection times to thereby store the data concerning the digital envelope signal Sdw in a memory, not shown, in the signal processing unit **4** (step S**3**), and a parameter utilizing for respective judgments or discriminations are operated based on the stored data, which is then stored in the memory (step S**4**).

[**0087**] In this embodiment, this parameter specifically includes four parameters representing: presence or absence of periodicity of the data of the digital envelope signal Sdw; a maximum value in the digital envelop signal data in the detection period preliminarily set in accordance with the moving distance and moving speed in one direction in the movable block reciprocating motion, for example, included in the LM system as an object to be diagnosed; an effective value in the detection period; and the event ratio in the detection period.

[**0088**] More specifically, the periodicity of the data of the digital envelope signal Sdw is one that detected by means of frequency analysis of the frequency repeating contact to and separation from a rail surface in the case that the ball revolves in accordance with the operation of the LM system, which is specific to the case of detecting the operating condition of the LM system.

[**0089**] Further, the effective value mentioned above is obtained by squaring and then averaging the values of the digital envelope signals Sdw with respect to the detection period thereof.

[**0090**] Furthermore, the event ratio mentioned above is a parameter that represents the times (numbers), in one detection period, in which the value of the digital envelope signal Sdw exceeds the preset threshold value.

[**0091**] Upon the completion of the operation or calculation and accumulation of the respective parameters, it is judged or discriminated, in the signal processing unit **4**, whether or not there exists the periodicity with respect to the values of the digital envelope signal Sdw with reference to the preset frequency analysis value (step S**5**).

[**0092**] In the judgment in the step S**5**, in a case that the periodicity is not detected, (i.e., NO, in step S**5**), the effective value of the digital envelope signal Sdw is called up from the memory (step S**6**).

[**0093**] Then, it is judged whether the call-up effective value exceeds the threshold value of the effective value as a threshold value which was experimentally preset for the judgment whether a foreign material is included or operation is normally performed (step S**7**).

[**0094**] Next, in the judgment in the step S**7**, in a case that the called-up effective value is less than the threshold value of the effective value (i.e., NO in step S7), it is judged that the LM system now as an object to be diagnosed is normally operated at the present stage (step S**8**), and this effect is displayed by using the display unit **5** (step S**10**). Then, a series of operation (operating) condition detection procedures has been completed.

[**0095**] On the other hand, in the judgment in the step S7, in the judgment in the step S7, in a case that the called-up effective value is not less than the threshold value of the effective value (i.e., YES in step S7), it is judged that any foreign material is included in the LM system as an object to be diagnosed (step S9), and this effect is displayed by using the display unit **5** (step S**10**). Then, a series of operation (operating) condition detection procedures has been completed.

[**0096**] Further, in the judgment in the step S**5**, in the case that the periodicity is detected (i.e., YES in step S**5**), the maximum value in the digital envelope signal Sdw is called up from the memory (step S**11**), and then, it is judged whether the called-up maximum value exceeds the threshold value of the maximum value as a threshold value which was experimentally preset for the judgment whether any lubrication fault is caused at the present stage (step S**12**).

[**0097**] In this judgment, in the case that the called-up maximum value is not less than the threshold value of the maximum value (i.e., YES in step S**12**), it is judged that the lubrication fault is caused at the present stage in the LM system as an object to be diagnosed (step S**13**), and this effect is displayed by using the display unit **5** (step S**10**). Then, a series of operation (operating) condition detection procedures has been completed.

[**0098**] Next, in the judgment in the step S**12**, in the case that the called-up maximum value is less than the threshold value of the maximum value (i.e., NO in step S**12**), the event ratio mentioned before to the digital envelope signal Sdw is called up from the memory (step S**14**).

[**0099**] Then, in order to judge or discriminate whether there is a possibility of generation of the flaking or lubrication fault in the LM system as the object to be diagnosed, it is judged whether or not the called-up event ratio is not less than the threshold value of the event ratio experimentally preset (step S**15**).

[**0100**] Next, in the judgment in step S**15**, in the case that the called-up event ratio is less than the threshold value of the event ratio (i.e., NO in step S**15**), it is judged that there is high possibility of causing the lubrication fault at the present stage in the LM system as an object to be diagnosed (step S**17**), and this effect is displayed by using the display unit **5** (step S**10**). Then, a series of operation (operating) condition detection procedures has been completed. Further, the degree of the lubrication fault judged in the step S**17** differs from the degree of the lubrication fault judged in the step S**13**, and the former (case of the step S**17**) only judges the possibility of the causing of the lubrication fault, and on the other hand, the latter (case of the step S**13**) can judge the surly causing of the lubrication fault.

[**0101**] Moreover, in the judgment in the step S**15**, in the case that the called-up event ratio is not less than the threshold value of the event ratio (i.e., YES in step S**15**), it is judged that the flaking is generated at the present stage in the LM system as an object to be diagnosed (step S**16**), and this effect is displayed by using the display unit **5** (step S**10**). Then, a series of operation (operating) condition detection procedures has been completed.

[**0102**] Further, the described series of operation condition detection result is displayed, accumulated in the memory in the signal processing unit **4** and then statistically processed, thereby detecting worsening of the operating condition and obviating the generation of faults.

[**0103**] As mentioned above, according to the operation of the condition diagnosing apparatus S of the present embodiment, since the present operating condition of the LM system can be detected by detecting the extended AE wave generated in accordance with the operation of the LM system, the operating condition can be detected during the operation thereof in a real time, without disassembling the LM system, while excluding influence due to vibration based on the operation of the LM system.

[**0104**] Therefore, it becomes possible to foresee the generation or causing of faults in the LM system, thus improving the maneuverability for a user of the LM system and elongating the usable life time thereof and improving the quality of devices or machineries manufactured by utilizing this LM system.

[**0105**] Furthermore, in the case that the generated digital envelope signal Sdw has the periodicity and the maximum value of this digital envelope signal Sdw is not less than the threshold value of the maximum value, it is judged that the LM system now falls in lubrication fault condition, which is then announced, so that the generation of the lubrication fault condition in the LM system can be precisely detected in a real time during the operation thereof.

[**0106**] Still furthermore, in the case that the generated digital envelope signal Sdw has the periodicity and the maximum value of this digital envelope signal Sdw is less than the threshold value of the maximum value, and that the event ratio of the digital envelope signal Sdw is less than the threshold value of the event ratio, it is judged that the LM system may have a possibility of falling in the lubrication fault condition, which is then announced, so that the possibility of the generation of the lubrication fault condition in the LM system can be precisely detected in a real time during the operation thereof.

[**0107**] Still furthermore, in the case that the generated digital envelope signal Sdw has the periodicity and the maximum value of this digital envelope signal Sdw is less than the threshold value of the maximum value, and that the event ratio of the digital envelope signal Sdw is not less than the threshold value of the event ratio, it is judged that the flaking is caused in the LM system, which is then announced, so that the generation of the flaking in the LM system can be easily and precisely detected in a real time during the operation thereof.

[**0108**] Still furthermore, in the case that the generated digital envelope signal Sdw has no periodicity and the effective value of this digital envelope signal Sdw is not less than the threshold value of the effective value, it is judged that the foreign material invades in the LM system, which is then announced, so that the generation of the invasion of the foreign material into the LM system can be easily and precisely detected in a real time during the operation thereof.

[0109] Still furthermore, in the case that the generated digital envelope signal Sdw has no periodicity and the effective value of this digital envelope signal Sdw is less than the threshold value of the effective value, it is judged that the LM system is now in the normally operating condition, which is then announced, so that the it can be easily and precisely detected in a real time whether the operating condition at the digital envelope signal Sdw is normal or not.

[0110] Further, by recording a program corresponding to the flowchart shown in **FIG. 7** to an information recording medium such as flexible disk or hard disk, or recording the program obtained by means of network such as internet, and reading out and then executing the program by a general-use (general) micro-computer, this micro-computer can be operated as the signal processing unit **4** in this embodiment. In this case, the AE sensor **1**, the waveform shaping unit **2** and the A/D converter **3**, which are mentioned hereinbefore, will be connected to the micro-computer as external-type devices.

[0111] Furthermore, in the above-mentioned embodiment, the condition detection apparatus S shown in **FIG. 2** is constructed as an apparatus having single structure, and more specifically, this embodiment is applied to a case that the present condition diagnosis apparatus S is carried to a site such as factory in which the LM system as the object to be diagnosed and is utilized at that site for detecting and diagnosing the operating condition of the LM system.

[0112] Further, other than the above-mentioned embodiment, the condition detection apparatus S of this embodiment may be applied to a case of detecting and diagnosing the operating condition of the LM system by usually providing the condition diagnosing apparatus S to a site such as factory in which the LM system as the object to be diagnosed are set and remotely controlling the condition diagnosing apparatus S through a telephone line or like by a diagnosing staff from an isolated position.

[0113] Furthermore, the present invention may be applied to a case that the condition diagnosing apparatus S is usually provided to a site such as factory in which the LM system as the object to be diagnosed is set and used, the operating condition of the LM system is automatically detected and diagnosed in the condition diagnosing apparatus S, in parallel to this operation, the detected result is transferred to another place, then accumulated there, and an accumulative fault diagnosing is executed on the basis of the accumulated detected result.

[0114] Still furthermore, in the described embodiment, although the condition detection apparatus S is composed such that one waveform shaping unit **2**, one A/D converter **3**, one signal processing unit **4** and one display unit **5** are utilized for one AE sensor **1**, there may be provided another example of the structure, other than the above, in which the detection signals Sae from a plurality of AE sensors **1** are inputted through a switching circuit into one waveform shaping unit **2** and processed by utilizing one waveform shaping unit **2**, one A/D converter **3**, one signal processing unit and one display unit **5**. In such example, it becomes necessary to synchronize the executing timing of the detection processing utilizing the waveform shaping unit **2**, the A/D converter **3**, the signal processing unit **4** and the display unit **5** with the take-in timing of the detection signal Sae from the corresponding AE sensor **1**.

EXAMPLES

[0115] A specific example will be shown hereunder with respect to the frequency analysis value, the threshold value of the effective value, the threshold value of the maximum value and the threshold value of the event ratio, all mentioned hereinbefore, as the basis of the judgments in the steps S**5**, S**7**, S**12** and S**15**, respectively.

[0116] Further, it is to be noted that examples of the respective threshold values shown hereunder are ones in the case where a mold of mold number SN55LR manufactured by the applicant is utilized as LM guide to which the AE sensor is set, an external load to the movable block is 0.1 C (14 kN), a stroke as moving distance of the movable block is 250 mm, a moving speed thereof is 24 m/min., the DTE26-type lubrication oil manufactured by Moville Oil. Ltd. is supplied as lubrication oil intermittently by a constant amount, a sample rate to the detection signal Sae is 10 kHz, and a measuring time is 0.4 second.

[0117] In accordance with the above respective conditions, as one example of the frequency analysis value, it is judged to have the periodicity in a case that a square voltage value (so-called V**2** value) obtained through the FFT conversion of the digital envelope signal Sdw and, then, frequency analysis (power spectrum) exceeds 1.0×10^{-9} (V**2**), and on the other hand, in a case of less than this value, it is judged not to have the periodicity.

[0118] Further, as one example of the threshold value of the effective value, as the effective value at the digital envelope signal Sdw, a value of 1.0×10^{-4} (V) is suitable.

[0119] Furthermore, as one example of the threshold value of the maximum value, as the maximum value at the digital envelope signal Sdw, a value of 2.0×10^{-3} (V) is suitable.

[0120] Finally, as one example of the threshold value of the event ratio, 5 to 7 times, at which the threshold value of the event ratio shows a value higher than a value of 5.0×10^{-4} (V) at the digital envelope signal Sdw is suitable.

[0121] Further, the respective values in the above examples specifically change in accordance with the change of conditions, excluding the load with respect to the movable block and the stroke of the movable block from the conditions mentioned hereinabove.

[0122] Possibility of Industrial Usage

[0123] As mentioned above, according to the invention of claim **1**, since the wave motion elastically generated by the operation of the linear rolling motion guide apparatus is detected to thereby detect the present operating condition thereof, the operating condition of the linear rolling motion guide apparatus can be detected in a real time without disassembling the apparatus while excluding influence of vibration caused by the operation of the apparatus.

[0124] Accordingly, the generation of a fault in the linear rolling motion guide apparatus can be foreseen, whereby the maintenance performance of the user using the linear rolling motion guide apparatus can be improved. In addition, the usable life time thereof can be elongated, and apparatus, machineries and the like manufactured by utilizing such linear rolling motion guide apparatus can be improved in their qualities.

[0125] According to the invention of claim **2**, in addition to the effects of the invention of claim **1**, in the case when the generated detected signal has the periodicity and the maximum value at the detected signal is not less than the threshold value of the maximum value, it is judged that the linear rolling motion guide apparatus falls in a lubrication fault condition and that fact is then announced, so that the generation of the lubrication fault in the linear rolling motion guide apparatus can be easily and precisely detected in a real time during the operation of the apparatus.

[0126] According to the invention of claim **3**, in addition to the effects of the invention of claim **1**, when the generated detected signal has the periodicity, the maximum value in the detected signal is less than the threshold value of the maximum value and the detected event ratio is less than the threshold value of the event value, it is judged that the linear rolling motion guide apparatus is in a possibility of falling in a lubrication fault condition and that fact is then announced, so that the possibility of the generation of the lubrication fault in the linear rolling motion guide apparatus can be detected easily and precisely in a real time during the operation of the apparatus.

[0127] According to the invention of claim **4**, in addition to the effects of the invention of claim **1**, when the generated detected signal has the periodicity, the maximum value in the detected signal is less than the threshold value of the maximum value and the detected event ratio is not less than the threshold value of the event value, it is judged that a flaking is generated in the linear rolling motion guide apparatus and that fact is then announced, so that the generation of the flaking in the linear rolling motion guide apparatus can be detected easily and precisely in a real time during the operation of the apparatus.

[0128] According to the invention of claim **5**, in addition to the effects of the invention of claim **1**, when the generated detected signal has no periodicity, and the effective value in the detected signal is not less than the threshold value of the effective value, it is judged that a foreign material is invaded in the linear rolling motion guide apparatus and that fact is then announced, so that the generation of the case of the invasion of the foreign material in the linear rolling motion guide apparatus can be detected easily and precisely in a real time during the operation of the apparatus.

[0129] According to the invention of claim **6**, in addition to the effects of the invention of claim **1**, when the generated detected signal has no periodicity and the effective value in the detected signal is less than the threshold value of the effective value, it is judged that the present operating condition is normal and that fact is then announced, so that it can be detected easily and precisely in a real time whether or not the operating condition in the linear rolling motion guide apparatus is normal.

[0130] According to the invention of claim **7**, since the wave motion elastically generated by the operation of the linear rolling motion guide apparatus is detected to thereby detect the present operating condition thereof, the operating condition of the linear rolling motion guide apparatus can be detected in a real time without disassembling the apparatus while excluding influence of vibration caused by the operation of the apparatus.

[0131] Accordingly, the generation of a fault in the linear rolling motion guide apparatus can be foreseen, whereby the maintenance performance of the user using the linear rolling motion guide apparatus can be improved. In addition, the usable life time thereof can be elongated, and apparatus, machineries and the like manufactured by utilizing such linear rolling motion guide apparatus can be improved in their qualities.

[0132] According to the invention of claim **8**, in addition to the effect of claim **7**, in the case when the generated detected signal has the periodicity and the maximum value at the detected signal is not less than the threshold value of the maximum value, it is judged that the linear rolling motion guide apparatus falls in a lubrication fault condition and that fact is then announced, so that the generation of the lubrication fault in the linear rolling motion guide apparatus can be easily and precisely detected in a real time during the operation of the apparatus.

[0133] According to the invention of claim **9**, in addition to the effect of claim **7**, when the generated detected signal has the periodicity, the maximum value in the detected signal is less than the threshold value of the maximum value and the detected event ratio is less than the threshold value of the event value, it is judged that the linear rolling motion guide apparatus is in a possibility of falling in a lubrication fault condition and that fact is then announced, so that the possibility of the generation of the lubrication fault in the linear rolling motion guide apparatus can be detected easily and precisely in a real time during the operation of the apparatus.

[0134] According to the invention of claim **10**, in addition to the effect of claim **7**, when the generated detected signal has the periodicity, the maximum value in the detected signal is less than the threshold value of the maximum value and the detected event ratio is not less than the threshold value of the event value, it is judged that a flaking is generated in the linear rolling motion guide apparatus and that fact is then announced, so that the generation of the flaking in the linear rolling motion guide apparatus can be detected easily and precisely in a real time during the operation of the apparatus.

[0135] According to the invention of claim **11**, in addition to the effect of claim **7**, when the generated detected signal has no periodicity, and the effective value in the detected signal is not less than the threshold value of the effective value, it is judged that a foreign material is invaded in the linear rolling motion guide apparatus and that fact is then announced, so that the generation of the case of the invasion of the foreign material in the linear rolling motion guide apparatus can be detected easily and precisely in a real time during the operation of the apparatus.

[0136] According to the invention of claim **12**, in addition to the effect of claim **7**, when the generated detected signal has no periodicity and the effective value in the detected signal is less than the threshold value of the effective value, it is judged that the present operating condition is normal and that fact is then announced, so that it can be detected easily and precisely in a real time whether or not the operating condition in the linear rolling motion guide apparatus is normal.

[0137] According to the invention of claim **13**, by reading out and executing the program for the condition detection by using the computer, the computer functions so as to detect the wave motion elastically generated by the operation of the linear rolling motion guide apparatus and to thereby detect the present operating condition thereof, so that the operating condition of the linear rolling motion guide apparatus can be detected in a real time without disassembling the apparatus while excluding influence of vibration caused by the operation of the apparatus.

[0138] Accordingly, the generation of a fault in the linear rolling motion guide apparatus can be foreseen, whereby the maintenance performance of the user using the linear rolling motion guide apparatus can be improved. In addition, the usable life time thereof can be elongated, and apparatus, machineries and the like manufactured by utilizing such linear rolling motion guide apparatus can be improved in their qualities.

[0139] According to the invention of claim **14**, the program for the condition detection of claim **13** is recorded to be readable by the computer, and by reading out and executing the program for the condition detection by utilizing the computer, the computer functions so as to detect the wave motion elastically generated by the operation of the linear rolling motion guide apparatus and to thereby detect the present operating condition thereof, so that the operating condition of the linear rolling motion guide apparatus can be detected in a real time without disassembling the apparatus while excluding influence of vibration caused by the operation of the apparatus.

1. A condition detection apparatus for detecting a present operation condition in a linear rolling motion guide apparatus comprising:

detection means for detecting a wave motion elastically generated on the basis of at least either one of contact or collision of a movable member or a track member to a rolling member contained in the linear rolling motion guide apparatus, contact or collision of a rolling surface to the rolling member contained in the linear rolling motion guide apparatus, or mutual contact or collision of the rolling members themselves, at a time when a plurality of rolling members contained in the linear rolling motion guide apparatus revolve in a circulation section therein, and generating an electric detection signal in accordance with the detected wave motion; and

judgment means for judging a content of the present operation condition in response to the generated detection signal.

2. The condition detection apparatus according to claim 1, wherein said judgment means comprises:

periodicity judgment means for judging presence or absence of a periodicity in the generated detection signal;

maximum value detection means for detecting a maximum value in the generated detection signal at a time when it is judged that the periodicity is present;

maximum value judgment means for judging whether or not the detected maximum value is not less than a preliminarily set threshold value of the maximum value; and

condition judgment means for judging that, when the detected maximum value is not less than the threshold value of the maximum value, the linear rolling motion guide apparatus falls in a lubrication fault condition, and then announcing that fact.

3. The condition detection apparatus according to claim 1, wherein said judgment means comprises:

periodicity judgment means for judging presence or absence of a periodicity of the generated detection signal;

maximum value detection means for detecting a maximum value in the generated detection signal at a time when it is judged that the periodicity is present;

maximum value judgment means for judging whether or not the detected maximum value is not less than a preliminarily set threshold value of the maximum value;

event ratio detection means for detecting an event ratio in the generated detection signal at a time when the detected maximum value is less than a threshold value of the maximum value;

event ratio judgment means for judging whether or not the detected event ratio is not less than a preliminarily set threshold value of the event ratio; and

condition judgment means for judging that, when the detected event ratio is less than the threshold value of the event value, the linear rolling motion guide apparatus is in a possibility of falling in a lubrication fault condition, and then announcing that fact.

4. The condition detection apparatus according to claim 1, wherein said judgment means comprises:

periodicity judgment means for judging presence or absence of a periodicity of the generated detection signal;

maximum value detection means for detecting a maximum value in the generated detection signal at a time when it is judged that the periodicity is present;

maximum value judgment means for judging whether or not the detected maximum value is not less than a preliminarily set threshold value of the maximum value;

event ratio detection means for detecting an event ratio in the generated detection signal at a time when the detected maximum value is less than a threshold value of the maximum value;

event ratio judgment means for judging whether or not the detected event ratio is not less than a preliminarily set threshold value of the event ratio; and

condition judgment means for judging that, when the detected event ratio is not less than the threshold value of the event value, a flaking is generated in the linear rolling motion guide apparatus, and then announcing that fact.

5. The condition detection apparatus according to claim 1, wherein said judgment means comprises:

periodicity judgment means for judging presence or absence of a periodicity of the detected detection signal;

effective value detection means for detecting an effective value of the detected detection signal at a time when it is judged that the periodicity is absent;

effective value judgment means for judging whether or not the detected effective value is not less than a preliminarily set threshold value of the effective value; and

condition judgment means for judging that, when the detected effective value is not less than the threshold value of the effective value, a foreign material invades in the linear rolling motion guide apparatus, and then announcing that fact.

6. The condition detection apparatus according to claim 1, wherein said judgment means comprises:

periodicity judgment means for judging presence or absence of a periodicity of the detected detection signal;

effective value detection means for detecting an effective value of the detected detection signal at a time when it is judged that the periodicity is absent;

effective value judgment means for judging whether or not the detected effective value is not less than a preliminarily set threshold value of the effective value; and

condition judgment means for judging that, when the detected effective value is less than the threshold value of the effective value, a present operation condition is normal, and then announcing that fact.

7. A condition detection method for detecting a present operation condition in a linear rolling motion guide apparatus comprising:

a detection step for detecting a wave motion elastically generated on the basis of at least either one of contact or collision of a movable member or a track member to a rolling member contained in the linear rolling motion guide apparatus, contact or collision of a rolling surface to the rolling member contained in the linear rolling motion guide apparatus, or mutual contact or collision of the rolling members themselves, at a time when a plurality of rolling members contained in the linear rolling motion guide apparatus revolve in a circulation section therein, and generating an electric detection signal in accordance with the detected wave motion; and

a judgment step for judging a content of the present operation condition in response to the generated detection signal.

8. The condition detection method according to claim 7, wherein said judgment step comprises:

a periodicity judgment step for judging presence or absence of a periodicity in the generated detection signal;

a maximum value detection step for detecting a maximum value in the generated detection signal at a time when it is judged that the periodicity is present;

a maximum value judgment step for judging whether or not the detected maximum value is not less than a preliminarily set threshold value of the maximum value; and

a condition judgment step for judging that, when the detected maximum value is not less than the threshold value of the maximum value, the linear rolling motion guide apparatus falls in a lubrication fault condition, and then announcing that fact.

9. The condition detection method according to claim 7, wherein said judgment means step:

a periodicity judgment step for judging presence or absence of a periodicity of the generated detection signal;

a maximum value detection step for detecting a maximum value in the generated detection signal at a time when it is judged that the periodicity is present;

a maximum value judgment step for judging whether or not the detected maximum value is not less than a preliminarily set threshold value of the maximum value;

an event ratio detection step for detecting an event ratio in the generated detection signal at a time when the detected maximum value is less than a threshold value of the maximum value;

an event ratio judgment step for judging whether or not the detected event ratio is not less than a preliminarily set threshold value of the event ratio; and

a condition judgment step for judging that, when the detected event ratio is less than the threshold value of the event value, the linear rolling motion guide apparatus is in a possibility of falling in a lubrication fault condition, and then announcing that fact.

10. The condition detection method according to claim 7, wherein said judgment step comprises:

a periodicity judgment step for judging presence or absence of a periodicity of the generated detection signal;

a maximum value detection step for detecting a maximum value in the generated detection signal at a time when it is judged that the periodicity is present;

a maximum value judgment step for judging whether or not the detected maximum value is not less than a preliminarily set threshold value of the maximum value;

an event ratio detection step for detecting an event ratio in the generated detection signal at a time when the detected maximum value is less than a threshold value of the maximum value;

an event ratio judgment step for judging whether or not the detected event ratio is not less than a preliminarily set threshold value of the event ratio; and

a condition judgment step for judging that, when the detected event ratio is not less than the threshold value of the event value, a flaking is generated in the linear rolling motion guide apparatus, and then announcing that fact.

11. The condition detection method according to claim 7, wherein said judgment step comprises:

a periodicity judgment step for judging presence or absence of a periodicity of the detected detection signal;

an effective value detection step for detecting an effective value of the detected detection signal at a time when it is judged that the periodicity is absent;

an effective value judgment step for judging whether or not the detected effective value is not less than a preliminarily set threshold value of the effective value; and

a condition judgement step for judging that, when the detected effective value is not less than the threshold value of the effective value, a foreign material invades in the linear rolling motion guide apparatus and then announcing that fact.

12. The condition detection method according to claim 7, wherein said judgment step comprises:

a periodicity judgment step for judging presence or absence of a periodicity of the detected detection signal;

an effective value detection step for detecting an effective value of the detected detection signal at a time when it is judged that the periodicity is absent;

an effective value judgment step for judging whether or not the detected effective value is not less than a preliminarily set threshold value of the effective value; and

a condition judgement step for judging that, when the detected effective value is less than the threshold value of the effective value, a present operation condition is normal and then announcing that fact.

13. A condition detection program, wherein a condition detection apparatus for detecting a present operation condition in a linear rolling motion guide apparatus, which includes detection means for detecting a wave motion elastically generated on the basis of at least either one of contact or collision of a movable member or a track member to a rolling member contained in the linear rolling motion guide apparatus, contact or collision of a rolling surface to the rolling member contained in the linear rolling motion guide apparatus, or mutual contact or collision of the rolling members themselves, at a time when a plurality of rolling members contained in the linear rolling motion guide apparatus revolve in a circulation section therein, and generating an electric detection signal in accordance with the detected wave motion, includes a computer which is operated as judgment means for judging a content of the operation condition in response to the generated detected signal.

14. An information recording medium, wherein the condition detection program as claimed in claim 13 is recorded to be readable by the computer.

(57) **ABSTRACT**

A seal device fixed to an end portion of a slider of a guide device includes: a casing; a plurality of seal members; and elastic members, wherein each seal member has a recess portion in which a rail penetrates. An inner circumferential face of the recess portion comes into contact with an outer surface of the rail when the seal member is pushed onto one side of the rail by the elastic members. The plurality of seal members are arranged in the casing in such a manner that when a seal portion of one seal member is pushed by the elastic member and contacted with one side of the rail, a seal portion of the next seal member is pushed by the elastic member and contacted with the other side of the rail.

SEAL DEVICE FOR A GUIDE DEVICE AND GUIDE DEVICE

BACKGROUND OF THE INVENTION

[0001] 1. Field of the Invention

[0002] The present invention relates to a seal device for a guide device used for a moving portion of various machine tools, industrial robots or various common machines. Particularly, the present invention relates to a seal device for a guide device in which a slider striding over a rail is guided along the rail. More particularly, the present invention relates to a seal device which effectively exhibits a sealing function even in a guide device in which the rail width is partially different. The present invention also relates to a guide device in which the seal device is used.

[0003] 2. Description of the Related Art

[0004] Conventionally, there is provided a seal device for a guide device shown in FIGS. **1**(*a*) and **1**(*b*). In the drawings, reference numeral **121** is referred to as an end seal attached to an end portion of the slider **120** arranged striding over the rail **130** and moved along the rail **130**. This end seal **121** is composed in such a manner that a rubber member **124** is coated on a plate-shaped core metal **123**. The core metal **123** has a recess portion **122** in which the rail **130** penetrates. A seal portion **125**, which is called a lip, is formed at the inner circumferential edge of the recess portion **122**. Since a forward end portion of the seal portion **125** closely comes into contact with the outer circumferential face of the rail **130** and moves together with the slider **120**, foreign objects such as dust does not get into the slider **120**. **FIG. 1**(*a*) is a front view of the slider **120** and end seal **121**, and **FIG. 1**(*b*) is a sectional view of the inner circumferential portion of the end seal **121**.

[0005] In the conventional seal device, the following problem may be encountered. The dimension t (interval between the inner circumferential face of the core metal **123** and the outer circumferential face of the rail **130**) of the seal portion **125** of the end seal **121** is 1 to 2 mm. In case where the width of the rail **130** is different as shown in **FIG. 2**, for example, a transport device described in Japanese Unexamined Patent Publication No. 2001-99152 in which the slider **120** moves on the rail **130**, the rail width of the curved portion **130**B of the rail **130** is smaller than that of the straight portion **130**A, it is impossible for the elastic extension and contraction of the seal portion **125** to absorb a change in the width of the rail **130**. That is, it is impossible for the elastic extension and contraction of the seal portion **125** to absorb a reduction of the width in the small width portion. Therefore, the forward end portion of the seal portion **125** is separated from the outer circumferential face of the rail **130**, which results in a defective sealing function.

[0006] In order to solve the above problem, Japanese Patent Publication No. 2939846 discloses a seal device as shown in **FIG. 3**. This seal device **110** includes a pair of end face plates **102, 103** made of metal arranged at the end portions of the slider **100** in the moving direction. The end face plates **102, 103** have an inside shape formed into the same profile as that of the outer face of the rail **101**. A small gap is formed between the inside of the end face plates **102, 103** and the rail **101**. The seal device further includes a support member **104** interposed between the end plates **102, 103**; two side seal members **105, 106** and one upper seal member **107** made of bearing metal and arranged in a cut-out portion provided inside the support member **104**. The two side seal members **105, 106** and one upper seal member **107** are formed in shapes that correspond to the profile of the outer face of the rail **101**. The two side seal members **105, 106** and one upper seal member **107** are restricted to move by the pair of end face plates **102, 103**. The seal device further includes compression springs **108** for elastically pushing the seal members **105, 106, 107** onto the outer face of the rail **101**.

[0007] However, even in the seal device **110** composed as described above, the following problems may be encountered. In case where the slider **100** is guided along the rail **101** in which a straight portion and curved portion are continuously connected with each other, a gap is caused between the rail **101** and the side seal members **105, 106** by an inner wheel difference of the curved portion, which deteriorates the sealing function of the seal member. Further, since the seal member is divided into three pieces of the side seal members **105, 106** and the upper seal member **107** so that the seal members do not come into contact with each other, a gap is caused at each of the intersections (opposing faces) of the divided seal members. Further, in case where the inner wheel difference is caused in the curved portion of the rail **101**, it is impossible to absorb the inner wheel difference. Further, this device is disadvantageous in that the number of parts is large and the structure becomes complicated. For example, when such a structure is adopted that the divided seal members come into contact with each other, a gap is formed by the abrasion caused between the divided seal members.

[0008] In the conventional-guide device, the end seal **121** is arranged at the end of the slider **120**, and the seal device **110** is arranged at the end of the moving member (slider) **100** as described above. However, no seal devices are arranged in the side portions of the slider **120** and the moving member (slider) **100**, that is, no seal devices are arranged in the portions opposed to the side of the rail **130**. Therefore, problems may be encountered in which dust gets into the slider from the side portion. Therefore, it is impossible to apply the conventional guide device, for example, to a wood working machine used in a dusty place.

SUMMARY OF THE INVENTION

[0009] The present invention has been accomplished to solve the above problems. It is an object of the present invention to provide a seal device for a guide device and a guide device which enable a simple structure and exhibit not only a sealing function of the slider end portion but also a sealing function of the slider side portion even in case where the rail width is changed and the shape of the rail is changed from a straight line to a curved line.

[0010] According to a first aspect of the present invention, there is provided a seal device for a guide device which is fixed to an end portion of a slider of the guide device so as to prevent foreign objects such as dust from getting into the seal device, the slider being arranged striding over a straight and/or curved rail and guided along the rail, the seal device comprising: a casing; a plurality of plate-shaped seal members accommodated in the casing; and an elastic member for pushing the seal members onto the rail, wherein each seal member has a recess portion in which the rail penetrates, an inner circumferential face of the recess portion includes a seal portion which comes into contact with an outer surface of the rail, and wherein the plurality of seal members are arranged in the casing in such a manner that the seal members are pushed by the elastic member, the seal portion of one seal member comes into contact with one side of the rail, and the seal portion of the next seal member comes into contact with the other side of the rail.

[0011] As described above, when the seal portion formed in the recess portion of one seal member in a plurality of seal members provided in the casing is pushed by the elastic member and contacted with one side of the guide rail, the seal portion formed in the next seal member is pushed onto the other side of the guide rail, that is, the plurality of seal members are arranged in the casing while the phase of the seal portion formed in the recess portion of one seal member and the phase of the seal portion formed in the recess portion of the other seal member are alternately changed from each other. Due to the above structure, sealing is performed in such a manner that the seal portions of a plurality of seal members (at least two seal members) slide on the circumferential face of the rail on which the slider moves. Therefore, a perfect sealing function can be provided. Especially when the rail width is locally different, for example even when the width of a curved portion is smaller than that of a straight portion, a difference in the width can be absorbed when the seal member is moved while being pushed by the elastic member. Therefore, the seal portion can be always contacted with the outer circumferential face of the guide rail, and the sealing function is not impaired.

[0012] According to a second aspect of the present invention, the elastic members are integrally formed on the outer periphery of the seal members.

[0013] When the elastic member is integrally formed in the outer periphery of the seal member, the number of parts composing the seal device can be decreased, and the assembling work can be easily performed.

[0014] According to a third aspect of the present invention, an isolation plate is arranged between the seal members.

[0015] When the isolation plate is arranged between the seal members as described above, each seal member can be smoothly moved regardless of the rail width by the function of the elastic member without interfering with the other seal members, and the seal portion comes into contact with the outer circumferential face of the guide rail. Therefore, the sealing function is effectively performed.

[0016] According to a fourth aspect of the present invention, there is provided a seal device for a guide device which is fixed to a side portion of a slider of the guide device so as to prevent foreign objects such as dust from getting into the seal device, the slider being arranged striding over a straight and/or curved rail and guided along the rail, the seal device comprising: a casing; a plurality of plate-shaped seal members accommodated in the casing; and an elastic member for pushing the seal members onto the rail, wherein a side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex or concave shape of a predetermined radius of curvature, a side of at least one seal member slidably coming into contact with the side of the rail is formed into a straight shape, and wherein the seal members are pushed by the elastic member and at least one portion of the side of each seal member comes into contact with the side of the rail.

[0017] As described above, the side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex or concave shape of a predetermined radius of curvature, and the side of at least one seal member slidably coming into contact with the side of the rail is formed into the straight shape. Therefore, in the straight portion of the rail, the straight side of the seal member closely comes into contact with the side of the rail, and in the curved portion of the seal member, the side of the seal member, which is formed into a convex or concave of a predetermined radius of curvature, closely comes into contact with the side of the rail. Therefore, even if the rail profile is changed from a straight shape to a curved shape, no foreign objects get into the slider from the side portion.

[0018] According to a fifth aspect of the invention, there is provided a seal device for a guide device which is fixed to a side portion of a slider of the guide device so as to prevent foreign objects such as dust from getting into the seal device, the slider being arranged striding over a straight and/or curved rail and guided along the rail, the seal device comprising: a casing; a plurality of plate-shaped seal members accommodated in the casing; and an elastic member for pushing the seal members onto the rail, wherein a side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex shape of a predetermined radius of curvature, a side of at least one seal member slidably coming into contact with the side of the rail is formed into a concave shape of a predetermined radius of curvature, and a side of at least one seal member slidably coming into contact with the side of the rail is formed into a straight shape, and wherein the seal members are pushed by the elastic member and at least one portion of the side of each seal member comes into contact with the side of the rail.

[0019] As described above, the side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex shape of a predetermined radius of curvature, and the side of at least one seal member slidably coming into contact with the side of the rail is formed into a concave shape of a predetermined radius of curvature, and further the side of at least one seal member slidably coming into contact with the side of the rail is formed into a straight-line-shape. Due to the above structure, in the straight rail portion, the straight side of the seal member closely comes into contact with the rail side. In the curved rail portion, the convex side of the seal member of a predetermined radius of curvature or the concave side of the seal member closely comes into contact with the rail side. In the portion where the rail is curved in the other direction, the concave side of the seal member of a predetermined radius of curvature or the convex side of the seal member closely comes into contact with the rail side. Therefore, even if the rail is curved from a straight shape to a curved shape which is curved to either the right or the left, no foreign objects get into the slider from the side portion of the slider.

[0020] According to a sixth aspect of the present invention, the elastic members of a guide device according to the fourth or fifth aspect are integrally formed on the outer periphery of the seal members.

[0021] When the elastic member is integrally formed in the outer periphery of the seal member, the number of parts composing the seal device can be decreased, and the assembling work can be easily performed.

[0022] According to a seventh aspect of the present invention, an isolation plate is arranged between the seal members of a guide device according to one of the fourth to sixth aspects.

[0023] When the isolation plate is arranged between the seal members as described above, each seal member can be smoothly moved regardless of the rail width by the function of the elastic member without interfering with the other seal members, and the seal portion comes into contact with the outer circumferential face of the guide rail. Therefore, the sealing function is effectively performed.

[0024] According to a eighth aspect of the present invention, there is provided a guide device comprising: a straight and/or curved rail; and a slider arranged striding over the rail, the slider having seal devices arranged at both end portions and both side portions respectively for preventing foreign objects from getting into the slider, wherein the seal device attached to both end portions of the slider is the seal device according to one of the first to third aspects, and the seal device attached to both side portions is the seal device according to one of the fourth to seventh aspects.

[0025] As described above, when the seal device attached to both end portions of the slider is the seal device according to one of the first to third aspects, and the seal device attached to both side portions is the seal device according to one of the fourth to seventh aspects, both end portions and both side portions of the slider are sealed. Accordingly, no foreign objects get into the slider.

DETAILED DESCRIPTION OF THE PREFFERD EMBODIMENTS

[0044] Referring to the drawings, embodiments of the present invention will be described below. **FIG. 4** is an exploded perspective view showing an arrangement of a seal device of a guide device of the present invention. As shown in the drawing, this seal device includes: a casing **1**; a plurality of seal members **2-1**, **2-2** accommodated in the casing **1** (In the drawing, two seal members are shown.); and an isolation plate **3** interposed between the seal members **2-1**, **2-2**. In the casing **1**, there is formed a recess portion **5** in which the rail (shown in **FIG. 6**) penetrates. In the seal members **2-1**, **2-2**, there are respectively formed recess portions **6-1**, **6-2** in which the rail **4** penetrates. In the isolation plate **3**, there is formed a recess **7** in which the rail **4** penetrates.

[0045] At both side portions of each seal member **2-1**, **2-2**, there are integrally provided elastic members **8-1**, **8-1**. As shown in **FIG. 5**, the center line l_6 of the recess portion **6-1** of the seal member **2-1** in the width direction is shifted from the center line l_2 of the seal member **2-1** itself in the width direction by the distance d. The inner circumferential face **6-1***a* on one side and the inner circumferential face **6-1***b* on the upper side are formed into a shape closely coming into contact with the outer circumferential face of the rail **4**. Although not shown in the drawing, the structure of the seal member **2-2** is the same as that of the seal member **2-1**, and the inner circumferential face **6-2***a* on one side and the inner circumferential face **6-2***b* on the upper side are formed into a shape closely coming into contact with the outer circumferential face of the rail **4**.

[0046] **FIG. 6** is a view showing a positional relation of the seal member **2-1** with the rail **4** in the case where the seal member **2-1** is accommodated in the casing **1** and the rail **4** is inserted into its recess portion **6-1**. As shown in **FIG. 5**, the center line l_6 of the recess portion **6-1** (not shown in **FIG. 6**) of the seal member **2-1** in the width direction is shifted from the center line l_2 of the seal member **2-1** itself in the width direction by the distance d. Therefore, when the seal member **2-1** is accommodated in the casing **1** and the rail **4** is inserted into its recess portion **6-1**, the elastic member **8-1** on one side (on the left in the drawing) contracts and pushes the seal member **2-1** as shown by the arrow f, however, the elastic member **8-1** on the other side (on the right in the drawing) does not contract but extends. Due to the foregoing, the inner circumferential face **6-1***a* on one side of the recess portion **6-1** composing the seal portion closely comes into contact with the outer circumferential face on one side of the rail **4**, however, a gap g is formed between the inner circumferential face **6-1***c* on the opposite side of the recess portion **6-1** and the outer circumferential face on the opposite side of the rail **4**.

[0047] The seal member **2-2** is arranged in the casing **1** interposing the isolation plate **3** while the phase is shifted (inverted by 180°) as follows. On the contrary to the seal member **2-1**, the inner circumferential face **6-2***a* on one side of the recess portion **6-2** composing the seal portion closely comes into contact with the outer circumferential face on one side on the opposite side of the rail **4**, so that the gap g can be formed between the inner circumferential face **6-2***c* on one side of the recess portion **6-2** and the outer circumferential face on the opposite side of the rail **4**.

[0048] Due to the above structure, the inner circumferential faces **6-1***a*, **6-2***a* on one side composing the seal portion of the seal members **2-1**, **2-2**, which are arranged on both sides of the isolation plate **3** in the casing, are pushed by the elastic members **8-1**, **8-2** and respectively contacted with the opposed outer circumferential face of the rail **4**. Under the above condition, the inner circumferential faces **6-1***a*, **6-2***a* on one side composing the seal portion of the seal members **2-1**, **2-2** are moved on the rail **4** together with the slider. Therefore, foreign objects such as dust are removed from the outer circumferential face of the rail **4** by the seal portion of the seal members **2-1**, **2-2**. Accordingly, no foreign objects get into the slider. The inner circumferential faces **6-1***a*, **6-2***a* on side of the seal members **2-1**, **2-2** are contacted with the outer circumferential face of the rail **4** on the opposed side when they are pushed by the elastic members **8-1**, **8-2**. Therefore, even if the width of the rail **4** differs within the expansion and contraction range of the elastic members **8-1**, **8-2**, the width difference can be absorbed in this expansion and contraction range. Accordingly, no gaps are formed between the seal portion and the outer circumferential face of the rail **4**. Therefore, the sealing function is not impaired.

[0049] **FIG. 7** is a view to explain a sealing function in the case where the seal device of the present invention is applied to a guide device in which the rail width of a curved portion is smaller than the rail width of a straight portion like the transport device (shown in **FIG. 2**) described in Japanese Unexamined Patent Publication No. 2001-99152. In the drawing, two-dotted chain line A expresses an outer circumference of the rail **4** in the straight portion, and solid line B expresses an outer circumference of the rail **4** in the curved portion. As shown in the drawing, since the seal member **2-1** is pushed onto the rail side by the elastic member **8-1**, the inner circumferential face **6-1***a* on one side composing the seal portion always closely comes into contact with and slides on the outer circumferential face in either the straight portion (portion shown by two-dotted chain line A) in which the width of the rail **4** is large or the curved portion (portion shown by solid line B) in which the width of the rail **4** is small. Although not shown in the drawing, the seal member **2-2** is also pushed by the elastic member **8-2**, and the inner circumferential face **6-2***a* on one side always closely comes into contact with and slides on the outer circumferential face of the rail **4** in either the straight portion or the curved portion of the rail **4**.

[0050] Due to the foregoing, the inner circumferential faces **6-1***a*, **6-2***a* on-one side of the seal members **2-1**, **2-2** and the upper side inner circumferential faces **6-1***b*, **6-2***b* always slidably come into contact with both the outer side faces and the upper face of the rail **4** irrespective of the width of the rail. Therefore, a sufficiently high sealing performance can be exhibited. In the above example, the width of the curved portion of the rail **4** is different from that of the straight portion. The seal device of the present invention is capable of exhibiting a sufficiently high sealing performance even in the case where the width is different within the curved portion and in the case where the width is different within the straight portion.

[0051] The seal members **2-1**, **2-2** are made of elastic material such as rubber or resin formed into a felt-shape, however, materials to compose the seal members **2-1**, **2-2** are not limited to the above specific examples. As far as the material is easily conformed to and seldom seized to and easily fitted to the rail **4**, any material such as resin or metal, for example, white metal used for a bearing metal may be used for the seal members **2-1**, **2-2**. In the above example, the cross sections of the inner circumferential faces **6-1***c*, **6-2***c* on one side of the seal members **2-1**, **2-2** which do not compose the seal portion are made to be similar to the cross section of the outer circumferential face of the rail **4**, however, the cross sections of the inner circumferential faces **6-1***c*, **6-2***c* are not limited to the above specific example.

[0052] **FIG. 8** is a view showing an appearance of the guide device to which the seal device of the present invention is applied. In the view, reference numeral **10** is a slider which is arranged striding over the rail. The slider **10** comprises a block **11**, the detail of which will be described later, and end plates **12**. The seal devices **13** of the present invention are arranged outside the end plates **12** which are attached to both ends of the slider **10**. The slider **10** is moved in the longitudinal direction of the rail **4**. When the slider **10** is moved, the inner circumferential faces **6-1***a*, **6-2***a* on one side of the seal members **2-1**, **2-2** (shown in **FIGS. 4 and 6**) and the inner circumferential faces **6-1***b*, **6-2***b* on the upper side of the seal members composing the seal device **13** closely-come into contact with and slide on both the side faces and the upper face of the rail **4**. Due to the foregoing, foreign objects such as dust can be prevented from getting into the slider **10** from the surface of the rail **4**.

[0053] **FIGS. 9 and 10** are a partially cutaway perspective view and lateral sectional view showing a composition of the guide device from which the seal device **13** is removed. The cross section of the rail **4** is formed into a substantial rectangle. Four ball running grooves **4***a*, **4***b*, in which the balls **20** are running, are formed in the longitudinal direction. These ball running grooves **4***a*, **4***b* are formed on both side faces and at both edge portions on the upper face of the rail **4**. The ball running grooves **4***a* located on both side faces are formed downward by the angle of about 30° with respect to the lateral direction on the surface of **FIG. 9**. On the other hand, the ball running grooves **4***b* on the upper face are formed upward in the vertical direction.

[0054] The slider **10** includes: a block **11** having an attaching face **21**, onto which the movable body such as a table is attached, and tap holes **22** in which bolts for fixing the movable body are screwed; and a pair of end plates **12**, **12** attached (fixed) to both end portions of the block **11**. When the end plates **12**, **12** are attached, an infinite circulating path for the balls **20** is composed in the slider **10**.

[0055] The block **11** includes: a horizontal portion **11***a* on which the attaching face **21** is formed; and a pair of skirt portions **11***b*, **11***b* which are hanging from the horizontal portion **11***a*. The cross section of the block **11** is substantially formed into a saddle. On the lower face side of the horizontal portion **11***a* and on the inside of each skirt portion **11***b*, four straight load running grooves **11***c*, **11***d*, which are opposed to the ball running grooves **4***a*, **4***b* of the rail **4**, are formed. In the horizontal portion **11***a* and each skirt portion **11***b*, the ball returning holes **11***e*, **11***f* respectively corresponding to the load running grooves **11***c*, **11***d* are formed. By the U-shaped direction converting paths formed on the end plates **12**, **12**, the load running grooves **11***c*, **11***d* and the corresponding ball returning holes **11***e*, **11***f* are connected with each other, so that the infinite circulating path of the balls can be formed.

[0056] Due to the foregoing, the balls **20** are running as follows. The balls **20**, which bear a load between the ball running grooves **4***a*, **4***b* of the rail **4** and the load running grooves **11***c*, **11***d* of the block **11**, run in the load running grooves **11***c*, **11***d* according to the movement of the slider **10** and are released from the load. Then the balls **20** get into the direction converting path formed on one end plate **12** and run in the opposite direction to the running direction of the load running grooves **11***c*, **11***d* while no load is being given to the balls **20**. In this way, the balls **20** run in the ball returning holes **11***e*, **11***f* formed in the block **11**. After the balls **20** have run in the ball returning holes **11***e*, **11***f*, they get between the rail **4** and the block **11** again via the direction converting path formed on the other end plate **12**. Then, while the balls **20** are bearing a load, they run in the load running grooves **11***c*, **11***d*.

[0057] The above-described guide device is an example of the guide device into which the seal device of the present invention is incorporated. Therefore, the guide device of the present invention is not limited to the above specific example. After all, as far as the guide device is composed in such a manner that the slider is arranged striding over a straight and/or curved rail and guided along the rail and the seal device of the present invention is fixed to the end portion of the slider, it is possible to exhibit a sealing function by which foreign objects such as dust can be prevented from getting into the slider.

[0058] In the seal device of the above structure, two seal members **2-1**, **2-2** are arranged while the isolation plate **3** is being interposed between them. However, the number of the seal members is not limited to two, that is, not less than three seal members may be arranged. The isolation plate **3** is not necessarily required. In the case where each seal member can be smoothly moved even when the seal members **2-1**, **2-2** are contacted with each other, the isolation plate **3** may be omitted. In the above example, the elastic members **8-1**, **8-2** are respectively arranged on both side portions of the seal members **2-1**, **2-2** integrally with the seal members **2-1**, **2-2**. However, the elastic members **8-1**, **8-2** are not necessarily arranged integrally with the seal members **2-1**, **2-2**. As far as each seal member **2-1**, **2-2** can be individually pushed toward the rail **4**, the elastic members **8-1**, **8-2** may be composed separately from the seal members **2-1**, **2-2**.

[0059] The elastic members are not necessarily formed separately from the seal members **2-1**, **2-2**. The following structure may be adopted. When the seal members **2-1**, **2-2** are made of elastic material, the inner circumferential face **6-1***a*, **6-2***a* on one side can be always contacted with the outer circumferential face of the rail by the elastic extension and contraction caused between the one side of the seal members **2-1**, **2-2** and the inner circumferential faces **6-1***a*, **6-2***a* on one side even if the rail width is changed. Further, the following structure may be adopted. For example, as shown in **FIG. 11**, a predetermined shape of hole **23** is formed in the seal member **2-1**. Since the shape of the hole **23** can be deformed, the inner circumferential face **6-1***a* on one side composing the seal portion of the recess portion **6-1** can be always contacted with the outer circumferential face of the rail even if the rail width is changed. Although not shown in the drawing, the situations are the same in the case of the seal member **2-2**.

[0060] **FIG. 12** is an exploded perspective view showing an example of the arrangement of the seal device of the guide device of the present invention. As shown in the drawing, the seal device **30** includes: a casing **31**; a plurality of (three in the case shown in the drawing) plate-shaped seal members **32-1**, **32-2**, **32-3**; and two isolation plates **33-1**, **33-2** interposed between the seal member **32-1** and the seal member **32-2** and between the seal member **32-2** and the seal member **32-3**. The seal members **32-1**, **32-2**, **32-3** and the isolation plates **33-1**, **33-2** are superposed to each other and accommodated in the casing **31**. As shown in FIGS. **13**(*a*) and **13**(*b*), the seal members **32-1**, **32-2**, **32-3** and the isolation plates **33-1**, **33-2** are attached (fixed) to both side bottom portions of the block **11** of the slider **10** by screws **34**. The seal members **32-1**, **32-2**, **32-3** are pushed onto the sides of the rail **4** by the elastic members, and the sides are slidably contacted with the side faces of the rail **4** as described later. **FIG. 13**(*a*) is a lateral sectional view of the rail **4** and slider **10** of the guide device, and **FIG. 13**(*b*) is an enlarged sectional view of the neighborhood portion of the seal device **30**.

[0061] The side **32-1***a* of the seal member **32-1** slidably coming into contact with the side of the rail **4** is formed into a convex (an arcuate shape) of a predetermined radius of curvature, the side **32-2***a* of the seal member **32-2** slidably coming into contact with the side of the rail **4** is formed into a straight shape, and further the side **32-3***a* of the seal member **32-3** slidably coming into contact with the side of the rail **4** is formed into a concave (an arcuate shape) of a predetermined radius of curvature. On the sides of the seal members **32-1**, **32-2**, **32-3** arranged on the side opposite to the rail **4**, the elastic members **35-1**, **35-1**, **35-2**, **35-2**, **35-3**, **35-3** are respectively integrally arranged. When the thus composed seal device **30** is attached to both side bottom portions of the block **11** of the slider **10**, the seal members **32-1**, **32-2**, **32-3** are pushed by the elastic members **35-1**, **35-1**, **35-2**, **35-2**, **35-3**, **35-3**.

[0062] Since the side **32-1***a* of the seal member **32-1** is formed into a convex (an arcuate shape) of a predetermined radius of curvature, the side **32-2***a* of the seal member **32-2** is formed into a straight shape, and further the side **32-3***a* of the seal member **32-3** is formed into a concave (an arcuate shape) of a predetermined radius of curvature, in a portion where the rail **4** is curved convex by a predetermined radius of curvature as shown in **FIG. 14**(*a*), the side **32-1***a* of the seal member **32-1** closely comes into contact with the side of the rail **4** so as compose the seal portion. In a portion where the rail **4** is curved concave by a predetermined radius of curvature as shown in **FIG. 14**(*b*), the side **32-3***a* of the seal member **32-3** closely comes into contact with the side of the rail **4** so as compose the seal portion. In a portion where the rail **4** is straight as shown in **FIG. 14**(*c*), the side **32-2***a* of the seal member **32-2** closely comes into contact with the side of the rail **4** so as compose the seal portion.

[**0063**] In the case where the rail **4** snakes as shown in **FIG. 15**, the rail **4** is composed of curved portions **4-1**, **4-2** and a straight portion **4-3**, wherein the curved portions **4-1**, **4-2** are respectively formed into arcs, the radiuses of curvature of which are predetermined. Therefore, the convex (arcuate) side **32-1***a* of the seal member **32-1** and the concave (arcuate) side **32-3***a* of the seal member **32-3** are previously manufactured according to the radiuses of curvature of these curved portions **4-1**, **4-2**. Due to the foregoing, when the seal device **30** in which the seal members **32-1**, **32-2**, **32-3** are superposed as shown in **FIG. 12** is attached to both side bottom portions of the block **11** of the slider **10** as shown in **FIG. 13**, if the slider **10** is moved on the snaking rail **4**, either of the sides **32-1***a*, **32-2***a*, **32-3***a* of the seal members **32-1**, **32-2**, **32-3** closely comes into contact with the side of the rail **4**, so that the seal portion can be formed.

[**0064**] The seal members **32-1**, **32-2**, **32-3** can be made of the same material as that of the seal members **2-1**, **2-2**. The isolation plates **33-1**, **33-2** can be made of the same material as that of the above isolation plate **3**.

[**0065**] In the seal device **30** of the above structure, three seal members **32-1**, **32-2**, **32-3** are arranged while the isolation plates **33-1**, **33-2** are being interposed between them, however, the number of the seal members is not limited to three. That is, not less than three seal members may be arranged. The isolation plates are not necessarily required. In the case where each seal member can be smoothly moved even when the seal members **32-1**, **32-2**, **32-3** are contacted with each other, the isolation plates may be omitted. In the above example, the elastic members **35-1**, **35-2**, **35-3** are respectively arranged on side portions of the seal members **32-1**, **32-2**, **32-3** integrally with the seal members **32-1**, **32-2**, **32-3**. However, the elastic members **35-1**, **35-2**, **35-3** are not necessarily arranged integrally with the seal members **32-1**, **32-2**, **32-3**. As far as each seal member **32-1**, **32-2**, **32-3** can be individually pushed toward the rail **4**, the elastic members **35-1**, **35-2**, **35-3** may be composed separately from the seal members **32-1**, **32-2**, **32-3**.

[**0066**] In the case of the guide device shown in **FIG. 15**, the rail **4** is snaking. However, for example, in the case where the rail **4** is annularly formed into an ellipse as shown in. **FIG. 16**, the seal device located outside the annular rail **4** is the seal device **30** composed as shown in **FIG. 17**, and the seal device located inside the annular rail **4** is the seal device **30** composed as shown in **FIG. 18**. The seal device **30** shown in **FIG. 17** is composed in such a manner that the side **32-2***a* slidably coming into contact with the outer circumferential side face of the rail **4** is the straight seal member **32-2**, the isolation plate is the isolation plate **33-1**, and the side **32-3***a* slidably coming into contact with the outer circumferential side face of the rail **4** is the seal member **32-3** of a concave (arc) of a predetermined radius of curvature. The seal device **30** shown in **FIG. 18** is composed in such a manner that the side **32-2***a* slidably coming into contact with the inner circumferential side face of the rail **4** is the straight seal member **32-2**, the isolation plate is the isolation plate **33-1**, and the side **32-1***a* slidably coming into contact with the inner circumferential side face of the rail **4** is the seal member **32-1** of a convex (arc) of a predetermined radius of curvature.

[**0067**] As described above, the seal device **30** located outside the annular rail **4** is composed as shown in **FIG. 17**, and the seal device **30** located inside the annular rail **4** is composed as shown in **FIG. 18**. Due to the above structure, in the seal device **30** located outside, either the straight side **32-2***a* of the seal member **32-2** or the concave (arcuate) side **32-3***a* of the seal member **32-3** closely comes into contact with the outer circumferential side of the rail **4**, so that the seal portion can be formed. In the seal device **30** located inside, either the straight side **32-2***a* of the seal member **32-2** or the convex (arcuate) side **32-1***a* of the seal member **32-1** closely comes into contact with the inner circumferential side of the rail **4**, so that the seal portion can be formed. Accordingly, there is no possibility that foreign objects get into the slider **10** from the bottom side portion.

[**0068**] When the seal device **30** composed as shown in **FIG. 4** is arranged at both end portions of the slider **10** of the guide device and when the seal device **30** composed as shown in **FIG. 12** or the seal device **30** composed as shown in **FIGS. 17 and 18** is arranged at both side portions of the bottom portion of the slider **10**, it becomes possible to provide a guide device incorporated into a wood working machine used in a dusty environment in which both end portions and both side portions of the slider **10** are sealed so that no foreign objects can not get into the slider **10**.

[**0069**] As explained above, according to each aspects of the present invention, it is possible to provide the following excellent effects.

[**0070**] According to the first aspect of the invention, a plurality of seal members are arranged in the casing so that the phase of arranging the plurality of seal members can be alternately changed in such a manner that when a seal portion of one seal member is pushed by the elastic member and contacted with one side of the rail, a seal portion of the next seal member is pushed by the elastic member and contacted with the other side of the rail. Accordingly, the seal portions of the plurality of seal members (at least two seal members) conduct sealing while they are sliding on the outer circumferential face of the rail on which the slider moves. Therefore, it is possible to provide a perfect sealing function. Especially when the rail width is locally different, for example even when the width of a curved portion is smaller than the width of a straight portion, a difference in the width can be absorbed when the seal member is, moved while being pushed by the elastic member. Therefore, the seal portion can be always contacted with the outer circumferential face of the guide rail. Accordingly, the sealing function is not impaired.

[**0071**] According to the second aspect of the invention, when the elastic member is formed in the outside portion of the seal member integrally with the seal member as described above, the number of parts composing the seal device can be decreased, and the assembling work can be easily performed.

[0072] According to the third aspect of the invention, the isolation plate is arranged between the seal members. Therefore, each seal member can be smoothly moved according to the rail width without interfering with the other seal members by the action of the elastic member, and the seal portion comes into contact with the outer circumferential face of the guide rail. Therefore, the sealing function can be effectively performed.

[0073] According to the fourth aspect of the invention, the side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex or concave of a predetermined radius of curvature, and the side of at least one seal member slidably coming into contact with the side of the rail is formed into the straight-line-shape. Therefore, in the straight portion of the rail, the straight side of the seal member closely comes into contact with the side of the rail, and in the curved portion of the seal member, the side of the seal member, which is formed into a convex or concave of a predetermined radius of curvature, closely comes into contact with the side of the rail, so that the seal portion can be formed. Therefore, even if the rail profile is changed from a straight shape to a curved shape, no foreign objects get into the slider from the side portion.

[0074] According to the fifth aspect of the invention, the side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex of a predetermined radius of curvature, and the side of at least one seal member slidably coming into contact with the side of the rail is formed into a concave of a predetermined radius of curvature, and further the side of at least one seal member slidably coming into contact with the side of the rail is formed into a straight shape. Due to the above structure, in the straight rail portion, the straight side of the seal member closely comes into contact with the rail side, so that the seal portion can be formed. In the curved rail portion, the convex side of the seal member of a predetermined radius of curvature or the concave side of the seal member closely comes into contact with the rail side, so that the seal portion can be formed. In the portion where the rail is curved in the other direction, the concave side of the seal member of a predetermined radius of curvature or the convex side of the seal member closely comes into contact with the rail side, so that the seal portion can be formed. Therefore, even if the rail is curved from a straight shape to a curved shape which is curved to either the right or the left, no foreign objects gets into the slider from the side portion of the slider.

[0075] According to the sixth aspect of the invention, the elastic members are formed on the outside of the seal members integrally with the seal members. Therefore, the number of parts composing the seal device can be reduced, and the assembling work can be easily performed.

[0076] According to the seventh aspect of the invention, the isolation plate is arranged between the seal members. Therefore, each seal member is pushed by the elastic member and smoothly moved according to the curved rail without interfering with the other seal members, and the side of the seal member comes into contact with the rail side. Therefore, the sealing function can be effectively performed.

[0077] According to the eighth aspect of the invention, when the seal device attached to both end portions of the slider is the seal device according to one of the first to third aspects and the seal device attached to both side portions is the seal device according to the fourth to seventh aspects, both end portions and both side portions of the slider are sealed. Accordingly, it becomes possible to provide a guide device, into the slider of which no foreign objects get.

1-4. (canceled)

5. A seal device for a guide device which is fixed to a side portion of a slider of the guide device so as to prevent foreign objects such as dust from getting into the seal device, the slider being arranged striding over a straight and/or curved rail and guided along the rail, the seal device comprising:

a casing;

a plurality of plate-shaped seal members accommodated in the casing; and

an elastic member for pushing the seal members onto the rail,

wherein a side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex or concave shape of a predetermined radius of curvature, a side of at least one seal member slidably coming into contact with the side of the rail is formed into a straight shape, and

wherein the seal members are pushed by the elastic member and at least one portion of the side of each seal member comes into contact with the side of the rail.

6. A seal device for a guide device which is fixed to a side portion of a slider of the guide device so as to prevent foreign objects such as dust from getting into the seal device, the slider being arranged striding over a straight and/or curved rail and guided along the rail, the seal device comprising:

a casing;

a plurality of plate-shaped seal members accommodated in the casing; and

an elastic member for pushing the seal members onto the rail,

wherein a side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex shape of a predetermined radius of curvature, a side of at least one seal member slidably coming into contact with the side of the rail is formed into a concave shape of a predetermined radius of curvature, and a side of at least one seal member slidably coming into contact with the side of the rail is formed into a straight shape, and

wherein the seal members are pushed by the elastic member and at least one portion of the side of each seal member comes into contact with the side of the rail.

7. A seal device for a guide device according to claim 5, wherein the elastic member is integrally formed on the outer periphery of each seal member.

8. A seal device for a guide device according to claim 6, wherein the elastic member is integrally formed on the outer periphery of each seal member.

9. A seal device for a guide device according to claim 5, further comprising an isolation plate arranged between the seal members.

10. A seal device for a guide device according to claim 6, further comprising an isolation plate arranged between the seal members.

11. A seal device for a guide device according to claim 7, further comprising an isolation plate arranged between the seal members.

12. A seal device for a guide device according to claim 8, further comprising an isolation plate arranged between the seal members.

13. A guide device comprising:

a straight and/or curved rail; and

a slider arranged striding over the rail, the slider having seal devices arranged at both end portions and both side portions respectively for preventing foreign objects from getting into the slider,

wherein the seal device attached to both side portions is the seal device described in claim 5.

14. A guide device comprising:

a straight and/or curved rail; and

a slider arranged striding over the rail, the slider having seal devices arranged at both end portions and both side portions respectively for preventing foreign objects from getting into the slider,

wherein the seal device attached to both side portions is the seal device described claim 6.

15. A seal device for a guide device according to claim 5, wherein the side of said at least one seal member slidably coming into contact with the side of the rail is formed into a convex shape of a predetermined radius of curvature.

16. A seal device for a guide device according to claim 5, wherein the side of said at least one seal member slidably coming into contact with the side of the rail is formed into a concave shape of a predetermined radius of curvature.

(57) **ABSTRACT**

The present invention mainly aims to provide cutting method and cutting apparatus for manufacturing a guide rail of a rolling guide device by efficiently cut-working a long scale hardened steel. In order to achieve such object, there is provided a cutting method of linearly cutting a work surface (**3**) of the long scale hardened steel (**2**) along the longitudinal direction thereof. In this process, it is desired to arrange a plurality of CBN tools (**7**) along the longitudinal direction of the long scale hardened steel (**2**) to thereby sequentially cut the work surface (**3**). Furthermore, a cutting apparatus of the present invention comprises a fixing device (**4**) for fixing the long scale hardened steel (**2**), a tool rest (**5**) which is guided by a guide device (**6**) disposed along the longitudinal direction of the fixing device (**4**) and the CBN tool (**7**) cut-working the work surface (**3**) of the long scale hardened steel (**2**) held by the tool rest (**5**).

METHOD AND APPARATUS FOR CUTTING LONG SCALE HARDENED STEEL

[0001] This application is a divisional of application Ser. No. 10/297,947 filed Dec. 26, 2002.

TECHNICAL FIELD OF THE INVENTION

[0002] The present invention relates to a cutting method and cutting apparatus for cutting extremely efficiently a hardened steel material having a long scale (called hereinlater "long scale hardened steel" or merely "hardened steel") used as work piece such as guide rail of a rolling guide device.

BACKGROUND ART

[0003] As shown in FIGS. **14** to **16**, a rolling guide device **101** for guiding a table carrying work piece mounted to a machine tool comprises a track table **102** having a rolling member rolling surface (which may be called "rolling member rolling groove") **105** formed along a longitudinal direction thereof, an endless circulation passage **110** including a loaded rolling member rolling passage **107** corresponding to the rolling member rolling surface **105**, and a movable table **104** to be mounted to the track table **102** through a number of rolling members **103** arranged in the endless circulation passage **110**. The track table **102** and the movable table **104** are constructed to be relatively movable by the rolling motion of the rolling members **103**.

[0004] In such rolling guide device **101**, the track table **102** has a complicated sectional shape such as a long scale hardened steel **2** shown in **FIG. 2**. It is required for the track table **102** to be formed, with high dimensional precision, the rolling member rolling surface **105** having a predetermined surface hardness. Such track table **102** is manufactured by a method of shaping a long scale round steel into a product having dimension and shape similar to those of a final product by drawing it through the hole in a modified die, hardening it to obtain a predetermined surface hardness and, then, finely finishing it so as to obtain a predetermined dimension and shape through cut-working.

[0005] In the track table manufacturing method of conventional art, there is adopted the drawing working capable of shaping a work with high precision having a complicated sectional shape and the cutting working capable of finely finishing it so as to have a predetermined dimension, so that the track table having a dimension with high accuracy can be manufactured.

[0006] The conventional track table, however, has been manufactured through the drawing working and cutting working which have required much working time and provided problem on working efficiency. According to this view, the track table could not efficiently manufactured.

DISCLOSURE OF THE INVENTION

[0007] The present invention was conceived to solve the above subjects and to provide cutting method and cutting apparatus for manufacturing, with high efficiency and high performance, a long scale hardened steel utilized as a work for a guide rail of a rolling guide device.

[0008] A cutting method of cutting a long scale hardened steel, for achieving the above object, is characterized in that a work surface of a long scale hardened steel along a longitudinal direction thereof is linearly cut by a CBN tool at a cutting speed of approximately 30 m/min. to 160 m/min.

[0009] According to this invention, the wearing amount of the CBN tool can be reduced by linearly cutting the long scale hardened steel at such cutting speed, so that the long scale hardened steel can be cut with extremely high efficiency and high precision in dimension, and as a result, a guide rail of a rolling guide device or like can be extremely efficiently manufactured.

[0010] In the cutting method of the long scale hardened steel of the present invention, it is preferred that a plurality of work surfaces of a long scale hardened steel along a longitudinal direction thereof are linearly cut simultaneously by a plurality of CBN tools. According to this invention, a plurality of work surfaces can be extremely efficiently cut-worked.

[0011] In the cutting method of the long scale hardened steel of the present invention, it is preferred that a plurality of CBN tools are arranged along the longitudinal direction of the long scale hardened steel and the work surface of the long scale hardened steel is cut sequentially along the longitudinal direction thereof. According to this invention, by moving the CBN tools arranged along the longitudinal direction of the long scale hardened steel from one side in the longitudinal direction thereof towards the other side, the work surface can be cut-worked in extremely short time.

[0012] In the cutting method of the long scale hardened steel of the present invention, it is preferred that the long scale hardened steel is a hardened steel for a guide rail of a rolling guide device. According to this invention, the guide rail of the rolling guide device can be extremely efficiently manufactured.

[0013] In the cutting method of the long scale hardened steel of the present invention, it is preferred that a plurality of CBN tools are arranged on a virtual plane normal to the longitudinal direction of the long scale hardened steel so as to provide linear symmetric or point symmetric arrangement. In this case, it is also preferred that at least one pair of CBN tools for cutting the work surface of the long scale hardened steel are arranged so that radial forces of cutting resistance thereof are mutually balanced. According to this invention, since the CBN tools are arranged so that the radial forces due to the cutting resistance in the cutting operation of the symmetrically arranged CBN tools are balanced, the generation of deflection of the long scale hardened steel and the CBN tools can be controlled, and as a result, the working accuracy of the work surface can be improved. In addition, since the combined force of the radial forces due to the cutting resistance of at least one pair of CBN tools are balanced and cancelled mutually, the generation of the deflection of the long scale hardened steel and the CBN tools can be suppressed and the working accuracy of the work surface can be further improved.

[0014] The cutting apparatus for cutting a long scale hardened steel according to the present invention for achieving the above object is characterized by comprising a fixing device for fixing a long scale hardened steel, a tool rest which is guided by a guide device disposed along the longitudinal direction of the fixing device, and a CBN tool for cutting a work surface of the long scale hardened steel.

According to this invention, a work surface of a long scale hardened steel can be cut-worked with extremely high efficiency by the CBN tool held by the tool rest, and as a result, a guide rail of a rolling guide device can be manufactured with extremely high efficiency.

[0015] In the cutting apparatus of the long scale hardened steel of the present invention, it is preferred that the tool rest is provided, to be detachable, with a holding member for holding the CBN tool. According to this invention, the CBN tool can be easily changed through a detachable mounting of the holding member.

[0016] In the cutting apparatus of the long scale hardened steel of the present invention, it is preferred that the holding member is provided with a position adjusting means for adjusting a fixing position of the CBN tool. According to this invention, the position of the CBN tool, for example, can be finely adjusted to thereby adjust the cut amount of the CBN tool.

[0017] In the cutting apparatus for the long scale hardened steel of the present invention, it is preferred that a plurality of CBN tools are arranged on a virtual plane normal to the longitudinal direction of the long scale hardened steel so as to provide linear symmetric or point symmetric fashion. In this case, it is also preferred that at least one pair of CBN tools for cutting the work surface of the long scale hardened steel are arranged so that radial forces of cutting resistance thereof are mutually balanced. According to this invention, since the generation of deflection of the long scale hardened steel and the CBN tools can be controlled, the long term use of the guide device can be realized, and in addition, the cutting apparatus can be driven smoothly for a long time. Thus, by the cut-working of such cutting apparatus, the working accuracy of the work surface can be further improved.

BRIEF DESCRIPTION OF THE DRAWINGS

BEST MODE FOR EMBODYING THE INVENTION

[0034] Hereunder, method and apparatus for cutting a long scale hardened steel according to the present invention will be described with reference to the accompanying drawings.

[0035] (1) Cutting Method and Cutting Apparatus

[0036] The cutting method of the present invention is a method of linearly cutting a work surface of a long scale hardened steel along its longitudinal direction at a cutting speed of about 30 m/min. to 160 m/min. by using a CBN tool, and the apparatus for cutting a long scale hardened steel of the present invention is an apparatus for realizing such cutting method (hereinlater, these method and apparatus may be called (cutting method and apparatus of the present invention). According to such cutting method and apparatus, long scale hardened steel or steel members can be extremely effectively cut or cut-worked. Moreover, by applying the present invention to the manufacturing of a guide rail, for example, of a rolling guide device as represented by a flowchart of **FIG. 1**, the guide rail or like can be manufactured extremely efficiently with high precision, thus reducing the working time and decreasing manufacturing cost while maintaining high quality.

[0037] **FIG. 2** is a perspective view showing one example of a long scale hardened steel **2** to which the cutting method and cutting apparatus according to the present invention are applicable, in which four rows of work surfaces **3** extending along the longitudinal direction of the hardened steel **2** are arranged in the symmetric fashion with each other. This example represents an exemplary embodiment of a track table **102** of a rolling guide device **101** shown in FIGS. **14** to **16**, which will be mentioned hereinlater, and the work surface **3** in FIG. **2** attains a function as a rolling member rolling surface **105** along which a rolling member **103** circulates endlessly. Further, it is to be noted that the work surface **3** mentioned herein is a surface to be cut and worked in accordance with the cutting method using the cutting apparatus of the present invention, and includes a surface having any shape which is not specifically limited. For example, the surface **3** includes a flat surface composed of a plane, a rectangular surface composed of combination of planes, a groove composed of curved surface and a composite surface composed of combination of plane and curved surface.

[**0038**] The cutting method and apparatus of the present invention is utilized preferably for the working of a hardened steel of which surface is hardened through hardened or quenching process or like. Such hardened steel is not limited in its type or kind as far as its surface is hardened through the quenching process, and for example, it is desirable to be applied to a hardened steel utilized for satisfying requirement of anti-abrasion property such as long scale linear rail or curved rail constituting a rolling guide device.

[**0039**] The cutting method and apparatus of the present invention has a characteristic feature such that it is especially applicable to the long scale hardened steel. Although a length of such hardened steel is not specifically limited, in a case where a long scale linear rail or curved rail of the rolling guide device is manufactured, it may be preferable for such rail member to have a work surface having length of about 2 m to 3 m. When the present invention is applied to a hardened steel having such length as mentioned above, the cutting efficiency can be improved and worked products can be manufactured with high productivity.

[**0040**] With reference to the cutting method and apparatus **1** which are applied to a linear rail or curved rail of the linear rolling guide device, as shown in **FIG. 3**, the long scale hardened steel **2**, having a work surface of a length of about 2 m to 3 m, for the rolling guide device is fixed to a fixing device **4**, and the work surface **3** extending along the longitudinal direction of the long scale hardened steel **2** is cut and worked by means of a CBN tool **7** mentioned hereinlater. Further, this fixing device **4** is provided, as mentioned hereinlater, with at least a mount table and fixing means and is adapted to fix the long scale hardened steel **2**.

[**0041**] As means for fixing the long scale hardened steel **2** to the fixing device **4**, there will be adopted a various clamps or chucks. Further, a power chuck may be also adopted, and for example, as a power chuck, hydraulic chuck, pneumatic chuck, electromagnetic chuck or like may be listed up.

[**0042**] The long scale hardened steel **2** fixed to the fixing device **4** is cut and worked by the CBN tool **7** holded by a tool rest **5**. The CBN tool **7** is formed from a sintered material of cubic boron nitride (CBN) and by sintering, under a high temperature and an extreme high pressure, a mixture of CBN powder with Co, Tic and like. The CBN tool **7** has superiority of high hardness, high elastic coefficiency and high heat transfer property, so that the CBN tool **7** can be preferably utilized for the cutting of high hardness material, hardened (quenched) steel, heat-resistant alloy and the like.

[**0043**] The CBN tool **7** is a tool, to be more specific as shown in **FIG. 4**, in shape of rod and is provided with a CBN sintered member **10** in form of chip at its front end. This, however, is not necessarily limited to one having the shape shown in **FIG. 4**, and an optimum one of conventionally known shapes such as one shown in **FIG. 8**(B), conforming with the shape of the work surface **3**, can be optionally selected. Further, it is desirable that the CBN sintered member **10** directly related to the cut-working utilizing the CBN tool **7** has a chip shape substantially the same as the shape of the work surface **3** of the long scale hardened steel **2**. By using the CBN tool **7** having the CBN sintered member **10** having such a chip shape as that mentioned above, the work surface **3** can be easily and precisely formed so as to provide substantially the same shape as that of the CBN sintered body **10** through the cutting working, thus reducing the number of cutting workings. As a result, the cutting working can be performed with extremely high efficiency and precision. Further, the use of such CBN tool **7** can make it possible to cut the work surface through a dry-type cutting working which is different from a conventionally known wet-type cutting working, thus being advantageous.

[**0044**] The tool rest **5** is one for mounting the CBN tool **7**, as shown in FIGS. **5** to **7**, which is a member for mounting the CBN tool **7**, and guided by the guide device **6** in form of rail arranged along the longitudinal direction of the fixing device **4** and driven by a driving means **15**. Further, it is to be noted that the shape or like of the tool rest **5** is not limited to a specific one and it is possible to adopt a structure which is movable along the longitudinal direction of the long scale hardened steel **2** fixed to the fixing device **4** and which can cut the work surface **3** of the long scale hardened steel **2** in its longitudinal direction. Furthermore, there will also be adopted with no specific limitation, as the tool rest **5**. it may be possible to adopt one to which one or more than one CBN tools **7** can be directly mounted, or one to which a holder member **8** holding one or more than one CBN tools **7** can be held.

[**0045**] Movement of the tool rest **5** is performed by the guidance of the guide device **6** and driving power applied by the driving means **15**. As such guide device **6**, there will be usable a device for guiding the tool rest **5** utilizing rolling contact such as shown in FIGS. **14** to **16**. One typical example of such guide device **6** performing the guiding motion by the rolling contact comprises a guide rail **6*b*** having a rolling member rolling surface extending along its longitudinal direction and a sliding block **6*a*** having an endless circulation passage including a loaded rolling member rolling surface corresponding to the rolling member rolling surface, the sliding block **6*a*** being mounted to the guide rail **6*b*** through a number of rolling members disposed and aligned in the endless circulation passage. The guide rail **6*b*** and the sliding block **6*a*** can be relatively movable at the high cutting speed of such as 30 m/min. to 160 m/min. by the rolling motion of the rolling members. Further, a guide device other than the guide device **6** utilizing the sliding contact may be usable, and furthermore, as the driving means **15**, although a ball screw **15*a*** and a motor, not shown, applying a driving force to the ball screw **15*a*** are utilized in the described embodiment, another means such as linear motor may be also used.

[**0046**] The holding member **8** for holding the CBN tool **7** is mounted to be detachable to the tool rest **5** (see FIGS. **5** to **7**). By the detachable mounting of the holding member **8**, it becomes possible to change the CBN tool **7** more easily by the integral detaching of the holding member **8**. As mentioned, the technique that the CBN tool **7**, which has been mounted to the holding member **8**, is then mounted to the tool rest **5** makes it possible, particularly, in the case of mounting a plurality of CBN tools **7**, to improve the dimensional adjustment and precision between the respective CBN tools **7** and to realize an excellent cut-working with high performance.

[**0047**] The dimensional adjustment in the case of mounting the CBM tool **7** to the holding member **8** is performed, as shown in FIGS. **5** to **7**, by a position adjusting means **9** for adjusting the fixing position of the CBN tool **7**. As such position adjusting means **9**, means composed of slot and a bolt which is slidably fitted to the slot is usually used, but any other means may be adopted. In the meantime, although, in a case where a desired cutting margin is cut by one cutting operation, manual or automatic means may be used as such position adjusting means **9**, in a case where the desired cutting margin is cut by two or more than two cutting operations, it is desired for the position adjusting means **9** to be automatically controlled.

[**0048**] The holding member **8** is fastened to a predetermined mount position **12** of the tool rest **5** by, for example, means of bolt. Such holding member **8** may, as shown in FIGS. **5** to **7**, have approximately a rectangular shape or semi-circular shape, which will not be limited thereto. The holding member **8** can be positioned only by inserting and fitting the holding member **8** to the mount position **12** by adopting the shape of the mount position **12** conforming with the shape of the holding member **8**. Moreover, the CBN tool **7** mounted to the holding member **8** is adjusted to the predetermined position, so that the cut-working excellent in the working precision can be realized.

[**0049**] One or more than one CBN tools **7** will be mounted to the holding member **8**. In the case of mounting a plurality of CBN tools **7**, since a plurality of work surfaces **3** along the longitudinal direction of the long scale hardened steel **2** can be simultaneously cut, a plurality of work surfaces **3** corresponding to the number of the CBN tools **7** can be extremely effectively cut and worked.

[**0050**] In the case of mounting a plurality of CBN tools **7**, it is desired to consider balance of load stress between the CBN tools **7** and the work surfaces **3**. More specifically, as shown in FIGS. **8** to **10**, it is desired to arrange the plural CBN tools **7** at linear symmetric or point symmetric portions on a virtual plane, which is a plane perpendicular in the longitudinal direction of the long scale hardened steel **2**. In such case, since the plural CBN tools **7** are arranged on the virtual plane in linear symmetry or point symmetry relation, radial forces Fp of cutting resistance in the cutting operation as shown in **FIG. 11** are balanced (see FIGS. **8** to **10**). In an example in which the radial forces Fp are balanced, the respective radial forces Fp elastically deform the tool rest **5**. However, such elastic deformation merely generates an inner stress to the tool rest **5** and is not transmitted as an external force with respect to the guide device **6**. Accordingly, by arranging the CBN tools **7** in the manner mentioned above in order to balance the radial forces Fp, the generation of deflection of the long scale hardened steel **2** and/or CBN tools **7** can be suitably controlled. Further, with reference to **FIG. 11**, Ff represents a feed force, Fp is a radial force and F represents a resultant force (Ff+Fp) of cutting resistance.

[**0051**] Here, the mode of "arranged in linear symmetric manner" means arrangement in a mirror relation with respect to a reference line, and on the other hand, the mode of "arranged in point symmetric manner" means arrangement in opposed-angle relation with respect to a reference point. As such reference line and reference point, a center line **22** or **24** and specific point **23** in FIGS. **8** to **10** will be indicated.

[**0052**] Especially, it is desired, as shown in **FIG. 8**(A), that at least one pair of CBN tools **7**, **7** are arranged on a virtual plane so as to provide a linear symmetry with respect to the center line **22** of the long scale hardened steel **2**. According to this technology, the resultant force of the radial forces Fp of the cutting resistance are balanced mutually and cancelled by each other, the deflection of the long scale hardened steel **2** and that of the CBN tools **7** due to the radial forces Fp at the cut working operation can be suppressed or substantially prevented from generating, and hence, the working performance of the work surface **3** can be further improved, thus being effective. Further, **FIG. 8**(B) is a plan view showing one example of the CBN tool **7**.

[**0053**] Furthermore, it is also desired that, as shown in **FIG. 9**, in the arrangement of a plurality of CBN tools, at least one pair of CBN tools **7** are arranged on the virtual plane so as to provide a linear symmetry with respect to the center line **22** of the long scale hardened steel **2** so as to mutually cancel the radial forces Fp of the cutting resistance and the other CBN tools **7'**, **7'** are arranged on the virtual plane so as to provide a linear symmetry with respect to the center line **22** of the long scale hardened steel **2**. According to such arrangement, as mentioned hereinabove, the generation of deflection of the long scale hardened steel **2** and that of the CBN tools **7** due to the radial forces Fp in the cut working operation can be controlled or substantially prevented as much as possible, and hence, the working performance of the work surface **3** can be further improved. In such occasion, the CBN tools **7'**, **7'** are not arranged so as to cancel the resultant force of the radial forces Fp, but the respective CBN tools **7'**, **7'** are arranged in the lateral symmetry with respect to the center line. For this reason, the radial forces Fp applied to the guide device **6** is made equivalent in the lateral direction, and radial loads having the same amount are applied with respect to the guide device **6**. As a result, since the loads applied to the guide device **6** can be laterally balanced, usable life time of the guide device **6** can be elongated and, in addition, the cutting device **1** can be used smoothly and safely for a long term, thus being effective. Moreover, the working performance or precision of the surface of the work to be cut-worked can be improved by working the long scale hardened steel **2** by using such cutting device **1**.

[**0054**] Furthermore, **FIG. 10** shows an arrangement mode in which CBN tools **7***a*, **7***b*, **7***c* and **7***d* are arranged on a virtual plane so as to provide point symmetry with respect to a specific point **23**. In addition to that the four CBN tools **7***a*, **7***b*, **7***c* and **7***d* are arranged on a virtual plane so as to provide point symmetry with respect to a specific point **23**, the CBN tools **7***a* and **7***c* and the CBN tools **7***b* and **7***d* are arranged in linear symmetry on the virtual plane with respect to the center line **22** of the long scale hardened steel **2**, and furthermore, the CBN tools **7***a* and **7***b* and the CBN tools **7***c* and **7***d* are arranged in linear symmetry on the virtual plane with respect to the line **24** parallel to the fixing device **4**. By arranging these four NBC tools in the described arrangement mode, the radial forces Fp of the respective CBN tools will be cancelled. As a result, as mentioned above, the usable life time of the guide device **6** can be achieved, the cutting device **1** can be driven smoothly and safely for a long term, and the working performance to the work surface **3** can be further improved. Further, it is to be noted that, although angles of the radial forces Fp of the CBN tools are respectively of 45°, these angles are not limited to specific angles, and may be optionally set in accordance with the structure of the long scale hardened steel **2** and the shape of the work surface **3** under the condition that the CBN tools are arranged at positions so that the radial forces Fp thereof are cancelled by each other.

[0055] In the present invention, a plurality of tool rests **5** may be arranged to the guide device **6**. For example, a plurality of tool rests **5** are arranged along the longitudinal direction of the long scale hardened steel **2**. Then, as shown in **FIGS. 12 and 13**, first, the cutting operation through the first stage is carried out by moving the first tool rest **5***a*, then, the cutting operation through the second stage is carried out by moving the second tool rest **5***b*, next, the cutting operation throug the third stage is carried out by moving the third tool rest **5***c*, and thereafter, succeeding cutting operations are carried out in the same manner. As mentioned above, by successively feeding these plural tool rests from one side towards the other side in the longitudinal direction by the guide device **6**, the work surface **3** having a predetermined cutting margin can be cut in an extremely short time. Particularly, by mounting the plural CBN tools **7** mentioned hereinbefore to such tool rests **5**, work surfaces **3** of a plurality of works can be extremely efficiently cut, thus achieving remarkable effects.

[0056] In the present invention, it is preferred to linearly cut the work surface **3** of the long scale hardened steel **2** at a speed of about 30 m/min. to 160 m/min., and more preferably, to linearly cut it at a speed of about 80 m/min. to 120 m/min. The reason why the linear cutting speed is prescribed to such range resides in the relation to wearing amount of the CBN tool **7**, and in this range, the wearing of the CBN tool **7** less occurs. In the case of the linear cutting speed of less than about 30 m/min., the cutting resistance becomes large and heat amount to be transferred to the CBN tool **7** will be increased, and as a result, the wearing of the CBN tool **7** will be increased in amount and the cutting efficiency will be deteriorated. On the other hand, in the case of the linear cutting speed of more than about 160 m/min., the CBN tool **7** will be also much worn.

[0057] The long scale hardened steel **2**, which has been cut-worked into predetermined dimensions by cutting the predetermined cutting margin (i.e., cutting amount), is cut as it is or thereafter so as to form a linear rail or curved rail having a predetermined length. Further, although a range of the cutting margin is not generally mentioned because the range of the cutting margin relates to the hardness of the work surface **3** of the hardened steel and the number of cutting of the CBN tool **7** mentioned above. As the cutting margin capable of being cut one time with excellent cutting efficiency, the range is generally of 0.05 to 0.3 mm. In a case where the cutting margin is cut in two or more than two times, the cutting margin can be changed in every cutting operation as shown in **FIG. 8**. For example, the work surface **3** to be cut having the cutting margin of 0.7 mm will be cut with cutting margin of 0.3 mm (first time), 0.3 mm (second time), 0.05 mm (third time) and 0.05 mm (fourth time). According to the cutting method and cutting apparatus of the present invention, different from a wet-type cut-working in prior art, the cut-working can be advantageously performed by the dry-type system, but as occasion demands, water-soluble working solution may be utilized or pneumatic air may be also utilized.

[0058] As mentioned hereinabove, the long scale hardened steel **2** worked by the cutting method and cutting apparatus of the present invention can be preferably utilized as a guide rail of a rolling guide device. According to the present invention, it is also possible to cut the hardened steel by the predetermined amount of the cutting margin through one working operation, so that the cut-working time can be shortened in comparison with prior art in which the work surface is worked particularly through the cutting operation. In addition, in the cutting apparatus of the present invention, since the tool rest on which the CBN tool is mounted can be moved, the tool rest can be made light in weight based on its structure, and hence, a faster cutting speed such as mentioned above can be easily realized. Furthermore, by moving, at predetermined speed, the tool rest mounted with at least the CBN tool, the work surface of the long scale hardened steel placed on the fixing device can be cut-worked, so that the size or dimension of the apparatus itself and complicated control function of the apparatus can be eliminated. As a result, the cutting apparatus can be made compact in size and manufacturing cost thereof can be reduced.

[0059] A guide rail or like worked in accordance with such cutting method by using such cutting apparatus as mentioned above can be manufactured extremely efficiently, thus easily manufacturing the apparatus, producing a product having merit in cost and preferably providing it in market.

[0060] Hereunder, an experimental example will be described.

[0061] First, a round steel material for a linear motion rail of a rolling guide device (material corresponding to S55C, medium carbon manganese steel) was cold-rolled, and thereafter, hardened to thereby form a work material (worked member) having a desired surface hardness.

[0062] The work material was fixed on a fixing device by means of clamp and a CBN tool (Manufactured by De Beers as DBA80). On the cut working, any cutting solution was not used and dry-type process was adopted. As conditions for the cutting operation, a linear cut working was performed at a cutting speed of 60 m/min. by changing the cutting rate within a range of 0.1 to 0.5 mm with each cut-working being performed by single-pass.

[0063] The evaluation to the cutting workability was done by considering the condition of the CBN tool (visual observation of defect, wearing and like) and the condition of the worked surface (visual observation of gouge, chatter, roughness and like).

[0064] As a result, under the cutting condition mentioned above, no defect and wearing was observed to the CBN tool.

There caused no phenomenon providing a problem with respect to the worked surface condition.

[0065] (2) Rolling Guide Device

[0066] According to the cutting method and apparatus for cutting a long scale hardened steel of the present invention, a track table (i.e., guide rail) as a constitutional member of a rolling guide device is manufactured. Hereunder, a rolling guide device provided with such track table, will be explained.

[0067] **FIG. 14** shows one example of such rolling guide device. The rolling guide device **101** is composed of a track table **102** and a movable block (member) **104** through a number of spherical rolling members **103**, **103**, - - - , **103** interposed therebetween.

[0068] The track table **102** is manufactured according to the cutting method by using the cutting apparatus of the present invention of the characters mentioned hereinbefore, and in the embodiment shown in **FIG. 14**, the track rail **102** is a long scale member having approximately a rectangular section. On both the side surfaces of the track table **102**, respectively two rolling member rolling surfaces **105**, **105** - -, each having a circular cross section, for rolling the rolling members **103** are disposed along the entire length thereof. Further, the number of the rolling member rolling surfaces **105** is not limited to two rows, and one, three in bilateral combination, or four rows may be adopted. Such rolling member rolling surfaces **105** can be worked with high precision and efficiency by utilizing the CBN tools arranged in predetermined positions in accordance with the cutting method and apparatus of the present invention mentioned hereinbefore.

[0069] The movable block **104** is composed of a movable block body **120** having a gate shape of one surface in a direction perpendicular to the moving direction of the movable block **104** and lid members **121** provided at both end portions in the moving direction of the movable block **104**.

[0070] Four rows (each two rows) of rolling member rolling surfaces **106**, each having approximately a semi-circular shape in cross section, are formed to inside surfaces of the movable block body **120**, as shown in **FIG. 15**, so as to oppose to the rolling member rolling surfaces **106**, **106**, - - - , respectively. These rolling member rolling surfaces **105** and **106** constitute four loaded rolling passages are formed between the track table **102** and the movable block **104**. The movable block **104** is also formed with return passages **108**, **108**, - - - , each having a circular cross section, so as to extend from one end to the other end in the moving direction of the movable block **104**.

[0071] On the other hand, as shown in **FIG. 16**, each of the lid member **121** is formed with a direction changing passage, for changing the rolling direction of the rolling members, on a surface opposing to the movable block body **120** of the lid member **121** so as to communicate the loaded ball rolling passage **107** and the return passage **108**. These loaded rolling passage **107**, the return passage **108** and the direction changing passage **109** constitute the endless circulation passage **110** for endlessly rolling the rolling members **103**, **103**, - - - , **103**.

[0072] A number of spherical rolling members **103**, **103**, - - - , **103** are disposed in the endless circulation passage so as to provide a continuous bead-like form by means of connection member **111**. The connection member is composed of a number of spacers **111***a* disposed between the respective rolling members **103**, **103**, - - - , **103** and belt-like portions in form of thin plate disposed so as to connect the respective spacers **111***a* and hold them from their both sides to be rotatable.

[0073] The endless circulation passage **110** is also formed therein with connection member guide grooves **112**, **112** to which the belt like portions **112***b*, **112***b* are fitted to be slidable for slidably guiding the connection members **111** therein.

[0074] The rolling members **103**, **103**, - - - , **103** roll in the loaded rolling passage **107** from its one end towards its other end. Thereafter, the rolling members are scooped by the direction changing passage **107**, guided toward one end of the return passage **108** and then guided to other end of the other return passage **108**. Thereafter, the rolling members **103** are again guided to the loaded rolling passage **107** through the direction changing passage **109**. By repeating the above rolling motions, the rolling members **103**, **103**, - - - , **103** are moved and circulated in the endless circulation passage **110** in accordance with the movement of the movable block **104**. The track table **102** manufactured by the cutting method and apparatus of the present invention has the rolling member rolling surface **105** which can be worked with high performance by using the CBN tool, so that the rolling members **103**, **103**, - - - , **103** can be smoothly circulated in the endless circulation passage **110**.

[0075] Furthermore, as shown in **FIG. 14**, end plates **122**, **122** are attached to the outer side surfaces of the lid members **121**, **121**. Each of these end plates **122** has substantially gate-shape and is attached, by means of screws **124**, **124**, - - - , **124**, to the lid member **121**.

PROVABILITY OF INDUSTRIAL USAGE

[0076] According to the long scale hardened steel cutting method and cutting apparatus of the present invention, since the long scale hardened steel can be extremely efficiently cut, the present invention can be contributed to the efficient manufacturing of a guide rail by applying, for example, to the manufacturing of the guide rail of a rolling guide apparatus

1. An apparatus for cutting a long scale hardened steel, comprising a fixing device for fixing a long scale hardened steel, a tool rest which is guided by a guide device disposed along the longitudinal direction of the fixing device, and a CBN tool for cutting a work surface of the long scale hardened steel.

2. The apparatus for cutting a long scale hardened steel according to claim 1, wherein said tool rest is provided, to be detachable, with a holding member for holding the CBN tool.

3. The apparatus for cutting a long scale hardened steel according to claim 2, wherein said holding member is provided with a position adjusting means for adjusting a fixing position of the CBN tool.

4. The apparatus for cutting a long scale hardened steel according to any one of claims 1 to 3, wherein a plurality of CBN tools are arranged on a virtual plane normal to the longitudinal direction of the long scale hardened steel so as to provide linear symmetric or point symmetric fashion.

5. The apparatus for cutting a long scale hardened steel according to claim 4, wherein at least one pair of CBN tools for cutting the work surface of the long scale hardened steel are arranged so that radial forces of cutting resistance thereof are mutually balanced.

ROLLING ELEMENT INTERFERENCE PREVENTER AND A GUIDE DEVICE

BACKGROUND OF THE INVENTION

[0001] 1. Field of the Invention

[0002] The present invention relates to a rolling element interference preventer for a guide device, such as a linear guide device having an continuous circulation path for rolling elements, a swing bearing, a ball screw, and a spline. The rolling element interference preventer prevents the rolling elements rolling at regular intervals within the continuous circulation path formed between a pair of bearing races from interfering with each other.

[0003] 2. Description of the Related Art

[0004] In various rolling guide devices having a bearing, a linear motion or rotation of a pair of bearing races is enabled by use of the rolling motion of rolling elements consisting of balls or rollers carried between the bearing races. To reduce the frictional resistance by avoiding the contact between each rolling element and to produce the smooth motion by arranging each rolling element at predetermined position, it is common practice that a number of rolling elements are incorporated between bearing races, using a metallic retainer.

[0005] In the conventional guide device using the metallic retainer, since a cage has a number of pockets and rolling elements are put rotatably into these pockets, there is an advantage that the operation of incorporating a number of rolling elements into the guide device is facilitated. However, it is required to hold a number of rolling elements incorporated into the pockets of the cage not to fall off, resulting in a problem that it takes a lot of time to fabricate the cage itself.

[0006] Thus, to solve this problem, a ball interference preventer (rolling element interference preventer) for use in a guide device to prevent interference between each ball has been proposed. The endless guide device includes a track rail having a rolling path, a sliding board having a rolling groove mutually opposed to the rolling path and moving along the track rail, and a number of balls (rolling elements). With a load applied, the balls roll in a continuous circulation path formed between the rolling path of the track rail and the rolling groove of the sliding board. The ball interference preventer is composed of a flexible resin connector having an interposing portion interposed between each ball and a connecting portion for connecting between the interposing portions, and holding each ball in an arranged state and rollably. Thereby, many appreciable results were achieved including 1) attaining low noise and good sound quality by removing the metallic sound due to collision between the balls (low noise), 2) reducing the wear of ball and increasing the retention of grease (maintenance free for long term), 3) attaining excellent high speed by decreasing the relative friction velocity (high speed), and 4) smoothing the motion by greatly reducing the roiling fluctuation (sliding property) (JP-B-6-56181, JP-A-5-52217, JP-A-5-126149, JP-A-5-196036, JP-A-5-196037, and JP-A-9-14264).

[0007] By the way, thus structured ball interference preventer composed of the resin connector is immersed in, or subjected to grease, lubricating oil, or coolant in the environment where the preventer is incorporated in the circulation path for the rolling guide device. Also, the ball interference preventer undergoes actions such as bending, tension, compression, twisting, or contact friction with the ball at any time. When reciprocated in the circulation path at high speed, this ball interference preventer undergoes an operation of bending, tension and compression severely and repeatedly. Further, when the ball interference preventer composed of the resin connector is immersed in, or subjected to grease, lubricating oil, or coolant, it absorbs water and oil to swell, causing a circulation failure in the circulation path and ablation of the preventer, and degrading the durability, sliding property and wear resistance.

[0008] Therefore, the rolling element interference preventer composed of the resin connector is required to have the excellent chemical strength of oil resistance, water resistance, and chemical resistance to the grease, lubricating oil and coolant, in addition to the mechanical strength of durability, sliding property and wear resistance. In view of the life of the guide device, it is required to be so durable and resistant to wear as to run about 30,000 km or more, with small sliding resistance variation, as well as resistant to oil, water and chemicals.

[0009] Moreover, the rolling element interference preventer composed of the resin connector was not too problematical in that an unnatural load was applied only on a part of the resin connector during the use, because the minimum radius of curvature for the continuous circulation path formed in the guide device was relatively large, the ball was employed as the rolling element, and the shape of the resin connector was devised. In recent years, however, the guide device is demanded for smaller size and higher speed, and the roller is employed as the rolling element, resulting in a problem that the durability, wear resistance and sliding property may be impaired.

SUMMARY OF THE INVENTION

[0010] The present inventors made researches to attain more excellent durability and wear resistance without impairing various features (low noise, maintenance free for long term, high speed, and sliding property) of the rolling element interference preventer, especially when subjected to severe and repetitive actions of bending, tension and compression, and found that the rolling element interference preventer should be produced using a thermoplastic resin elastomer having specific balance (relation) for a 10% elongation stress, a tensile stress and a bending modulus of elasticity to achieve the aim, thus completing this invention.

[0011] Accordingly, it is an object of the invention to provide a rolling element interference preventer for a guide device, which prevents a number of rolling elements rolling at regular intervals in a continuous circulation path of the guide device from interfering with each other. The rolling element interference preventer is not only excellent in low noise, maintenance free for long term, high speed and sliding property, but also excellent in durability and wear resistance, and can be used stably over the long term.

[0012] The present invention provides a rolling element interference preventer for a guide device to prevent a number of rolling elements rolling at regular intervals in a continuous circulation path of the guide device from interfering with each other, wherein the rolling element interference preventer is formed of a thermoplastic resin elastomer having a physical property in accordance with an expression, $(A\times B)\div C\geqq 18$, where A is a 10% elongation stress, B is a tensile strength, and C is a bending modulus of elasticity.

[0013] As the thermoplastic resin elastomer, polyamide resin elastomer, polyester resin elastomer, polyurethane resin elastomer, styrene resin elastomer, and olefine resin elastomer are exemplified. They should be highly resistant to oil, water and chemicals in the service environment of the rolling guide device, especially in the service environment where the guide device is immersed in, or subjected to grease, lubricating oil, or coolant. The coefficient of water absorption measured in the environment of equilibrium moisture percentage 23° C., 65% RH is 1.5 wt % (% by weitht) or less, and preferably 0.5 wt % or less. The swelling factor measured in an immersion test of chemical at a temperature of 85° C. for 672 hours is 3% or less. Furthermore, the tensile strength retention in an immersion test of boiling water at 100° C. is 70% or more after ten days, and preferably 80% or more.

[0014] In this invention, the thermoplastic resin elastomers satisfying a physical property in accordance with the expression, $(A\times B)\div C\geqq 18$ (A: 10% elongation stress, B: tensile strength, and C: bending modulus of elasticity) are employed. Though slightly different depending on the type of the rolling guide device and whether the rolling element is a ball or a roller, the 10% elongation stress A is from 60 to 200 kgf/cm^2, and preferably from 90 to 160 kgf/cm^2, the tensile strength B is from 340 to 460 kgf/cm^2, and preferably from 360 to 430 kgf/cm^2, and the bending modulus of elasticity C is from 1000 to 5000 kgf/cm^2, and preferably from 1200 to 2700 kgf/cm^2.

[0015] If the 10% elongation stress of the thermoplastic resin elastomer is not less than 60 kgf/cm^2, the shape of the rolling element interference preventer is maintained against a centrifugal force acting on the rolling element of the guide device in the fast operation, resulting in that the sliding resistance decreases in the continuous circulation path of the guide device. On the contrary, if it is not more than 200 kgf/cm^2, a problem of flexure fatigue failur is prevented. If the tensile strength is not less than 340 kgf/cm^2, the durability is increased, or conversely if it is not more than 460 kgf/cm^2, the problem of flexure fatigue failure is prevented. Moreover, if the bending modulus of elasticity is not less than 1000 kgf/cm^2 and not more than 5000 kgf/cm^2, the sliding property is increased.

[0016] Herein, it is needed that the guide device for use with the rolling element interference preventer of the invention has a pair of bearing races, and the continuous circulation path for the rolling elements rolling with a load applied between the pair of bearing races, and the guide device may be a linear guide device for endless track, a swing bearing, a ball screw, and a spline, for example.

[0017] And the rolling element interference preventer of this invention can take various forms, depending on the type of guide device to which it is applied. For example, in a case where the guide device is a linear guide device for endless track having a track rail (one bearing race) having a rolling path, a sliding board (other bearing race) having a rolling groove mutually opposed to the rolling path and moving along the track rail, and a number of rolling elements rolling with a load applied between the rolling path of the track rail and the rolling groove of the sliding board, it is preferred that the rolling element interference preventer consists of a flexible resin connector having an interposing portion interposed between each rolling elements, and a connecting portion for connecting each interposing portions, and preferably can hold a number of rolling elements rollably by the interposing portions and the connecting portion.

[0018] Moreover, in the case where the rolling element interference preventer is made up of this flexible resin connector, the resin connector may be provided with a chamfer guide portion at either terminal end to guide the top end portion of the resin connector, whereby when the guide device is moved in the continuous circulation path, especially when the top end portion of the rolling element interference preventer enters a direction converting path of the circulation path, or exits from the direction converting path, the top end portion is guided to move the guide device smoothly. By forming the chamfer guide portion at either terminal end of the resin connector, the rolling element interference preventer can be guided smoothly in any of forward and backward directions in the reciprocating motion of the guide device.

[0019] The length of the rolling element interference preventer to be molded is decided in consideration of the length of the circulation path for the guide device using it. However, if the guide device is increased in size and the length of circulation path is great, the rolling element interference preventer may be divided into two or three for molding, whereby the size of mold can be reduced. In this case, each resin connector constituting each of two or three parts divided from the rolling element interference preventer is formed with a chamfer guide portion at either terminal end.

[0020] In the case where the rolling element interference preventer of the invention is applied to the linear guide device for endless track, if the rolling elements are balls, the thermoplastic resin elastomer forming the resin connector has the properties that the 10% elongation stress A is from 60 to 150 kgf/cm^2, and preferably from 90 to 130 kgf/cm^2, the tensile strength B is from 340 to 400 kgf/cm^2, and preferably from 350 to 380 kgf/cm^2, and the bending modulus of elasticity C is from 1000 to 2000 kgf/cm^2, and preferably from 1200 to 1800 kgf/cm^2. By employing the values in the above ranges for the 10% elongation stress A, tensile strength B and bending modulus of elasticity C, the ball interference preventer can exhibit the excellent and balanced performances (low noise, maintenance free for long term, high speed, sliding property, durability and wear resistance).

[0021] In the case where the rolling element interference preventer of this invention is applied to the linear guide device for endless track, if the rolling elements are rollers, the thermoplastic resin elastomer forming the resin connector has the properties that the 10% elongation stress A is from 80 to 200 kgf/cm^2, and preferably from 100 to 1160 kgf/cm^2, the tensile strength B is from 380 to 460 kgf/cm^2, and preferably from 430 to 460 kgf/cm^2, and the bending modulus of elasticity C is from 1500 to 5000 kgf/cm^2, and preferably from 2000 to 4000 kgf/cm^2. By employing the values in the above ranges for the 10% elongation stress A, tensile strength B and bending modulus of elasticity C, the roller interference preventer can exhibit the excellent and balanced performances (low noise, maintenance free for long term, high speed, sliding property, durability and wear resistance).

[0022] Moreover, in the case where the guide device is a ball screw having a screw axis (one bearing race) with a helical rolling path for a ball, a nut (other bearing race) with a helical rolling groove mutually opposed to the helical rolling path, and a number of balls rolling with a load applied between the helical rolling path of the screw axis and the helical rolling groove of the nut, the ball interference preventer may be the resin connector like that of the linear guide device for endless track, or a spacer interposed between each balls.

[0023] The rolling element interference preventer of this invention can be produced by conventional well-known methods, using the thermoplastic resin elastomer as described above. For example, in a case where the rolling element interference preventer is made up of the resin connector, a number of rolling elements can be produced as a core by injection molding or a so-called insert molding (as described in JP-A-6-56181, JP-A-5-52217, JP-A-5-126149, JP-A-5-196036, JP-A-5-196037, and JP-A-9-14264), or other methods.

BRIEF DESCRIPTION OF THE DRAWINGS

DETAILED DESCRIPTION OF THE PREFFERD EMBODIMENTS

[0042] The preferred embodiments of the present invention will be described below with reference to the accompanying drawings.

[0043] First Embodiment

[0044] FIGS. **1** to **6** show a roller interference preventer RC according to a first embodiment of the invention and a linear sliding roller bearing having incorporated the roller interference preventer RC.

[0045] This roller interference preventer RC includes a flexible resin connector **12** having interposing portions **12***a* interposed between each of a number of rollers **11** made of bearing steel (SUJ2) disposed at regular intervals, and a pair of connecting portions **12***b* connecting each interposing portions **12***a*, and carrying a number of rollers **11** in linear state and rollably, as shown particularly in FIGS. **3** to **6**. At either terminal end of the resin connector **12**, a chamfer guide portion **13** having an almost similar shape of a roller **11***a* is formed to surround the roller **11***a* located at the terminal end, as shown in **FIG. 6**.

[0046] The linear sliding roller bearing having incorporated the roller interference preventer RC fundamentally includes a metallic track rail (one bearing race) **14** having rigidity, a metallic sliding board (other bearing race) **15** having rigidity, a roller guide member **16** made of synthetic resin and attached in a hole **15***b* punched along the longitudinal direction in the sliding board **15**, a lid **17** made of synthetic resin and attached on the sliding board **15** together with the roller guide member **16**, and a number of rollers **11** carried like a chain by the resin connector **12**, as shown in **FIGS. 1 and 2**.

[0047] In this first embodiment, the track rail **14** is formed with a plain surface-like rolling path **14***a* for the roller **11** at either shoulder portion, and the sliding board **15** is formed with a load roller rolling path **15***a* for the roller **11** applying a load. Further, the roller guide member **16** is formed with a no-load roller guide bore **16***a* for guiding the roller **11** to roll in no-load state, and the lid **17** is formed with a direction converting path, not shown, constituting the continuous circulation path of the roller **11** by linking the load roller rolling path **15***a* of the sliding board **15** and the no-load roller guide bore **16***a* of the roller guide member **16**.

[0048] Second Embodiment

[0049] **FIG. 7** shows a roller interference preventer RC according to a second embodiment of the invention. This roller interference preventer RC includes of a flexible resin connector **22** having plate-like interposing portions **22***a* interposed between each of a number of rollers **21** made of bearing steel (SUJ2) disposed at regular intervals, and a pair of connecting portions **22***b* connecting each interposing portions **22***a* on either side of the roller **21**, and arranging a number of rollers **21** in linear state and rollably. At either terminal end of the resin connector **22**, a chamfer guide portion **23** having a semi-cylindrical shape and the almost same radius of curvature as the roller **21***a* is formed.

[0050] The roller interference preventer RC according to the second embodiment does not carry the rollers **21** by using the resin connector **22**, but is incorporated into the continuous circulation path of the linear sliding roller bearing in the same manner as the roller interference preventer RC of the first embodiment, whereby the rollers **21** are prevented from contacting and interfering with each other.

[0051] Third Embodiment

[0052] FIGS. **8** to **11** shows a ball interference preventer BC according to a third embodiment of the invention. This ball interference preventer BC includes of a flexible resin connector **32** having interposing portions **32***a* interposed between each of a number of balls **31** made of bearing steel (SUJ2) disposed at regular intervals, and a pair of connecting portions **32***b* for connecting each interposing portions **32***a*, and carrying a number of balls **21** in linear state and rollably. At either terminal end of the resin connector **32**, a chamfer guide portion **33** having the almost same shape as the ball **31***a* is formed to surround the ball **31***a* located at the terminal end.

[0053] This ball interference preventer BC is also incorporated into the continuous circulation path of the linear sliding ball bearing in the same manner as the roller interference preventer RC of the first embodiment.

[0054] Fourth Embodiment

[0055] FIGS. **12** to **15** show a ball interference preventer BC according to a fourth embodiment of the invention and a ball screw BS with the ball interference preventer BC incorporated.

[0056] This ball interference preventer BC includes a number of spacers **42** having a spherical concave portion **42***a* for receiving a ball **41** partly on the front face and the rear face. The ball interference preventer BC is incorporated into a continuous circulation path of the ball screw including a screw axis (one bearing race) **44** having a helical rolling path **44***a* for the ball **41**, a nut (other bearing race) **45** with a helical rolling groove **45***a* mutually opposed to the helical rolling path, and a number of balls **41** rolling between the helical rolling path **44** of the screw axis **44** and the helical rolling groove **45***a* of the nut **45** with a load applied, and is placed between adjacent balls **41** to prevent the balls **41** from contacting and interfering with each other.

[0057] In this fourth embodiment, the nut **45** has a return pipe **46** of almost U-character shape attached on a clamp face **45***b* formed by cutting away a part of the outer circumferential portion. Both end portions of the return pipe **46** penetrate through a peripheral wall of the nut **44** to open into the helical rolling groove **45***a* mutually opposed to the helical rolling path **44***a* of the screw axis **44**. Further, at either end, ball pickup portions **46***a* are formed to pick up the balls **41** rolling between the helical rolling path **44***a* and the helical rolling groove **45***a* with a load applied into the return pipe **46**, and to feed the balls **41** rolling through the return pipe **46** to between the helical rolling path **44***a* and the helical rolling groove **45***a*. The continuous circulation path of the ball **41** is made up of the screw axis **44**, the nut **45** and the return pipe **46**.

[0058] The spacer **42** constituting the ball interference preventer BC of the fourth embodiment is located between adjacent balls **41** incorporated into the continuous circulation path of the ball screw, circulates in this circulation path together with the balls **41**, and prevents the balls **41** from contacting and interfering with each other.

[0059] Fifth Embodiment

[0060] FIGS. **16** to **18** show a ball interference preventer BC incorporated into a ball screw BS in the same manner as in the fourth embodiment of the invention.

[0061] This ball interference preventer BC, unlike that of the fourth embodiment but like that of the third embodiment, includes a flexible resin connector **52** having interposing portions **52***a* interposed between each of a number of balls **51** disposed at regular intervals, and a connecting portion **52***b* connecting each interposing portions **52***a*, and carrying a number of balls **51** rollably. At either terminal end of the resin connector **52**, there is formed a chamfer guide portion **53** to surround the ball **51***a* located at the terminal end.

[0062] In FIGS. **16** to **18**, the ball rolling groove **54***a* is formed in the screw axis **54**, and the no-load rolling groove **55***a* is formed in the nut **55**. Further, a deflector **56** attached to the nut **54** and forming the continuous circulation path between the screw axis **54** and the nut **55** is formed with a ball return groove **56***a*, whereby a number of balls connected by the resin connector **52** can roll in the circulation path formed by the ball rolling groove **54***a* of the screw axis **54**, the no-load rolling groove **55***a* of the nut **55**, and the ball return groove **56***a* of the deflector **56**, with a load applied.

[0063] This ball interference preventer BC of the fifth embodiment prevents the balls **51** from contacting and interfering with each other, like the ball interference preventer BC of the fourth embodiment.

EXAMPLES

[0064] The present invention will be described below more specifically on the basis of some experimental examples (examples and comparative examples).

Experimental Examples 1 to 4

[0065] Using polyester resin elastomer (trade name Perplene EN1000, EN2000, EN3000 and EN5000 made by TOYOBO Co., Ltd.) as listed in Table 1 as the thermoplastic resin elastomer, 75 rollers made of bearing steel (SUJ2) as large as 4 mmϕ×7 mm were produced as a core by injection molding, and released from the mold, together with a number of rollers, thereby molding the roller interference preventer having a length of about 340 mm and a shape as shown in FIGS. **3** to **6** for the first embodiment.

[0066] The obtained roller interference preventer of each of experimental examples 1 to 4 was investigated for the durability, sliding property, wear resistance, water absorptivity, swelling property and water resistance.

[0067] The results are listed below in Table 1.

[0068] Durability

[0069] As shown in **FIGS. 1 and 2**, the roller interference preventer of each of experimental examples 1 to 4 was incorporated into the continuous circulation path of the linear sliding roller bearing, with its track rail fixed, and the sliding board was reciprocated under the conditions with a speed f of 200 m/min, a stroke St of 2500 mm, and acceleration **1**G. The durability was evaluated at three levels, in which ○ indicates no abnormality after running 30,000 km, Δ indicates some damage in part after running 30,000 km but no abnormality for running, and x indicates abnormality such as breakage after running less than 30,000 km.

[0070] Sliding property

[0071] In the same manner as the measurement of durability, the roller interference preventer of each of experimental examples 1 to 4 was incorporated into the continuous circulation path of the linear sliding roller bearing, with its track rail fixed, and the sliding board was pushed by a load cell to measure the rolling resistance of the sliding board in the track rail at a sampling frequency of 500 Hz for this load cell. The sliding property was evaluated at three levels, in which ○ is suitable for service because the resistance variation is 25% or less of the rolling resistance, Δ is usable for service though the resistance variation is beyond 25% of the rolling resistance in part, and x is unusable because the resistance variation is totally beyond 25% of the rolling resistance.

[0072] Wear resistance

[0073] In the same manner as the measurement of durability, the roller interference preventer of each of experimental examples 1 to 4 was incorporated into the continuous circulation path of the linear sliding roller bearing, with its track rail fixed, and the sliding board was reciprocated under the conditions with a speed f of 200 m/min, a stroke St of 2500 mm, and acceleration **1**G to measure the wear amount at the top end corner of the resin connector for the roller interference preventer. The wear resistance was evaluated at three levels, in which ○ is no abnormality in wear, Δ is some initial wear but no progressive wear, and x is progressive wear at the top end while running to lead to breakage.

[0074] Water absorptivity

[0075] Using four kinds of polyester resin elastomer employed in each of the experimental examples 1 to 4 as listed in Table 1, a dumbbell specimen of JIS 3 type was produced in conformance with JIS K6251, and the size variation of the dumbbell specimen was measured in the environment of equilibrium moisture percentage 23° C., 65% RH, and the water absorptivity was evaluated at three levels in which ○ is 0.5% or less, Δ is from 0.5% to 1.5%, and x is more than 1.5%.

[0076] Swelling property

[0077] In the same manner as the test of water absorptivity, a dumbbell specimen of JIS 3 type was produced, and the dumbbell specimen was immersed in the test oil at a temperature of 85° C. for 672 hours, employing synthetic coolant (Synthylo made by Castorol), soluble coolant (Microcut 3850-LH made by Japan Quakerchemical), and emulsion coolant (Yushiroken EC50T-3 made by Yushiro Chemical Industries) as test oils, and using an environmental test machine (made by KATO: SSE740RA). The swelling factor was calculated from the values of size variation of the dumbbell specimen due to swelling and evaluated at three levels in which ○ is 1.5% or less, Δ is from 1.5% to 3%, and x is more than 3%.

[0078] Water resistance

[0079] In the same manner as the test of water absorptivity and swelling property, a dumbbell specimen of JIS 3 type was produced, and immersed in the boiling water at 100° C. for ten days to measure the tensile strength change (tensile strength: 500 mm/min) of the dumbbell specimen. The tensile strength retention was calculated from this tensile strength change, and evaluated at three levels in which ○ is the tensile strength retention of 80% or more after ten days, Δ is the tensile strength retention from 70% to 80% after ten days, and x is the tensile strength retention of less than 70% after ten days.

Experimental Examples 5 to 9

[0080] Using polyester resin elastomer (trade name Perplene EN1000, EN2000, EN3000 and EN5000 made by TOYOBO Co., Ltd.) as listed in Table 2 as the thermoplastic resin elastomer, a 10% elongation stress a of 54 kgf/cm^2, a tensile strength b of 220 kgf/cm^2, a bending modulus of elasticity c of 1100 kgf/cm^2, $(A \times B) \div C = 10.8$), 34 balls made of bearing steel (SUJ2) as large as 3.969 mmϕ were produced as a core by injection molding, and released from the mold, together with a number of balls, thereby molding the ball interference preventer with a shape as shown in FIGS. **8** to **11**.

[0081] The obtained ball interference preventer of each of experimental examples 5 to 9 was investigated for the durability, sliding property, wear resistance, water absorptivity, swelling property and water resistance in the same manner as in the previous experimental examples 1 to 4.

[0082] The results are listed below in Table 2.

[0083] With the rolling element interference preventer of the invention, in the guide device incorporating it, it is possible to exhibit the excellent low noise, maintenance free for long term, high speed and sliding property, and at the same time, the excellent durability and wear resistance, whereby the guide device can be stably employed over long term to deal with the reduction in size and increase in speed.

What is claimed is:

1. A rolling element interference preventer for a guide device having a continuous circulation path and a plurality of rolling elements rolling at regular intervals in the continuous circulation path, wherein the rolling element interference preventer prevents the rolling elements from interfering with each other, and

wherein the rolling element interference preventer is formed of a thermoplastic resin elastomer having a physical property in accordance with an expression, $(A\times B)\div C \geqq 18$, where A represents a 10% elongation stress, B represents a tensile strength, and C represents a bending modulus of elasticity.

2. The rolling element interference preventer according to claim 1, wherein the thermoplastic resin elastomer has the 10% elongation stress A of 60 to 200 kgf/cm^2, the tensile strength B of 340 to 460 kgf/cm^2, and the bending modulus of elasticity C of 1000 to 5000 kgf/cm^2.

3. The rolling element interference preventer according to claim 1, wherein a coefficient of water absorption for the thermoplastic resin elastomer is not more than 1.5 wt %.

4. The rolling element interference preventer according to claim 1, wherein a swelling factor of the thermoplastic resin elastomer is not more than 3%.

5. The rolling element interference preventer according to claim 1, wherein a tensile strength retention of the thermoplastic resin elastomer is not less than 70% after ten days in 100° C. boiling water immersion test.

6. A guide device comprising:

a track rail having a rolling path;

a sliding board having a rolling groove opposed to the rolling path and moving along the track rail;

a plurality of rolling elements rolling with a load applied between the rolling path and the rolling groove; and

a rolling element interference preventer including a flexible resin connector having a plurality of interposing portions interposed between each rolling elements, and a connecting portion for connecting each interposing portions,

wherein the rolling element interference preventer is formed of a thermoplastic resin elastomer having a physical property in accordance with an expression, $(A\times B)\div C \geqq 18$, where A represents a 10% elongation stress, B represents a tensile strength, and C represents a bending modulus of elasticity.

7. The guide device according to claim 6, wherein the resin connector carries the rolling elements in an arranged state and rollably by the interposing portions and the connecting portion.

8. The guide device according to claim 6, wherein the rolling elements are balls, and the thermoplastic resin elastomer has the 10% elongation stress A of 60 to 100 kgf/cm^2, the tensile strength B of 340 to 400 kgf/cm^2, and the bending modulus of elasticity C of 1000 to 2000 kgf/cm^2.

9. The guide device according to claim 6, wherein the rolling elements are rollers, and the thermoplastic resin elastomer has the 10% elongation stress A of 80 to 200 kgf/cm^2, the tensile strength B of 380 to 460 kgf/cm^2, and the bending modulus of elasticity C of 2000 to 5000 kgf/cm^2.

10. A guide device comprising:

a screw axis having a helical rolling path;

a nut having a helical rolling groove opposed to the helical rolling path;

a plurality of balls rolling between the helical rolling path and the helical rolling groove; and

a boll interference preventer,

wherein the ball interference preventer comprises a plurality of spacers interposed between each balls, and wherein the ball interference preventer

is formed of a thermoplastic resin elastomer having a physical property in accordance with an expression, $(A \times B) \div C \geqq 18$, where A represents a 10% elongation stress, B represents a tensile strength, and C represents a bending modulus of elasticity.

(57) ABSTRACT

A motion guide device is provided with a rolling member connection belt for holding a series of rolling members which circulate in a circulation passage provided with a loaded rolling passage, a non-loaded return passage and a pair of rolling direction changing members connecting the loaded rolling passage and the non-loaded return passage to thereby constitute the circulation passage. The rolling member connection belt is formed from a metal plate member having a corrugated-shape, in section in a longitudinal direction thereof, formed at least to one portion thereof or entire portion thereof in the longitudinal direction, and the corrugated-shape has peak and valley portions each extending in a direction normal to the longitudinal direction of the metal plate member.

ROLLING MEMBER CONNECTION BELT AND MOTION GUIDE DEVICE PROVIDED WITH SAME

BACKGROUND OF THE INVENTION

[0001] 1. Field of the Invention

[0002] The present invention relates to a connection belt connecting rolling members for holding the rolling members, to be rotatably, rolling along a path defined by a track member and a movable member of, for example, a linear guide, ball spline and the like and also relates to a motion guide device provided with such rolling member connection belt.

[0003] 2. Related Art

[0004] A linear guide is generally composed of a track rail, a movable block assembled to the track rail to be movable relative to the track rail and a number of balls as rolling members disposed between the track rail and the movable block.

[0005] **FIG. 8** shows one example of such linear guide, in which balls **1** roll in a passage or path defined by the track rail **2** and the movable block **3** and are scooped up by an end cap **4** at each of the end portions of the movable block **3**. The balls **1** then roll in a ball return passage **5** formed in the movable block **3** and return to the ball rolling passage formed between the track rail **2** and the movable block **3** through another end cap **4** formed at the other end portion of the movable block **3**.

[0006] A rolling member retainer is a member for holding and retaining the balls **1** so that the balls **1** roll and move smoothly in the ball rolling passage without contacting to each other.

[0007] In a linear guide provided with a separate-type retainer, a plurality of retainers each disposed between the balls are arranged independently, i.e., separated from each other in arrangement.

[0008] On the other hand, in a linear guide provided with a connection-type retailer, as shown in **FIG. 9, a** plurality of retainers **6**, **6**, - - - disposed between the balls **1** are connected by a belt **7**. Each of these retailers **6** is disposed between adjacent balls **1** to thereby prevent the balls **1** from contacting each other. In such connection-type retainer, the balls **1** can be guided in the ball advancing direction with a constant distance being maintained between the adjacent balls **1**, thus the movable member being smoothly moved.

[0009] In general, such retainer for the rolling members (which may be called hereinlater merely "retainer") is manufactured through an injection molding process using a resin material such as elastomer. In the connection-type retailer, it has been required to make compact the retainer according to recent requirement of compact-sized linear guide. However, in the structure made to satisfy such requirement for compactness, there may often causes short-circuited and, moreover, it becomes difficult to carry out the injection molding. In addition, it is also difficult to ensure high strength at the connection portion of the retainer and the belt therefor.

[0010] In order to solve the defects or inconvenience described above, the applicant of the subject application has provided a rolling member retainer manufactured through a pressing working of a metal plate member such as disclosed in Japanese Patent Laid-open (KOKAI) Publication No. 2000-65053, in which the rolling member retainer made from the metal material is formed with a number of ball retaining (holding) holes at a predetermined distance between the adjacent ones and the ball is retained in each of the ball retaining holes to be rotatable.

[0011] Generally, as shown in **FIG. 8, a** circulation passage of a linear guide through which the balls circulates has a circuit structure configured such that a loaded rolling passage and a non-loaded return passage, both extending linearly, are connected, at both end portions, by a pair of U-shaped rolling direction changing passages. Because of such structure, the rolling member retainer circulates in the circulation passage in the linearly extending fashion in the loaded rolling passage and non-loaded return passage and also in the bent fashion in U-shape in the direction changing passages. The rolling member retainer is moved and circulated while repeatedly taking the above fashions in the circulation passage.

[0012] In the above meaning, if the rolling member retainer is made of metal material, there may cause a case that the retainer are not sufficiently bent in the desired shape during the circulating motion in the direction changing passages, and hence, the smooth circulation of the rolling members therein may be obstructed.

SUMMARY OF THE INVENTION

[0013] An Object of the present invention is therefore to substantially eliminate defects or inconveniences encountered in the prior art described above and to provide a rolling member connection belt made of metal material, for holding rolling members, capable of being bent with flexibility, during the circulation of corner portions in a circular passage.

[0014] Another object of the present invention is to provide a motion guide provided with such rolling member connection belt.

[0015] The above and other objects can be achieved according to the present invention by providing, in one aspect, a rolling member connection belt for holding, to be rotatable, a series of rolling members which circulate in a circulation passage provided with a loaded rolling passage composed of a rolling member rolling portion formed on a track member and another rolling member rolling portion formed on a movable member, a non-loaded return passage formed in the movable member and a pair of rolling direction changing members connecting the loaded rolling passage and the non-loaded return passage to thereby constitute the circulation passage,

> [0016] the rolling member connection belt being made of a metal plate member having a corrugated-shape, in section in a longitudinal direction thereof, formed at least at a portion in the longitudinal direction, the corrugated-shape having peak and valley portions each extending in a direction normal to the longitudinal direction of the metal plate member.

[0017] In a further aspect of the present invention, there is also provided a motion guide device comprising:

[0018] a track member formed with a rolling member rolling portion;

[0019] a movable member formed with another rolling member rolling portion and assembled to the track member to be rotatable relatively thereto;

[0020] a number of rolling members which circulate in a circulation passage provided with a loaded rolling passage composed of both the rolling member rolling portions formed on the track member and the movable member, a non-loaded return passage formed in the movable member and a pair of rolling direction changing members connecting the loaded rolling passage and the non-loaded return passage to thereby constitute the circulation passage; and

[0021] a rolling member connection belt holding the rolling members to be rotatable in the circulation passage,

[0022] the rolling member connection belt being made of a metal plate member having a corrugated-shape, in section in a longitudinal direction thereof, formed at least at a portion in the longitudinal direction, the corrugated-shape having peak and valley portions each extending in a direction normal to the longitudinal direction of the metal plate member.

[0023] According to the above aspects, the connection belt member has a good flexibility even formed from a metal plate, so that the rolling member connection belt can smoothly circulate in a circuit-shaped rolling member circulation passage. Furthermore, since the rigidity of the rolling member connection belt in its width direction is increased, the rolling members can sufficiently be suppressed from wandering during its circulation motion. Moreover, the moving (rolling) speed of the rolling member may be changed at the time when the rolling member moves from the non-loaded area to the loaded area or vise versa. Such speed changing can be effectively absorbed by forming the connection belt with corrugated peak-and-valley portions which extend in its width direction thereof and are flexible (contractable) in its longitudinal direction. Accordingly, the rolling member can be smoothly moved from the non-loaded area to the loaded area, thus being advantageous.

[0024] Furthermore, in preferred embodiments of the above aspects, the metal plate member is provided with a number of rolling member holding holes formed along the longitudinal direction thereof and a plurality of sets of peak-and-valley portions exist in each of the rolling member holding holes.

[0025] The rolling member holding hole is provided, at peripheral portions thereof, with a plurality of claw portions so as to surely hold the rolling member in the hole.

[0026] The peak-and-valley portions may be formed along an entire longitudinal direction of the connection belt.

[0027] According to these preferred embodiments, the rolling members can be held by the plural sets of peak-and-valley portions (corrugated structure) in the accommodation hole, so that the rolling members can be more surely held in comparison with the conventional structure in which the rolling members are supported by a flat-plate shaped connection belt member.

[0028] The natures and further characteristic features of the present invention will be made more clear from the following descriptions made with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

[0029] In the accompanying drawings:

[0030] **FIG. 1** is a perspective view showing a linear guide provided with a rolling member connection belt as a retainer according to one embodiment of the present invention;

[0031] **FIG. 2** is a sectional view, in a longitudinal direction, of a track rail of the linear guide of **FIG. 1**;

[0038] **FIG. 9** is a sectional view of the conventional linear guide showing a ball circulation state.

DESCRIPTION OF THE PREFERRED EMBODIMENT

[0039] Preferred embodiments of the present invention will be described in detail hereunder with reference to the accompanying drawings.

[0040] **FIG. 1** shows a linear guide **11** to which a rolling member connection belt as a retainer according to the present invention is assembled. The linear guide **11** is a motion guide device for guiding a linear or curvilinear motion of a member, such as table. The linear guide **11** is composed of a track rail **12** as a track member and a movable block **13** as a movable member which is assembled to be movable relative to the track rail **12**. The movable block **13** is mounted, as an object member for guidance, to the track rail **12**. A number of balls **14**, **14** - - - , as rolling members, are disposed between the track rail **12** and the movable member **13** to be rollable.

[0041] The track rail **12** has a linearly extending structure in the longitudinal direction thereof and having, for example, a rectangular section. The track rail **12** is formed with plural rows of ball rolling grooves **12*a***, **12*a*** - - - , as rolling member rolling portion, forming a track for the rolling of the balls **14**, **14**, - - - . Such track rail **12** is manufactured through machine workings including drawings, cutting, grinding and so on. Further, in a case where a curvilinear motion of an object member is guided, a track rail **12** having a curved structure will be utilized.

[0042] The movable block **13** entirely has a straddle-type structure having substantially ⊐-shaped cross-section, and the movable block **13** is composed of a movable block body **16** and end plates **17** and **18** disposed at both ends of the block body **16**. This movable block body **16** is provided with a flat horizontal portion **16***a* opposing to the upper surface of the track rail **12** and a pair of leg (skirt) portions **16***b* facing both side surfaces of the track rail **12** when the movable block **13** is assembled to the track rail **12**.

[0043] The lateral pair of leg portions **16***b* have inside surface portions formed with loaded ball rolling grooves **20**, as rolling member rolling portions, corresponding to ball rolling grooves **12***a* formed on the respective side surfaces of the track rail **12**. The lateral pair of leg portions **16***b* are also formed with ball return passages A, as rolling member returning passages, for returning the balls **14** rolling along the loaded ball rolling grooves **20** in parallel thereto. The ball returning passage A has substantially a circular section having an inner diameter slightly larger than that of the ball **14**.

[0044] Each of the end plates **17** and **18** has a sectional shape substantially identical to the cross-sectional shape of the movable block body **16**. As shown in **FIG. 2, a** rolling member rolling direction changing passage having U-shape is formed at each end portion of the movable block body **16** for guiding the balls **14** by scooping up the balls **14** rolling along the loaded ball rolling passage **20** to the ball return passage A or vise versa. That is, each rolling direction changing passage is composed of an outer peripheral side surface **22** formed in the end plate **17** (**18**) and an inner peripheral side surface as an R-piece portion **23** formed on each of both end portions of the movable block body **16** in the advancing direction. When the end plates **17** and **18** are mated each other and assembled to the movable block body **16**, these outer and inner peripheral side surfaces **22** and **23** constitute U-shaped direction changing passages C at both ends of the movable block body **16** so as to connect the non-loaded return passage A and the loaded ball rolling passage B (which is constituted by the ball rolling groove **12***a* and the non-loaded ball rolling groove **20**). Thus, as mentioned above, by combining the non-loaded return passage A, the loaded rolling passage B and the U-shaped direction changing passages C, the ball circulation passage in form of circuit is constituted.

[0045] The movable block body **16** may be formed through the injection molding of metal material, or manufactured by a machine working including drawing, cutting and/or grinding working. Further, the end plates **17** and **18** may be also manufactured by injection-molding metal material or resin material.

[0046] The plural balls **14, 14**, - - - disposed and arranged in the ball circulation passage are held by a rolling member connection belt **26** to be rotatable. The rolling member holding belt **26** is manufactured, for example, by press-molding a thin metal plate such as stainless steel plate for spring.

[0047] With reference to **FIG. 3 (FIGS. 3A and 3B)** showing the details of the rolling member connection belt **26**, the rolling member connection belt **26** has a shape extending in its longitudinal direction so as to hold a series of balls **14**. The longitudinal end portions thereof are formed to have round portions for smoothly inserting the rolling member connection belt **26** into the passage formed in the movable block **13**.

[0048] The rolling member connection belt **26** is formed with a plurality of ball accommodation holes **26***a* along its longitudinal direction. Claw portions **27***a*, **27***a*, **27***b*, **27***b*, - - - are formed to the peripheral portions of the ball accommodation holes **26***a* so as to surely hold the balls **14**, respectively. That is, four claws **27***a*, **27***a*, **27***b*, **27***b* are formed to each of the ball accommodation holes **26***a* so as to extend inside the hole **26***a* in a manner such that a pair of claws **27***a*, **27***a* arranged to diagonal positions are folded in one direction from a flat plane side on which the rolling member connection belt **26** lies and the other pair of claws **27***b*, **27***b* are also folded in the other direction to thereby form a ball holding structure.

[0049] As can be seen from **FIG. 3**, the rolling member connection belt **26** has a corrugated structure in which a plurality of peak portions **31, 31**, - - - and valley portions **32, 32**, - - - alternatively appear in sets in its longitudinal direction "L" in **FIG. 3A** so as to be expandable or contractable (flexible) in its longitudinal direction. Each of the peak and valley portions **31** and **32** extends in its width direction "W" normal to the longitudinal direction L. Within a range (diameter) "D" in the longitudinal direction of the ball accommodation hole **26***a* of the rolling member connection belt **26**, there exist a plurality of sets of the corrugated peak and valley portions **31** and **32** as shown in **FIG. 3B**. In other wards, the length "D" in the longitudinal direction of the hole **26***a* is larger than the pitch between the adjacent peaks **31** or valleys **32**.

[0050] Further, in an alternation, the rolling member connection belt **26** has such corrugated shape partially in its longitudinal direction in place of the entire length thereof. Furthermore, the corrugated shape is not limited to that shown in **FIG.** 3B and other shapes such as sine-curve shape, circular-arc shape or triangular-saw-teeth shape may be adopted as far as it includes plural sets of peak-and-valley arrangements.

[0051] **FIG. 4** shows another example of the rolling member connection belt **26**. In this example, the pitch P between the peak portions **31** or valley portions **32** is made substantially equal to the thickness H (i.e., height between the top of the peak portion **31** and the bottom of the valley portion **32**) of, for instance, 0.3 mm. This pitch P is made extremely small in comparison with various sizes of balls **14, 14***a*, **14***b*, - - - , and a plurality of peak and valley portions **31** and **32** exist within the range "D" of the ball accommodation hole **26***a* in the longitudinal direction of the rolling member (ball) connection belt **26**.

[0052] **FIG. 5** shows another example of the rolling member connection belt **26**. In this example, the thickness t1 of the rolling member connection belt **26** at the peak portion **31** and the valley portion **32** is larger than the thickness t2 (t1>t2) at an intermediate portion **33** connecting the peak and valley portions **31** and **32**. According to this example, the rolling member connection belt **26** is made to be more flexible or easily bendable at its intermediate portion **33** and, hence, the rolling member connection belt **26** will be more easily expanded or contracted in its longitudinal direction.

[0053] Incidentally, as shown in **FIG. 2** and as mentioned before, the circulation passage or path, along which the balls **14**, **14**, - - - roll, has a circuit structure composed of the linearly extending loaded rolling passage B, the linearly extending non-loaded return passage A and a pair of U-shaped direction changing passages C connecting the passages A and B. This circuit-shaped circulation passage lies in one plane, and the rolling member connection belt **26** is arranged so that the width direction "W" thereof is normal to the plane in which the ball circulation passage exists. The ball circulation passage is provided with a guide groove for guiding both lateral ends of the rolling member connection belt **26**.

[0054] According to the movement of the movable block **13** along the track rail **12**, the rolling member (ball) connection belt **26** together with the balls **14** is moved, while being loaded, from one end to the other end of the loaded rolling passage B, thereafter, scooped up by one end plate **18** at one end and then returned to the non-loaded return passage A via one direction changing passage C. The rolling member connection belt and the balls **14** are thereafter returned to the other one end of the loaded rolling passage B via the other direction changing passage C. Thus, the rolling member connection belt **26** is moved, in the linearly extending shape, in the loaded rolling passage B and the non-loaded return passage A, and on the other hand, is moved, in the bent fashion in the U-shaped direction changing passages C. During such circulation motion in the ball circulation passage, the rolling member connection belt **26** repeats the above-mentioned motion.

[0055] According to the described embodiments, the rolling member connection belt **26** has a corrugated shape having peak-and-valley portions **31** and **32** each extending in its width direction and arranged in its longitudinal direction, thus being easily bent in the direction changing passage. Accordingly, the rolling member connection belt **26** can easily and smoothly circulate in the circuit-shaped circulation passage. On the other hand, the rigidity in the width direction of the rolling member connection belt **26** increases, so that the balls **14** can be suppressed from being drifted or wandering during their circulation motion.

[0056] Further, the balls **14**, **14**, - - - may change in their speeds at the time when the balls **14** move from the non-loaded return passage A and the non-loaded area constituted by the direction changing passage C to the loaded area constituted by the loaded rolling passage B, or from the loaded area to the non-loaded area. In addition, because of the corrugated shape of the rolling member connection belt **26** expandable in its longitudinal direction, the change in speed can be absorbed and, hence, the transferring motion of the balls **14**, **14**, - - - from the non-loaded area to the loaded area will be smoothly performed.

[0057] Moreover, according to the embodiments of the rolling member connection belt **26** of the present invention, the injection molding of the resin material can be performed substantially with no difficulty for manufacturing a compact rolling member connection belt, and the strength at the connecting portion of the rolling member holding member (retainer) and the belt can be ensured substantially with no problem. Thus, the rolling member connection belt having compact and sufficient strength can be provided. Moreover, since the rolling member connection belt is formed of metal material, it is usable at a high temperature even of more than 100° C.

[0058] **FIGS. 6 and 7** represent a method of manufacturing the rolling member connection belt **26** of the structure mentioned above. The corrugated shape of the rolling member connection belt **26** is formed, for example, as shown in **FIG. 6**, through the press-working in which the flat connection belt is squeezed between lower and upper dies **41** and **42** to which corrugated shapes are formed. This press-working will be carried out after punching a metal plate into a flat belt shape or before punching the metal plate. Furthermore, the corrugated shape may be formed to the rolling member connection belt **26** by, as shown in **FIG. 7**, drawing out the metal belt from a roll and then clamping it between a pair of roll dies formed with corrugated shapes.

[0059] Further, it is to be noted that the present invention is not limited to the described embodiments and many other changes and modifications without departing from the scopes of the appended claims.

[0060] For example, although, in the described embodiment, single row of ball rolling groove is formed to each of the side surfaces of the track rail **12**, the number of rows and their arrangement may be optionally changed in consideration of magnitude of load and direction of loading. Furthermore, the sectional shape of the track rail **12** may be changed, and in addition, rollers may be utilized in place of balls as rolling members.

[0061] The present application claims priority under 35 U.S.C § 119 to Japanese Patent Application No. 2003-52936 filed Feb. 28, 2003 entitled "ROLLING MEMBER CONNECTION BELT AND MOTION GUIDE DEVICE PROVIDED WITH SAME". The contents of that application are incorporated herein by reference in their entirety.

What is claimed is:

1. A rolling member connection belt for holding, to be rotatable, a series of rolling members which circulate in a circulation passage provided with a loaded rolling passage composed of a rolling member rolling portion formed on a track member and another rolling member rolling portion formed on a movable member, a non-loaded return passage formed in the movable member and a pair of rolling direction changing members connecting the loaded rolling passage and the non-loaded return passage to thereby constitute the circulation passage,

said rolling member connection belt being made of a metal plate member having a corrugated-shape, in section in a longitudinal direction thereof, formed at least at a portion in the longitudinal direction, said corrugated-shape having peak and valley portions each extending in a direction normal to the longitudinal direction of the metal plate member.

2. A rolling member connection belt according to claim 1, wherein said metal plate member is provided with a number of rolling member holding holes formed along the longitudinal direction thereof and a plurality of sets of peak-and-valley portions exist in each of the rolling member holding holes.

3. A rolling member connection belt according to claim 2, wherein said rolling member holding hole is provided, at peripheral portions thereof, with a plurality of claw portions so as to surely hold the rolling member in the hole.

4. A rolling member connection belt according to claim 1, wherein said peak-and-valley portions are formed along an entire longitudinal direction of the connection belt.

5. A motion guide device comprising:

a track member formed with a rolling member rolling portion;

a movable member formed with another rolling member rolling portion and assembled to the track member to be rotatable relatively thereto;

a number of rolling members which circulate in a circulation passage provided with a loaded rolling passage composed of both the rolling member rolling portions formed on the track member and the movable member, a non-loaded return passage formed in the movable member and a pair of rolling direction changing members connecting the loaded rolling passage and the non-loaded return passage to thereby constitute the circulation passage; and

a rolling member connection belt holding the rolling members to be rotatable in the circulation passage,

said rolling member connection belt being made of a metal plate member having a corrugated-shape, in section in a longitudinal direction thereof, formed at least at a portion in the longitudinal direction, said corrugated-shape having peak and valley portions each extending in a direction normal to the longitudinal direction of the metal plate member.

6. A motion guide device according to claim 5, wherein said metal plate member is provided with a number of rolling member holding holes formed along the longitudinal direction thereof and a plurality of sets of peak-and-valley portions exist in each of the rolling member holding holes.

7. A motion guide device according to claim 5, wherein said peak-and-valley portions are formed along an entire longitudinal direction of the connection belt.

(57) **ABSTRACT**

A linear actuator realizing low generation of dust and low generation of noise and bearing a large axial load is provided. A plurality of spacers 30, - - - , each having at its both ends spherical recessed portions corresponding to curved surfaces of balls 28, - - - , are arranged between the balls 28, - - - of the guide portion of the linear actuator, and the spacers 30, - - - are connected to each other in series by belt-shaped members 31 having flexibility. On the other hand, a plurality of spacers 35, - - - , each having at its both ends spherical recessed portions corresponding to curved surfaces of balls 33, - - - for the screw shaft of a screw portion, are arranged between the balls 33, - - - in a manner separated from each other. By selecting a retainer 27 and the spacer 35 in accordance with the shapes of the guide portion and the screw portion, unnecessary contacting of the mutual balls and unnecessary contacting of the balls to the surrounding circulation passage can be prevented, thus realizing low generation of dust and low generation of noise.

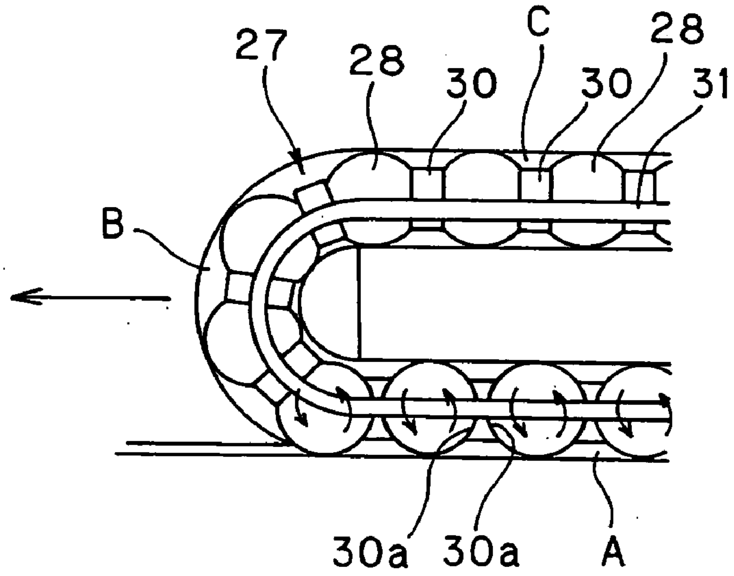

FIG. 11

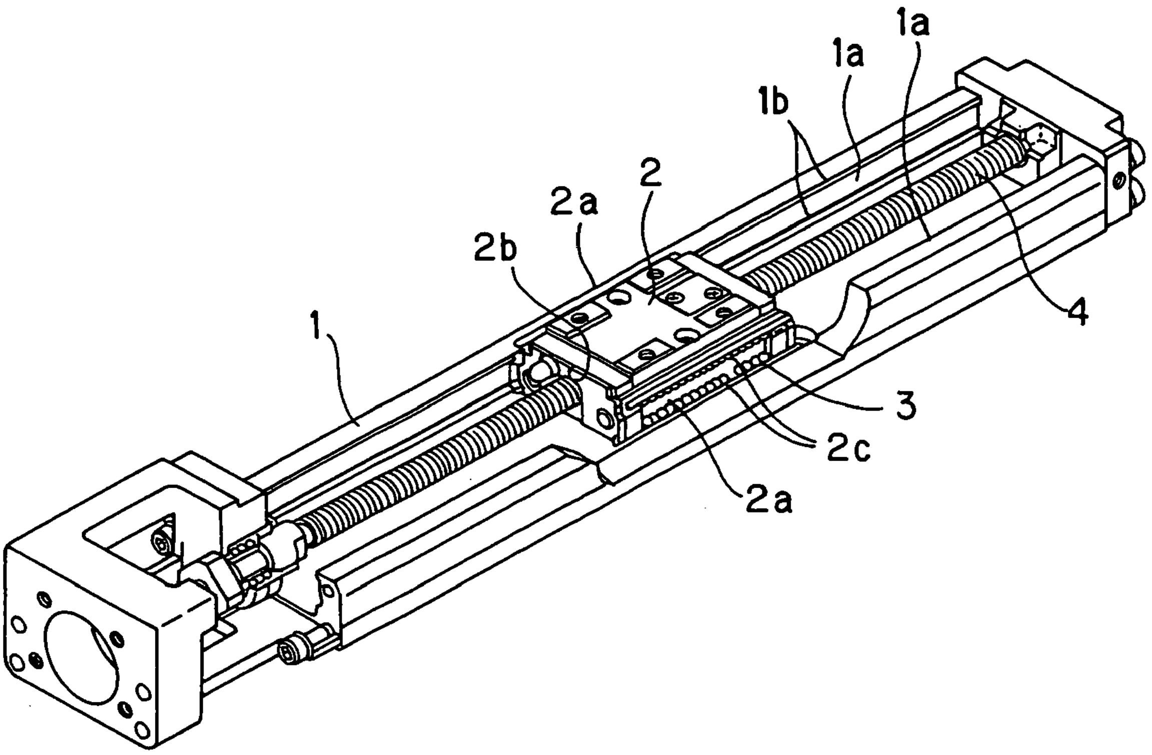

LINEAR ACTUATOR

TECHNICAL FIELD

[0001] The present invention relates to an actuator comprising a track member having substantially U-shape in section and a movable member integrally provided with guide portions formed on both side surfaces thereof and a ball screw portion formed in a central portion thereof.

BACKGROUND OF THE INVENTION

[0002] As shown in **FIG. 11**, there is known a linear actuator provided with an outer rail **1** having substantially U-shape and an inner block **2** disposed inside the outer rail **1** and integrally provided with guide portions **2***a*, **2***a* formed on both side surfaces thereof and a ball screw portion **2***b* formed in a central portion thereof.

[0003] The guide portions **2***a*, **2***a* have the following structures. The outer rail **1** has a pair of opposing inner wall sections **1***a*, **1***a*, on which upper and lower two rows of ball rolling grooves **1***b*, **1***b* are formed, respectively. On the other hand, the inner block **2** disposed inside the outer rail **1** has both side surfaces, on which loaded ball rolling groove **2***c*, **2***c* are formed so as to oppose to the ball rolling grooves **1***b*, **1***b*, and a number of balls **3**, **3**, - - - are disposed to be movable between the mutually opposing ball rolling grooves **1***b*, **1***b* and loaded rolling grooves **2***c*, **2***c*.

[0004] The screw portion **2***b*, on the other hand, has the following structure. A screw shaft **4** penetrates the central portion of the inner block **2**. The screw shaft **4** is formed, on its outer peripheral surface, with a spiral ball rolling groove. A spiral loaded ball rolling groove corresponding to this spiral ball rolling groove is formed on a through hole of the inner block **2**.

DISCLOSURE OF THE INVENTION

[0005] Since such a linear actuator has a integrally-provided guide portions **2***a*, **2***a* and ball screw portion **2***b*, the actuator provides functions, as actuator, of high rigidity and high performance in the minimum space. Accordingly, such linear actuator has been mainly utilized for a semiconductor manufacturing system or a liquid crystal manufacturing system, or under a clean environment in a medical or like equipment. For such clean environment, it is required to generate less dust or less noise, or like.

[0006] In order to reduce the dust to be generated from the actuator, a driving portion including a guide member of the actuator is covered by a case, to which air-sucking may be further conducted. However, even if the driving portion including the guide member is covered by the case, dust is yet generated from a sliding portion, therefore it is not fundamentally solution.

[0007] Moreover, a preload is applied to the ball screw portion **2***b* of the linear actuator for enhancing the positioning performance. The inner block **2** of the linear actuator is, however, different from a ball screw composed of a screw shaft and a nut, and has a structure in which the guide portions **2***a*, **2***a* and the ball screw portion **2***b* are integrally formed. According to such structure, in a manufacturing process, there is not adopted a method or system for applying a preload, as like a general ball screw, by displacing a phase of a ball rolling groove formed to the nut, and in substitution therefor, there is adopted an over-size preloading method or system in which over-sized balls, each having a diameter slightly larger than a gap between the screw shaft **4** and the inner block **2**, are arranged. In the case where this over-size preloading method is adopted, a spacer ball, having a diameter slightly smaller than that of the over-size ball, is arranged between the over-sized balls for smooth circulation of the balls. However, the arrangement of such spacer balls reduces the number of the balls to which load is applied, and load in the axial direction to be loaded will be reduced.

[0008] Then, the present invention has an object to provide a linear actuator which can realize reduced dust generation and low noise generation and providing a large load in the axial direction to be loaded.

[0009] The present invention will be explained hereunder, in which although reference numerals on the accompanying drawings are added with parentheses in order for easy understanding of the invention, the present invention is not limited to an embodiment illustrated in the drawings by the added reference numerals.

[0010] The inventor of the subject application conceived to locate spacers between rolling members at a guide portion and a screw (thread) portion, the spacer having recessed portions, on both end portions of a rolling member, each having a shape corresponding to a curved surface of the rolling member, in order to prevent metal contact of the rolling members and to perform smoothly arranged movement of the rolling members. Furthermore, in view of the fact that circulation motion of the rolling member at the guide portion is a two-dimensional motion in a plane in which a linear loaded rolling passage and a linear return passage are connected through a U-shaped direction changing passage and the circulation motion of the rolling member at the screw portion is a complicated spiral three-dimensional motion, there was conceived that a plurality of spacers arranged in the guide portion are connected to each other in series by means of belt-shaped member and a plurality of spacers arranged in the screw portion are, on the contrary, separated from each other, thus preventing the rolling members from contacting with the circulation passages surrounding the rolling members.

[0011] More specifically, the above object can be achieved by providing a linear actuator of the invention of claim **1**, which comprises a track member **(7)**, having U-shape in section, provided with inner wall surfaces **(7***a*, **7***a***)** opposing to each other, a movable member **(8)** disposed between the inner wall surfaces **(7***a*, **7***a***)** and a screw shaft **(9)** penetrating the movable member **(8)**, in which rolling member rolling portions **(11)** are formed on the inner wall surfaces of the track member **(7)**; loaded rolling member rolling portions **(19)** are formed on both side surfaces of the movable member **(8)** so as to correspond to the rolling member rolling portions **(11)**; rolling member return passages (C) extending in parallel to each other with a predetermined distance from the loaded rolling member rolling portions **(19)** and direction changing passages (B) each connecting the loaded rolling member rolling portions **(19)** and the rolling member return passages (C) are formed in the movable member so as to circulate the rolling members **(28**, - - -) rolling between the rolling member rolling portions **(11)** and the loaded rolling member rolling portions **(19)**; a rolling member rolling portion (**9**a) for the screw shaft (**9**) in form of spiral is formed to an outer peripheral surface of the screw shaft (**9**); a loaded rolling member rolling passage (**15**a) for the screw shaft is formed on the through hole formed in the movable member so as to correspond to the rolling member rolling portion (**9**a) of the screw shaft; and a rolling member return passage (E) for circulating the rolling member (**33**, - - -) for the screw shaft rolling between the rolling member rolling portion (**9**a) for the screw shaft and the loaded rolling member rolling portion (**15**a) for the screw shaft is formed in the movable member,

[0012] wherein a plurality of spacers (**30**, - - -), each having, at both ends thereof, curved recessed portions (**30**a, - - -) corresponding to curved surface of the rolling member (**28**,- - -) are arranged between the rolling members, the plural spacers (**30**, - - -) being connected in series by belt-shaped members (**31**, **31**) having flexibility;

[0013] a plurality of spacers (**35**, - - -), each having, at both ends thereof, curved recessed portions corresponding to the curved surface of the rolling member (**33**, - - -), are disposed between the rolling members for the screw shaft in a manner separated from each other; and

[0014] a holding member (**17**) extending along both side edges of the loaded rolling member rolling portion (**19**) is mounted to the movable member (**8**) for preventing the rolling member (**28**, - - -) held by the belt-shaped members (**31**, **31**) and the spacers (**30**, - - -) from coming off at a time when the movable member (**8**) is removed from the track member (**7**).

[0015] According to the present invention, a plurality of spacers, having curved recessed portions corresponding to the curved surfaces of the rolling members, are disposed between the rolling members of the guide portion and the screw portion, so that the mutual contact between the respective metal rolling members can be prevented. Furthermore, since the plural spacers arranged in the guide portion, in which two-dimensional motion is carried out, are connected to each other in series by the belt-shaped members, the rolling members circulate in the constant track, and unnecessary contacting of the rolling members and their surrounding circulation passage can be prevented. In the screw portion, on the other hand, the twisting motion around the advancing direction is required as well as the two-dimensional and three-dimensional direction changing motions, so that unnecessary contacting of the rolling members and their surrounding circulation passage can be prevented by separating the spacers without connecting the spacers by the belt-shaped members. Thus, since the mutual contact of the rolling members and the unnecessary contacting of the rolling members and their surrounding circulation passage can be prevented, low generation of dust or like and low generation of noise can be realized.

[0016] Still furthermore, by arranging the spacers, each having curved recesses at its both end portions corresponding to the curved surface of the rolling member, the distance between the adjacent balls can be shortened in comparison with the case of using the spacer balls, for example. Accordingly, there is provided a linear actuator having a large axial load to be applied.

[0017] The invention of claim **2** is characterized, in the linear actuator of claim **1**, in that the rolling member rolling passage composed of the loaded rolling member rolling passage (**19**, A), the rolling member return passage (C) and the direction changing passage (B) is provided with a guide portion (**16**a, **26**) for guiding the belt-shaped member (**31**, **31**).

[0018] According to this invention, since the belt-shaped member is guided by the guide portions provided for the rolling member circulation passage, the belt-shaped member circulates in the more constant track, and hence, the plural spacers connected by the belt-shaped member and the rolling members disposed between the spacers can be also circulated in the more constant track.

[0019] Still furthermore, according to the invention of claim **3**, in the linear actuator of claim **1** or **2**, it is characterized in that the return passage constituting member (**16**) constituting the return passage (C), the direction changing inner periphery side constituting member (**25**) constituting the inner periphery side of the direction changing member (B), the direction changing outer periphery side constituting member (**18**) constituting the outer periphery side of the direction changing member (B), and the holding member (**17**) are formed from resin material independent from a body portion of the movable member (**8**).

[0020] According to this invention, in the guide portion, the metallic contact is only made between the rolling member and the rolling member rolling portion of the track and between the rolling member and the loaded rolling member rolling portion, so that the generation of dust and noise can be suppressed.

BRIEF DESCRIPTION OF THE DRAWINGS

[0021] In the accompanying drawings:

[0022] **FIG. 1** is a perspective view, partially cutaway, showing an essential portion of a linear actuator according to one embodiment of the present invention.

[0023] **FIG. 2** is a developed perspective view of the linear actuator.

[0032] **FIG. 11** is a perspective view of a linear actuator of conventional structure.

BEST MODE FOR EMBODYING THE INVENTION

[0033] FIGS. **1** to **4** represent a linear actuator according to one embodiment of the present invention, in which **FIG. 1** is a perspective view, partially cutaway, showing an essential portion of a linear actuator, **FIG. 2** is a developed perspective view, **FIG. 3** is a plan view and **FIG. 4** is a side view, partially in section, of the linear actuator.

[0034] The linear actuator is provided with an outer rail **7** as track member having an approximately U-shaped section and an inner block **8** as movable member disposed inside the outer rail and having an integral structure of guide portions disposed on both side surface sides and a central ball screw portion. When a screw shaft **9** screw-engaged with the inner block **8** is rotated by a driving source such as electric motor, not shown, the inner block **8** is linearly moved along the outer rail **7**. In such a linear actuator, since the guide portion and the ball screw portion are integrally composed, functions as actuator having high rigidity and high performance are attained in the minimum space.

[0035] Hereunder, the guide portion of the linear actuator will be first mentioned. The outer rail **7** has an approximately U-shaped structure having a pair of opposing inner wall surfaces **7***a*, **7***a*. The inner wall surfaces **7***a*, **7***a* are formed with recessed grooves **10, 10** so as to extend throughout the full length thereof, and two rows of ball rolling grooves **11, 11** are formed, as rolling member rolling portion, at upper and lower corner portions of each of the recessed grooves **10, 10**, respectively. That is, upper and lower two ball rolling grooves **11, 11** are formed on each of the paired inner wall surfaces **7***a*, **7***a* of the outer rail **7** (totally, four ball rolling grooves). Each of the ball rolling groove **11** is composed of a so-called single circular arc groove having a curvature of its section slightly larger than a radius of a ball. As shown in **FIGS. 3 and 4**, housings **13** and **14** supporting a screw shaft **9** to be rotatable are disposed at longitudinal both end portions of the outer rail **7**. The housings **13, 14** and the outer rail **7** are connected by fastening means such as bolts. A drive source is mounted to the housing **13** and a joint is disposed between the screw shaft and an output shaft of the drive source.

[0036] As shown in **FIGS. 1 and 2**, the inner block **8** is disposed so as to be clamped between the inner wall surfaces **7***a*, **7***a* of the outer rail **7**. The inner block **8** comprises a block body **15**, a resin mold member (including return passage constituting member **16** - - - and holding members **17, 17**) assembled with the block body **15** and end plates **18, 18** mounted to both end surfaces of the block body **15**.

[0037] Loaded ball rolling grooves **19, 19** as upper and lower two rows of loaded rolling member rolling grooves are formed on both the side surfaces of the block body **15** so as to oppose respectively to the ball rolling grooves **11, 11** of the outer rail **7**. That is, two loaded ball rolling groove **19, 19** are formed on each of the side surfaces of the block body **15** (i.e., totally four grooves **19**). Each of these loaded ball rolling grooves is also composed of a so-called single circular arc groove having a curvature of its section slightly larger than the radius of the ball. A loaded ball rolling passage as a portion of ball circulation passage (rolling member circulation passage) in which the balls circulate is formed between each of the ball rolling grooves **11** of the outer rail **7** and each of the loaded ball rolling grooves **19** of the inner block **8**.

[0038] **FIG. 5** shows a section of the linear actuator, and with reference to this **FIG. 5**, contact angle line of ball rows will be explained hereunder. The contact angle line means, herein, a line connecting a contact point of the ball and the ball rolling groove **11** of the outer rail **7** and a contact point of the ball and the loaded ball rolling groove **19** of the inner block **8**. In this linear actuator, four rows of loaded ball rolling passages are formed, and accordingly, four contact angle lines exit. The upper two contact angle lines ① inclines by, for example, 45° from a horizontal line so as to be directed obliquely upward towards the outside from the center of the actuator and the lower two contact angle lines ② inclines by, for example, 45° from a horizontal line so as to be directed obliquely downward towards the outside from the center of the actuator. According to such structure, there is provided a linear actuator capable of bearing loads in four directions including radial direction (lower direction), opposite radial direction (upper direction) and horizontal direction (including lateral both directions).

[0039] As shown in **FIGS. 1 and 2**, in the block body, there are formed two through holes **21, 21** extending in parallel with a predetermined distance from the upper and lower two rows of loaded ball rolling grooves **19, 19**, respectively, formed on both side portions of the block body. Return passage constituting members **16**, - - - formed from a resin material and constituting ball return passages are inserted into these through holes **21**, - - - , respectively. On these return passage constituting members **16**, - - - , there are formed guide grooves **16***a* (guide portions) for guiding a belt-like member of a retainer, mentioned hereinlater, so as to extend in its axial direction (see **FIG. 5**).

[0040] The inner block **8** is formed with a U-shaped direction changing passage for circulating the balls by connecting the loaded ball rolling passage and the ball return passage. A circuit-shaped ball circulation passage is composed by the loaded ball return passage, the direction changing passage and the ball return passage. Four, two in each lateral side, rows of such ball circulation passages are formed. Each ball circulation passage is formed in one plane so that the balls circulate in the ball circulation passage two-dimensionally. To this ball circulation passage, a guide portion for guiding the belt-shaped portion of the retainer is arranged around the entire periphery.

[0041] The outer peripheral side of the direction changing passage is formed on the end plate **18** as an outer peripheral side constituting member of the direction changing passage, and the inner peripheral side of the direction changing passage is formed on the holding member as an inner peripheral side constituting member of the direction changing passage. By combining these end plate **18** and holding member **17**, the guide groove (guide portion) for guiding the belt-like member of the retainer in the direction changing passage is formed.

[0042] FIGS. **6** to **8** represent the holding member. The holding member **17** is provided with holding portions **24** extending along both side edges of the loaded ball rolling groove **19** and preventing the ball held by the retainer from coming off from the outer rail **7** at the time of removal of the inner block **8** from the outer rail **7** and provided with direction changing passage inner peripheral side constituting portions **25**, - - - , constituting the inner peripheral side of the direction changing passage, disposed at longitudinal both end portions of the holding portions **24**. When such holding member **24** is mounted to the block body **15**, it cooperates with the outer side surface of the block body **15** to thereby form the guide portion **26** (guide groove) for guiding the belt-shaped member of the retainer.

[**0043**] The holding portion **24** includes a first holding piece **24***c* for holding the lower side of the retainer mounted to the lower side ball circulation passage, a second holding piece **24***b* for holding the upper side of the retainer mounted to the lower side ball circulation passage and mounted to the upper side ball circulation passage, and a third holding piece **24***a* for supporting the upper side of the retainer mounted to the upper side ball circulation passage. Each of the respective direction changing passage inner periphery constituting members **25** has an approximately semicircular-arc shape.

[**0044**] These holding members **17**, **17**, return passage constituting members **16**, - - - and end plates **18**, **18** are independently formed from resin material, which are then assembled with the block body **15**.

[**0045**] As shown in **FIG. 2, a** number of balls **28**, - - - supported by the retainer **27** to be rotatable and slidable are accommodated in each ball circulation passage. The retainer **27** is provided with a plurality of spacers **30**, - - - each disposed between the balls and belt-shaped members **31**, **31** connecting both side edge portions of the respective spacers **30**, **30** (see **FIG. 10**). The spacers **30**, - - - are formed so as to provide a cylindrical shape having an outer diameter smaller than a diameter of the ball **28**. Each of the spacers **30** is formed, at its axial both ends, with spherical recessed portions **30***a*, **30***a* as curved recesses each having a curvature radius substantially equal to the radius of the ball **28** so as to correspond thereto. In an arrangement that the spacers **30**, - - - are disposed between the balls **28**, - - - , the axes of the spacers **30**, - - - lie on the line connecting the centers of the balls **28**, - - - . The axial length of the spacer **30** is set to be thin so that the interval of the adjacent balls **28**, **28** has necessarily minimum value.

[**0046**] The belt-shaped members **31**, **31** have constant thickness and are connected to both sides of the side surface of the spacer **30**. These belt-shaped members **31**, **31** have flexibility so as to flexibly cooperate with the direction changing passage. In an interfering position of the belt-shaped members **31**, **31** and the balls **28**, - - - , there is formed a cut-in portion having a curvature radius substantially equal to the radius of the ball **28**. The belt-shaped members **31**, **31** project over both the side edge portions of the balls **28**, and the projected portions are guided by the guide portions formed in the ball circulation passages. Furthermore, corner portions of the longitudinal both end portions of belt-shaped members **31**, **31** are formed so as to provide round portions **31***a*, **31***a*. The spacers **30**, - - - and the belt-shaped members **31**, **31** are integrally formed from synthetic resin material through an injection molding process.

[**0047**] Hereunder, the screw portion of the linear actuator will be explained. As shown in **FIG. 1**, the screw shaft **9** penetrates the central portion of the inner block **8**. On the outer peripheral surface of the screw shaft **9**, there is formed a ball rolling groove **9***a* for the screw shaft **9** as rolling member rolling groove for the spiral screw shaft. This ball rolling groove **9***a* for the screw shaft **9** has a cross section formed into a gothic-arch including two circular-arc portions having a curvature radius slightly larger than the radius of a ball **33** for the screw shaft. On the other hand, the through hole formed in the block body **15** is also formed with a loaded ball rolling groove **15***a* for the screw shaft as loaded ball rolling member for the screw shaft so as to correspond to the ball rolling groove **9***a* for the screw shaft. This loaded ball rolling groove **15***a* for the screw shaft **9** also has a cross section formed into a gothic-arch including two circular-arc portions having a curvature radius slightly larger than the radius of the ball **33** for the screw shaft. A loaded rolling passage of the ball circulation passage is composed of the ball rolling groove **9***a* for the screw shaft **9** and the loaded ball rolling groove **15***a* of the block body **15**.

[**0048**] The ball **33** contacts the ball rolling groove **9***a* for the screw shaft **9** at two points, and the ball **33** also contacts the loaded ball rolling groove **15***a* for the screw shaft of the block body **15** at two portions. That is, the ball **33** contacts the ball rolling groove **9***a* and the loaded ball rolling groove **15***a* at four points. Further, in order to apply a preload, there is adopted a so-called over-size system in which a ball having an over-size having a diameter slightly larger than the interval between the screw shaft **9** and the block body **15**.

[**0049**] A return pipe **34** for circulating the ball rolling between the ball rolling groove **9***a* for the screw shaft **9** and the loaded ball rolling groove **15***a* for the block body **15** is provided with the inner block **8**. This return pipe **34** constitutes a ball return passage for the screw shaft (rolling member return passage for screw shaft) communicating one and the other ends of the loaded rolling passage.

[**0050**] The return pipe **34** has a circular cross section and is bent by about 90 degrees at both end portions with respect to its body portion so as to provide an approximately gate shape. The leg portions thereof are not parallel to each other and their extending directions are twisted respectively in accordance with lead angles. Both the end portions of the return pipe **34** are formed with cutouts for scooping up the balls rolling in the loaded rolling passage. Both side portions of the return pipe **34** are fitted into the loaded rolling passage with several pitches of interval. Furthermore, this return pipe **34** is inserted from the lower surface side of the inner block **8**, i.e. on a side opposing to the upper surface of the outer rail **7**, and fixed to the inner block **8** by means of pipe holder. By disposing the return pipe **34** to the lower surface side of the inner block **8**, a portion on the upper surface side of the inner block **8** can be freely utilized, thus making easy the assembling working of a table or like.

[**0051**] A number of balls **33**, - - - for screw shaft are arranged in the loaded rolling passage. A number of spacers **35**, - - - are also arranged each between the balls **33**. The spacers **35** are formed so as to provide a cylindrical shape having an outer diameter smaller than a diameter of the ball **33**. Each of the spacers **30** is formed, at its axial both ends, with spherical recessed portions as curved recesses each having a curvature radius substantially equal to the radius of the ball **33** so as to correspond thereto. In an arrangement that the spacers **35**, - - - are disposed between the balls **33**, - - - , the axes of the spacers **35** lie on the line connecting the centers of the balls **23**, - - - . The axial length of the spacer **35** is set to be thin so that the interval of the adjacent balls **33**, **33** has necessarily minimum value.

[**0052**] When the screw shaft **9** is rotated, the balls **33**, - - - rolling in the circumferential direction in the loaded rolling passage under the loaded state are scooped up by one front end of both end portions of the return pipe **34**. The scooped-up balls **33** pass through the inside of the return pipe **34** and return again to the loaded rolling passage from the other one front end of both the end portions of the return pipe part from the one end by several pitches. The balls **33** circulate in a manner reverse to that mentioned above by reversing the rotating direction of the screw shaft **9**.

[0053] **FIG. 9** shows a perspective view of the balls **33**, - - - and spacers **35**, - - - which are arranged in the ball circulation passage of the screw portion and **FIG. 10** shows the balls **28**, - - - and retainer **27** which are arranged in the ball circulation passage of the guide portion. The arrangement of the spacers **35**, - - - and **30**, - - - having recessed portions corresponding to the curved surfaces of the balls **33**, - - - and **28**, - - - between these balls **33**, - - - and **28**, - - - permits to prevent the metal balls from being contacted to each other and realize a low dust and low noise generation structure.

[0054] As shown in **FIG. 10**, the balls **28** move two-dimensionally on a plane in the ball circulation passage of the guide portion. That is, the balls **28** circulate in the order of the linear loaded rolling passage A→the U-shaped direction changing passage B→the linear return passage C→the U-shaped direction changing passage B. In the direction changing passage B, the belt-shaped member **31** of the retainer is freely bent. Since a number of spacers **30** disposed in the guide portion are connected in series to each other by the belt-shaped members, the balls **28** can circulate in the predetermined track and, hence, unnecessary contacting of the balls **28** to the surrounding circulation passage can be prevented. Furthermore, since the belt-shaped members **31** are guided by the guide portions formed to the ball circulation passage, the belt-shaped members **31** can circulate in the more constant track, and hence, the spacers **30**, - - - connected in series by the belt-shaped members **31** and the balls **28** disposed between these spacers **30** can also circulate in the more constant track.

[0055] Particularly, in the case where the return passage constituting members **16**, the holding members **17** and the end plates **18** are molded independently with resin material different from the metal block body, only the loaded rolling passage and the balls are metal-to-metal contacted. Thus, the generation of dust or like can be preferably suppressed.

[0056] On the other hand, with reference to **FIG. 9**, the loaded rolling passage D in the screw portion is formed into spiral shape and the ball return passage E (return pipe) is circumferentially twisted in the advancing direction of the balls **33** as mentioned before. That is, in the screw portion, the rolling directions of the balls **33** and spacers **35** are three-dimensionally changed and moved in the complicated manner. The unnecessary contacting of the balls **33** to the surrounding circulation passage can be prevented by separating the spacers **35** without connecting them with the belt-shaped member. In addition, the spacers **35**, each having curved recesses at its both end portions corresponding to the curved surface of the ball **33**, are arranged in the screw portion without using conventional spacer balls, so that the distance between the adjacent balls can be shortened in comparison with the case of using the spacer balls. Accordingly, the number of balls **33** which can receive the load is not reduced.

[0057] The linear actuator of the characters mentioned above will be assembled in the following manner with reference to **FIG. 2**.

[0058] First, the screw shaft **9** is inserted into the block body **15** and balls **33**, - - - and spacers **35** - - - are then alternatively accommodated and arranged in the space between the screw shaft **9** and the block body **15**. The balls **33** and spacers **35** are also accommodated and arranged in the return pipe **34**. The return pipe **34** is then mounted to the block body **15**. In thus manner, the assembling of the block body **15** and the screw shaft **9** is completed.

[0059] Next, the return passage constituting members **16**, - - - are inserted into the through holes **21** of the block body **15**, and the holding members **17**, **17** are assembled to both the side surfaces of the block body **15**. Then, the end plate **18** is mounted to one end surface of the block body **15**. In the next step, the balls **28**, - - - arranged and held by the retainer **27** is inserted in the ball circulation passage of the guide portion from the side opposing to the mounting side of the above-mentioned one end plate **18**, and the other end plate **18** is thereafter mounted to the other one end surface of the block body **15**. Finally, the inner block **8** is forcibly fitted into the outer rail **7** and the housings **13** and **14** supporting both the ends of the screw shaft are fastened to both ends of the outer rail **7**.

[0060] Further, it is to be noted that tubular rollers may be used as rolling members in substitution for the balls.

[0061] As mentioned hereinbefore, according to the present invention, a plurality of spacers, each formed at its both ends, with curved recessed portions corresponding to the curved surface of the rolling member, are disposed between the rolling members of the guide portion, and these plural spacers are connected in series by the belt-shaped members having flexibility. On the other hand, a plurality of spacers, each formed at its both ends, with curved recessed portions corresponding to the curved surface of the rolling member, are disposed between the rolling members for the screw shaft of the screw portion in a manner separated from each other. The mutual contact between the respective metal rolling members can be prevented by disposing the spacers, having recessed portions corresponding to the curved surfaces corresponding to the rolling members, arranged in the guide portion and the screw portion. Furthermore, since the plural spacers arranged in the guide portion, in which two-dimensional motion is carried out, are connected to each other in series by the belt-shaped members, the rolling members circulate in the constant track, and unnecessary contacting of the rolling members and their surrounding circulation passage can be prevented. In the screw portion, the twisting motion around the advancing direction is required as well as the two-dimensional and three-dimensional direction changing motions, so that unnecessary contacting of the rolling members and their surrounding circulation passage can be prevented by separating the spacers without connecting the spacers by the belt-shaped members. Thus, since the mutual contact of the rolling members and the unnecessary contacting of the rolling members and their surrounding circulation passage can be prevented, low generation of dust or like and low generation of noise can be realized.

1. A linear actuator comprising a track member, having U-shape in section, provided with inner wall surfaces oppos-

ing to each other, a movable member disposed between the inner wall surfaces and a screw shaft penetrating the movable member, in which rolling member rolling portions are formed on the inner wall surfaces of the track member; loaded rolling member rolling portions are formed on both side surfaces of the movable member so as to correspond to the rolling member rolling portions; rolling member return passages extending in parallel to each other with a predetermined distance from the loaded rolling member rolling portions and direction changing passages each connecting the loaded rolling member rolling portions and the rolling member return passages are formed in the movable member so as to circulate the rolling members rolling between the rolling member rolling portions and the loaded rolling member rolling portions; a rolling member rolling portion for the screw shaft in form of spiral is formed to an outer peripheral surface of the screw shaft; a loaded rolling member rolling passage for the screw shaft is formed on the through hole formed in the movable member so as to correspond to the rolling member rolling portion of the screw shaft; and a rolling member return passage for circulating the rolling member for the screw shaft rolling between the rolling member rolling portion for the screw shaft and the loaded rolling member rolling portion for the screw shaft is formed in the movable member,

wherein a plurality of spacers, each having, at both ends thereof, curved recessed portions corresponding to curved surface of the rolling member are arranged between the rolling members, the plural spacers being connected in series by belt-shaped members having flexibility;

a plurality of spacers, each having, at both ends thereof, curved recessed portions corresponding to the curved surface of the rolling member, are disposed between the rolling members for the screw shaft in a manner separated from each other; and

a holding member extending along both side edges of the loaded rolling member rolling portion is mounted to the movable member for preventing the rolling member held by the belt-shaped members and the spacers from coming off at a time when the movable member is removed from the track member.

2. The linear actuator according to claim 1, wherein the rolling member rolling passage composed of the loaded rolling member rolling passage, the rolling member return passage and the direction changing passage is provided with a guide portion for guiding the belt-shaped member.

3. The linear actuator according to claim 1 or **2**, wherein the return passage constituting member constituting the return passage, the direction changing inner periphery side constituting member constituting the inner periphery side of the direction changing member, the direction changing outer periphery side constituting member constituting the outer periphery side of the direction changing member, and the holding member are formed from resin material independent from a body portion of the movable member.

(57) **ABSTRACT**

An object of the invention is to provide a method of manufacturing a rolling element string wherein a smaller rolling element string can be manufactured easily at low cost, and a rolling element string being superior in the tensile strength and the flexural strength even after downsizing can be manufactured. The present invention to achieve the object is a method of manufacturing a rolling element string having a number of rolling elements aligned and rollably retained at prescribed intervals, comprising a first step of forming a flat band shaped belt member with a synthetic resin, a second step of forming retaining holes aligned on said belt member in a row for receiving the rolling elements loosely, and a third step of aligning the rolling elements within said retaining holes and forming the spacer portions between the respective adjacent retaining holes by injection molding for retaining said rolling element with said rolling elements used as cores, so that said rolling elements are trapped within said retaining holes.

METHOD OF MANUFACTURING ROLLING ELEMENT STRING

BACKGROUND OF THE INVENTION

[0001] 1. Field of the Invention

[0002] The present invention relates to a method of manufacturing a rolling element string in which a number of rolling elements are aligned and rollably held in a row at prescribed intervals, and which is used by integrating, for example, in a linear guide device for endless sliding. More specifically, the invention relates to an improved rolling element string the tensile strength and the flexural strength of which are enhanced.

[0003] 2. Description of the Related Art

[0004] Conventionally, the known linear guide device for guiding a movable body such as a table along the fixed portion such as a bed is of the type that comprises a rollway having a ball rolling groove, a slider having a loaded rolling groove opposed to the ball rolling groove and a no-load rollway in which the ball is circulated from one end to the other end of the loaded rolling groove and moving along the rollway, and a number of balls rolling between the slider and the rollway under loaded conditions and circulating along the endless raceway composed of a loaded rolling groove and a no-load rollway of the slide.

[0005] In the conventional linear guide device in this arrangement, since the endless raceway of the slider is filled with balls, when the slider moves along the rollway, the adjacent balls tend to collide with or rub against each other as they circulate along the endless raceway, which results in earlier abrasion of balls and shorter operational life of the device.

[0006] Therefore, in order to solve the problem described above, a linear guide device incorporating a rolling element string having a plurality of balls aligned in a row into the endless raceway has been proposed (Japanese Patent Laid-Open No. 5-52217). As shown in **FIG. 17** and **FIG. 18**, the rolling element string **100** comprises ball retaining members **102** interposed between the respective adjacent balls **101** and is constructed in such a manner that the balls are linked consecutively by linking the respective ball retaining members **102** with a pair of belt members **103** disposed in the direction of alignment of the balls **101**, and is manufactured by injection molding of a flexible resin with the balls **101** disposed in a mold as cores.

[0007] In the conventional rolling element string **100** arranged in such a manner being incorporated into the endless raceway **105** and circulating along the endless raceway as shown in **FIG. 19**, since the ball retaining members **102** are interposed between the respective adjacent balls **101**, friction or collision between balls are prevented from being occurred and abrasion of the balls **101** could be avoided as much as possible.

[0008] However, in the conventional method, since an elongated rolling element string of the length corresponding to an orbit of the endless raceway is manufactured by injection molding, there has been a problem in that a number of gates for injecting molten resin into a cavity in the mold must be provided to make the belt member **103** for linking the respective ball retaining members **102** form in a uniform thickness, whereby the mold becomes complex and the cost increases.

[0009] There has been another problem in that considering further downsizing of the linear guide device requires the thinner belt member for the rolling element string to be incorporated in the endless raceway, and decrease in the tensile strength and the flexural strength of the belt member associated with thinning thereof may cause breakage of the rolling element string in the endless raceway, thereby impairing the ball retaining capability of the rolling element string.

[0010] There has been still another problem in that when contemplating further thinning of the belt member, the molten resin injected from the gate may not reach the deepest portion of the cavity in the mold, thereby resulting in a number of defective moldings and thus reducing yields.

SUMMARY OF THE INVENTION

[0011] The present invention is directed toward the problems described above, and accordingly, it is an object of the present invention to provide a method of manufacturing a rolling element string in which further downsized rolling element string may be manufactured easily at low cost, and in which the rolling element string having superior tensile strength and flexural strength may be manufactured even after downsizing.

[0012] In other words, the present invention is a method of manufacturing a rolling element string having a number of rolling elements aligned and rollably held in a row at prescribed intervals comprising a first step of forming a flat band shaped belt member with a synthetic resin, a second step of forming retaining holes aligned in a row on the belt member for receiving rolling elements loosely, and a third step of placing the rolling elements in the respective retaining holes, forming spacer portions between the respective adjacent retaining holes for retaining the rolling elements therein by injection molding with these rolling elements used as cores, and trapping the rolling elements within the retaining holes.

[0013] According to the method of the present invention, since the spacer portions are formed after the flat band shaped belt member is molded in the first step, and then the rolling elements are trapped within the retaining holes formed on the belt member, the belt member may be formed consecutively in a long strip for example by extrusion molding of a synthetic resin, not by injection molding. Therefore, even when the thickness of the belt member is reduced in association with downsizing of the rolling element string, the belt member of uniform thickness may be formed stably.

[0014] In addition, since the belt member and the spacer portions are formed separately, the belt member can be formed of a synthetic resin material that is completely different from a molding material used for the spacer portions. Therefore, by forming the belt member with a synthetic resin the tensile strength or flexural strength of which has been improved by adding, for example, carbon filler, the rolling element string of high tensile strength may be manufactured even if the thickness of the belt portion is reduced. On the other hand, since the spacer portions are to be kept in slide-contact with the rolling elements, the material for the spacer portions may be selected to have a low friction coefficient such as oleoresin, thereby ensuring smooth rotation of the rolling elements.

[0015] It is also possible to integrate a reinforcing material such as a carbon fiber or a glass fiber along the length of the belt member as the belt member is formed by extrusion molding, whereby the tensile strength of the belt member can be increased even when the tensile strength or flexural strength of the synthetic resin constituting the belt member is low.

[0016] As is described thus far, according to the method of manufacturing the rolling element string of the present invention, since the spacer portions for retaining the rolling element within the belt member are formed by injection molding after the belt member for aligning the rolling elements is molded, the belt can be consecutively formed in a long strip by extrusion molding, but not by injection molding, whereby the belt member of a uniform thickness may be formed easily at low cost even when the thickness of the belt member is reduced in association with downsizing of the rolling element string.

BRIEF DESCRIPTION OF THE DRAWINGS

[0017] **FIG. 1** is a plan view showing the first embodiment of the rolling element string manufactured according to the method of the present invention;

DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0036] Referring now to the drawings, the present invention will be described.

[0037] FIGS. **1** to **3** show the first embodiment of the rolling element string manufactured according to the method of the present invention. The rolling element string **1** comprises a string belt **2** formed of a synthetic resin and balls **3** as rolling elements aligned in a row at prescribed intervals, and these balls **3** are rollable in the state of being retained in the string belt **2**.

[0038] The string belt **2** comprises a belt member **21** formed in the flat band shape and having retaining holes **20** for retaining balls **3** at prescribed intervals, and spacer portions **22** projecting from both surfaces of the belt member **21** between the respective adjacent retaining holes **20**, wherein balls **3** are rollably trapped within the retaining holes **20** of the belt member **21** by the respective spacer portions **22**.

[0039] The method of manufacturing the rolling element string **1** will now be described step-by-step.

[0040] **FIG. 4** shows a belt member **21** formed in the first step of the present invention. The belt member **21** is manufactured by extrusion molding of a synthetic resin. The belt member **21** consecutively extruded from the molding die is cooled down in a water tank, and then wound by a reel. In the subsequent step, the belt member **21** wound on the reel is cut into a prescribed length and used.

[0041] Since the belt member **21** before the spacer portions **22** are built up thereon has an uniform cross section along its length, the belt member **21** of a uniform thickness can be formed by extrusion molding easily at low cost even when the belt member **21** is thin.

[0042] The belt member **21** formed in such a manner is cut into a length corresponding to one orbit of the endless raceway of the linear guide device, and then formed with retaining holes **20** for retaining balls **3** along its length at prescribed intervals. The retaining hole **20** is formed in such a manner that the inner diameter thereof is somewhat larger than the diameter of the ball **3**, so that the ball **3** can be put in and taken out without any friction. Injection molding of the spacer portions **22** is carried out with the balls **3** aligned within these retaining holes **20**.

[0043] Injection molding is carried out in the state where the belt member **21** cut into a prescribed length is set in the mold at a prescribed position and the balls **3** are placed in the respective retaining holes **20** formed on the belt member **21**, with such belt member **21** and balls **3** used as cores. The spacer portions **22** are built up between the respective adjacent retaining holes **20** on the belt member **21** so as to cover a part of the surfaces of the balls **3**, and the balls **3** partly covered are trapped within the retaining holes **20** of the belt member **21**. Accordingly, as shown in **FIG. 6, a** string belt **2** having balls **3** aligned and retained at prescribed intervals on the belt member **21** is completed. In injection molding of the spacer portions **22**, a synthetic resin such as polyamide elastomer or polyester elastomer is used as in the case of molding the belt member **21**. By forming the spacer portions **22** by injection molding using the identical synthetic resin as the belt member **21**, the spacer portions **22** are welded to the belt member **21** when being molded, and as a consequent, the spacer portion **22** and the belt member **21** are securely integrated.

[0044] When the spacer portions **22** are formed by injection molding with the balls **3** as cores, the spacer portions **22** come into intimate contact with the surfaces of the balls **3**, thereby preventing smooth rolling of the ball. Therefore, upon completion of such injection molding, the belt member **21** is soaked into oil for a certain period of time. Since the string belt **2** formed of a synthetic resin takes up oil and thus swells, small gaps are formed between the spacer portions **22** and the balls **3** after a prescribed period of time has elapsed, thereby permitting free rolling of the balls **3** without falling off the retaining holes **20**. The rolling element string **1** is thus completed.

[0045] On the other hand, it is also possible to mold the spacer portions **22** by aligning ball models (rolling element model), which is slightly larger than the ball **3** in diameter, in the retaining holes **20** of the belt member **21** and molding with the ball models and the belt member **21** used as cores. When the balls **3** are used as cores, the step of forming gaps between respective balls **3** and spacers **22** is required after the completion of molding of the spacer portions **22**, as described above. On the other hand, in case where the ball models are used as cores, since the ball models are slightly larger than the balls **3**, the spacer portions **22** become smaller correspondingly. Therefore, by forcing the ball models out the string belt **2** and then fitting balls **3** instead when molding of the spacer portions **22** is finished, the balls **3** can roll within the retaining holes **20** freely without a time consuming step of soaking the string belt **2** into oil for a prescribed period of time.

[0046] According to the method of manufacturing the rolling element string **1** as described above, formation of an elongated rolling element string in a mold by injection molding as in the conventional manner is not necessary any more, and the rolling element string **1** comprising a thin belt member **21** can be manufactured simply at low cost and stably.

[0047] According to the method of manufacturing the rolling element string **1** as described thus far, the same material as the spacer portion **22** is used for the belt member **21**, and a reinforcing material **23** is integrated within the belt member **21** in order to enhance the tensile strength and the flexural strength of the belt member **21**. However, it is also possible to enhance the tensile strength and the flexural strength of the belt member **21** by adding carbon filler or the like to the material for the belt member **21** itself to compensate deterioration of the tensile strength and the flexural strength of the belt member **21** associated with the reduction of the thickness thereof.

[0048] FIGS. **7** to **9** show the second embodiment of the rolling element string manufactured according to the method of the present invention.

[0049] The rolling element string **1A** has almost the same structure as the rolling element string **1** of the first embodiment. However, as shown in cross sectional views of **FIG. 8** and **FIG. 9**, the belt member **21** includes a reinforcing material such as a glass fiber, a carbon fiber, or a ceramics fiber integrated in both edge portions along its length. Therefore, when the tensile force is applied along the length of the string belt **2**, the tensile force is loaded onto the reinforcing material **23**, whereby breakage of the string belt **2** can be prevented more effectively than in the first embodiment. The same reference numerals are designated to the components identical to the first embodiment, and detailed description will be omitted.

[0050] The method of manufacturing the rolling element string **1A** will now be described step-by-step.

[0051] **FIG. 10** shows a belt member **21** formed in the first step of the present invention. The belt member **21** is manufactured by extrusion molding of a synthetic resin, and a reinforcing material **23** described above is integrated therein during extrusion molding.

[0052] **FIG. 11** is a schematic illustration showing the step of carrying out extrusion molding of the belt member **21** while integrating a reinforcing material. The reinforcing material **23** is wound on a large diameter reel **4**. The reinforcing material **23** unwound from the reel **4** is preheated by the pre-heater **5**, then passed through the mandrel **7** of the cross head die **6** and pulled out of the molding die **8**. A molten synthetic resin such as polyamide elastomer or polyester elastomer is forced into the cross head die **6** by a screw, not shown, and built up around the reinforcing material **23** as the reinforcing material **23** is extruded from the molding die **8**, whereby an elongated belt member **21** is consecutively extruded from the cross head die **6**. The extruded belt member **21** is cooled down in the water tank **9** and then wound by the reel **10**, which is cut into a prescribed length and used in the subsequent step.

[0053] The reinforcing material **23** may not be necessarily a glass fiber itself, but may be a synthetic resin the tensile strength or the flexural strength of which has been improved by adding carbon filler or the like. In such a case, double-layer extrusion molding may be employed to form the belt member **21** of the shape shown in **FIG. 10**. As shown in **FIG. 12**, two extruders **11**, **12** are used in this double-layer extrusion. After setting a synthetic resin for forming a reinforcing material in the hopper **13** of one extruder **11** and a synthetic resin for covering the reinforcing material in the hopper **14** of the other extruder **12**, these synthetic resins are extruded from the common die **15**. Then, as in **FIG. 11**, the extruded belt member **21** is cooled down in the water tank and wound by the reel, and an elongated belt member **21** including a synthetic resin of high tensile strength and flexural strength as a reinforcing material **23** covered with another type of synthetic resin can be obtained.

[0054] In this manner, even when a reinforcing material **23** is integrated within the belt member **21**, the belt member **21** before the spacer portion **22** is built up thereon has a uniform cross section along its length, whereby the belt member **21** of a uniform thickness may be formed simply at low cost as in the case of the first embodiment.

[0055] Subsequently, molding of the spacer portion **22** is carried out in the same manner as the rolling element string **1** of the first embodiment that does not comprise a reinforcing material **23**. In other words, the belt member **21** cut into the length corresponding to one orbit of the endless raceway of the linear guide device is formed with retaining holes **20** for retaining the balls **3** along its length at prescribed intervals as shown in **FIG. 13**, and injection molding of the spacer portions **22** is carried out with the balls **3** aligned in these retaining holes **20**. The string belt **2** after molding of the spacer portion **22** has finished is soaked in oil for a certain period of time, thereby gaps for allowing the balls **3** to roll are formed between the spacers **22** and the balls **3**. As a consequent, as shown in **FIG. 14**, the rolling body string **1A** of the second embodiment having a reinforcing material **23** integrated therein is completed.

[0056] In the embodiments as is described thus far, balls are employed as rolling elements to be aligned in the belt member. However, this invention may be applied to the case where rollers are employed as rolling elements. More specifically, as shown in **FIG. 15**, after forming retaining holes **31** for rollers **30** on the belt member **21** along its length at prescribed intervals, injection molding is carried out with the rollers **30** aligned in these retaining holes **31** as shown in **FIG. 16**. As a consequent, the rollers **30** are trapped within the retaining holes **31** of the belt member **21**, and as is in the case where the balls **3** are employed as rolling elements, the string belt **2** having the rollers **30** aligned and retained in the belt member **21** at prescribed intervals may be completed.

What is claimed is:

1. A rolling element string comprising a number of rolling elements for rolling between a slider and a rollway of a linear guide device under loaded conditions and circulating along an endless raceway of the slider, and a string belt by which these rolling elements aligned in a row at prescribed intervals and each rolling elements rollably retained, the string belt comprising:

a belt member formed in the flat band shape and having retaining holes with a central portion in width direction of it for retaining these rolling elements;

spacer portions projecting from both surfaces of the belt member between the respective adjacent retaining holes for trapping the rolling element within the retaining holes of the belt member;

a pair of reinforcing material included the belt member integrated in both edge portions along its length;

wherein a thickness of the central portion of the belt member is thinner than the both edge portions of the belt member.

(57) **ABSTRACT**

A ball screw comprises a screw shaft, a nut assembled with the screw shaft, a number of balls disposed in the ball rolling passage formed by a ball rolling groove formed to the screw shaft and a loaded ball rolling groove formed to the nut, a number of spacers disposed between the balls in the ball rolling passage, and a circulation member for circulating the balls and spacers in accordance with a relative motion of the nut with respect to the screw shaft. The circulation member is provided with a scoop-up groove for scooping the balls, when contacting the ball rolling in the ball rolling passage, at both side edge portions of the scoop-up groove and is also provided with a spacer scoop-up portion which contacts and scoops the spacer moving in the ball rolling passage without contacting the balls. Such circulation member will be preferably utilized for a motion guide device such as linear motion guide or spline shaft.

PRIOR ART

CIRCULATION MEMBER, MOTION GUIDE DEVICE PROVIDED WITH CIRCULATION MEMBER AND BALL SCREW PROVIDED WITH CIRCULATION MEMBER

BACKGROUND OF THE INVENTION

[0001] 1. Field of the Invention

[0002] The present invention relates to a circulation member for circulating a number of balls and spacers disposed in a ball rolling passage formed between a track member and a movable member in conformity with a relative motion of the movable member with respect to the track member, and also relates to motion guide device and ball screw provided with such circulation member.

[0003] 2. Related Art

[0004] The applicant of the subject application provided a circulation member such as shown in **FIG. 20** applied to a ball screw, which is disclosed in Japanese Patent Application No. HEI 10-180767.

[0005] With reference to **FIG. 20, a** ball screw is formed with a ball rolling groove, and balls **1** rolling along the ball rolling groove contact both edge portions **3***a*, **3***b* of a scoop-up groove **3** formed in a circulation member **2** and are then scooped from the ball rolling groove **3** in an embraced fashion. In the case where scoop-up groove **3** is formed in the circulation member **2**, an impact force is substantially not applied to the circulation member **2**, and therefore, it becomes possible to rotate a screw shaft at high speed to thereby move the balls **1** also at high speed.

[0006] Such circulation member **2** may be functionally sufficient to act only to circulate the balls **1**. However, there are many cases where spacers are disposed between the balls **1** for preventing friction or like. Such a spacer has substantially cylindrical shape having a diameter smaller than that of the ball **1** and is provided, at its both end portions in the ball advancing direction, with recesses in conformity with the spherical shape of the ball.

[0007] When scooping the ball **1** and the spacer by using the circulation member of the conventional structure mentioned above, for example, because the ball **1** has a spherical surface, the ball **1** is embraced and scooped by both side edge portions **3***a*, **3***a* of the scoop-up groove **3**. In a case where there exists a small gap between the adjacent balls **1**, **1**, the spacer put between the balls **1**, **1** may be also scooped together with the balls. However, as shown in **FIGS. 21 and 22**, in a case where the spacer **4** freely moves between the adjacent balls **1**, **1**, there is a fear that the spacer **4** engages with the side edge portions **3***a*, **3***b* of the scoop-up groove **3** because the spacer **4** has nearly flat end portions in the advancing direction, thus being inconvenient.

SUMMARY OF THE INVENTION

[0008] An object of the present invention is therefore to substantially eliminate defects or inconveniences encountered in the prior art and to provide a circulation member capable of surely scooping a spacer as well as a ball even in an arrangement that a gap exist between balls, for example, of a ball screw.

[0009] Another object of the present invention is to provide a ball screw and a motion guide device provided with an improved circulation member mentioned above.

[0010] These and other objects can be achieved according to the present invention by providing, in a general aspect, a circulation member formed with a scoop-up groove for scooping the ball and a spacer scoop-up portion by contacting the spacer without contacting the ball.

[0011] That is, in one main aspect, the circulation member for achieving the above objects is a circulation member for circulating a number of balls and a number of spacers, each spacer being disposed between the balls, which are arranged in a ball rolling groove formed between a track member and a movable member, in accordance with a relative motion of the movable member with respect to the track member, wherein the circulation member is provided with a scoop-up groove for scooping the balls by contacting the ball rolling in the ball rolling passage at both side edge portions of the scoop-up groove and is also provided with a spacer scoop-up portion which contacts and scoops the spacer moving in the ball rolling passage without contacting the balls.

[0012] According to this aspect, the ball rolling on the ball rolling passage is embraced by both side edge portions of the scoop-up groove formed in the circulation member and is then scooped. In such operation, even if the gap between the balls is widened and the spacer tends to come off from a track of the ball, the spacer can be scooped by the spacer scoop-up portion. Also, since the spacer scoop-up portion does not contact the balls being scooped by the scoop-up groove, the spacer scoop-up portion will not be damaged.

[0013] In a preferred embodiment of this aspect, the spacer scoop-up portion is formed with an escape surface which is apart from a track of the ball scooped by the scoop-up groove and contacts the spacer, thus contacting only the spacer without contacting the ball.

[0014] In another aspect of the present invention, there is provided a ball screw comprising:

[0015] a screw shaft formed, on an outer periphery thereof, with a spiral ball rolling groove;

[0016] a nut assembled with the screw shaft and formed, on an inner periphery thereof, with a spiral loaded ball rolling groove so as to oppose to the ball rolling groove formed on the screw shaft to thereby form a ball rolling passage;

[0017] a number of balls disposed in the ball rolling passage;

[0018] a number of spacers disposed between the balls in the ball rolling passage; and

[0019] a circulation member for circulating a number of balls and spacers, each spacer being disposed between the balls in accordance with a relative motion of the nut with respect to the screw shaft, wherein the circulation member is provided with a scoop-up groove for scooping the balls by contacting the ball rolling in the ball rolling passage at both side edge portions of the scoop-up groove and is also provided with a spacer scoop-up portion which contacts and scoops the spacer moving in the ball rolling passage without contacting the balls.

[0020] In preferred embodiments of this aspect, the spacer scoop-up portion is also formed with an escape surface which is apart from a track of the ball scooped by the scoop-up groove and contacts the spacer.

[0021] The circulation member has a linear passage having a circular section for linearly moving the ball scooped by the scoop-up groove, and the spacer scoop-up portion is formed at a bottom portion of the scoop-up groove and is formed with an escape surface which is inclined by a predetermined angle with respect to an inner peripheral surface of the linear passage in a sectional area including a center line of the linear passage.

[0022] In a further aspect of the present invention, there is also provided a motion guide device comprising:

[0023] a track rail formed with a ball rolling groove;

[0024] a slide member mounted to the track member to be relatively movable with respect thereto and is formed with a loaded ball rolling groove so as to oppose to the ball rolling groove of the track member to thereby form a ball rolling passage;

[0025] a number of balls disposed in the ball rolling passage;

[0026] a number of spacers disposed between the balls in the ball rolling passage; and

[0027] a circulation member for circulating a number of balls and spacers, each spacer being disposed between the balls in accordance with a relative motion of the slide member with respect to the track member, wherein the circulation member is provided with a scoop-up groove for scooping the balls by contacting the ball rolling in the ball rolling passage at both side edge portions of the scoop-up groove and is also provided with a spacer scoop-up portion which contacts and scoops the spacer moving in the ball rolling passage without contacting the balls.

[0028] According to the ball screw and the motion guide device, the circulation member has an improved structure of spacer scoop-up portion, so that the ball and the spacer can be surely scooped without damaging the constitutional elements.

[0029] The nature and further characteristic features will be made more clear from the following descriptions made with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

[0030] In the accompanying drawings:

[0031] **FIG. 1** is a perspective view, partially in section, of a ball screw provided with a circulation member according to a first embodiment of the present invention;

[0032] **FIG. 2** shows the circulation member and includes **FIG. 2A** being a plan view of the circulation member, **FIG. 2B** being a side view thereof as viewed from an axial direction of a screw shaft of the ball screw, **FIG. 2C** being a side view thereof as viewed from a direction perpendicular to the axis of the screw shaft and **FIG. 2D** being a front view thereof;

[0033] **FIG. 3** shows a leg portion of the circulation member and includes **FIG. 3A** being a sectional view thereof indicating a radius of curvature of a scoop-up groove and **FIG. 3B** showing a sectional view thereof indicating an inclination (inclining angle) of an escape surface;

[0034] **FIG. 4** is an illustration showing a ball scooping state by the scoop-up groove;

[0035] **FIG. 5** is an illustration, in an enlarged scale, showing a comparison of gaps between the scoop-up groove and the screw shaft in a case of a circulation member provided with a scoop-up portion and in a case of a circulation member provided with no scoop-up portion;

[0036] **FIG. 6** is an illustration showing a ball scooping state by the scoop-up portion;

[0037] **FIG. 7** is an illustration showing a spacer scooping state by a spacer scooping portion;

[0038] **FIG. 8** is a perspective view, partially in section, showing an end-cap type ball screw provided with a circulation member according to a second embodiment of the present invention;

[0039] **FIG. 9** shows a combination of a side lid and the circulation member of the second embodiment and includes **FIG. 9A** showing a state viewed from the axial direction of the screw shaft and **FIG. 9B** showing a state viewed from the side of the screw shaft;

[0040] **FIG. 10** is an illustration showing the circulation member of the second embodiment;

[0041] **FIG. 11** is a perspective view showing one example of a deflector type ball screw provided with the circulation member of the present invention;

[0042] **FIG. 12** is a perspective view of a linear motion guide device provided with a circulation member according to a third embedment of the present invention;

[0043] **FIG. 13** is a perspective view showing the circulation member;

[0044] **FIG. 14** is a sectional view of the circulation member;

[0045] **FIG. 15** is an illustration showing a track of the ball scooped by the scoop-up groove;

[0046] **FIG. 16** is an illustration showing a ball scooping state by the scoop-up groove and a spacer scooping state by the spacer scoop-up portion;

[0047] **FIG. 17** is an illustration comparative with **FIG. 16**, provided with no spacer scooping portion;

[0048] **FIG. 18** is a perspective view, comparative with **FIG. 16**, provided with no spacer scooping portion;

[0049] **FIG. 19** is a perspective view of a ball spline provided with the circulation member of the present invention;

[0050] **FIG. 20** is a perspective view of a ball screw provided with a circulation member of conventional structure;

[0051] **FIG. 21** is an illustration, viewed from the axial direction of a screw shaft, showing a state that a ball is engaged with the scoop-up groove; and

[0052] **FIG. 22** is an illustration, viewed from the front side of the scoop-up groove, showing a state that a gap grows between adjacent balls.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0053] Preferred embodiments of the present invention will be described hereunder in detail in conjunction with the accompanying drawings.

[0054] **FIG. 1** shows a ball screw provided with a circulation member according to the first embodiment of the present invention.

[0055] With reference to **FIG. 1, a** ball screw **8** is composed of a screw shaft **9** formed with a spiral ball rolling groove **9***a* formed on an outer peripheral surface thereof and a nut **10** mounted to the screw shaft **9**. The spiral ball rolling groove **9***a* is formed by a grinding or rolling working so as to have a constant lead and approximately semi-circular section.

[0056] On the other hand, the nut **10** is formed, on its inner peripheral surface, with a spiral loaded ball rolling groove **10***a* corresponding to the ball rolling groove **9***a* of the screw shaft **9**. The nut **10** generally has a cylindrical shape and the nut **10** is provided, at its one end, with a flanged potion **14** for mounting the ball screw **8** to a machine or like. The spiral loaded ball rolling groove **10***a* of the nut **10** is formed so as to have an approximately semi-circular section of the shape corresponding to the ball rolling groove **9***a* of the screw shaft **9**.

[0057] The nut **10** is formed with insertion holes, at plural portions, for inserting leg portions **12***b*, **12***b* of a circulation member **12**.

[0058] The ball rolling groove **9***a* of the screw shaft **9** and the loaded ball rolling groove **10***a* formed on the nut **10** constitute, in their combination, a ball rolling passage in which a number of balls **11, 11**, - - - are accommodated and spacers **16, 16**, - - - are also accommodated to prevent the balls **11** from contacting each other.

[0059] In this first embodiment, the nut **10** is mounted with, for example, two circulation members **12, 12**, which are called "return pipes". The circulation member **12** constitutes a non-loaded return passage communicating one end of the ball rolling passage with the other one end thereof so that a number of balls **11, 11**, - - - and spacers **16, 16**, - - - circulate in accordance with the relative motion of the nut **10** with respect to the screw shaft **9**.

[0060] The circulation member **12** has a gate shape having a central portion **12***a* and a pair of leg portions **12***b*, **12***b* extending from both side end portions of the central portion **12***a*. These leg portions **12***b*, **12***b* are inserted into the ball rolling passage with an interval of several pitches, and the circulation member **12** is fastened to the nut **10** by means of bolts **13** or like.

[0061] With reference to **FIG. 2 (FIGS. 2A** to 2D), the circulation member **12** is disposed so that center lines **19, 19** of the inner peripheries of the paired leg portions **12***b*, **12***b* are positioned to the tangential direction of the center line **18** of the spiral ball track as shown in **FIG. 2**B, and the leg portions **12***b*, **12***b* are inclined in directions different from each other in conformity with lead angles of the center line **18**.

[0062] According to such arrangement of the center lines of the leg portions **12***b*, **12***b*, the ball **11** can be scooped in the tangential direction and lead angle direction of the track center line **18**. That is, the ball **11** can be scooped up along its rolling (advancing) direction. Therefore, no forcible force is not applied to the leg portions **12***b*, **12***b* at the time of scooping the ball **11**.

[0063] The circulation member **12** is divided into two sections or parts along its axial direction as a pair of divided bodies **20, 20**, which are then jointed by means of heat calking, fusing, bonding or like process or by using fastening means, adhesive sheet, clip or like.

[0064] Next, with reference to **FIG. 3**, each of the leg portions **12***b* has a linear passage **21**, having a circular section, for substantially linearly moving the ball **11**. As mentioned above, the center line **19** of the inner periphery of this linear passage **21** is arranged in the tangential direction of the ball track center line **18** as shown in **FIG. 2**. The leg portion **12***b* has a front end extending to the position at which the ball track center line **18** and the center line **19** of the linear passage **21** contact each other, and at a portion near the front end of the leg portion **12** is formed with a scoop-up groove **22** for scooping the ball **11**.

[0065] Referring to **FIG. 3**A, the radius R1 of curvature of the scoop-up groove **22** viewed from the axial direction of the screw shaft **9** is designed to be slightly smaller than the radius R2 of curvature of the track center line **18** of the ball **11** and slightly larger than the outer diameter R3 of the screw shaft **9**. Further, the scoop-up groove **22** has a lateral width gradually reduced towards the deep direction of the circulation member **12**.

[0066] A spacer scoop-up portion **23** is formed at the bottom portion of the scoop-up groove **22**. The spacer scoop-up portion **23** is formed with an escape surface **24** so as to be apart from the track of the ball **22** scooped by the scoop-up groove **22** and to contact the spacer **16**.

[0067] With reference to **FIG. 3**B, in the sectional area including the center line **19** of the linear passage **21**, the escape surface **24** of the spacer scoop-up portion **23** is inclined by a predetermined angle a with respect to the inner peripheral surface **25** of the linear passage **21**. According to such design, a boundary portion **26** is formed between the inner peripheral surface **25** of the linear passage **21** and the escape surface **24** of the spacer scoop-up portion **23**. This escape surface **24** can contact the spacer **16** without contacting the ball **11** and scoop the spacer **16** moving in the ball rolling passage.

[0068] In the structure of this first embodiment, the ball scoop-up groove **22** has a width gradually reduced towards inward the circulation member **12**, and the ball **11** can be scooped by the contact of both the side edges of the scoop-up groove **22** to the ball **11**. Furthermore, in this embodiment, the spacer scoop-up portion **23** is formed at the bottom of the scoop-up groove **22** so as to guide the spacers **16, 16**, - - - disposed between the balls **11, 11**, - - - into the circulation member **12**.

[0069] Although it was difficult to manufacture, through machine working, these scoop-up groove **22** and the spacer scoop-up portion **23** because of complicated structures thereof, it becomes possible to manufacture the scoop-up groove **22** and the spacer scoop-up portion **23** having complicated structures by molding the circulation member from resin or metal material. When the circulation member is formed as metal product, it is molded by thermally treating metal powder. On the other hand, a resin product will be molded through an injection molding process. However, it is still difficult to mold the complicated scoop-up groove **22** and spacer scoop-up portion **23** only by using a lateral pair of mold halves. In this embodiment, therefore, the scoop-up groove **22** and spacer scoop-up portion **23** are molded by using a slide mold capable of being slid in the axial direction of the leg portions **12***b*, **12***b*.

[0070] More specifically, at the molding operation, the slide mold is inserted into a lateral pair of mold halves. Next, under the slide mold inserted state, the scoop-up grooves **22** and the spacer scoop-up portions **23** are formed to the leg portions **12***b*, **12***b*. On the other hand, at the mold releasing operation, the slide mold is slid in the opposing direction. As mentioned, by using the slide mold, the scoop-up grooves **22** and the spacer scoop-up portions having complicated structures can be manufactured, as well as the inner peripheral surfaces of the leg portions **12***b*, **12***b*.

[0071] The ball scoop-up state by the scoop-up groove **22** is shown in **FIG. 4**, in which the spacers **16** and the scoop-up portions **23** are removed for the sake of easy understanding of the description for scooping the ball **11** by the scoop-up groove **22**.

[0072] When the ball **11** rolling along the peripheral direction on the ball rolling groove **9***a* of the screw shaft **9** rolls in the circulation member **12**, both the edge portions **22***a*, **22***b* of the scoop-up groove **22** contact the bal **11**. At this time, since the width of the scoop-up groove **22** is reduced gradually towards the ball rolling direction (from the lower side towards the upper side as viewed in **FIG. 4**), the ball **11** can be scooped, as if it is embraced, from the ball rolling groove into the circulation member **12**.

[0073] The circulation member **12** has an inner diameter, which is slightly larger than an outer diameter of the ball **11** so that the ball **11** can pass the circulation member **12** even in a case where lubricant or like adheres to the ball **11** or the circulation member **12** is slightly displaced. In more strictly, the ball **11** is scooped at after the shifting by an angle β in the screw shaft side and not in the tangential direction of the track center line **18** of the ball **11**.

[0074] In **FIG. 4**, the line L denotes the track of the center of the ball **11**. As mentioned above, according to this embodiment, the ball **11** can be scooped by both the edge portions of the scoop-up groove **22**, a load caused at the time when the ball **11** contacts the scoop-up groove **22** can be significantly reduced.

[0075] On the other hand, in a conventional structure of the ball screw having a return pipe type circulation member, it is general that the ball is scooped by a tongue portion formed to the return pipe. In the use of such conventional ball screw, however, when the screw shaft is rotated at a high speed, the ball moves at a high speed (ball movement becomes faster), there is a fear of damaging the tongue portion through the collision of the ball with the tongue portion. In order to obviate such defect, it was necessary to determine the upper limit of the revolution number of the screw shaft, thus having been inconvenient.

[0076] Therefore, the present invention has been conceived to overcome such inconvenience and provides a screw shaft capable of being rotated at a high speed by forming the scoop-up groove **22** to the circulation member **12**. According to the present invention, as mentioned before, since the ball can be scooped by both the edge portions of the scoop-up groove **22**, there is no need for forming the tongue portion as in the conventional structure.

[0077] The spacer scoop-up portion **23** acts to scoop up only the spacer **16** and has an outer shape similar to a shape of the tongue portion, which scoops the ball in the return pipe, in the conventional structure. However, the most essential difference of the present invention from the conventional structure resides in the presence of the escape surface **24**.

[0078] That is, in general, the tongue portion of the conventional return pipe is formed by cutting or grinding, for example, metal tube or grinding stone. Hence, an escape surface (such as escape surface **24** in this embodiment) having a predetermined inclination a with respect to the linear passage is never formed in the return pipe. Since the escape surface **24** is inclined by the predetermined angle of a, a projecting amount from the bottom of the scoop-up groove **22** is made smaller than that of the tongue portion.

[0079] **FIG. 5** shows a comparison of gaps between the scoop-up groove **22** and the screw shaft **9** in the case of the circulation member **12** provided with the scoop-up portion **23** and in the case of a circulation member **27** provided with no scoop-up portion. Further, it is to be noted that, in order to observe the gaps, in this **FIG. 5**, wall sections of the circulation members **12** and **27** on the side opposing to the scoop-up grooves **22** are eliminated in the illustration.

[0080] With reference to **FIG. 5**, the balls **11** are scooped by the scoop-up grooves **22** positioned on the sides opposing to the illustrated state. In the case of the circulation member **27** provided with no spacer scoop-up portion **23**, a relatively large gap S appears between the scoop-up groove **22** and the screw shaft **9**, and there is a fear that the spacer **16** dropping off from the ball **11** is adversely engaged with this space S. However, in the embodiment in which the spacer scoop-up portion **23** is formed, such space S can be clogged by the spacer scoop-up portion **23**.

[0081] Next, with reference to **FIGS. 6 and 7**, the ball **11** is scooped up in the manner of being embraced with both the edge portions of the scoop-up groove **22** (FIG. **6**). Furthermore, the spacer **16** can be surely scooped up by the escape surface **24** formed to the spacer scoop-up portion **23** contacting the spacer **16** even if the distance between the adjacent balls **11** is widened and the spacer **16** comes off from the moving passage. The spacer **16** does not always contact the spacer scoop-up portion **23**, and only in the case that the distance between the balls **11** is widened and the spacer **16** tends to come off from its track, the spacer **16** contacts the spacer scoop-up portion **23**. In the other cases, the spacers **16** are moved together with the balls **11**. Further, the spacer scoop-up portion **23** does not contact the ball **11** at the time when the ball **11** is scooped up, thus being not damaged or broken.

[0082] **FIG. 8** represents a ball screw of end-cap structure provided with a circulation member according to the second embodiment of the present invention.

[0083] The ball screw of this embodiment comprises a screw shaft **34** formed with a ball rolling groove **34***a* and a nut **31** composed of a nut body **32** formed with a ball rolling groove and side lids as end caps **33, 33** mounted to both ends of the nut body **32**. The nut body **32** is formed with the ball rolling groove and a ball return passage, and the side lids **33, 33** are formed with communication passages each communicating the ball rolling groove and the return passage. The circulation member is mounted to each of the side lids **33, 33** so as to act to scoop the balls **11, 11**, - - - and the spacers **16, 16**, - - - disposed between the balls.

[**0084**] **FIG. 9** shows the assembled state of the side lid **33** and the circulation member **35**. The circulation member **35** is mounted inside the side lid **33** and fixed to the nut body **32** by means of bolt or like. The circulation member **35** may have a various outer appearances in accordance with a mounting condition to the side lid **33**.

[**0085**] With reference to **FIG. 10** showing the mounting condition of the circulation member **35**, the circulation member **35** is provided with a ball scoop-up groove **36** which contacts and then scoops the ball **11** rolling in the ball rolling passage at its both side edge portions. The ball scoop-up groove **36** is formed, at its bottom portion, with a spacer scoop-up portion **37** for contacting and scooping the spacer **16** in the ball rolling groove without contacting the ball **11**. The spacer scoop-up portion **37** is formed with an escape surface **38** positioned apart from the ball rolling track and contacting the spacer **16**.

[**0086**] The circulation member **35** is formed with a linear passage **39**, having a circular section, for moving substantially linearly the ball **11** scooped by the scoop-up groove **36**. Further, in the sectional area including the center line of the linear passage **39**, the escape surface **38** of the spacer scoop-up portion **37** is inclined by a predetermined angle a with respect to the inner peripheral surface **40** of the linear passage **39**. According to this embodiment, the spacer **16** can be scooped up by the escape surface **38** even in the case where the distance between the adjacent balls **11, 11** is widened and the spacer **16** is come off from the moving track.

[**0087**] **FIG. 11** also represents a ball screw **41** provided with a circulation member of deflector structure type according to another embodiment of the present invention.

[**0088**] With reference to this embodiment of **FIG. 11**, the balls **11, 11**, - - - and the spacers **16, 16**, - - - traveling on the ball rolling groove **41***a* of the ball screw **41** once separated therefrom by the circulation member **42** having deflector structure and returned, by one lead, to a portion of the ball rolling groove **41***a* by jumping over the outer diameter portion of the screw shaft **41**. This circulation member **42** is formed with a ball return groove having approximately S-shape. The ball return groove has a most recessed portion at the central portion of the circulation member **42** so that the ball **11** and the spacer **16** advancing in the ball return groove can jump over the outer peripheral portion of the screw shaft **41**.

[**0089**] The circulation member **42**, i.e., deflector, acts to forcibly push the ball rolling on the ball rolling groove **41***a* from its lateral side so as to jump the ball over the outer periphery of the screw shaft **41**. Further, a spacer scoop-up portion for scooping only the spacer **16** by contacting it without contacting the ball **11** is formed to the circulation member **42**. In this deflector type circulation member **42**, the escape surface formed to the scoop-up portion has a three-dimensional shape apart from the three-dimensional ball track.

[**0090**] The present invention further provides a linear motion guide provided with a circulation member according to the third embodiment with reference to **FIG. 12**.

[**0091**] The linear motion guide of this embodiment is, for example, a device for guiding a movable member or body such as table on a stationary member such as bed or saddle.

[**0092**] The linear motion guide comprises a track rail **51** disposed on a stationary member and having a longitudinal extension, and a slide member assembled with the track rail **5l** to be relatively movable. The track rail **51** is formed with a ball rolling groove **51***a* formed along the longitudinal direction thereof and the slide member is also formed with a loaded ball rolling groove so as to correspond to the ball rolling groove **51***a* formed to track rail **51**.

[**0093**] The linear motion guide further comprises a number of balls disposed in a ball rolling passage formed by, in combination, the ball rolling groove **51***a* of the track rail **51** and the loaded ball rolling groove formed to the slide member **52**, a number of spacers disposed between the balls, and circulation members **53, 53**, provided for the slide member **52**, for circulating the balls and the spacers in conformity with the relative motion of the slide member **52** with respect to the track rail **51**.

[**0094**] The track rail **51** has an elongated scale so as to provide, for example, a rectangular shape in section. The ball rolling groove **51***a* constitutes a track for ball rolling, and a plurality of rows of ball rolling grooves **51***a* may be formed in accordance with the object on use of the linear motion guide. In the illustrated embodiment, the track rail **51** has a linear structure, but it may have a curved rail structure. The track rail **51** has screw holes to which screws are fastened so as to secure the track rail **51** to the stationary member.

[**0095**] The slide member **52** comprises a block body **54** and end plates as the circulation members **53, 53** disposed both end portions of the block body **54**. The circulation members **53, 53** are formed with U-shaped direction changing passage for changing the rolling direction of the ball.

[**0096**] The block body **54** of the slide member **52** is a ⊐-shaped member having a flat horizontal portion **54***a* opposing to the upper surface of the track rail **51**, when assembled, and a pair of support leg (skirt) portions **54***b*,**54***b* opposing to the bilateral side surfaces of the track rail **51**. Loaded ball rolling grooves are formed to the inside surfaces of the block body **54** so as to oppose to the ball rolling grooves **51***a*, **51***a* formed to the outside surface of the track rail **51**. Ball return passages are also formed to the block body **54**, as bores, in parallel to the ball rolling grooves **51***a*. The ball rolling passage and the ball return passage are communicated by means of the direction changing passage formed to the circulation member **53**. A plurality of fastening holes are formed to the upper surface of the block body **54** for fastening and securing an object to be guided to the block body **54** by means of screws or bolts.

[**0097**] The circulation member **53** will be further described hereunder with reference to **FIGS. 13 and 14**, in which **FIG. 13** is a perspective view of a portion of the circulation member **53** and **FIG. 14** is a sectional view showing the direction changing passage **55** formed to the circulation member **53**.

[0098] The circulation member **53** is formed with, as shown, the ball rolling direction changing passage **55** communicating the ball return passage **56** and the ball rolling passage **57**. More specifically, the circulation member is formed with an outer periphery guide portion **58** constituting the outer periphery of the direction changing passage **55** and, on the other hand, the block body **54** is formed with an arch-shaped inner periphery guide portion **59** constituting the inner periphery of the direction changing passage **55**.

[0099] As shown in **FIG. 13, a** ball scoop-up groove **60** is formed to the lower portion of the direction changing passage **55** of the circulation member **53** for contacting and then scooping the ball in the ball rolling passage **57** by both side edge portions of the groove **60**. The scoop-up groove **60** is formed on one flat surface, in parallel to the track rail **51**, on the side of the track rail **51** more than the center line **63** of the direction changing passage **55**. The scoop-up groove **60** has a horizontal width gradually reduced towards the ball advancing direction. The ball scooping manner of this scoop-up groove **60** is substantially the same as that of the former embodiment.

[0100] As shown in **FIGS. 13 and 14**, in this embodiment, there is formed, at the bottom portion of the scoop-up groove **60**, a spacer scoop-up portion **62** for contacting and then scooping the spacer without contacting the ball in the ball rolling passage **57**. The spacer scoop-up portion **62** has an escape surface **61** apart from the track **64** of the ball scooped by the scoop-up groove **60** but contacting the spacer.

[0101] **FIG. 15** shows the track of the ball **11** scooped by the scoop-up groove **60**. In this embodiment, different from the embodiment of the ball screw, the direction changing passage **55** of the circulation member **53** is bent in a circular-arc shape. Further, since the small gap exists between the ball **11** and the direction changing passage **55**, the track **66** of the center of the ball **11** passes slightly outside the center line **63** of the direction changing passage. Therefore, the escape surface **61** of the spacer scoop-up portion **62** is formed in consideration of this track of the ball **11** so as not to contact the ball. This escape surface **61** may have a curved shape as shown in **FIG. 15** as well as linear shape.

[0102] **FIG. 16** shows the scooping state of the ball **11** by the scoop-up groove and the scooping state of the spacer **16** by the spacer scoop-up portion **62**. As shown, the ball **11** is first embraced and then scooped by both the edge portions of the scoop-up groove **60**. Even if the distance between the balls **11** and the spacer **16** tends to come off from the track, the spacer scoop-up portion **62** contacting the ball **11** can scoop the ball **11**.

[0103] An example provided with no spacer scoop-up portion is shown in **FIGS. 17 and 18** for comparison.

[0104] In this comparative example, the ball **11** having a spherical outer surface is scooped by both the edge portions of the scoop-up groove **60** in the embraced manner. On the other hand, the spacer **16** has a flat end shape, and in the case when the distance between the balls **11, 11** is widened and the spacer **16** tends to come off from the track, there may cause a fear that the flat end portion of the spacer **16** adversely engages with the scoop-up groove **60**, thus being inconvenient.

[0105] **FIG. 19** also shows an example of a ball spline provided with the circulation member according to the present invention.

[0106] The ball spline is composed of a spline shaft **71** as track rail and an outer sleeve **72** as a slide member mounted to the spline shaft **71** through a number of balls **11, 11** - - - disposed therebetween.

[0107] The spline shaft **71** has a columnar structure having true circularity and has an outer surface formed as a ball track on which a ball rolling groove **71***a* so as to extend its axial direction.

[0108] The outer sleeve **72** mounted to the spline shaft **71** is formed with a loaded ball rolling groove corresponding to the ball rolling groove **71***a* so as to constitute a ball rolling passage as a ball circulation passage in form of circuit. In this ball circulation passage, a number of balls **11, 11**, - - - and spacers **16, 16**, - - - are accommodated so as to circulate therein in accordance with the relative linear motion of the outer sleeve **72** with respect to the spline shaft **71**. That is, the ball rolling passage **73** is formed by the ball rolling groove **71***a* of the spline shaft **71** and the loaded ball rolling groove of the outer sleeve **72**. A non-loaded return passage **74**, in which the balls **11, 11**, - - - released from the load, is formed adjacent to the ball rolling passage **73**. On the other hand, the outer sleeve **72** is mounted with a circulation member **75** as a retainer for arranging and retaining the balls **11, 11**, - - - in the axial direction of the spline shaft **71**.

[0109] The circulation member **75** as a retainer is integrally mounted to the outer sleeve **72** and has an inner hollow cylindrical structure into which the spline shaft **71** is disposed in a penetrating manner. The circulation member **75** has an outer surface to which the circuit-formed ball circulation passage is formed. According to this circulation member **75**, the balls **11, 11**, - - - rolling on the ball rolling passage **73** are held from both sides between the outer sleeve **72** and the spline shaft **71** and the balls **11, 11**, - - - rolling on the loaded return passage **74** are held between the outer sleeve **72** and the passage **74** to thereby prevent the balls **11, 11**, - - - from coming off at the time when the outer sleeve **72** is withdrawn from the spline shaft **71**.

[0110] A ball scoop-up groove for scooping the balls **11, 11**, - - - rolling on the ball rolling passage **73** is formed to the circulation member **75**, which may also be formed with a spacer scoop-up portion for scooping us the spacers **16**.

[0111] It is to be noted that the present invention is not limited to the described embodiments and many other changes and modifications may be made without departing from the scopes of the appended claims.

[0112] For example, a number of spacers arranged independently between the adjacent balls may be connected in series by using a band or belt member. Furthermore, the track rail of the motion guide device may be formed to provide a curved structure in place of the linear structure.

[0113] The present application claims priority under 35 U.S.C §119 to Japanese Patent Application No.2002-184540 filed Jun. 25, 2002 entitled "CIRCULATION MEMBER, MOTION GUIDE DEIVCE PROVIDED WITH CIRCULATION MEMBER AND BALL SCREW PROVIDED WITH CIRCULATION MEMBER". The contents of that application are incorporated herein by reference in their entirety.

What is claimed is:

1. A circulation member for circulating a number of balls and a number of spacers, each spacer being disposed between the balls, which are arranged in a ball rolling groove formed between a track member and a movable member, in accordance with a relative motion of the movable member with respect to the track member,

wherein the circulation member is provided with a scoop-up groove for scooping the balls by contacting the ball rolling in the ball rolling passage at both side edge portions of the scoop-up groove and is provided with a spacer scoop-up portion which contacts and scoops the spacer moving in the ball rolling passage without contacting the balls.

2. The circulation member according to claim 1, wherein said spacer scoop-up portion is formed with an escape surface which is apart from a track of the ball scooped by the scoop-up groove and contacts the spacer.

3. A ball screw comprising:

a screw shaft formed, on an outer periphery thereof, with a spiral ball rolling groove;

a nut assembled with the screw shaft and formed, on an inner periphery thereof, with a spiral loaded ball rolling groove so as to oppose to the ball rolling groove formed on the screw shaft to thereby form a ball rolling passage;

a number of balls disposed in the ball rolling passage;

a number of spacers disposed between the balls in the ball rolling passage; and

a circulation member for circulating a number of balls and spacers, each spacer being disposed between the balls in accordance with a relative motion of the nut with respect to the screw shaft, wherein the circulation member is provided with a scoop-up groove for scooping the balls by contacting the ball rolling in the ball rolling passage at both side edge portions of the scoop-up groove and is provided with a spacer scoop-up portion which contacts and scoops the spacer moving in the ball rolling passage without contacting the balls.

4. The ball screw according to claim 3, wherein said spacer scoop-up portion is formed with an escape surface which is apart from a track of the ball scooped by the scoop-up groove and contacts the spacer.

5. The ball screw according to claim 4, wherein said circulation member has a linear passage having a circular section for linearly moving the ball scooped up by the scoop-up groove, and said spacer scoop-up portion is formed at a bottom portion of the scoop-up groove and is formed with an escape surface which is inclined by a predetermined angle with respect to an inner peripheral surface of the linear passage in a sectional area including a center line of the linear passage.

6. A motion guide device comprising:

a track rail formed with a ball rolling groove;

a slide member mounted to the track member to be relatively movable with respect thereto and is formed with a loaded ball rolling groove so as to oppose to the ball rolling groove of the track member to thereby form a ball rolling passage;

a number of balls disposed in the ball rolling passage;

a number of spacers disposed between the balls in the ball rolling passage; and

a circulation member for circulating a number of balls and spacers, each spacer being disposed between the balls in accordance with a relative motion of the slide member with respect to the track member, wherein the circulation member is provided with a scoop-up groove for scooping the balls by contacting the ball rolling in the ball rolling passage at both side edge portions of the scoop-up groove and is provided with a spacer scoop-up portion which contacts and scoops the spacer moving in the ball rolling passage without contacting the balls.

7. The motion guide device according to claim 6, wherein said spacer scoop-up portion is formed with an escape surface which is apart from a track of the ball scooped by the scoop-up groove and contacts the spacer.

(57) **ABSTRACT**

In a roller retainer assembly, a roller retainer **15** is thinned to retain individual one of plural rollers **7** circulating in a roller circulation path inclusive of linear and curved races and to hold opposite side surfaces of the roller **7** and front and rear surfaces thereof in the roller moving direction. A combination of linear and curve guide portions **16***a* and **16***b* different in inclination angle and a combination of linear and curve guide portion **17***a* and **17***b* different in inclination angle are formed respectively in opposite end surfaces of the roller retainer **15** in a retainer moving direction. In a linear race, the linear guide portions **16***a* and **17***a* come into contact with adjacent roller retainers **15** respectively. In a curved race, the curve guide portions **16***b* and **17***b* come into contact with adjacent roller retainers **15** respectively.

ROLLER RETAINER, DIRECT-ACTING GUIDE DEVICE AND ROLLER SCREW USING THE ROLLER RETAINER

BACKGROUND OF THE INVENTION

[0001] 1. Field of the Invention

[0002] The present invention relates to a roller retainer which is used in a direct-acting guide device, a roller screw, or the like, and in which a roller rolling in a circulation path is held so as to be rotatable/slidable.

[0003] 2. Description of the Related Art

[0004] A roller screw having rollers interposed between a screw shaft and a nut member is known. When the screw shaft is rotated relative to the nut member, the nut member makes reciprocating motion in a direction of the axis of the screw shaft. The rollers make rolling motion so as to go around the outer circumference of a screw groove between the screw shaft and the nut member. Thus, the rollers circulate in a roller circulation path. A helical roller rolling groove is formed in the screw shaft. The roller circulation path containing a helical load rolling groove corresponding to the roller rolling groove is formed in the nut member. In the roller screw, the plurality of rollers may be arranged in the roller circulation path so as to be parallel to one another to keep the axes of adjacent rollers approximately parallel to each other, or the plurality of rollers may be arranged in the roller circulation path so as to cross one another to intersect the axes of adjacent rollers.

[0005] Generally, in the case of a full-roller type roller screw in which only rollers are arranged in the roller circulation path, the respective rollers make no consistent motion so that each of the rollers falls down in a plane containing the axis of the roller and the direction of the movement of the roller to cause skew. Hence, the rollers are prevented from circulating while arranged in the roller circulation path. Though not relating to the roller screw, a belt-like ball retainer for rotatably/slidably holding a plurality of balls of a ball screw to make arranged circulation of the balls is known (for example, see JP-A-11-223258). The ball retainer holds the balls in the form of a linear chain so that front-side and rear-side adjacent balls can circulate smoothly.

[0006] On the other hand, a cage for holding corresponding one of rollers arranged and received in a circulation path of a direct-acting guide device is known (see JP-A-60-205013). **FIG. 17** shows such cages circulating in the roller circulation path of the direct-acting guide device. A plurality of rollers **1** are cross-arranged in the roller circulation path **2** so that the axes of adjacent rollers **1** cross each other. The direction of the roller **1** is changed two-dimensionally in between a linear load passage **2***a* and a U-shaped changing-direction passage **2***b*. **FIG. 18** is a front view of a cage **3** with a roller **1** when viewed in the direction of the movement thereof. **FIG. 19** is a sectional view taken along the line A-A in **FIG. 18**. Because of the cross arrangement of the rollers **1**, the roller circulation path **2** is shaped substantially like a square in section. The cages **3** rotatably/slidably hold the rollers **1** in container holes **3***a* of the cages **3** individually and correspondingly while the outer circumferences **1***a* of the rollers **1** are exposed partially slightly. The thickness of the cage **3** (the radial thickness of the roller) is set to be approximately equal to that of the roller **1**. As shown in the drawings, the shape of the cage **3** viewed from the front side in the direction of the movement forms a square approximately equal to the sectional shape of the roller circulation path **2** so that the roller **1** can be guided by the cage **3**. As shown in **FIG. 17**, two end surfaces **3***a* and **3***b* which form an angle of not smaller than 90° are formed at two ends of the adjacent cages **3** in the direction of the movement thereof. When the cage **3** is located on the linear load passage **2***a*, one end surface **3***a* is positioned so as to be approximately perpendicular to the load passage **2***a*. When the cage **3** is located on the U-shaped changing-direction passage **2***b*, the other end surface **3***b* is directed to the direction of the radius of the changing-direction passage **2***b*. Thus, the cages **3** with the rollers **1** circulate in the roller circulation path **2** while the end surfaces **3***a* and **3***b* of adjacent cages **3** press each other.

[0007] In the background-art ball retainer holding balls in the form of a straight chain, however, the circulation path of the ball screw draws a spiral. Hence, the ball retainer is twisted so spirally that load is applied on the ball retainer. There is a risk that the ball retainer may be broken by the load.

[0008] On the other hand, the cages **3** by which the rollers **1** arranged and received in the roller circulation path **2** of the direct-acting guide device are held individually are adapted to the case where the linear load passage and the U-shaped changing-direction passage are positioned on one plane so that the direction of the rollers **1** is changed two-dimensionally. For example, in a circulation path of a roller screw, however, not two-dimensional direction changing but three-dimensional direction changing and, accordingly, twisting motion around the direction of the movement, may be required. In the aforementioned cages **3**, the circulating cages **3** are not allowed to rotate slightly around the axes of the rollers **1** respectively so that the cages **3** can hardly make such complex motion. This is because the shape of each cage **3** is formed to be approximately equal to the sectional shape of the roller circulation path **2** and because adjacent cages **3** are in surface contact with each other at large-area flat end surfaces **3***a* and **3***b*. Moreover, a lubricant can hardly enter in between the cage **3** and a corresponding roller **1** because the circumference of the roller **1** except part of the outer circumference **1***a* is covered with the cage **3**. Hence, the roller **1** cannot be lubricated sufficiently. Moreover, the approximately whole section of the roller circulation path **2** is covered with the cage **3**. There is a problem that a support member for supporting the cage **3** to prevent the cage **3** from dropping down from the slide member when the slide member is removed from the race rail is hardly provided in the circulation path.

SUMMARY OF THE INVENTION

[0009] An object of the present invention has been made to solve the above object, and therefore an object of the invention is to provide a roller retainer which can circulate smoothly even in a complex kinetic condition such as a three-dimensional changing-direction passage and in which lubricating oil can be supplied sufficiently to rollers, and to provide a direct-acting guide device and a roller screw using such roller retainers.

[0010] The present invention will be described below. Although the reference numerals in the accompanying drawings are put in parentheses to make understanding of the present invention easy, the present invention is not limited to the embodiments based on the accompanying drawings.

[0011] To solve the problem, the inventor of the present invention provides a system in which rollers circulating in a circulating path are not held in the form of a straight chain but are held in roller retainers individually so that the rollers circulate in a circulation path while the rear-side roller retainer presses the front-side roller retainer. Further, because linear portions and curved portions mainly exit in the circulation path, the inventor considers the shape of each end of the roller retainer in a direction of the movement thereof so that pressing force is transmitted smoothly either in the linear portions or in the curved portions. Further, the inventor provides a system in which roller retainers can circulate while allowed to rotate slightly around the axes of the rollers respectively when the roller retainers circulate while pressing each other. Accordingly, the roller retainers can be adapted to a three-dimensionally complex circulation path on the assumption that the rollers are arranged in the circulation path and the axes of adjacent rollers are substantially kept parallel to each other.

[0012] Specifically, according to a first aspect of the present invention, there is provided a roller retainer assembly having roller retainers (**15**) for individually and correspondingly retaining a plurality of rollers (**7**) circulating in a roller circulation path inclusive of linear and curved races, wherein: each of the roller retainers (**15**) is made thin to hold opposite side surfaces of the roller (**7**) and front and rear surfaces of the roller (**7**) in a direction of movement of the roller (**7**); a linear guide portion (**16***a*, **17***a*) and a curve guide portion (**16***b*, **17***b*) which are different in inclination angle from each other are formed in opposite end surfaces of the roller retainer (**15**) in a direction of movement of the roller retainer (**15**); and the linear guide portion (**16***a*, **17***a*) of the roller retainer (**15**) comes into contact with an adjacent roller retainer (**15**) in the linear race and the curve guide portion (**16***b*, **17***b*) of the roller retainer (**15**) comes into contact with an adjacent roller retainer (**15**) in the curved race. By the provision of the roller retainer assembly, the above-mentioned problem is therefore solved. The thickness of the roller retainer (**15**) is selected to be not larger than 90%, preferably not larger than 60% of the roller diameter.

[0013] According to this invention, in either of linear races and curved races constituting a circulation race, adjacent roller retainers can press each other without spoiling the posture of a roller located in the front side in the direction of the movement of the roller. Hence, rollers can be aligned so that smooth circulation can be obtained. Further, because the roller retainer is made thin, the following effects are obtained.

[0014] (1) Adjacent roller retainers can press each other while they are allowed to rotate slightly around the axes of corresponding rollers respectively. As a result, the roller retainer can be obtained as a roller retainer adapted to a complex circulation path such as a three-dimensional changing-direction passage or a helical load rolling passage shaped like a screw.

[0015] (2) A large space can be secured for reserving lubricating oil in the circulation path. Hence, the rollers can be lubricated sufficiently.

[0016] (3) A drop-down prevention member for supporting the roller retainer can be provided in the circulation path so that the roller retainer is prevented from dropping down from the nut member, or the like.

[0017] According to a second aspect of the invention, there is provided a roller retainer assembly having roller retainers (**31**) for individually and correspondingly retaining a plurality of rollers (**7**) circulating in a roller circulation path inclusive of linear and curved races, wherein: each of the roller retainers (**31**) is made thin to hold the opposite side surfaces of the roller (**7**) and either one of front and rear surfaces of the roller (**7**) in a direction of movement of the roller (**7**); a linear guide portion (**32***a*) and a curve guide portion (**32***b*) which are different in inclination angle are formed in one end surface of the roller retainer (**31**) in a direction of movement of the roller retainer (**31**); and the linear guide portion (**32***a*) of the roller retainer (**31**) comes into contact with an adjacent roller (**7**) in the linear race and the curve guide portion (**32***b*) of the roller retainer (**31**) comes into contact with an adjacent roller (**7**) in the curved race. By the provision of the roller retainer assembly, the above-mentioned problem is therefore solved.

[0018] According to this invention, in addition to the same operation and effect as those of the aforementioned invention, the roller retainer holds either of front and rear surfaces of a corresponding roller in the direction of the movement of the roller. Hence, the space occupied by one roller retainer in the circulation path is reduced so that the number of rollers can be increased Hence, the load capacity of a direct-acting guide device or roller screw using such roller retainers can be increased.

[0019] According to a third aspect of the invention, in the first aspect of the invention, each of the linear guide portion (**16***a*, **17***a*) and the curve guide portion (**16***b*, **17***b*) of the roller retainer (**15**) is formed to be a curved surface shaped like a circular arc in section so as to come into linear contact with the adjacent roller retainer (**15**).

[0020] According to this invention, adjacent roller retainers can press each other while they are securely allowed to rotate slightly around the axes of corresponding rollers respectively.

[0021] According to a fourth aspect of the invention, in the second aspect of the invention, each of the linear guide portion (**32***a*) and the curve guide portion (**32***b*) of the roller retainer (**31**) is formed to be a curved surface in accordance with an outer circumference of the roller (**7**).

[0022] According to this invention, a roller and a roller retainer which are adjacent to each other can press each other while the roller retainer is securely allowed to rotate slightly around the axis of a corresponding roller. Moreover, because the roller retainer comes into surface contact with a roller located in the front side or rear side in the direction of the movement of the roller retainer, contact surface pressure can be reduced.

[0023] According to a fifth aspect of the invention, in the roller retainer assembly as stated in the first or third aspect, a hinge protrusion (**26**) is provided at a point of intersection between the linear guide portion (**16***a*) and the curve guide portion (**16***b*) in one end surface of the roller retainer (**25**); and a hinge recess (**27**) is provided at a point of intersection between the linear guide portion (**17***a*) and the curve guide portion (**17***b*) in the other end surface of the roller retainer

(**25**) so that the hinge recess (**27**) engages with the hinge protrusion (**27**) of an adjacent roller retainer.

[**0024**] According to this invention, the roller retainer is only allowed to swing around a hinge constituted by a combination of the hinge protrusion and the hinge recess in a plane containing the axis of a corresponding roller and the direction of the movement of the roller. Hence, the roller can be prevented from falling down even in a boundary shifting from a linear race to a curved race. Hence, smooth circulation of the roller can be ensured.

[**0025**] According to a sixth aspect of the invention, in any one of the first to fifth aspects, drop-down prevention protrusions (**20**) are formed on either one of the roller retainer (**15**) and the opposite side surfaces of the roller (**7**); and drop-down prevention recesses (**21**) are formed in the other one of the roller retainer and the opposite side surfaces of the roller so that the drop-down prevention protrusions are fitted into the drop-down prevention recesses.

[**0026**] According to this invention, the roller can be prevented from dropping out from the roller retainer. For example, even in the case where a slide member such as a nut member is removed from the race rail, the roller retainer can prevent the roller from dropping down from the slide member so that the roller can be prevented from dropping down from the slide member.

[**0027**] According to a seventh aspect of the invention, in any one of first to sixth aspects, a thickness of the roller retainer (**15**) is selected to be not smaller than 50% of a diameter of the roller. When a tapered roller is used as each of the rollers, the terminology "roller diameter" used herein means the smallest roller diameter.

[**0028**] If the thickness of each of the roller retainers is smaller than 50% of the roller diameter, the front end of the succeeding roller retainer in the circulation path enters the gap between the front-side roller retainer and the roller rolling groove so that adjacent roller retainers overlap each other. As a result, there is a risk that the circulation of rollers may stop. When the thickness of each of the roller retainers is not smaller than 50% of the roller diameter, such adjacent roller retainers can be prevented from overlapping each other.

[**0029**] Further, according to the invention, there is also provided a direct-acting guide device comprising: a race shaft (**41, 51**) containing a roller rolling surface (**41***a*, **51***a*); a slide member (**42, 52**) including a roller circulation path containing a load rolling surface (**42***a*, **52***a*) corresponding to the roller rolling surface (**41***a*, **51***a*), the slide member (**42, 52**) being fitted to the race shaft (**41, 51**) so as to be freely movable relative to the race shaft (**41, 51**); a plurality of rollers (**43, 53**) arranged and received in the roller circulation path so as to circulate in accordance with movement of the slide member (**42, 52**) relative to the race shaft (**41, 51**); and a plurality of roller retainers (**15**) for holding the plurality of rollers (**43, 53**) individually and correspondingly so that the plurality of rollers (**43, 53**) are rotatable/slidable, wherein: the plurality of rollers (**43, 53**) are arranged and received so that the axes of adjacent rollers (**43, 53**) are kept approximately parallel to each other; each of the roller retainers (**15**) is made thin to hold opposite side surfaces of corresponding one of the rollers (**7**) and front and rear surfaces of the roller (**7**) in a direction of movement of the roller (**7**); a linear guide portion (**16***a*, **17***a*) and a curve guide portion (**16***b*, **17***b*) which are different in inclination angle from each other are formed in each of opposite end surfaces of the roller retainer (**15**) in a direction of movement of the roller retainer (**15**); and the linear guide portion (**16***a*, **17***a*) of the roller retainer (**15**) comes into contact with an adjacent roller retainer (**15**) in a linear race and the curve guide portion (**16***b*, **17***b*) of the roller retainer (**15**) comes into contact with an adjacent roller retainer (**15**) in a curved race.

[**0030**] Further, according to the invention, there is also provided a direct-acting guide device comprising: a race shaft (**41, 51**) containing a roller rolling surface (**41***a*, **51***a*); a slide member (**42, 52**) including a roller circulation path containing a load rolling surface (**42***a*, **52***a*) corresponding to the roller rolling surface (**41***a*, **51***a*), the slide member (**42, 52**) being fitted to the race shaft (**41, 51**) so as to be freely movable relative to the race shaft (**41, 51**); a plurality of rollers (**43, 53**) arranged and received in the roller circulation path so as to circulate in accordance with movement of the slide member (**42, 52**) relative to the race shaft (**41, 51**); and a plurality of roller retainers (**15**) for holding the plurality of rollers (**43, 53**) individually and correspondingly so that the plurality of rollers (**43, 53**) are rotatable/slidable, wherein: the plurality of rollers (**43, 53**) are arranged and received so that the axes of adjacent rollers (**43, 53**) are kept approximately parallel to each other; each of the roller retainers (**31**) is made thin to hold opposite side surfaces of corresponding one of the rollers (**7**) and either one of front and rear surfaces of the roller (**7**) in a direction of movement of the roller (**7**); a linear guide portion (**32***a*) and a curve guide portion (**32***b*) which are different in inclination angle are formed in one end surface of the roller retainer (**31**) in a direction of movement of the roller retainer (**31**); and the linear guide portion (**32***a*) of the roller retainer (**31**) comes into contact with an adjacent roller (**7**) in a linear race and the curve guide portion (**32***b*) of the roller retainer (**31**) comes into contact with an adjacent roller (**7**) in a curved race.

[**0031**] Further, according to the invention, there is also provided a roller screw comprising: a race shaft (**5**) containing a helical roller rolling surface (**5***a*); a slide member (**6**) including a roller circulation path (**8**) containing a helical load rolling surface (**6***a*) corresponding to the roller rolling surface (**5***a*), the slide member (**6**) being fitted to the race shaft (**5**) so as to be freely movable relative to the race shaft (**5**); a plurality of rollers (**7**) arranged and received in the roller circulation path (**8**) so as to circulate in accordance with movement of the slide member (**6**) relative to the race shaft (**5**); and a plurality of roller retainers (**15**) for holding the plurality of rollers (**7**) individually and correspondingly so that the plurality of rollers (**7**) are rotatable/slidable, wherein: the plurality of rollers (**7**) are arranged and received so that axes of adjacent rollers (**7**) are kept approximately parallel to each other; each of the roller retainers (**15**) is made thin to hold opposite side surfaces of corresponding one of the rollers (**7**) and front and rear surfaces of the roller (**7**) in a direction of movement of the roller (**7**); a linear guide portion (**16***a*, **17***a*) and a curve guide portion (**16***b*, **17***b*) which are different in inclination angle from each other are formed in each of opposite end surfaces of the roller retainer (**15**) in a direction of movement of the roller retainer (**15**); and the linear guide portion (**16***a*, **17***a*) of the roller retainer (**15**) comes into contact with an adjacent roller retainer (**15**) in a linear race and the curve guide portion (**16***b*, **17***b*) of the roller retainer (**15**) comes into contact with an adjacent roller retainer (**15**) in a curved race.

[0032] Further, according to the invention, there is also provided a roller screw comprising: a race shaft (**5**) containing a helical roller rolling surface (**5***a*); a slide member (**6**) including a roller circulation path (**8**) containing a helical load rolling surface (**6***a*) corresponding to the roller rolling surface (**5***a*), the slide member (**6**) being fitted to the race shaft (**5**) so as to be freely movable relative to the race shaft (**5**); a plurality of rollers (**7**) arranged and received in the roller circulation path (**8**) so as to circulate in accordance with movement of the slide member (**6**) relative to the race shaft (**5**); and a plurality of roller retainers (**15**) for holding the plurality of rollers (**7**) individually and correspondingly so that the plurality of rollers (**7**) are rotatable/slidable, wherein: the plurality of rollers (**7**) are arranged and received so that axes of adjacent rollers (**7**) are kept approximately parallel to each other; each of the roller retainers (**31**) is made thin to hold opposite side surfaces of corresponding one of the rollers (**7**) and either one of front and rear surfaces of the roller (**7**) in a direction of movement of the roller (**7**); a linear guide portion (**32***a*) and a curve guide portion (**32***b*) which are different in inclination angle are formed in one end surface of the roller retainer (**31**) in a direction of movement of the roller retainer (**31**); and the linear guide portion (**32***a*) of the roller retainer (**31**) comes into contact with an adjacent roller (**7**) in a linear race and the curve guide portion (**32***b*) of the roller retainer (**31**) comes into contact with an adjacent roller (**7**) in a curved race.

BRIEF DESCRIPTION OF THE DRAWINGS

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0054] Now, a description will be given in more detail of preferred embodiments of the invention with reference to the accompanying drawings.

[0055] **FIG. 1** shows a roller screw in which roller retainers according to a first embodiment of the present invention are incorporated. The roller screw comprises a screw shaft **5** (race shaft), a nut member **6** (slide member), and a plurality of rollers **7**. The screw shaft **5** has a helical roller rolling groove **5***a* in its outer circumferential surface so that the helical roller rolling groove **5***a* serves as a roller rolling surface. The nut member **6** has a roller circulation path formed in its inner cirumferential surface. The roller circulation path includes a helical load rolling groove **6***a* so that the helical load rolling groove **6***a* serves as a load rolling surface corresponding to the roller rolling groove **5***a*. The nut member **6** is fitted to the screw shaft **5** so as to be relatively movable. The plurality of rollers **7** are arranged and received in the roller circulation path and circulate in accordance with the relative movement of the nut member **6** to the screw shaft **5**. The plurality of rollers **7** are arranged and received in the roller circulation path so that axes of adjacent rollers **7** are kept substantially parallel to each other. In the roller circulation path, a load rolling passage **8** is formed between the roller rolling groove **5***a* of the screw shaft **5** and the load rolling groove **6***a* of the nut member **6**. The nut member **6** has a return pipe. The return pipe forms a no-load return passage by which one end of the load rolling passage **8** communicates with the other end of the load rolling passage **8**.

[0056] **FIG. 2** shows the return pipe **9**. The return pipe **9** has a body portion **9***b*, and opposite end portion **9***a* bent with respect to the body portion **9***b*. The opposite end portions **9***a* are fitted into the load rolling passage so that a distance of several pitches is left between the opposite end portions **9***a*. Incidentally, the return pipe **9** is fixed to the nut member **6** by a pipe pressing.

[0057] **FIG. 3** shows the screw shaft **5**. The helical roller rolling groove **5***a* having a predetermined lead is formed in the outer circumferential surface of the screw shaft **5**. The roller rolling groove **5***a* is shaped like a trapezoid in section. Each of the rollers **7** rolls on a wall surface **12***a* or **12***b* of the roller rolling groove **5***a*.

[0058] As shown in **FIG. 1**, the nut member **6** is substantially shaped like a cylinder. The helical load rolling groove **6***a* having a lead equal to the lead of the screw shaft **5** is formed in the inner circumferential surface of the nut member **6**. The load rolling groove **6***a* is also shaped like a trapezoid in section. A protrusion **10** for forming the load rolling groove **6***a* of the nut member **6** is fitted into the roller rolling groove **5***a* so that the inner diameter of the nut member **6** is made smaller than the outer diameter of the screw shaft **5**. Each of the rollers **7** rolls on a wall surface **11***a* or **11***b* of the load rolling groove **6***a*. The load rolling groove **6***a* of the nut member **6** may be shifted in the middle way. Hence, up to the shift position, a space for arranging the rollers **7** is formed between the wall surface **12***b* of the roller rolling groove **5***a* and the wall surface **11***b* of the load rolling groove **6***a* and, after the shift position, a space for arranging the rollers **7** is formed between the wall surface **12***a* of the roller rolling groove **5***a* and the wall surface **11***a* of the load rolling groove **6***a*. Return pipe fitting holes are formed in the nut member **6** so that the opposite sides of the return pipe **9** are inserted in the holes respectively. The return pipe fitting holes extend into the load rolling groove **6***a*.

[0059] As is obvious from **FIG. 2**, the return pipe **9** has opposite end portions **9***a* bent by about 90° with respect to the body portion **9***b*. That is, the return pipe **9** is substantially formed of a double housing type. A section of the no-load return passage of the return pipe **9** is determined in accordance with the shape of each roller **7**. As shown in **FIG. 2**, the opposite end portions **9***a* are not parallel to each other so that the respective directions of the opposite end portions **9***a* make a torsional angle $\theta 1$ (which changes in accordance with the lead angle).

[0060] FIGS. **4** to **6** show roller retainers **15** and rollers **7** which are incorporated in the roller screw. **FIG. 4** is a view (front view) in a direction perpendicular to the direction of the axis of each roller **7** and perpendicular to the direction of the movement of each roller **7**. **FIG. 5** is a view (side view) from the direction of the movement of each roller **7**. **FIG. 6** is a view (bottom view) from the direction of the axis of each roller **7**. Roller retainers **15** of the same number as that of the rollers **7** are provided to retain the rollers **7** individually. Each of the roller retainers **15** is made thin to hold front and rear surfaces of a corresponding roller **7** in the direction of the movement of the roller **7**. The frontal shape of the roller retainer **15** (viewed from the direction perpendicular to the axis of the roller and perpendicular to the direction of the movement of the roller) is formed like a frame. The thickness W of each side surface of the roller retainer **15** is set to be in a range of from 50% to 90% , preferably in a range of from 50% to 60% of the diameter of the roller. Incidentally, when a tapered roller is used as the roller **7**, the diameter of the roller is minimized.

[0061] A linear guide portion **16***a* and a curve guide portion **16***b* different in inclination angle from each other are formed in an end surface **16** of a roller retainer **15** in the direction of the movement of the roller retainer **15**. A linear guide portion **17***a* and a curve guide portion **17***b* different in inclination angle from each other are formed in the other end surface **17** of the roller retainer **15** in the direction of the movement of the roller retainer **15**. The linear guide portions **16***a* and **17***a* are formed so as to be substantially parallel to the axis of each roller **7**. The curve guide portions **16***b* and **17***b* are formed so that the curve guide portions **16***b* and **17***b* face radial directions respectively when roller retainers are arranged in a curved race. That is, in a curved race, the curve guide portions **16***b* and **17***b* of the roller retainer **15** come into contact with adjacent roller retainers **15** and, in a linear race, the linear guide portions **16***a* and **17***a* of the roller retainer **15** come into contact with adjacent roller retainers **15**. The linear guide portions **16***a* and **17***a* and the curve guide portions **16***b* and **17***b* of the roller retainer **15** are formed to be sectionally circular arc-shaped curved surfaces so as to come into linear contact with adjacent roller retainers **15** (see **FIG. 6**). As shown in **FIG. 5**, four corners of side surfaces of the roller retainer **15** are cut to be chamfered portions **18**. Hence, the roller retainer **15** can be prevented from interfering with the screw shaft **5** even in the case where the axis **19** of the roller **7** is arranged not to be perpendicular to the center line **5***c* of the screw shaft **5** but to be inclined at an angle α as shown in **FIG. 1**. As shown in **FIG. 4, a** pair of drop-down prevention protrusions **20, 20** are formed on the upper and lower portions, on the roller **7** side, of the roller retainer **15**. Further, a pair of recesses **21, 21** are formed on the side surface of the roller **7** so that the recesses **21** are fitted to the protrusions **20, 20**. Hence, the roller retainer **15** holds the roller **7** so that the roller **7** can rotate around its axis **19**. Incidentally, the drop-down prevention protrusions **20** may be provided on the roller **7** side while the drop-down prevention recesses **21** may be provided on the roller retainer **15** side. The roller retainer **15** is made from a synthetic resin or the like, as a raw material, by injection molding, or the like.

[0062] A tapered roller can be used as the roller **7**. The apex Q of the cone of the tapered roller is located on the center line **5***c* of the screw shaft **5**. Hence, the tapered roller rolls without slipping between the load rolling groove **6***a* and the roller rolling groove **5***a*. Incidentally, the sectional shape of the roller rolling groove **5***a*, the sectional shape of the load rolling groove **6***a* and the side shape of the roller can be set freely in accordance with load, accuracy, etc. required of the roller screw.

[0063] As shown in **FIG. 1**, when the screw shaft **5** is rotated, rollers **7** and roller retainers **15** rolling in the load rolling passage **8** in the direction of the circumference of the screw shaft **5** while suffering load are scooped by the return pipe **9**. The scooped rollers **7** and roller retainers **15** pass through the return pipe **9**. Then, the rollers **7** and roller retainers **15** are returned to the load rolling passage **8** after the distance of several pitches. When the direction of the rotation of the screw shaft **5** is inverted, the respective rollers **7** circulate in the reverse course. Incidentally, the nut member **6** may be rotated in the condition that the screw shaft **5** is provided as a stationary side. Also in this case, the rollers **7** can circulate in the aforementioned manner.

[0064] **FIG. 7** shows rollers **7** and roller retainers **15** circulating in the return pipe **9** and the load rolling passage **8**. As shown in **FIG. 7**, in a linear race (in a return pipe **9**) constituting a circulation path, a linear guide portion **16***a* of a roller retainer **15** located in the rear side in the direction **(1)** of the movement of the roller **7** presses a linear guide portion **17***a* of another roller retainer **15** located in the front side. In a curved race (in a load rolling passage **8**), the curve guide portion **16***b* of the rear-side roller retainer **15** presses the curve guide portion **17***b* of the front-side roller retainer **15**. Either in the linear race or in the curved race, the rear-side roller retainer **15** can press the front-side roller retainer **15** without spoiling the posture of the roller **7** located in the rear side in the direction of the movement of the rollers **7**. When a tapered roller is used as each of the rollers **7**, particularly in a linear race, the roller **7** tries to fall down in a plane containing the axis and the direction of the movement of the roller. In the linear race, linear guide portions **16***a* and **17***a* of adjacent roller retainers **15** come into close contact with each other, while, in the curved race, curve guide portions **16***b* and **17***b* of adjacent roller retainers **15** come into close contact with each other. As a result, the rollers **7** are aligned so that smooth circulation can be obtained. In most cases, the return pipe **9** in a no-load region has a linear race, a circular-arc race, a linear race, and a circular-arc race. When the curvature of a circular arc **24** of the return pipe **9** is made coincide with the curvature of the load rolling passage **8**, rollers **7** can be aligned so that smooth circulation can be obtained. This is because the curve guide portions **16***b* and **17***b* of adjacent roller retainers **15** come into close contact with each other even in the circular arc portion of the return pipe **9**. When the curvature of the circular arc **24** of the return pipe **9** does not coincide with the curvature of the load rolling passage **8**, the curve guide portions **16***b* and **17***b* may be further separated into two portions different in inclination angle. That is, guide portions may be separated into three stages, for example, a linear guide portion, a curve guide portion for load rolling passage and a curve guide portion for return pipe, may be formed.

[0065] As described above, the load rolling passage **8** of the roller screw is formed helically. As described above with reference to **FIG. 2**, the return pipe for changing the direction of the scooped roller **7** has a torsion (torsional angle θ1) around the direction of the movement of the roller. That is, in the roller screw, the rollers **7** and roller retainers **15** change their directions three-dimensionally and make complex motion. The aforementioned roller retainers **15** are adapted to such a complex motion. As shown in **FIG. 5**, the thickness W of each side of each roller retainer **15** is made small. Furthermore, the linear guide portions **16***a* and **17***a* (to be in close-contact) and curve guide portions **16***b* and **17***b* (to be in close-contact) of adjacent roller retainers **15** are shaped like circular arcs in section so as to come into linear contact with each other. Hence, such adjacent roller retainers **15** press each other while they are allowed to rotate slightly around the axes of corresponding rollers **7** respectively. As a result, the roller retainers **15** freely change their direction three-dimensionally with corresponding rollers **7** respectively, so that complex motion required of the roller screw in this embodiment can be made. Particularly when the axis **19** of each roller **7** is not perpendicular to the center line **5***c* of the screw shaft **5** but inclined at a predetermined angle as shown in **FIG. 1**, the roller **7** circulates in an umbrella-like curved race. Therefore, adjacent roller retainers **15** need to come into close contact with each other while a crossing angle β between the adjacent roller retainers **15** is kept constant as shown in **FIG. 8**. According to the present invention, adjacent roller retainers **15** press each other while they are allowed to rotate slightly around the axes of corresponding rollers **7** respectively. Accordingly, roller retainers **15** sufficiently adapted to such circulation form can be obtained.

[0066] Because each of the roller retainers **15** is made thin, a large space can be ensured for reserving lubricating oil in the circulation path. Hence, the rollers **7** can be lubricated sufficiently. Furthermore, because each of the roller retainers **15** is made thin, a large gap can be taken between the roller retainers **15** and the load rolling groove **6***a*. Hence, a support member for supporting the roller retainers **15** can be provided in the circulation path to prevent the roller retainers **15** from dropping down from the nut member **6**, or the like.

[0067] **FIG. 9** shows the case where the thickness of each roller retainer **15** is selected to be smaller than 50% of the roller diameter. If the thickness of the roller retainer **15** is made smaller than 50% of the roller diameter, the front end of the succeeding roller retainer **15** enters the gap between the front-side roller retainer **15** and the roller rolling groove **5***a* so that adjacent roller retainers **15** may overlap each other. As a result, there is a risk that the circulation of the rollers **7** may stop. When the thickness of the roller retainer **15** is selected to be not smaller than 50% of the roller diameter, adjacent roller retainers **15** can be prevented from overlapping each other as described above.

[0068] **FIG. 10** shows a second embodiment of the present invention concerning rollers and roller retainers incorporated in the roller screw. Each of the roller retainers **25** has substantially the same configuration as that of the roller retainer **15** according to the first embodiment. The roller retainer **25** further has a hinge protrusion **26**, and a hinge recess **27** fitted to the hinge protrusion **26** of the adjacent roller retainer **25**. The hinge protrusion **26** is provided at a point of intersection between the linear guide portion **16***a* and the curve guide portion **16***b* on one end surface of the roller retainer **25** in the direction of the movement of the roller **7**. The hinge recess **27** is provided at a point of intersection between the linear guide portion **17***a* and the curve guide portion **17***b* on the other end surface of the roller retainer **25**. Because the hinge protrusion **26** and the hinge recess **27***a* reprovided in the aforementioned manner, the roller retainer **25** is only allowed to swing around a hinge constituted by a combination of the hinge protrusion **26** and the hinge recess **27** in a plane containing the axis of a corresponding roller **7** and the direction **(1)** of the movement of the roller **7**. Hence, the roller **7** can be prevented from falling down even in the boundary in which the roller is moving from the linear race to the curved race. Hence, smooth circulation of the roller **7** can be ensured.

[0069] FIGS. **11** to **13** and **FIGS. 14A** to **14C** show a third embodiment of the present invention concerning roller retainers incorporated in the roller screw. **FIG. 11** is a view (front view) from a direction perpendicular to the axis of each roller **7** and perpendicular to the direction (**1**) of the movement of the roller **7**. **FIG. 12** is a view (side view) from the rear side in the direction of the movement of the roller **7**. **FIG. 13** is a view (bottom view) from the direction of the axis of the roller **7**. **FIGS. 14A** to **14**C are views showing the case where roller retainers with rollers **7** are aligned in a line. In this embodiment, each of the roller retainers **31** is made thin to hold only the opposite side surfaces of a corresponding roller **7** and the front surface of the same roller **7** in the direction of the movement of the roller **7**. Each of the roller retainers **31** is shaped like a U figure in front view. The thickness W of each side of the roller retainer **31** is selected to be in a range of from 50% to 90% , preferably in a range of from 50% to 60% of the roller diameter.

[**0070**] A linear guide portion **32***a* and a curve guide portion **32***b* which are different in inclination angle from each other are formed in one end surface of the roller retainer **31** in the direction of the movement thereof. The linear guide portion **32***a* is inclined at a predetermined angle with respect to the axis of the roller **7** so that the axes of adjacent rollers **7** are kept parallel to each other. The curve guide portion **32***b* is inclined so that the roller retainers **31** face radial directions when the roller retainers **31** are arranged in a curved race. That is, in a curved race, the curve guide portion **32***b* comes into contact with an adjacent roller **7** and, in a linear race, the linear guide portion **32***a* comes into contact with the adjacent roller **7**. The linear guide portion **32***a* and the curve guide portion **32***b* are formed as a curved surface corresponding to the outer circumference of the roller **7**.

[**0071**] According to this roller retainer **31**, the roller retainer **31** and a roller **7** adjacent to the roller retainer **31** can press each other while the roller retainer **31** is allowed to rotate slightly around the axis of a corresponding roller **7** in the same manner as that in the roller retainer **15** in the first embodiment. Hence, the roller retainer **31** can fulfil the same operation and effect as those of the roller retainer **15** obtained in the first embodiment. Furthermore, because the roller retainer **31** comes into surface contact with a roller **7** located in the front side or rear side in the direction of the movement of the roller, contact surface pressure can be also reduced.

[**0072**] In the example of this roller screw, rollers **7** rolling in the roller rolling groove **5***a* of the screw shaft **5** are scooped by the return pipe **9** and returned by several pitches. Alternatively, a deflector for scooping rollers **7** may be provided in the nut member **6**. That is, one of rollers **7** rolling on the roller rolling groove **5***a* of the screw shaft **5** may be picked out from the roller rolling groove **5***a* by the deflector so that the roller **7** skips over the outer diameter portion of the screw shaft **5** and returns to the roller rolling groove **5***a* before one lead. Though not shown, a so-called side cover type roller screw may be used. That is, the nut member **6** is constituted by a nut body having a load rolling groove formed therein and side covers attached to opposite ends of the nut body. A roller return passage is formed in the nut body. A communication passage by which the load rolling groove and the return passage communicate with each other is formed in each of the side covers.

[**0073**] The roller retainer according to the present invention is not limited only to the roller screw, but can be applied to a direct-acting guide device such as a linear guide or a spline. Particularly the roller retainer according to the present invention can be adapted to a direct-acting guide device except the case where each roller circulates two-dimensionally in a plane perpendicular to the axis of the roller. That is, the roller retainer according to the present invention can be adapted to a direct-acting guide device having a circulation path which is so complex that the path is bent while the roller is twisted.

[**0074**] **FIG. 15** shows a linear guide in which roller retainers **15** according to the first embodiment of the present invention are incorporated. The linear guide is a well known device for guiding a movable body such as a table on a stationary portion such as a bed or a saddle. The linear guide has a guide rail **41** (race shaft), a moving block (slide member) **42**, and a plurality of rollers **43**. The guide rail **41** is disposed on the stationary portion and has a roller rolling groove **41***a* which is formed along the direction of the length thereof so that the roller rolling groove **41***a* serves as a roller rolling surface. The moving block **42** is fitted to the guide rail **41** so as to be relatively movable. A roller circulation path containing a load rolling groove **42***a* corresponding to the roller rolling grove **41***a* of the guide rail **41** is formed in the moving block **42** so that the load rolling groove **42***a* serves as a load rolling surface. The plurality of rollers **43** are arranged and received in the roller circulation path and circulate in the roller circulation path in accordance with the relative movement of the moving block **42** to the guide rail **41**. The plurality of rollers **43** are held in the roller retainers **15** individually and correspondingly. The rollers **43** are arranged and received in the roller circulation path so that the axes of the rollers **43** are substantially kept parallel to one another. With the endless circulation of the rollers **43**, the moving block **42** supporting the rollers makes linear motion along the guide rail **41**.

[**0075**] The guide rail **41** is slenderly elongated to form a quadrilateral in section. A roller rolling groove **41***a*, which serves as a race when a roller **43** rolls, is formed in each of left and right side surfaces of the guide rail **41** so as to extend over the whole length of the guide rail. Although **FIG. 15** shows the case where the race rail is linear, the invention may be applied also to the case where the rail is curved. Although **FIG. 15** shows the case where two roller rolling grooves **41***a* are provided in left and right, the invention may be applied also to the case where the number of roller rolling grooves is changed variously in accordance with the purpose of use of the linear guide, or the like.

[**0076**] The moving block **42** is roughly constituted by a combination of a moving body **44** and a pair of side covers (not shown) disposed at opposite ends of the moving body **44**. Two load rolling grooves **42***a* corresponding to the roller rolling grooves **41***a* are provided in the moving body **44**. The combination of the load rolling grooves **42***a* and the roller rolling grooves **41***a* forms two load rolling passages C between the guide rail **41** and the moving block **42**.

[**0077**] Two return passages D extending in parallel to the load rolling passages C respectively and changing-direction passages B for connecting the load rolling passages C to the return passages respectively are further provided in the moving body **44**. The combination of the load rolling passages C, the return passages D and the pair of changing-direction passages for connecting the load rolling passages C to the return passages D respectively forms one roller circulation path. Each of the changing-direction passages B has a three-dimensionally complex race.

[0078] As the moving block **42** moves along the guide rail **41**, the roller **43** rolls in the load rolling passage C from one end to the other end while the roller **43** suffers load from the moving block **42**. Then, each of the rollers **43** is scooped by one changing-direction passage B and led to the return passage D. The roller **43** is further returned to one end of the load rolling passage C through the opposite changing-direction passage B. On this occasion, in the load rolling passages C and return passages D constituting a linear race, the linear guide portion of the rear-side roller retainer **15** presses the linear guide portion of the front-side roller retainer **15**. In the changing-direction passages B constituting a curved race, the curve guide portion of the rear-side roller retainer **15** presses the curve guide portion of the front-side roller retainer **15**. Either in the linear race or in the curved race, the rear-side roller retainer **15** can press the front-side roller retainer **15** without spoiling the posture of the roller **7** located in the front side in the direction of the movement of the rollers.

[0079] As described above, each side surface of the roller retainer **15** is made thin, and the linear guide portion and curve guide portion for making adjacent roller retainers in close contact with each other are shaped like circular arcs in section so that they come into linear contact with adjacent roller retainers. Hence, adjacent roller retainers press each other while they are allowed to rotate slightly around the axes of corresponding rollers respectively. In such a manner, the roller retainers **15** with the rollers **43** can change their direction three-dimensionally freely. Hence, the roller retainers **15** can make such complex motion as that required of the changing-direction passages B of the linear guide in this embodiment.

[0080] Although this embodiment has shown the case where the relative movement of the moving block **42** to the guide rail **41** is made linearly, the present invention may be preferably applied also to a guide device which is configured so that the relative motion is curved.

[0081] **FIG. 16** shows a spline in which roller retainers according to the first embodiment of the present invention are incorporated. The spline has a spline shaft **51**, and an outer cylinder **52**. The spline shaft **51** serves as a race member whereas the outer cylinder **52** serves as a slide member. The outer cylinder **52** is mounted on the spline shaft **51** so as to be movable through a plurality of rollers **53**. The plurality of rollers **53** are held in roller retainers **15**, individually, obtained in the first embodiment. Further, the axes of adjacent rollers are substantially kept parallel to each other.

[0082] The spline shaft **51** is shaped like a column of a true circle. A plurality of roller rolling grooves **51***a*, which act as roller races and serve as roller rolling surfaces extending in the axial direction of the spline shaft **51**, are formed in a surface of the spline shaft **51**. For example, six roller rolling grooves **51***a* are formed.

[0083] The outer cylinder **52** mounted on the spline shaft **51** has load rolling grooves **52***a* corresponding to the roller rolling grooves **51***a*. The load rolling grooves **52***a* serve as load rolling surfaces. A plurality of rollers **53** are arranged in the roller circulation path so that the rollers **53** circulate in addition to the linear movement of the outer cylinder **52** relative to the spline shaft **51**. A load rolling passage C is formed between each load rolling groove **52***a* formed in the outer cylinder **52** and a corresponding roller rolling groove **51***a* formed in the spline shaft **51**. Ano-load return passage D is formed adjacently to each load rolling passage C. In the no-load return passage D, rollers **53**, which is released from load, roll. A changing-direction passage B for connecting each load rolling passage C to a corresponding no-load return passage D is further formed in the outer cylinder **52**. The changing-direction passage B has a three-dimensionally complex race like that of the linear guide.

[0084] When the outer cylinder **52** is moved relatively to the spline shaft **51**, the roller **53** rolls in the no-load rolling passage C while it suffers load. Hence the roller **53** changes its direction in the changing-direction passage B and moves to the no-load return passage D. In the no-load return passage D, the roller **53** moves in the reverse direction against the load rolling passage C. The rollers **53** moving in the no-load return passage D change its direction again in the other changing-direction passage B and return to the no-load return passage C again. On this occasion, in the load rolling passages C and no-load return passages D constituting linear races, the linear guide portion of the rear-side roller retainer **15** presses the linear guide portion of the front-side roller retainer **15**. In the changing-direction passage B constituting curved race, the curve guide portion of the rear-side roller retainer **15** presses the curve guide portion of the front-side roller retainer **15**. Either in the linear race or in the curved race, the rear-side roller retainer **15** can press the front-side roller retainer **15** without spoiling the posture of the roller **53** located in the front side in the direction of the movement of the roller.

[0085] Further, each side surface of the roller retainer **15** is made thin, and the linear guide portion and curve guide portion for making adjacent roller retainers **15** in close contact with each other are shaped like circular arcs in section so that they come into linear contact with adjacent roller retainers. Hence, adjacent roller retainers **15** press each other while they are allowed to rotate slightly around the axes of corresponding rollers respectively. In such a manner, the roller retainers **15** with the rollers **53** can change their direction three-dimensionally freely. Hence, the roller retainers **15** can make such complex motion as that required of the changing-direction passages B of the spline in this embodiment.

[0086] As described above, according to the present invention, a roller retainer is made thin to hold opposite side surfaces of a corresponding roller and front and rear surfaces of the roller in the direction of the movement of the roller. A linear guide portion and a curve guide portion different in inclination angle from each other are formed in each end surface of the roller retainer in the direction of the movement of the roller retainer. Hence, in the curved race, the curve guide portion comes into contact with an adjacent roller retainer. In the linear race, the linear guide portion comes into contact with an adjacent roller retainer. Hence, in either of the linear race and curved race constituting a circulation race, the rear-side roller retainer can press the front-side roller retainer without spoiling the posture of the roller located in the front side in the direction of the movement of the roller. Hence, rollers can be aligned so that smooth circulation can be obtained. Further, because the roller retainer is made thin, the following effects are obtained.

[0087] (1) Adjacent roller retainers can press each other while they are allowed to rotate slightly around the axes of corresponding rollers respectively. As a result, the roller retainer can be obtained as a roller retainer adapted to a complex circulation path such as a three-dimensional changing-direction passage or a helical load rolling passage shaped like a screw.

[0088] (2) A large space can be secured for reserving lubricating oil in the circulation path. Hence, the rollers can be lubricated sufficiently.

[0089] (3) A drop-down prevention member for supporting the roller retainer can be provided in the circulation path so that the roller retainer is prevented from dropping down from the nut member, or the like.

What is claimed is:

1. A roller retainer assembly, comprising:

a plurality of roller retainers for individually correspondingly retaining a plurality of rollers circulating in a roller circulation path inclusive of linear and curved races;

wherein each of said roller retainers are made thin to hold opposite side surfaces of said roller and front and rear surfaces of said roller in a direction of movement of said roller;

wherein a linear guide portion and a curve guide portion which are different in inclination angle from each other are formed in opposite end surfaces of said roller retainer in a direction of movement of said roller retainer; and

wherein said linear guide portion of said roller retainer comes into contact with an adjacent roller retainer in said linear race and said curve guide portion of said roller retainer comes into contact with said adjacent roller retainer in said curved race.

2. A roller retainer assembly, comprising:

a plurality of roller retainers for individually correspondingly retaining a plurality of rollers circulating in a roller circulation path inclusive of linear and curved races;

wherein each of said roller retainers is made thin to hold said opposite side surfaces of said roller and either one of front and rear surfaces of said roller in a direction of movement of said roller;

wherein a linear guide portion and a curve guide portion which are different in inclination angle from each other are formed in one end surface of said roller retainer in a direction of movement of said roller retainer; and

wherein said linear guide portion of said roller retainer comes into contact with an adjacent roller in said linear race and said curve guide portion of said roller retainer comes into contact with said adjacent roller in said curved race.

3. A roller retainer assembly according to claim 1, wherein each of said linear guide portion and said curve guide portion of said roller retainer is formed to be a curved surface shaped like a circular arc in section so as to come into linear contact with said adjacent roller retainer.

4. A roller retainer assembly according to claim 2, wherein each of said linear guide portion and said curve guide portion of said roller retainer is formed to be a curved surface in accordance with an outer circumference of said roller.

5. A roller retainer assembly according to claim 1 or 3, wherein a hinge protrusion is provided at a point of intersection between said linear guide portion and said curve guide portion in one end surface of said roller retainer in the direction of movement of said roller retainer; and

wherein a hinge recess is provided at a point of intersection between said linear guide portion and said curve guide portion in the other end surface of said roller retainer in the direction of movement of said roller retainer so that said hinge recess engages with said hinge protrusion of an adjacent roller retainer.

6. A roller retainer assembly according to claim 1, wherein drop-down prevention protrusions are formed one either one of said roller retainer and said opposite side surfaces of said roller; and

wherein drop-down prevention recesses are formed in the other one of said roller retainer and said opposite side surfaces of said roller so that said drop-down prevention protrusions are fitted into said drop-down prevention recesses.

7. A roller retainer assembly according to claim 1, wherein a thickness of said roller retainer is selected to be not smaller than 50% of a diameter of said roller.

8. A direct-acting guide device comprising:

a race shaft containing a roller rolling surface;

a slide member including a roller circulation path containing a load rolling surface corresponding to said roller rolling surface, said slide member being fitted to said race shaft so as to be freely movable relative to said race shaft;

a plurality of rollers arranged and received in said roller circulation path so as to circulate in accordance with movement of said slide member relative to said race shaft; and

a plurality of roller retainers for holding said plurality of rollers individually and correspondingly so that said plurality of rollers are rotatable/slidable;

wherein said plurality of rollers are arranged and received so that axes of adjacent rollers are kept approximately parallel to each other;

wherein each of said roller retainers is made thin to hold opposite side surfaces of corresponding one of said rollers and front and rear surfaces of said roller in a direction of movement of said roller;

wherein a linear guide portion and a curve guide portion which are different in inclination angle from each other are formed in each of opposite end surfaces of said roller retainer in a direction of movement of said roller retainer; and

wherein said linear guide portion of said roller retainer comes into contact with an adjacent roller retainer in a linear race and said curve guide portion of said roller retainer comes into contact with said adjacent roller retainer in a curved race.

9. A direct-acting guide device comprising:

a race shaft containing a roller rolling surface;

a slide member including a roller circulation path containing a load rolling surface corresponding to said roller rolling surface, said slide member being fitted to said race shaft so as to be freely movable relative to said race shaft;

a plurality of rollers arranged and received in said roller circulation path so as to circulate in accordance with movement of said slide member relative to said race shaft; and

a plurality of roller retainers for holding said plurality of rollers individually and correspondingly so that said plurality of rollers are rotatable/slidable;

wherein said plurality of rollers are arranged and received so that axes of adjacent rollers are kept approximately parallel to each other;

wherein each of said roller retainers is made thin to hold opposite side surfaces of corresponding one of said rollers and either one of front and rear surfaces of said roller in a direction of movement of said roller;

wherein a linear guide portion and a curve guide portion which are different in inclination angle from each other are formed in one end surface of said roller retainer in a direction of movement of said roller retainer; and

wherein said linear guide portion of said roller retainer comes into contact with an adjacent roller in a linear race and said curve guide portion of said roller retainer comes into contact with said adjacent roller in a curved race.

10. A roller screw comprising:

a race shaft containing a helical roller rolling surface;

a slide member including a roller circulation path containing a helical load rolling surface corresponding to said roller rolling surface, said slide member being fitted to said race shaft so as to be freely movable relative to said race shaft;

a plurality of rollers arranged and received in said roller circulation path so as to circulate in accordance with movement of said slide member relative to said race shaft; and

a plurality of roller retainers for holding said plurality of rollers individually and correspondingly so that said plurality of rollers are rotatable/slidable;

wherein said plurality of rollers are arranged and received so that axes of adjacent rollers are kept approximately parallel to each other;

wherein each of said roller retainers is made thin to hold opposite side surfaces of corresponding one of said rollers and front and rear surfaces of said roller in a direction of movement of said roller;

wherein a linear guide portion and a curve guide portion which are different in inclination angle from each other are formed in each of opposite end surfaces of said roller retainer in a direction of movement of said roller retainer; and

wherein said linear guide portion of said roller retainer comes into contact with an adjacent roller retainer in a linear race and said curve guide portion of said roller retainer comes into contact with said adjacent roller retainer in a curved race.

11. A roller screw comprising:

a race shaft containing a helical roller rolling surface;

a slide member including a roller circulation path containing a helical load rolling surface corresponding to said roller rolling surface, said slide member being fitted to said race shaft so as to be freely movable relative to said race shaft;

a plurality of rollers arranged and received in said roller circulation path so as to circulate in accordance with movement of said slide member relative to said race shaft; and

a plurality of roller retainers for holding said plurality of rollers individually and correspondingly so that said plurality of rollers are rotatable/slidable;

wherein said plurality of rollers are arranged and received so that axes of adjacent rollers are kept approximately parallel to each other;

wherein each of said roller retainers is made thin to hold opposite side surfaces of corresponding one of said rollers and either one of front and rear surfaces of said roller in a direction of movement of said roller;

wherein a linear guide portion and a curve guide portion which are different in inclination angle from each other are formed in one end surface of said roller retainer in a direction of movement of said roller retainer; and

wherein said linear guide portion of said roller retainer comes into contact with an adjacent roller in a linear race and said curve guide portion of said roller retainer comes into contact with said adjacent roller in a curved race.

(57) **ABSTRACT**

A rolling guide device comprises: a track rail formed with a rolling member rolling surface extending along a longitudinal direction thereof; a movable rail formed with a loaded rolling member rolling surface extending along a longitudinal direction thereof so as to oppose to the rolling member rolling surface of the track rail; a track rail side rolling member circulation passage formed to the track rail so as to circulate the rolling members rolling between the track rail and the movable rail; a movable rail side rolling member circulation passage formed to the movable rail so as to circulate the rolling members rolling between the track rail and the movable rail; and a number of rolling members disposed and arranged in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage. A drive system comprises such rolling guide device and linear motors having a primary side mounted to either one of the track rail and the movable rail and a secondary side mounted to another one of the track rail and the movable rail.

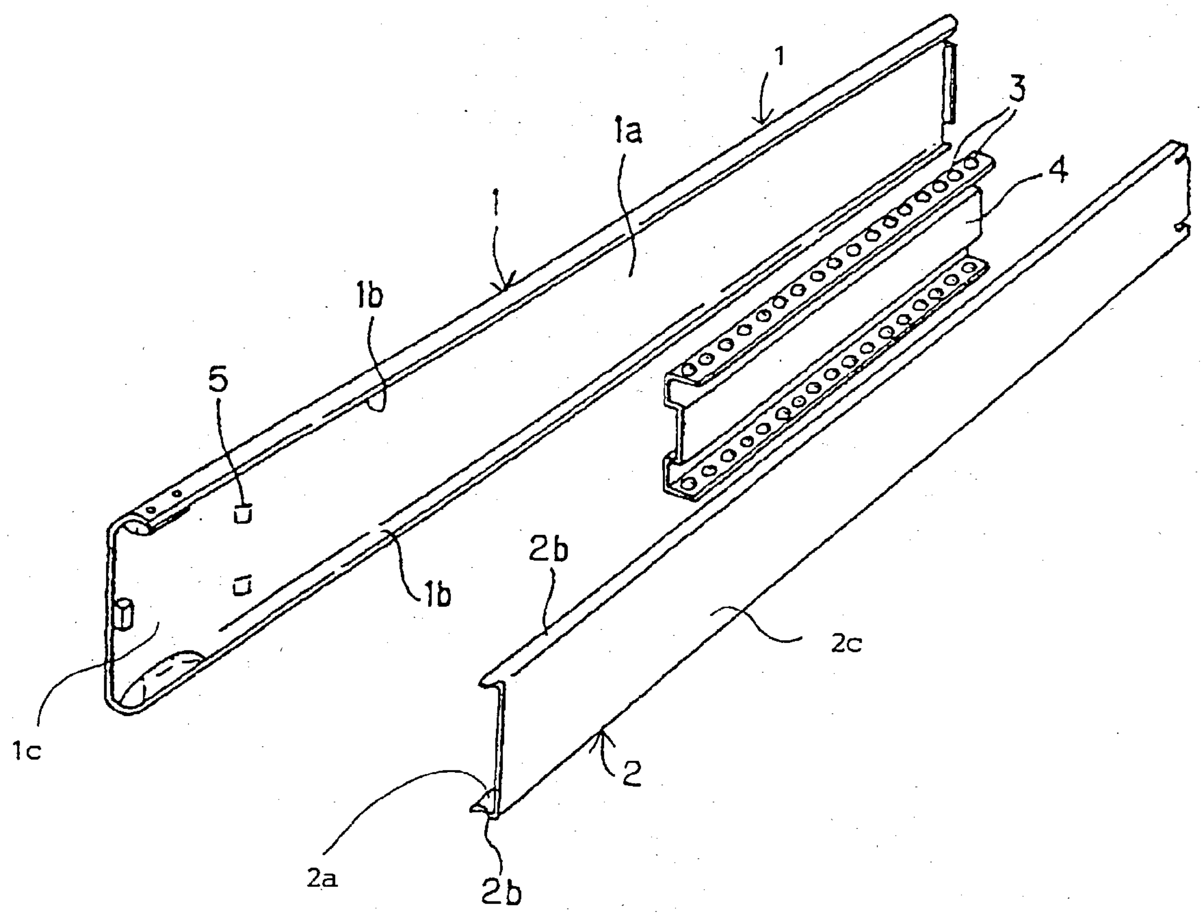
PRIOR ART



ROLLING GUIDE DEVICE AND DRIVE SYSTEM USING ROLLING GUIDE DEVICE

[0001] The present application claims priority under 35 U.S.C §119 to Japanese Patent Application No.2000-073932 filed Mar. 13, 2000 entitled "ROLLING GUIDE DEVICE ", No.2000-367605 filed Dec. 1, 2000 entitled "ROLLING GUIDE DEVICE AND DRIVE SYSTEM USING ROLLING GUIDE DEVICE", and No.2001-037486 filed Feb. 14, 2001 entitled "ROLLING GUIDE DEVICE AND DRIVE SYSTEM USING ROLLING GUIDE DEVICE". The contents of that application are incorporated herein by reference in their entirety.

BACKGROUND OF THE INVENTION

[0002] The present invention relates to a rolling guide device in which a movable rail is made slidable with respect to a track rail and also relates to a drive system using such rolling guide device.

[0003] As a rolling guide device in which a movable rail is made slidable with respect to a track rail, there has been known a slide rail such as shown in **FIG. 25** (see Japanese Utility Model Publication No. SHO 62-8765). Such slide rail comprises a track rail member **1** having an opened recess **1***a* (i.e. having substantially ⊐-shaped (box-shaped) cross section) formed by both inner side surfaces **1***b*, **1***b* and a bottom surface **1***c* and a movable rail member **2** which is supported between both the inner side surfaces **1***b*, **1***b* of the track rail member **1** to be movable in the longitudinal direction thereof. The movable rail member **2** also has an opened recess **2***a* (i.e. having substantially ⊐-shaped (box-shaped) cross section).

[0004] The track rail member **1** and the movable rail member **2** have substantially the same longitudinal length. The inner side surfaces **1***b* of the track rail member **1** are formed with ball rolling grooves, respectively, along which balls roll in the longitudinal direction thereof, and outer side surfaces **2***b* of the movable rail member **2** are also formed with loaded ball rolling grooves, respectively, so as to extend in the longitudinal direction thereof and oppose to the ball rolling grooves formed to the track rail member **1**.

[0005] A number of balls **3** are arranged and housed between these ball rolling grooves and loaded ball rolling grooves, and these balls **3** are held by a cage **4** to be rotatable and slidable. When the movable rail member **2** is slid with respect to the track rail member **1** in the longitudinal direction thereof, these balls **3** roll and, hence, the slide rail becomes smoothly expandable or contractive.

[0006] Further, though not shown, there is also known a cam-follower type drawer device of a structure that movable and track rails are both provided with wheels so that the movable rail is drawn with respect to the track rail, as a rolling guide device in which a movable rail is slidable with respect to a track rail.

[0007] However, in the conventional slide rail such as mentioned above, a number of balls **3** disposed and arranged between the track rail member **1** and the movable rail member **2** do not completely perform the rolling motion and will roll with a slight sliding motion. In the conventional slide rail, since the balls **3** do not circulate and only reciprocally move along the loaded rolling passage between the ball rolling grooves and the loaded ball rolling grooves, if the balls **3** are slid, the cage **4** supporting (bearing) the balls **3** would be displaced from the initial position. As a result, in spite of the fact that an effective stroke of the movable rail member **2** is not achieved, the cage **4** collides with a stopper **5** of the track rail member **1** and, hence, such effective stroke could not be obtained. In this case, when it is required to slide the movable rail member **2** with the cage **4** colliding with the stopper **5**, the movable rail member **2** will be slid with the balls **3** being slipped, and accordingly, a large force is required to move the movable rail member **2**.

[0008] Furthermore, in the conventional structure of the slide rail, in order to obtain a large stroke of the movable rail member **2**, it is necessary for the movable rail member **2** to be once come off from a portion at which the balls **3** exist and then to be engaged with that portion at which the balls **3** exist. That is, in the case where the movable rail member **2** is come off from the portion at which the balls **3** exist, for example, the movable rail member **2** which has been loaded with ten (10) balls **3** is loaded with, for example, six (6) balls **3**, and hence, ability for bearing moment load, radial load and thrust load is deteriorated, thus being inconvenient.

[0009] Moreover, with the cam-follower type drawer device, since the wheels generally have backlash or looseness, the movable rail member **2** is not smoothly slid, and furthermore, since the wheel has a cylindrical structure, a direction along which a load is received is determined, and hence, the thrust load cannot be received.

SUMMARY OF THE INVENTION

[0010] An object of the present invention is to substantially eliminate defects or drawbacks encountered in the prior art mentioned above and to provide a rolling guide device capable of taking a large expansion/contraction stroke and sufficiently bearing moment load, radial load and thrust load at any expanded (contracted) attitude and also provide a drive system incorporated with such rolling guide device.

[0011] This and other objects can be achieved according to the present invention by providing, in one aspect, a rolling guide device comprising:

[0012] a track rail formed with a rolling member rolling surface extending along a longitudinal direction thereof;

[0013] a movable rail formed with a loaded rolling member rolling surface extending along a longitudinal direction thereof so as to oppose to the rolling member rolling surface of the track rail;

[0014] a track rail side rolling member circulation passage formed to the track rail so as to circulate the rolling members rolling between the track rail and the movable rail;

[0015] a movable rail side rolling member circulation passage formed to the movable rail so as to circulate the rolling members rolling between the track rail and the movable rail; and

[0016] a number of rolling members disposed and arranged in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage.

[0017] According to the invention of this aspect, when the movable rail is slid with respect to the track rail, the rolling members arranged between the track rail and the movable rail endlessly circulate in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage while rolling therealong. As mentioned, since the rolling members circulate in the endless manner, even if the rolling member slides during the rolling motion, there is no causing of a case that a cage is shifted from the initial position as in the conventional structure, and hence, a large expansion (contraction) stroke is obtainable. Furthermore, in an optional expanded (contracted) attitude, there remains a considerable distance between the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage, so that a rolling guide device, which can bear even the moment load, can be realized.

[0018] Further, when the movable rail is slid and its stroke is made large, the considerable distance corresponding to this stroke is made short and capability of bearing the moment load is reduced. However, according to the present invention, the movable rail is not come off from the balls, so that the capability of bearing the moment load is not extremely reduced. Moreover, since the movable rail is not come off from the balls and the number of the rolling members supported at an optional expansion (contraction) attitude is not changed, different from the conventional slide rail, there can be provided a rolling guide device bearing the constant radial load and thrust load.

[0019] In the above aspect, the following preferred embodiments or examples may be provided with advantageous functions and effects thereof.

[0020] The track rail side rolling member circulation passage is formed to one longitudinal end side of the track rail and the movable rail side rolling member circulation passage is formed to one longitudinal end side, opposing to that one end side of the track rail, of the movable rail.

[0021] Accordingly, the distance between the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage can be made large, so that a rolling guide device bearing the large moment load can be provided.

[0022] Furthermore, the track rail has an opened recess having a ⊐-shaped section and has inside surfaces to which the rolling member rolling surfaces are formed, the movable rail is fitted into the recess of the track rail, and the movable rail has outside surfaces to which the loaded rolling member rolling surfaces are formed so as to oppose to the rolling member rolling surfaces formed to the track rail inside surfaces.

[0023] Thus, various kinds of loads including radial load, thrust load and moment load can be supported in a balanced condition.

[0024] The track rail side rolling member circulation passage is provided with a rolling member return passage substantially parallel to the rolling member rolling surface and a rolling direction changing passage communicating the rolling member rolling surface and the rolling member return passage, the movable rail side rolling member circulation passage is provided with a rolling member return passage substantially parallel to the loaded rolling member rolling surface and a rolling direction changing passage communicating the rolling member rolling surface and the rolling member return passage, the rolling direction changing passages of the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage are formed to a deflector which is formed independently from a track rail body and a movable rail body, and the deflector is fitted to holes formed to the track rail body and movable rail body from the side portions thereof.

[0025] According to this embodiment, the rolling direction changing passages can be easily formed to fine long track rail and movable rail.

[0026] The return passages are drilled to the track rail body and the movable rail body from the longitudinal end portions thereof.

[0027] According to this embodiment, the return passages can be easily formed to fine long track rail and movable rail.

[0028] The deflector is composed of a plurality of sections splittable along the rolling direction changing passages.

[0029] Accordingly, the rolling direction changing passages having complicated structure may be easily formed to the deflector.

[0030] The deflector is made of a synthetic resin.

[0031] Accordingly, the rolling direction changing passages having complicated structure may be easily formed to the deflector, and moreover, noise which may be generated when the rolling members roll in the rolling direction changing passages will be suppressed.

[0032] The above mentioned object of the present invention can be also achieved by providing, in another aspect, a drive system comprising:

[0033] a track rail formed with a rolling member rolling surface extending along a longitudinal direction thereof;

[0034] a movable rail formed with a loaded rolling member rolling surface extending along a longitudinal direction thereof so as to oppose to the rolling member rolling surface of the track rail;

[0035] a track rail side rolling member circulation passage formed to the track rail so as to circulate the rolling members rolling between the track rail and the movable rail;

[0036] a movable rail side rolling member circulation passage formed to the movable rail so as to circulate the rolling members rolling between the track rail and the movable rail;

[0037] a number of rolling members disposed and arranged in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage; and

[0038] a linear motor means having a primary side mounted to either one of the track rail and the movable rail and a secondary side mounted to another one of the track rail and the movable rail.

[0039] According to the present invention of this aspect, the expansion (contraction) stroke can be made large and the moment load, the radial load and the thrust load can be sufficiently supported at an optional attitude of the system. Furthermore, since the linear motors are incorporated between the track rail and the movable rail, the use of the ball screw or like can be eliminated, thus moving the movable rail at high speed with less noise. Moreover, since it is not necessary to provide a space for a rotary motor, the drive system can be made thin and compact.

[0040] According to preferred embodiments or examples of this aspect, the following advantageous functions and effects may be attained.

[0041] The track rail side rolling member circulation passage is formed to one longitudinal end side of the track rail and the movable rail side rolling member circulation passage is formed to one longitudinal end side, opposing to that one end side of the track rail, of the movable rail, and the linear motor means comprises first and second linear motors, the first linear motor having a primary side mounted to a portion near the track rail side rolling member circulation passage of the track rail, the second linear motor having a secondary side mounted to the track rail along the longitudinal direction thereof so as to be continuous to the primary side of the first linear motor, and the second linear motor having a primary side mounted to a portion near the movable rail side rolling member circulation passage of the movable rail, the first linear motor having a secondary side mounted to the movable rail along the longitudinal direction thereof so as to be continuous to the primary side of the second linear motor.

[0042] According to this embodiment, since two sets of linear motors are incorporated in the drive system, the thrust force can be made two times (twice), and the excitation is averaged to thereby make smooth the movement of the movable rail. Furthermore, the first linear motor has a primary side mounted to a portion near the track rail side rolling member circulation passage of the track rail and the second linear motor has a primary side mounted to a portion near the movable rail side rolling member circulation passage of the movable rail, so that the thrust force can be generated at substantially the same positions of the movable side rolling member circulation passage and the track rail side rolling member circulation passage, regardless of the stroke of the movable rail. Therefore, even if pitching or yawing moment is applied to the movable rail, the thrust force can be stably applied to the movable rail.

[0043] The first and second linear motors may be composed of linear induction motors or linear pulse motors such that the secondary sides thereof are opposed to each other.

[0044] For example, in a case where linear D.C. motors are used, two sets of linear motors are disposed in back-to-back arrangement and a distance between the secondary side magnets is short, an alternating magnetic field may be generated between the magnets. However, according to this embodiment of the present invention, since the linear induction motors or linear pulse motors are used without using the magnets, there is no fear of causing any alternating magnetic filed. However, a linear D.C. motor may be utilized as far as a relatively large distance between the secondary sides of the linear D.C. motors can be taken so as not to influence from each other.

[0045] The nature and further characteristic features of the present invention may be made clear from the following descriptions made with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0072] FIGS. **1** to **3** represent a first embodiment of a rolling guide device according to the present invention.

[0073] With reference to FIGS. **1** to **3**, a rolling guide device comprises an outer rail **7** as a track rail, an inner rail **8**, as a movable rail, supported by the outer rail **7** to be slidable in the longitudinal direction thereof and a ball screw **9** driving the inner rail **8**. When a screw shaft **10** of the ball screw **9** is rotated, the inner rail **8** is slid with respect to the outer rail **7**. Such rolling guide device will be utilized for a welding servo-gan, fork-lift or like usable in a stockroom, for example. In a case where the rolling guide device is utilized for the welding servo-gan, a welding rod is attached to the inner rail **8** and, then, the inner rail **8** is slid so as to press the welding rod against an object to be welded. On the other hand, in a case where the rolling guide device is utilized for the fork-lift, an inner rail **8** having a front fork member is slid and the fork-lift is then moved while supporting a cargo by the projected fork member. It is of course to be noted that the illustrated rolling guide device is not limited in its use to the welding servo-gan and the fork-lift and can be applied for various usages as far as expansion/contraction stroke is required and a load is supported.

[0074] The outer rail **7** has a recess **7***a* having an upper opening, in an illustrated state, so as to provide substantially a ⊐-shaped (box-shaped) section having an upper opening. That is, the recess **7***a* is defined by a bottom portion and a lateral pair of ridges **7***b*, **7***b* extending in parallel to each other at both longitudinal side portions of the bottom portion. Each of the ridges **7***b* has an inside surface **7***c* to which one row of ball rolling groove **11** is formed as a rolling member rolling surface extending in the longitudinal direction thereof. An outer rail side ball circulation passage **14** for circulating balls **13**, as rolling members, rolling between the inner rail **8** and the outer rail **7** is formed to one longitudinal side end portion of the outer rail **7**.

[0075] The inner rail **8** is fitted to the recess **7***a* of the outer rail **7** and supported thereby through balls **12, 13** so as to be clamped between the ridges **7***b*, **7***b* of the outer rail **7**. The inner rail **8** has a recess **8***a* having a lower opening, in an installed state, so as to provide substantially a ⊐-shape section having a lower opening, thus easily forming a space into which the screw shaft **10** is moved.

[0076] In the fitted state of the inner and outer rails **8** and **7**, the inside surfaces **7***c*, **7***c* of the outer rail **7** face the outside surfaces **8***c*, **8***c* of the inner rail **8**, respectively, so that the ball rolling grooves **11** formed to the inside surfaces **7***c*, **7***c* of the outer rail **7** oppose to the loaded ball rolling grooves **15** formed to the outside surfaces **8***c*, **8***c* of the inner rail **8**. Inner rail side ball circulation passages **16** are formed to one longitudinal end side of the inner rail **8** opposing to the outer rail side ball circulation passages **14** so as to circulate the balls **12** rolling between the outer and inner rails **7** and **8**. That is, in the structure in which the inner rail **8** projects from (extends over) the outer rail **7**, the outer rail side ball circulation passages **14** on the exit side end of the outer rail **7** and the inner rail side ball circulation passages **16** are formed to the rear side end of the inner rail **8**. This will be explained through a manufacturing processes. The outer rail side ball circulation passages **14** are formed to one end side of the outer rail **7** and the inner rail side ball circulation passages **16** are formed to one end side of the inner rail **8**, and thereafter, the inner and outer rails **8** and **7** are assembled (fitted) from the direction in which both the circulation passages **14** and **16** do not interfere.

[0077] As shown in **FIG. 2**, each of the outer rail side ball circulation passages **14** is composed of a portion of the ball rolling groove **11**, a ball return passage A as a rolling member return passage substantially parallel to the ball rolling groove **11** and a pair of rolling member rolling direction changing passages B communicating with the ball rolling groove **11** and the ball return passage A. On the other hand, each of the inner rail side ball circulation passage **16** is also composed of a portion of the loaded ball rolling groove **15**, a ball return passage A as a rolling member return passage substantially parallel to the ball rolling groove **15** and a pair of rolling member rolling direction changing passages B communicating with the loaded ball rolling groove **15** and the ball return passage A. The ball return passage A is formed through a drilling working effected along the longitudinal direction from the end portions of an outer rail body **7***d* and an inner rail body **8***d*. The rolling direction changing passages B formed to the outer and inner ball circulation passages **14** and **16** are formed to deflectors **19** formed independently from the inner and outer rail bodies **8***d* and **7***d*. The details of such deflector **19** will be described hereinlater.

[0078] The ball screw **9** is engaged with the inner rail **8** so that the ball screw **9** is arranged in the recess **8***a* of the inner rail **8**.

[0079] With reference to **FIG. 4** showing the ball screw **9**, the ball screw **9** comprises the screw shaft **10**, a nut member **22** assembled to the screw shaft **10** to be relatively movable and a number of balls **23** disposed in the ball circulation passage. The screw shaft **10** has an outer peripheral surface on which a spiral rolling member rolling groove **10***a* is formed, the nut member **22** has an inner peripheral surface to which is formed a ball circulation passage including a spiral loaded rolling member rolling groove **22***a* opposing to the ball rolling groove, and the number of balls **23** are arranged in the ball circulation passage so as to circulate therein in association with the relative movement of the nut member **22** with respect to the screw shaft **10**. The nut member **22** has a flanged portion **24** formed at its one end side and is secured to the inner rail **8** by means of screws or like. The nut member **22** is also provided with a deflector **25** (direction changing passage forming member) for taking out the ball **23** rolling along the ball rolling groove **10***a* formed to the screw shaft **10** at one portion thereof and returning the ball **23** to the other portion (one-lead on this side from the ball taken out portion) of the ball rolling groove **10***a* over an outer large diameter portion of the screw shaft **10**. The screw shaft **10** is operatively coupled with an output (drive) shaft of a motor, mentioned hereinlater.

[0080] When the screw shaft **10** is rotated, the ball **23** rolling in the circumferential direction of the screw shaft under load is scooped up by the deflector **25** and the scooped ball **23** is then returned to the position, one-lead on this side of the ball rolling groove **10***a*. When the screw shaft **10** is rotated in the reverse direction, the balls **23** are circulated along the route reverse to that mentioned above. Further, in the described embodiment, although the balls **23** are scooped up by using the direction changing passage forming member (deflector) **25** and returned to the position, one-lead on this side of the ball rolling groove **10***a*, a return pipe may be substituted for such deflector **25**. That is, according to the structure using the return pipe, the ball **23** rolling along the ball rolling groove **10***a* of the screw shaft **10** is scooped up by one end of the return pipe and is then returned through the other one end thereof. Furthermore, so-called a side-cover (lid) type ball screw may be adapted, in which the nut member **22** is composed of a nut body formed with a loaded rolling groove and side lids applied to both ends of this nut body, a ball return passage is formed to the nut body, and both the side lids are formed with communication passages communicated with the loaded rolling groove and the return passage, respectively. An arrangement utilizing rollers in place of balls may be also applicable to the present invention.

[0081] **FIG. 5** shows the details of the deflector **19**, which is utilized commonly for the inner rail side ball circulation passage **16** and the outer rail side ball circulation passage **14**. With reference to the deflector **19** of **FIG. 5**, the deflector **19** is formed with rolling direction changing passage **26** in a semi-circular shape, and the deflector is composed of two bodies **19***a* and **19***b* divided along the rolling direction changing passage **26** for the sake of easy formation of this passage **26**. That is, these two body sections **19***a* and **19***b* are divided vertically, as viewed, through a plane including a central line of the rolling direction changing passage **26**. Both the body sections **19***a* and **19***b* are positioned through the engagement of dowels **27** and holes **28** formed to the body sections **19***a* and **19***b*. The deflector **19** is further formed with a stepped abutment portion **29** for the purpose of positioning it to the inner rail side ball circulation passage **16** and the outer rail side ball circulation passage **14**. The deflector **19** of the structure mentioned above will be formed from synthetic resin, for example, through an injection formation process.

[0082] **FIG. 6** shows another example of the deflector **30**. This deflector **30** is also composed of two divided body sections **30***a* and **30***b* separated along the rolling direction changing passage **26** for the easy formation thereof as mentioned before. In this example, however, the rolling direction changing passage **26** is divided into two sections as inner peripheral side section and outer peripheral side section. This deflector **30** is also formed with a stepped abutment portion **31**.

[0083] With reference to **FIGS. 2 and 3**, the outer rail body **7***d* is drilled from the side thereof to form holes **33** by means of end mill, for example, and the deflectors **19** are fitted to these holes **33**. The fitted deflectors **19** is secured to the outer rail body **7***d* by fastening means **32** such as binder members. The holes **33** are formed so as to penetrate the ball return passages A and extend ball rolling grooves **11** or ball rolling grooves **15** and formed inside with stepped portions **33***a* abutting against the abutment portions **29** of the deflectors **19**. When fitting the deflector **19**, the outer periphery of the deflector **19** is fitted to the hole **33** and the abutment portion **29** of the deflector **19** abuts against the stepped portion **33***a* of the hole **33**, thus positioning the deflector **19** with respect to the outer rail body **7***d* or inner rail body **8***d*.

[0084] Through such positioning of the deflector **19**, the balls **12** and **13** can be surely scooped from the ball rolling groove **11** or loaded ball rolling groove **15** and then returned to the ball return passage A.

[0085] On the other hand, other holes **33** are formed to the inner rail body **8***d* from the side thereof by means of end mill, for example, and the deflectors **19** are fitted to these holes **33**. Furthermore, in the described embodiment, although the holes **33** are formed to the outer rail body **7***d* from the outside thereof and formed to the inner rail body **8***d* from the inside thereof, the holes **33** may be formed to the outer rail body **7***d* from the inside thereof and formed to the inner rail body **8***d* from the outside thereof.

[0086] **FIG. 7** shows one preferred example of a drive system according to the present invention, which uses the rolling guide device mentioned above and is assembled with a rotation motor.

[0087] The screw shaft **10** is screwed with the nut member **22** and has one end rotatably supported by a bearing **35** disposed at one end portion of the outer rail **7** and coupled to a motor, not shown, through a joint member **36**. According to this structure, when the motor is driven, the screw shaft **10** is rotated and the rotational motion thereof is transferred to the inner rail **8** through the ball screw to thereby linearly move the inner rail **8** along the outer rail **7**. According to this linear motion of the inner rail **8** along the outer rail **7**, the rolling guide device is expanded or contracted, and the balls **12** and **13** circulate in an endless manner in the inner rail side ball circulation passage **16** and the outer rail side ball circulation passage **14** while rolling therealong. Since the balls **12** and **13** endlessly circulate, even if the balls **12** and **13** be slid during the rolling motion, there is no fear of being shifted from the original position as in a conventional slide rail, and a rolling guide device having a large expansion stroke can be realized, in which the inner rail **8** can be smoothly moved.

[0088] **FIG. 8** is an illustration showing a state that a load P is applied to the front end of the inner rail **8** of the rolling guide device. In an optional expanded or contracted state, since a considerable distance **1** exists between the outer rail side ball circulation passage **14** and the inner rail side ball circulation passage **16**, there can be provided a rolling guide device bearing the moment load. For example, when the load P is applied to the front end portion of the inner rail **8**, a reaction force Ro acts on the outer rail side ball circulation passage **14** and a reaction force Ri acts on the inner rail side ball circulation passage **16**, thus bearing the moment load of (Ri×1). When the inner rail **8** slides and the stroke of the rolling guide device is made large, the above-mentioned distance **1** is gradually reduced and an ability for loading this moment load is also reduced. However, even if the inner rail

8 is slid, the inner rail 8 never come off as in the conventional slide rail from the balls, so that the moment load bearing ability cannot be largely reduced. Furthermore, the movable rail is not come off from the ball as in the conventional slide rail and the number of balls born in the optional expanded or contracted attitude does not change, so that a rolling guide device capable of bearing constant radial load and thrust load can be realized.

[0089] Furthermore, as mentioned above, the outer rail **7** has a recess **7***a* having an upper opened portion has a box-shaped section and the ball rolling grooves **11** are formed to the inside surfaces **7***c*, respectively. The inner rail **8** is fitted into the recess **7***a* of the outer rail **7** and the loaded ball rolling grooves **15** are formed to the outside surfaces **8***c* of the inner rail **8** so as to oppose to the inside surfaces **7***c* of the outer rail **7**. Accordingly, there is provided the rolling guide device capable of bearing the radial load, the thrust load and the moment load in a balanced condition.

[0090] **FIG. 9** includes perspective views of the rolling guide device according to another embodiment of the present invention. Referring to **FIG. 9**A, the device is provided with inner and outer rails **8** and **7**, constituting a single-stroke structure in which only the inner rail **8** is slid. Further, as shown in **FIG. 9**B, the rolling guide device may be composed of three rail sections comprising the outer rail **7**, a first inner rail **41** fitted to the outer rail **7** and a second inner rail **42** fitted to the first inner rail **41**. In this structure, the first inner rail **41** is slid with respect to the outer rail **8** and the second inner rail **42** is slid with respect to the first inner rail **41**. That is, the first inner rail **41** acts like the inner rail **8** of the aforementioned embodiment with respect to the outer rail **7** and also acts like the outer rail **7** of the aforementioned embodiment with respect to the second inner rail **42**. The second inner rail **42** has a structure identical to that of the inner rail **8**. According to this rolling guide device of the embodiment of **FIG. 9**B, since the first inner rail **41** is slid with double strokes, the expansion stroke can be made further long. As mentioned above, when the rolling guide device is composed of a plurality of members (rail members), the expansion stroke composed of a plurality of expansion stages can be realized, thus providing a rolling guide device having a large stroke.

[0091] In the embodiment described above, although the inner rail side ball circulation passage **16** and the outer rail side ball circulation passage **14** are formed to the inner rail **8** and the outer rail **7**, respectively, these passages may be formed as block members independently from the inner and outer rails **8** and **7**. Furthermore, although the inner rail **8** and the outer rail **7** are formed as linear (straight) rail members, a curved rail member may be utilized therefor. The balls may be also substituted with other rolling members such as rollers. Retainers each having a belt shape having flexibility may be arranged for supporting the balls **12** and **13** to be rotatable, and spacers may be also arranged between the balls **12** and **13** for supporting them to be rotatable and slidable.

[0092] **FIGS. 10 and 11** represent a drive system, using a linear motor as drive source, according to one embodiment of the present invention.

[0093] This drive system comprises an outer rail **7** as a track rail, an inner rail **8** as a movable rail supported by the outer rail **8** to be linearly slidable along the longitudinal direction thereof and first and second linear motors **51** and **52** disposed between the inner and outer rails **8** and **7** to be back-to-back arrangement. The outer rail **7** is provided with a primary side movable piece (called merely movable piece i hereinlater) of the first linear motor **51** and a secondary side stationary piece (called merely stationary piece O' hereinlater) of the second linear motor **52**. On the other hand, the inner rail **8** is provided with a secondary side movable piece (called merely movable piece i' hereinlater) of the second linear motor **52** and a primary side stationary piece (called merely stationary piece O hereinlater) of the first linear motor **51**. According to this structure, when energized, suction (attracting) forces are induced between the movable piece i and the stationary piece O and between the movable piece i' and the stationary piece O'.

[0094] As like as the rolling guide device mentioned above, the outer rail **7** is formed with a recess **7***a* having a box-shaped section with an upper opening and also formed with a lateral pair of ridges **7***b*, **7***b* extending on both the sides of the recess **7***a* in parallel to each other along the longitudinal direction of the outer rail **7**. Each of the ridges **7***b*, **7***b* has an inside surfaces **7***c*, to which a single row of ball rolling groove **11** as a rolling member rolling surface is formed so as to extend along the longitudinal direction thereof as shown in **FIG. 11**. An outer rail side ball circulation passage **14** for circulating the balls **13** rolling between the inner and outer rails **8** and **7** is formed to one (front) end side portion of the outer rail **7**.

[0095] The inner rail **8** is fitted to the recess **7***a* of the outer rail **7** and supported thereby so as to be clamped between the ridges **7***b* of the outer rail **7** through the balls **12** and **13**. The inner rail **8** is also formed with a recess **8***a* having an opening opened downward so as to provide a box-shaped section. The inner rail **7** has outside surfaces **8***c* to which loaded ball rolling grooves **15** are formed as loaded rolling member rolling surfaces which face the ball rolling grooves **11** of the outer rail **7**. An inner rail side ball circulation passage **16** for circulating the balls **12** rolling between the inner and outer rails **8** and **7** is formed to one (rear) end side portion of the outer rail **7** in the longitudinal direction thereof.

[0096] As shown in **FIG. 11**, the outer rail side ball circulation passage **14** is composed of a portion of the ball rolling groove **11**, a ball return passage A as a rolling member return passage extending substantially in parallel to the ball rolling groove **11** and a pair of rolling direction changing passages B communicated with the ball rolling groove **11** and the ball return passage A. On the other hand, the inner rail side ball circulation passage **16** is also composed of a portion of the loaded ball rolling groove **15**, a ball return passage A as a rolling member return passage extending substantially in parallel to the loaded ball rolling groove **15** and a pair of rolling direction changing passages B communicated with the loaded ball rolling groove **15** and the ball return passage A. The ball return passages A are formed through drilling working effected from the end portions of the outer rail body **7***d* and the inner rail body **8***d* in their longitudinal directions. The rolling direction changing passages B of the outer rail side ball circulation passage **14** and the inner rail side ball circulation passage **16** are formed to a deflector **19** which is mounted to the inner rail body **8***d* and the outer rail body **7***d* as independent member.

[0097] Holes **33** are formed to the outer rail body **7***d* by means of end mill, for example, from the longitudinal sides thereof, and the deflector **19** is fitted to these holes **33** and then fastened to the outer rail body **7***d*. Holes **33** are also formed to the inner rail body **8***d* by means of end mill, for example, from the longitudinal sides thereof, and the deflector **19** is fitted to these holes **33** and then fastened to the inner rail body **8***d*. Since these deflectors have substantially the same structures as that mentioned herein before with reference to the rolling guide device, the details thereof are omitted herein by adding the same reference numeral of **19**.

[0098] Two linear motors **51** and **52** are interposed between the inner rail **8** and the outer rail **7**, and the linear motors **51** and **52** in this embodiment are linear induction motors and composed of the movable pieces i and i' and the stationary pieces O and O', the induction motors being driven and operated by passing polyphase alternating current to primary windings of the movable pieces i and i'.

[0099] With reference to **FIG. 10**, the movable piece i of the first linear motor **51** is mounted to a portion near one end (front end) in the longitudinal direction of the upper surface of the outer rail **7**, and the stationary piece O' of the second linear motor **52** is also mounted to the upper surface of the outer rail **7** so as to be continuous to the movable piece i of the first linear motor **51** in the longitudinal direction of the outer rail **7**. On the other hand, the movable piece i' of the second linear motor **52** is mounted to a portion near one end (rear end) in the longitudinal direction of the lower surface of the inner rail **8**, and the stationary piece O of the first linear motor **51** is also mounted to the lower surface of the inner rail **8** so as to be continuous to the movable piece i' of the second linear motor **52** in the longitudinal direction of the inner rail **8**. In such arrangement, the movable piece i of the first linear motor **51** and the outer rail side ball circulation passage **14** have substantially the same positions in the longitudinal direction of the outer rail **7**, and on the other hand, the movable piece i' of the second linear motor **52** and the inner rail side ball circulation passage **16** have substantially the same positions in the longitudinal direction of the inner rail **8**. Further, it is to be noted that the terms "upper", "lower" and the like are used herein in the illustrated state in the figures or usable state of the device or system.

[0100] As shown in **FIG. 12**, the movable piece i of the first linear motor **51** is opposed to the stationary piece O of the first linear motor **51**, and as shown in **FIG. 13**, the movable piece i' of the second linear motor **52** is opposed to the stationary piece O' of the second linear motor **52** so that the first and second linear motors **51** and **52** are disposed in the back-to-back arrangement as shown in **FIG. 14**.

[0101] **FIG. 15** shows a linear induction motor **53** constituting one example of the first and second linear motors **51** and **52**. The linear induction motor **53** is provided with the movable piece i and the stationary piece O which is composed of a non-magnetic conductor plate **54** and a magnetic conductor plate **55** by laminating them vertically as viewed. This linear induction motor **53** is driven in a manner basically identical to that of a cage (rotary type) induction motor having an operational function explained by the Lenz's law and the Fleming's left-hand rule.

[0102] When the polyphase alternating current passes the polyphase primary winding **56**, a traveling (progressive) magnetic field moving timely and spacially is generated, and this traveling field induces an eddy current on the non-magnetic conductor plate **54** constituting the secondary side element. The thus generated eddy current constitutes a thrust generation source in cooperation with the traveling field. Further, in the illustrated example of **FIG. 15**, the movable piece i is disposed only to the upper portion of the stationary piece O, but the movable pieces i may be disposed to both the upper and lower portions thereof.

[0103] **FIG. 16** shows a linear pulse motor **57** as another example of the linear motor **51** (**52**).

[0104] With reference to **FIG. 16**, the movable piece i is, for example, composed of a central permanent magnet **58** and two magnetic core members **59** and **60** opposed to each other with the permanent magnet **58** being interposed therebetween. One **59** of the magnetic cores is formed with first and second magnetic poles **61** and **62** magnetized in N-pole by the permanent magnet **58** and, on the contrary, the other one **60** of the magnetic cores is formed with third and fourth magnetic poles **63** and **64** magnetized in S-pole by the permanent magnet **58**.

[0105] On the other hand, the stationary piece O is formed with stationary teeth **65**, each having, a ⊐-shaped section, extending in a direction normal to the longitudinal direction of the stationary piece O equally with the same pitch. The magnetic poles **61** to **64** are formed with magnetic pole teeth **61***a* to **64***a*, respectively, each having the same pitch as that of the stationary piece O.

[0106] A first coil **66** and a second coil **67** are wound up around the first magnetic pole **61** and the second magnetic pole **62** of the N-pole side and connected in series to each other so as to generate magnetic fluxes opposed to each other in directions at a time when current flows. The first coil **66** and the second coil **67** are electrically connected to a pulse generation source, not shown.

[0107] On the other hand, a third coil **68** and a fourth coil **69** are also wound up around the third magnetic pole **63** and the fourth magnetic pole **64** of the S-pole side and connected to a pulse generation source.

[0108] In the described arrangement, the first and second magnetic poles **61** and **62** are arranged so that the magnetic pole teeth **61***a* and **62***a* thereof are shifted from each other by ½ pitch in their phases, and the third and fourth magnetic poles **63** and **64** are also arranged so that the magnetic pole teeth **63***a* and **64***a* thereof are shifted from each other by ½ pitch in their phases. Furthermore, the magnetic pole teeth **63***a* and **64***a* of the third and fourth magnetic poles **63** and **64** of the S-pole side are shifted, by ¼ pitch in phases, from the first and second magnetic pole teeth **61***a* and **62***a* of the first and second magnetic poles **61** and **62** of the N-pole side.

[0109] The linear pulse motor is driven by the following operation theory with reference to **FIGS. 17A** to **17D**.

[0110] Pulses are inputted to the first and second coils **66** and **67** from terminals a, and pulses are also inputted to the third and fourth coils **68** and **69** from terminals b. That is, the pulses are inputted to the terminal a in a direction to energize the first magnetic pole **61** in the state shown in **FIG. 17A**, to the terminal b in a direction to energize the fourth magnetic pole **64** in the state shown in **FIG. 17B**, to the terminal a in a direction to energize the second magnetic pole **62** in the state shown in **FIG. 17C**, and to the terminal b in a direction to energize the third magnetic pole **63** in the state shown in **FIG. 17D**, respectively.

[0111] When the pulse is inputted to the terminal a in a direction to energize the first magnetic pole **61** in the state shown in **FIG. 17**A, the first magnetic pole **61** maintains its stable state under the application of the magnetic fluxes of the permanent magnet **58** and the first coil **66**. Next, in the state shown in **FIG. 17**B, when the pulse is inputted to the terminal b in a direction to energize the fourth magnetic pole **64**, the fourth magnetic pole **64** is moved to a direction so as to maintain its stable state, that is, in the right direction facing the drawing paper by ¼ pitch. As mentioned above, the movable piece is operated continuously as shown in **FIGS. 17C and 17D** by passing alternately the pulse current.

[0112] **FIG. 18** represents a linear D.C. motor **70** as another example of the linear motor.

[0113] With reference to **FIG. 18, a** movable piece of this example is composed of exciting coils **71** and yokes, and a stationary piece O is composed of magnets **72** and yokes. A plurality of exciting coils **71** constituting the movable piece i are arranged along the longitudinal direction thereof, and a plurality of magnets **72** constituting the stationary piece O are arranged along the longitudinal direction so as to provide alternately N- and S-poles.

[0114] The position of the movable piece i is detected by a sensor, and the direction of the current passing the exciting coil **71** at the detected position is changed sequentially reversely. The exciting coil **71** generates a thrust force in accordance with the Fleming's left-hand rule through the relative reaction between the exciting coils **71** and the magnets **72**.

[0115] In the case where such linear D.C. motor is utilized, two sets of linear motors **51** and **52** are disposed in the back-to-back arrangement, and in an arrangement that a distance between the adjacent secondary side magnets **72**, **72** is short, there causes a fear that an alternating magnetic field is caused between the magnets **72** and **72**, which may cause a defective operation. Accordingly, in the case where two sets of the linear motors **51** and **52** are used in the back-to-back arrangement, the linear induction motor **53** and the linear pulse motor **57**, which do not utilize the secondary side magnets **72**, could be effectively utilized. However, in an arrangement in which a relatively large distance could be maintained on the secondary side, no adverse effect is not caused between the magnets **72** and **72**, so that the linear D.C. motor **70** may be utilized.

[0116] The drive system incorporated with the linear motors **51** and **52** of the structures mentioned above will operate in the following manner.

[0117] When the current is applied to the movable pieces i and i' of the first and second linear motors **51** and **52**, suction (attracting) force acts between the movable pieces i and i' and the stationary pieces O and O' to thereby move the inner rail **8** with respect to the outer rail **7** by a predetermined distance in the longitudinal direction thereof. In this case, the movable piece i of the first linear motor **51** moves forward with respect to the stationary piece O. However, with the second linear motor **52**, a current is applied to the movable piece i' in a backward movement direction with respect to the stationary piece O' because of the movement of the stationary piece O', and as a reaction motion thereto, the stationary piece O' is moved forward. Hence, the inner rail **8** is slid with respect to the outer rail **7**, and therefore, the entire structure of the drive system is expanded and contracted.

[0118] In the structure utilizing the linear motors **51** and **52** as driving source, it is not necessary to utilize a ball screw or like, and hence, the inner rail can be moved at high speed with less noise. Furthermore, there is no need for locating a space for a rotary motor or like, thus making the drive system thin and compact in its structure. Still furthermore, since the two sets of linear motors **51** and **52** are arranged between the inner rail **8** and the outer rail **7**, two times of the thrust force is obtainable and the excitation of the linear motors **51** and **52** is averaged, thus making smooth the movement of the inner rail **7**.

[0119] Still furthermore, the movable piece i of the first linear motor **51** is mounted to a portion near the outer rail side rolling member circulation passage **14** and the movable piece i' of the second linear motor **52** is mounted to a portion near the inner rail side rolling member circulation passage **16**, the points on which the thrust force is applied are always positioned at portions near the the outer rail side rolling member circulation passage **14** and the inner rail side rolling member circulation passage **16** irrespective of the stroke of the inner rail **8**. The inner rail **8** is supported by the outer rail **7** at the positions of the inner rail side rolling member circulation passage **16** and the outer rail side rolling member circulation passage **14**. Accordingly, even if a moment causing pitching or yawing acts on the inner rail **8**, the thrust force can be stably generated for the inner rail **8**.

[0120] **FIG. 19** represents a drive system according to a further embodiment of the present invention. The drive system of this embodiment is incorporated with two sets of rod-type linear motors as first and second linear motors **51** and **52**. This drive system is also composed of, like the drive system mentioned hereinbefore, an outer rail **7**, an inner rail **8** supported by the outer rail **7** to be slidable in the longitudinal direction thereof and first and second linear motors **51** and **52** disposed between the outer rail **7** and the inner rail **8** both having box-shaped sections so that the inner rail **8** is fitted into the outer rail **8**. First and second rod-type linear motors are composed of rods O and O' as stationary pieces and cylindrical coils i and i' as movable pieces.

[0121] The cylindrical coil i of the first rod-type linear motor **51** is mounted to the front end portion of the outer rail **7** and, to this front end portion, is also mounted an outer rail side bearer **75** supporting the rod O' of the second rod-type linear motor to be slidable in an axial direction thereof. On the other hand, the cylindrical coil i of the second rod-type linear motor **52** is mounted to the rear end portion of the inner rail **8** and, to this rear end portion, is also mounted an inner rail side bearer **76** supporting the rod O of the first rod-type linear motor to be slidable in an axial direction thereof. The operation theory due to this arrangement is substantially the same as that of the drive system of the embodiment mentioned hereinbefore, and by operating the first and second rod-type linear motors **51** and **52**, the distance between the outer rail side bearer **75** and the inner rail side bearer **76** are expanded or contracted, thus the inner rail **8** being slid with respect to the outer rail **7**. As mentioned above, the rod-type linear motors are also usable as linear motors for the drive system of the present invention.

[0122] Description will be come back to the rolling guide device hereunder.

[0123] **FIG. 20** is a partial sectional view of a drive system using a rolling guide device of a further embodiment of the present invention. The rolling guide device of this embodiment comprises, like the rolling guide device shown in FIGS. **1** to **3**, an outer rail **7** as track rail and an inner rail **8** as movable rail supported to be slidable in the longitudinal direction of the outer rail **7**, and hence, like reference numerals are added to elements or members corresponding to those shown in FIGS. **1** to **3**. The embodiment of **FIG. 20** is provided with a ball screw **9** for driving the inner rail **8**.

[0124] In the rolling guide device of the aforementioned embodiment, although the outer rail **7** and the inner rail **8** are formed with single ball rolling groove to each side portion thereof, in the rolling guide device of this embodiment, the outer rail **7** and the inner rail **8** are formed with two ball rolling grooves **11**, **11** (totally four grooves) to each side portion thereof as shown in **FIG. 20** in section. That is, in the rolling guide device of this embodiment, upper and lower two ball rolling grooves **11**, **11** are formed respectively to each of the inside surfaces of the opposing ridges **7***b*, **7***b* of the outer rail **7**, i.e. four ball rolling grooves **11**, **11** for the outer rail **7**. On the other hand, upper and lower two loaded ball rolling grooves **15**, **15** are formed respectively to each of the outside surfaces of the opposing ridges **8***b*, **8***b* of the inner rail **8**, i.e. four loaded ball rolling grooves **15**, **15** for the inner rail **8** so as to oppose to the ball rolling grooves **11**, **11** of the outer rail **7**, respectively.

[0125] An outer rail side ball circulation passage **14** for circulating the balls rolling between the inner rail **8** and the outer rail **7** is provided to one end side in the longitudinal direction of the outer rail **7** as like as that of the rolling guide device mentioned hereinbefore. This outer rail side ball circulation passage **14** is composed of upper and lower two passages, and more concretely, is composed of portions of the ball rolling grooves **11**, **11**, ball return passages A, A as rolling member return passages substantially parallel to the ball rolling grooves **11**, **11** and a pair of rolling direction changing passages communicated with the ball rolling grooves **11**, **11** and the ball return passages A, A.

[0126] An inner rail side ball circulation passage **16** for circulating the balls rolling between the inner rail **8** and the outer rail **7** is provided to one end side in the longitudinal direction of the outer rail **7** on the side opposing to the outer rail side ball circulation passage **14**. This inner rail side ball circulation passage **16** is composed of upper and lower two passages, and more concretely, is composed of portions of the loaded ball rolling grooves **15**, **15**, ball return passages A, A as rolling member return passages substantially parallel to the loaded ball rolling grooves **15**, **15** and a pair of rolling direction changing passages communicated with the ball rolling grooves **11**, **11** and the ball return passages A, A.

[0127] In the illustration of **FIG. 20**, although it seems that the outer rail side ball circulation passage **14** and the inner rail side ball circulation passage **16** are positioned on the same sectional surface, in an actual arrangement, the outer rail side ball circulation passage **14** and the inner rail side ball circulation passage **16** are shifted in their positions as shown in **FIG. 1**.

[0128] The rolling direction changing passages, each having a semi-circular shape, constituting portions of the outer rail side ball circulation passage **14** and the inner rail side ball circulation passage **16** are formed to deflectors **79** mounted, as independent members, to the inner rail body **8***d* and the outer rail body **7***d*. The deflector **79** is utilized commonly for the outer rail side ball circulation passage **14** and the inner rail side ball circulation passage **16** and is provided with vertical two rolling direction changing passages. The deflector **79** is composed of three sections **79***a*, **79***b* and **79***c* which are splittable vertically along the rolling direction changing passage for easy formation of the vertical two tolling direction changing passages. These three splittable sections **79***a*, **79***b* and **79***c* are divided vertically at planes including central lines of the rolling direction changing passages. These three sections **79***a*, **79***b* and **79***c* are positioned and assembled with each other through fitting of dowels and holes formed to the respective sections. Furthermore, the deflector **79** is formed with a stepped abutment portion **29** to position the deflector **79** at the time when it is mounted to the inner rail side ball circulation passage **16** and the outer rail side ball circulation passage **14**. Holes **33** are formed to the outer rail body **7***d* and the inner rail body **8***d* from the sides thereof, and stepped portions **33***a* are formed to inside surfaces of these holes **33**. Accordingly, the deflector **79** is positioned with respect to the outer rail body **7***d* and the inner rail body **8***d* through the abutment of the stepped abutment portion **29** against the stepped portions **33***a* formed to the holes **33**, i.e. outer rail body **7***d* and the inner rail body **8***d*.

[0129] The ball screw **9** is screw-engaged with the inner rail **8**. This ball screw **9** is composed of a screw shaft **10** having an outer periphery on which a spiral ball rolling groove is formed, a nut (member) **22** having an inner periphery to which a ball circulation passage including a spiral loaded ball rolling groove corresponding to the ball rolling groove formed to the screw shaft **10** and assembled with the screw shaft **10** to be relatively movable thereto, and a number of balls arranged in the ball circulation passage and circulating in accordance with the relative movement of the nut member **22** with respect to the screw shaft **10**.

[0130] **FIG. 21** illustrates a contacting state of the ball rolling groove **11**, the loaded ball rolling groove **15** and the ball **12** or **13**. The ball rolling groove **11** is formed as a single circular groove, so-called, circular arc groove, having a diameter slightly larger than a diameter of the ball so that the ball **12** (**13**) contacts the ball rolling groove **11** at one point P1. On the other hand, the loaded ball rolling groove **15** is formed as a single circular groove, so-called, circular arc groove, having a diameter slightly larger than a diameter of the ball so that the ball **12** (**13**) contacts the loaded ball rolling groove **15** at one point P2. Further, it is to be noted that a line L connecting the contact point P1 at which the ball **12** (**13**) and the ball rolling groove **11** are contacted and the contact point P2 at which the ball **12** (**13**) and the loaded ball rolling groove **11** are contacted is defined herein as contact angle line L. In this meaning, the contact angle lines L1, L2, L3 and L4 will be defined as shown in **FIG. 20**.

[0131] That is, with reference to **FIG. 20**, the mutually opposing two ball rolling grooves **11**, **11** and the two loaded ball rolling grooves **15**, **15** are offset from each other so that the vertical two lines L1 and L2 are inclined towards the horizontal line H passing the center of the screw shaft **10** while reducing a distance therebetween.

[0132] Further, it is desired that a contact angle constituted by the contact angle line L1 (L2) and the horizontal line H is approximately 45o. The center of the screw shaft **10** is positioned on the line passing the intermediate portion between the ball rolling grooves **11**, **11** and on the central line of a span of the loaded ball rolling grooves **15**, **15**. Furthermore, it is desired that the center of the screw shaft **10** (center of the thrust force of the ball screw **9**) is also positioned on a line connecting a point P3 of the left side contact angle lines L1 and L2 and a point P4 of the right side contact angle lines L1 and L2.

[0133] The moment load as shown in **FIG. 8** will be easily loaded on the rolling guide device of the present invention, and accordingly, the vertical load will be also easily born by the balls **12** and **13**. However, the contact angle lines L1 and L2 between the balls **12**, **13** and the ball rolling grooves **11**, **11** and between the balls **12**, **13** and the loaded ball rolling grooves **15**, **15** are inclined with respect to the horizontal line H, thus the vertical load acting on the inner rail **7** being effectively born by the balls **12**, **13**. For this reason, the moment load as shown in **FIG. 8** can be surely loaded. Particularly, by setting the inclination angle to 45o, loads acting on the inner rail **7** from vertical and lateral four directions can be effectively supported by the balls **12** or **13**. Furthermore, the ball screw **9** may be smoothly operated by positioning the center of the thrust force of the ball screw **9** on the line connecting the crossing point P3 of the left side contact angle lines L1 and L2 and the crossing point P4 on the right side contact angle lines L1 and L2.

[0134] **FIG. 22** illustrates a contacting state of a ball rolling groove **11***b*, a loaded ball rolling groove **15***b* and the ball **12** (**13**) in a rolling guide device in which one ball rolling groove **11***b* and one loaded ball rolling groove **15***b* are formed laterally as like as the rolling guide device shown in **FIGS. 1 and 3**. The ball rolling groove **11***b* and the loaded ball rolling groove **15***b* are each formed as a Gothic arch groove. That is, by forming so-called Gothic arch groove in combination of the ball rolling groove **11***b* and the loaded ball rolling groove **15***b* into two circular arcs, two contact angle lines L3 and L4 inclined from the horizontal line H can be obtained to thereby effectively support the vertical load by the ball **12**, **13**.

[0135] **FIG. 23** is an illustration of one embodiment, partially in section, of an essential portion of a drive system utilizing a rolling guide device using rollers **80** as rolling members. In this embodiment, the rollers **80** are utilized in place of the balls **12**, **13** in the former embodiments. In this embodiment of **FIG. 23**, the outer rail **7** is provided with ridges **7***b*, **7***b* as mentioned before having opposing inside surfaces **7***c*, **7***c* to which roller rolling grooves **81**, each having a V-shaped section with opening angle of 90°, are formed, respectively. On the other hand, the inner rail **8** has the opposing outside surfaces **8***c*, **8***c* to which loaded roller rolling grooves **82**, each having a V-shaped section with opening angle of 90°, are formed, respectively. Therefore, a roller rolling passage having substantially square cross section is defined between the roller rolling groove **81** and the loaded roller rolling groove **82**. Within this roller rolling passage, a plurality of rollers **80**, **80**, - - - are arranged in shape of cross (cross arrangement) so that axes of the adjacent two rollers **80** cross each other.

[0136] The structure of this embodiment other than the above mentioned structure is substantially the same as that of the rolling guide device mentioned with reference to FIGS. **1** to **3**, so that the description thereof is omitted herein by adding the same reference numerals to the corresponding portions or elements.

[0137] According to this embodiment, in which the rollers **80**, **80**, - - - are arranged in crossing shape, the rollers **80** can effectively support the vertical load.

[0138] **FIG. 24** is an illustration of another embodiment, partially in section, of an essential portion of a drive system utilizing a rolling guide device using rollers **83**, **84** as rolling members. In this embodiment, the outer rail **7** is provided with ridges **7***b*, **7***b* having opposing inside surfaces **7***c*, **7***c* each to which vertical two roller rolling grooves **81**, **81** each having a V-shaped section with opening angle of 90°, are formed, respectively. On the other hand, the inner rail **8** has the opposing outside surfaces **8***c*, **8***c* each to which two loaded roller rolling grooves **82**, **82** each having a V-shaped section with opening angle of 90°, are formed, respectively. Therefore, vertical two roller rolling passages each having substantially square cross section are defined between the roller rolling grooves **81**, **81** and the loaded roller rolling grooves **82**, **82**. Within these roller rolling passages, a plurality of rollers **83**, **84** are arranged in parallel to each other (parallel arrangement) so that axes of the adjacent two rollers are parallel to each other.

[0139] The rollers **83** disposed in the upper side roller rolling passage are arranged so as to support the load acting in the direction shown by the line L5 (different from the horizontal line H), and on the other hand, the rollers **84** disposed in the lower side roller rolling passage are arranged so as to support the load acting in the direction shown by the line L6 (different from the horizontal line H). Angles constituted by the line L5 and the horizontal line H and by the line L6 and the horizontal line H are defined approximately 45o, respectively. The structure of this embodiment of **FIG. 24** other than the above-mentioned structure is substantially the same as that of the rolling guide device mentioned with reference to **FIG. 20** so that the description thereof is omitted herein by adding the same reference numerals to the corresponding portions or elements.

[0140] According to this embodiment of **FIG. 24**, in which the rollers **83** and **84** are arranged in the vertical two roller rolling passages and the directions along which the rollers **83** and **84** can bear the loads are inclined with respect to the horizontal line H, so that the rollers **83** and **84** can effectively support the vertical loads.

[0141] According to the various preferred embodiments or examples of the present invention mentioned above, the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage, in which the rolling members rolling between the track rail and the movable rail circulate, are formed to the track rail and the movable rail, respectively. Therefore, when the movable rail is slid with respect to the track rail, the rolling members arranged between the track rail and the movable rail endlessly circulate in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage while rolling therealong. As mentioned, since the rolling members circulate in the endless manner, even if the rolling member be slid during the rolling motion, there is no causing of a case that a cage is shifted from the initial position as in the conventional structure, and hence, a large expansion (contraction) stroke can be realized. Furthermore, in an optional expanded (contracted) attitude, there remains a relatively large distance between the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage, so that a rolling guide device, which can bear even the moment load, can be realized.

[0142] Furthermore, according to the present invention, since the linear motor means is incorporated between the track rail and the movable rail, no specific ball screw or like mechanism is needed, so that the movable rail can be moved at high speed with reduced noise.

[0143] It is further to be noted that the present invention is not limited to the described embodiments and many other changes and modifications may be made without departing from the scopes of the appended claims.

What is claimed is:

1. A rolling guide device comprising:

a track rail formed with a rolling member rolling surface extending along a longitudinal direction thereof;

a movable rail formed with a loaded rolling member rolling surface extending along a longitudinal direction thereof so as to oppose to the rolling member rolling surface of the track rail;

a track rail side rolling member circulation passage formed to the track rail so as to circulate the rolling members rolling between the track rail and the movable rail;

a movable rail side rolling member circulation passage formed to the movable rail so as to circulate the rolling members rolling between the track rail and the movable rail; and

a number of rolling members disposed and arranged in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage.

2. A rolling guide device according to claim 1, wherein said track rail side rolling member circulation passage is formed to one longitudinal end side of the track rail and said movable rail side rolling member circulation passage is formed to one longitudinal end side, opposing to said one end side of the track rail, of the movable rail.

3. A rolling guide device according to claim 1, wherein said track rail has an opened recess having a ⊐-shaped section and has inside surfaces to which said rolling member rolling surfaces are formed, said movable rail is fitted into the recess of the track rail, and said movable rail has outside surfaces to which the loaded rolling member rolling surfaces are formed so as to oppose to the rolling member rolling surfaces formed to the track rail inside surfaces.

4. A rolling guide device according to claim 3, wherein said track rail side rolling member circulation passage is provided with a rolling member return passage substantially parallel to said rolling member rolling surface and a rolling direction changing passage communicating the rolling member rolling surface and the rolling member return passage, said movable rail side rolling member circulation passage is provided with a rolling member return passage substantially parallel to said loaded rolling member rolling surface and a rolling direction changing passage communicating the rolling member rolling surface and the rolling member return passage, said rolling direction changing passages of the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage are formed to a deflector which is formed independently from a track rail body and a movable rail body, and said deflector is fitted to holes formed to the track rail body and movable rail body from side portions thereof.

5. A rolling guide device according to claim 4, wherein said return passages are drilled to the track rail body and the movable rail body from longitudinal end portions thereof.

6. A rolling guide device according to claim 4, wherein said deflector is composed of a plurality of sections splittable along the rolling direction changing passages.

7. A rolling guide device according to claim 4, wherein said deflector is made of a synthetic resin.

8. A drive system comprising:

a track rail formed with a rolling member rolling surface extending along a longitudinal direction thereof;

a movable rail formed with a loaded rolling member rolling surface extending along a longitudinal direction thereof so as to oppose to the rolling member rolling surface of the track rail;

a track rail side rolling member circulation passage formed to the track rail so as to circulate the rolling members rolling between the track rail and the movable rail;

a movable rail side rolling member circulation passage formed to the movable rail so as to circulate the rolling members rolling between the track rail and the movable rail;

a number of rolling members disposed and arranged in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage; and

a linear motor means having a primary side mounted to either one of the track rail and the movable rail and a secondary side mounted to another one of the track rail and the movable rail.

9. A drive system according to claim 8, wherein said track rail side rolling member circulation passage is formed to one longitudinal end side of the track rail and said movable rail side rolling member circulation passage is formed to one longitudinal end side, opposing to said one end side of the track rail, of the movable rail, and said linear motor means comprises first and second linear motors, said first linear motor having a primary side mounted to a portion near the track rail side rolling member circulation passage of the track rail, said second linear motor having a secondary side mounted to the track rail along the longitudinal direction thereof so as to be continuous to the primary side of the first linear motor, and said second linear motor having a primary side mounted to a portion near the movable rail side rolling member circulation passage of the movable rail, said first linear motor having a secondary side mounted to the movable rail along the longitudinal direction thereof so as to be continuous to the primary side of the second linear motor.

10. A drive system according to claim 9, wherein said first and second linear motors are linear induction motors having secondary sides being opposed to each other.

11. A drive system according to claim 9, wherein said first and second linear motors are linear pulse motors having secondary sides being opposed to each other.

12. A drive system according to claim 8, wherein said track rail has an opened recess having a ⊐-shaped section and has inside surfaces to which said rolling member rolling surfaces are formed, said movable rail is fitted into the recess of the track rail, and said movable rail has outside surfaces to which the loaded rolling member rolling surfaces are formed so as to oppose to the rolling member rolling surfaces formed to the track rail inside surfaces.

(57) **ABSTRACT**

The present invention provides a track rail mounting structure of a rectilinear guide apparatus comprising a track rail having a rotating/running surface where a plenty of rotating/running bodies rotate and run; an endless circulation route for guiding the plenty of rotating/running bodies; and a slider movably arranged with respect to the track rail via the rotating/running bodies; wherein a base where the track rail is mounted has a groove for inserting a bottom portion of the track rail, so that the bottom portion of the track rail is inserted into the groove, and a pressure member is provided for pressing at least one side surface of the track rail toward an inner side surface of the groove.

As has been described above, since the pressure member is provided to press the side surface of the track rail toward the inner side surface of the groove, the side surface of the track rail is pressed by the pressure member so as to press the opposite side of the track rail to the inner side surface of the groove or both side surfaces of the track rail are pressed by the pressure member so as to be fixed to the track rail. Accordingly, even when a thermal expansion difference is caused between the track rail and the base by a temperature change, a contact portion of the pressure member slides along the side surface of the track rail so as to absorb the thermal expansion difference and accordingly, no distortion is caused in the track rail.

TRACK RAIL MOUNTING STRUCTURE OF RECTILINEAR GUIDE APPARATUS

BACKGROUND OF THE INVENTION

[0001] 1. Field of the Invention

[0002] The present invention relates to a track rail mounting structure of a rectilinear guide apparatus, and more particularly, it relates to a track rail mounting structure of a rectilinear guide apparatus which can preferably be used in the case that a track rail and a base on which the track rail is mounted are made from materials having different thermal expansion coefficients.

[0003] 2. Description of the Prior Art

[0004] **FIG. 1** shows a constitution example of a rectilinear guide apparatus.

[0005] A rectilinear guide apparatus **1** of this type generally comprises a track rail **2** fixed to a fixing portion such as a head of a machining apparatus; and a slider **4** on which a movable member such as a table is mounted and which is engaged with the track rail **2** via a plenty of balls **3** as rotating/running members so as to perform rectilinear motion along the track rail **2**.

[0006] The track rail **2** has a ball rotating/running groove **7** formed as a track where the balls **3** rotate and run, and on the other hand, the slider **4** has a ball rotating/running groove **8** formed as a load track opposing to the ball rotating/running groove **7** of the track rail **2**, so that the balls **3** rotate and run between the ball rotating/running groove **7** and the ball rotating/running groove **8** while being subjected to a load.

[0007] Moreover, the slider **4** has a passage **6** formed for returning balls from one end to the other end of the ball rotating/running groove **8**. This passage **6** and the aforementioned ball rotating/running groove **8** constitute an endless circulation route of the balls **3**. The balls **3** circulate in this endless circulation route following the movement of the slider **4**. Thus, the aforementioned slider **4** smoothly moves along the track rail **2**.

[0008] When fixing to a base the track rail **2** of the rectilinear guide apparatus **1** having the aforementioned constitution, as shown in **FIG. 2, a** reference plane **10***a* is provided on the base **10**, and one side surface of the track rail **2** is brought into abutment with the reference plane **10***a,* which is fixed to the upper surface of the base **10** with a bolt **20**. Moreover, the other side surface of the track rail **2** is brought into abutment with a reinforcing member **21**, which is fixed with a bolt **22**.

[0009] However, as described above, when the track rail **2** is fixed to the base **10** with the bolt **20** (or a fixing member), in case the track rail **2** is made from a material having a thermal expansion coefficient different from that of a material constituting the base **10** (for example, the track rail **2** is made from iron and the base **10** is made from aluminum), a difference is caused in thermal expansion between the track rail **2** and the base **10** by a temperature change, which in turn causes distortion in the track rail **2**.

[0010] Especially when arranging a plurality of rectilinear guide apparatuses **1** in parallel to one another on the base **10** and mounting a common table on their sliders **4**, there is a problem that the table plane is displaced. This problem becomes especially remarkable when the rectilinear guide apparatus is used in an environment of a great temperature change.

SUMMARY OF THE INVENTION

[0011] It is therefore an object of the present invention to provide a track rail mounting structure of a rectilinear guide apparatus capable of absorbing an expansion difference between a track rail and a base caused by thermal expansion, so as not to distort the track rail by a temperature change even when the track rail of the rectilinear guide apparatus is made from a material having a thermal expansion coefficient different from that of a material constituting the base on which the track rail is mounted.

[0012] In order to achieve the aforementioned object, a track rail mounting structure of a rectilinear guide apparatus comprises a track rail having a rotating/running surface where a plenty of rotating/running bodies rotate and run; an endless circulation route for guiding the plenty of rotating/running bodies; and a slider movably arranged with respect to the track rail via the rotating/running bodies; wherein a base where the track rail is mounted has a groove for inserting a bottom portion of the track rail, so that the bottom portion of the track rail is inserted into the groove, and a pressure member is provided for pressing at least one side surface of the track rail toward an inner side surface of the groove.

[0013] As has been described above, since the pressure member is provided to press the side surface of the track rail toward the inner side surface of the groove, the side surface of the track rail is pressed by the pressure member so as to press the opposite side of the track rail to the inner side surface of the groove or both side surfaces of the track rail are pressed by the pressure member so as to be fixed to the track rail. Accordingly, even when a thermal expansion difference is caused between the track rail and the base by a temperature change, a contact portion of the pressure member slides along the side surface of the track rail so as to absorb the thermal expansion difference and accordingly, no distortion is caused in the track rail.

[0014] Moreover, the track rail mounting structure of the rectilinear guide apparatus is characterized in that the pressure member has a convex contact surface which is brought into abutment with the track rail side surface.

[0015] As has been described above, since the contact surface of the pressure member which is brought into abutment with the track rail side surface has a convex shape, the contact between the track rail side surface and the convex surface is a point-to-point contact or a linear contact. Even when a thermal expansion difference is caused between the track rail and the base by a temperature change, the convex contact portion slides along the side surface of the track rail so as to absorb the thermal expansion difference and accordingly, no distortion is caused in the track rail.

[0016] Moreover, the track rail mounting structure of the rectilinear guide apparatus is characterized in that the pressure member is an elastic corrugated spacer inserted between the side surface of the track rail and the inner side surface of the groove.

[0017] As has been described above, since the pressure member is the elastic corrugated spacer inserted between the side surface of the track rail and the inner side surface of the groove, a contact portion between the side surface of the track rail and the corrugated spacer is a linear contact. Even when a thermal expansion difference is caused between the track rail and the base, the contact portion of the corrugated spacer slides along the side surface of the track rail so as to absorb the thermal expansion difference and accordingly, no distortion is caused in the track rail.

[0018] Moreover, the track rail mounting structure of the rectilinear guide apparatus is characterized in that the pressure member is a spherical body which is inserted with pressure into a plurality of holes opened at a predetermined interval on the inner side surface of one side of the groove, so that the spherical body presses the side surface of the track rail.

[0019] As has been described above, the pressure member is a spherical body and a contact between the side surface of one side of the track rail and the spherical body is a point-to-point contact. Even when a thermal expansion difference is caused between the track rail and the base, the contact portion of the spherical body slides along the side surface of one side of the track rail so as to absorb the thermal expansion difference and accordingly, no distortion is caused in the track rail.

[0020] Moreover, the track rail mounting structure of the rectilinear guide apparatus is characterized in that a pressing force of the spherical body is reinforced by a pressing force reinforcing member inserted into the hole where the spherical body is inserted with pressure.

[0021] As has been described above, by inserting the pressing force reinforcing member with pressure into the hole where the spherical body is inserted with pressure, the pressing force of the spherical body is reinforced by the pressure member and the track rail is fixed firmly. Simultaneously with this, even when a thermal expansion difference is caused between the track rail and the base, a contact portion of the spherical body slides along the side surface of one side of the track rail so as to absorb the thermal expansion difference and accordingly, no distortion is caused in the track rail.

[0022] Moreover, the track rail mounting structure of the rectilinear guide apparatus is characterized in that the pressure member is a spherical body which is held by a holding metal member, and the metal member holding the spherical body is inserted with pressure into a plurality of holes opened at a predetermined interval on the inner side surface of the groove, so that the spherical body presses the side surface of the track rail.

[0023] As has been described above, in case the metal member holding the spherical body is inserted with pressure into a plurality of holes opened at a predetermined interval on the inner side surface of one side of the groove, so that the spherical body presses the side surface of one side of the track rail, similarly as the aforementioned, the side surface of one side of the track rail is in contact with the spherical body as a point-to-point contact. Even when a thermal expansion difference is caused between the track rail and the base, the contact portion of the spherical body slides along the side surface of one side of the track rail so as to absorb the thermal expansion difference and accordingly, no distortion is caused in the track rail.

BRIEF DESCRIPTION OF THE DRAWINGS

[0036] **FIG. 13** shows a displacement amount of a track rail caused by a heated base of the track rail mounting structure of the rectilinear guide apparatus according to the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0037] Hereinafter, explanation will be given on embodiments of the present invention with reference to the attached drawings. **FIG. 3** to **FIG. 6** show a constitution example of a rectilinear guide apparatus having a track rail mounting structure according to the present invention. **FIG. 3** shows the entire constitution of the rectilinear guide apparatus; **FIG. 4** is a cross sectional view about B-B of **FIG. 3**; **FIG. 5** is an enlarged view of a portion A of **FIG. 3**; and **FIG. 6** shows a corrugated spacer.

[0038] In **FIG. 3** to **FIG. 6**, like reference symbols as in **FIG. 1** and **FIG. 2** denote like or equivalent components. Moreover, this applies to the other drawings. In **FIG. 3** and **FIG. 4, a** reference symbol **10** denotes a base on which a track rail **2** is mounted. The base **10** is made from a material (such as aluminum) having a different thermal expansion coefficient from that of a material (such as iron) constituting the track rail **2**.

[**0039**] The base **10** has at its center portion a belt-shaped groove **12** in which a bottom portion of the track rail **2** is inserted. A corrugated spacer **9** is inserted between the inner side surface of the groove **12** and the side surface of the track rail **2**. As shown in **FIG. 6**, the corrugated spacer **9** is an elastic metal material (such as a steel plate) which is made into a corrugated form.

[**0040**] When inserting the corrugated spacer **9** between the inner surface of the groove **12** and the side surface of the track rail **2**, by pulling the corrugated spacer **9** in its longitudinal direction, the dimension C in the thickness direction is reduced. Accordingly, when the corrugated spacer **9** is in a state pulled in the longitudinal direction, the spacer **9** can easily be inserted between the inner surface of the groove **12** and the side surface of the track rail **2**.

[**0041**] After the corrugated spacer **9** is inserted between the inner surface of the groove **12** and the side surface of the track rail **2**, the pulling is released, so that the track rail **2** is pressed by an elastic force of the corrugated spacer **9** against the inner surface of the other side of the groove **12** and the track rail **2** is fixed in the groove **12**.

[**0042**] By inserting the corrugated spacer **9** between the inner side surface of the groove **12** and the side surface of the track rail **2**, a contact portion of the corrugated spacer **9** with the track rail **2** becomes linear. Even when a thermal expansion difference is caused between the track rail **2** and the base **10**, the contact portion of the corrugated spacer **9** slides along the side surface of the track rail **2** and absorbs the thermal expansion difference. Accordingly, no distortion is caused in the track rail **2**.

[**0043**] It should be noted that in the aforementioned example, explanation has been given on a case that the corrugated spacer **9** is inserted between one side surface of the track rail **2** and one inner side surface of the groove **12**. However, it is also possible to insert the corrugated spacer **9** between both side surfaces of the track rail **2** and both inner side surfaces of the groove **12**.

[**0044**] Moreover, the corrugated spacer **9** may have a length to cover the entire length of the space between the side surface of the track rail **2** and the inner side surface of the groove **12**. Alternatively, it is also possible to arrange at a predetermined interval a plurality of the corrugated spacers **9** cut into a predetermined length.

[**0045**] Moreover, in the aforementioned example, the base **10** has a rectangular cross sectional view and a flat upper surface. However, the cross sectional view of the base **10** is not limited to this and, as shown in **FIG. 7**, may have a mountain-shaped protrusion **10***a* at both sides and a belt-shaped convex base mounting portion at a center portion for mounting the track rail **2**.

[**0046**] Thus, when the protrusion **10***a* is present at both sides of the base **10**, as will be detailed later, the protrusions **10***a* disturb when a hole is formed to open into the inner side surface of the groove **12** and a steel ball is inserted into this hole to press the side surface of the track rail **2**. Accordingly, the mounting structure that the corrugated spacer **9** is inserted into a space between the side surface of the track rail **2** and the inner side surface of the groove **12** is effective.

[**0047**] **FIG. 8** and **FIG. 9** show a constitution example of the track rail mounting structure of the rectilinear guide apparatus according to the present invention. **FIG. 8** is a cross sectional view (about D-D of **FIG. 9**) and **FIG. 9** is a side view.

[**0048**] In **FIG. 8** and **FIG. 9**, like the aforementioned example, the base **10** is made from a material (for example, aluminum) having a different thermal expansion coefficient from that of a material (for example, iron) constituting the track rail **2**.

[**0049**] The base **10** has a belt-shaped base mounting portion **11** for mounting the track rail **2**. At a center portion of this base mounting portion **11**, there is formed a belt-shaped groove **12** into which a bottom portion of the track rail **2** is inserted.

[**0050**] On a side wall portion **11***a* of the groove **12**, at a predetermined interval, there are provided a plenty of holes **13** opening into one side surface of the groove **12** and arraigned in parallel to the upper surface of the base **10** and vertical to the one side surface. The bottom portion of the track rail **2** is inserted into the groove **12** and steel balls **14** are inserted into the holes **13** with a pressure, so as to press the one side surface of the track rail **2** in the groove **12** and to press the opposite side surface of the track rail **2** to an inner side surface of an opposite side wall portion **11***b*, thereby fixing the track rail **2** into the groove **12** of the base **10**.

[**0051**] As has been described above, by inserting with pressure the steel balls **14** into the respective holes **13** formed in the side wall portion **11***a* of the groove **12** and pressing the side surface of the track rail **2** to the side surface of the groove **12**, thereby fixing the track rail **2** to the base **10**, even when a difference is caused by a temperature change, between a thermal expansion of the track rail **2** and that of the base **10** in the longitudinal direction of the track rail **2**, contact portions of the steel balls **14** slide with respect to the one side surface of the track rail **2**, so as to absorb the thermal expansion difference. Accordingly, no distortion is caused in the track rail **2**.

[**0052**] **FIG. 10** shows another example of the track rail mounting structure of the rectilinear guide apparatus according to the present invention. This track rail mounting structure differs from the track rail mounting structure shown in **FIG. 8** and **FIG. 9** in that in order to reinforce a pressing force of the steel ball **14** inserted with pressure into the hole **13**, a pin **15** is inserted with pressure as a pressure reinforcing member from back of the steel ball **14** and a concave portions **16** is formed by caulking on the upper surface of the side wall portion **11***a* at a position corresponding to the pin **15**, thereby fixing the pin **15**.

[**0053**] As has been described above, by inserting and fixing pins **15** from back of the steel balls **14**, the pressing force of the steel balls **14** to press the side surface of the track rail **2** is reinforced and the mounting of the track rail **2** is reinforced. Simultaneously with this, even when a thermal expansion difference is caused between the track rail **2** and the base **10**, similarly as in the track rail mounting structure of **FIG. 8** and **FIG. 9**, the contact portions of the steel balls **14** with the one side surface of the track rail **2** slide to absorb the thermal expansion difference and no distortion is caused in the track rail **2**.

[0054] **FIG. 11** shows still another example of the track rail mounting structure of the rectilinear guide apparatus according to the present invention. In this track rail mounting structure, instead of the pin **15** which is the pressure reinforcement member of the track rail mounting structure shown in **FIG. 10, a** dedicated metal member **17** is used for holding the steel ball **14**. The metal member **17** holding the steel ball **14** is inserted into the hole **13** with pressure and a concave portion **16** is formed by caulking on the upper surface of the side wall portion **11***a*, thereby fixing the metal member **17**.

[0055] The metal member **17** has a tip end where a concave portion **17***a* is formed to hold the steel ball **14**. When the track rail mounting structure has such a constitution, it is also possible to obtain an effect approximately identical to that of the track rail mounting structure shown in **FIG. 8** and **FIG. 9**.

[0056] **FIG. 12** and **FIG. 13** show examples of deformation of the track rail **2** when the base **10** is heated. **FIG. 12** shows a case of the conventional track rail mounting structure in which the track rail **2** is fixed to the base by bolts as shown in **FIG. 2** while **FIG. 13** shows a case of the track rail mounting structure according to the present invention.

[0057] In **FIG. 12**, curves A, B, C, D, E, F, G, and H show displacement amounts δ (μm) of the track rail (made from iron) **2** when the base (made from aluminum) **10** is heated to 22.6° C., 40.5° C., 58.8° C., 70.7° C., 75.1° C., 81,7° C., 85.1° C., and 91.2° C., respectively.

[0058] In **FIG. 13**, curves A, B, C, and D show displacement amounts δ (μm) of the track rail (made from iron) **2** when the base (made from aluminum) **10** is heated to 90.5° C., 80.6° C., 41.0° C., and 21.4° C., respectively.

[0059] In the conventional track rail mounting structure of **FIG. 12**, with respect to a displacement amount of the track rail **2** indicated by the curve A when the base temperature is 22.6° C., the displacement amount δ is greatly changed as the heating temperature is increased as shown by the curves B, C, D, E, F, G, and H while in the track rail mounting structure of **FIG. 13** according to the present invention, with respect to a displacement amount of the track rail **2** indicated by the curve D when the base temperature is 21.4° C., the displacement amount δ does not change greatly when the heating temperature is increased as shown by the curves C, B, and A.

[0060] It should be noted that in the aforementioned example, the steel balls **14** are used as pressure members to press the one side surface of the track rail **2**. However, the pressure member is not limited to a spherical shape but may be, for example, an arc surface or a convex surface of a paraboloid, i.e., a surface providing a point-to-point contact with the one side surface of the track rail **2**.

[0061] Moreover, in the aforementioned example, explanation has been given on the track rail **2** of the rectilinear guide apparatus **1** using the balls **3** as rotating/running members. However, the rectilinear guide apparatus is not limited to this. The present invention can also be applied to a track rail mounting structure of the rectilinear guide apparatus using rolls as the rotating/running members.

[0062] According to the present invention, the pressure member is provided to press the side surface of the track rail toward the inner side surface of the groove. Accordingly, the side surface of the track rail is pressed by this pressure member so as to press the opposite side of the track rail to the inner side surface of the groove or both sides of the track rail are pressed by the pressure member so as to be fixed to the track rail. Accordingly, even when a thermal expansion difference is caused between the track rail and the base, the contact portion of the pressure member slides along the side surface of the track rail and absorbs the thermal expansion difference. Accordingly, no distortion is caused in the track rail.

[0063] Moreover, since the surface of the pressure member in contact with the track rail side surface is a convex surface, the track rail side surface and the convex surface are in contact with each other as a point-to-point contact or a linear contact. Accordingly, even when a thermal expansion difference is caused between the track rail and the base, the contact portion of the convex shape slides along the side surface of the track rail so as to absorb the thermal expansion difference and no distortion is caused in the track rail.

[0064] Moreover, since the pressure member inserted between the side surface of the track rail and the inner side surface of the groove is the elastic corrugated spacer, the contact portion between the side surface of the track rail and the corrugated spacer is a linear contact. Accordingly, even when a thermal expansion difference is caused between the track rail and the base, the contact portion of the corrugated spacer slides along the side surface of the track rail so as to absorb the thermal expansion difference and accordingly, no distortion is caused in the track rail.

[0065] Moreover, when the pressure member is a spherical body, the contact between the one side surface of the track rail and the spherical body is a point-to-point contact. Accordingly, even when a thermal expansion difference is caused between the track rail and the base, the contact portion of the spherical body slides along the one side surface of the track rail so as to absorb the thermal expansion difference and accordingly, no distortion is caused in the track rail.

[0066] Moreover, by inserting the pressure reinforcement member with pressure into the hole where the spherical body is inserted with pressure, the pressing force of the spherical body is reinforced by the pressure member and the track rail is fixed firmly. Simultaneously with this, even when a thermal expansion difference is caused between the track rail and the base, the contact portion of the spherical body slides along one side surface of the track rail so as to absorb the thermal expansion difference and accordingly, no distortion is caused in the track rail.

[0067] Moreover, a metal member holding a spherical body may be inserted with pressure into a plurality of holes opened at a predetermined interval on the inner surface of one side of the groove, so as to press one side surface of the track rail. In this case also, like in the invention claimed in claim 4, one side surface of the track rail is in contact with the spherical body to make a point-to-point contact. Even when a thermal expansion difference is caused between the track rail and the base, the contact portion of the spherical body slides along the one side surface of the track rail so as to absorb the thermal expansion difference and accordingly, no distortion is caused in the track rail.

What we claim is:

1. A track rail mounting structure of a rectilinear guide apparatus comprising a track rail having a rotating/running surface where a plenty of rotating/running bodies rotate and run; an endless circulation route for guiding the plenty of rotating/running bodies; and a slider movably arranged with respect to the track rail via the rotating/running bodies;

wherein a base where the track rail is mounted has a groove for inserting a bottom portion of the track rail, so that the bottom portion of the track rail is inserted into the groove and a pressure member is provided for pressing at least one side of track rail toward an inner side surface of the groove.

2. The track rail mounting structure of the rectilinear guide apparatus according to claim 1, wherein the pressure member has a convex contact surface which is brought into abutment with the track rail side surface.

3. The track rail mounting structure of the rectilinear guide apparatus according to claim 1, wherein the pressure member is an elastic corrugated spacer inserted between the side surface of the track rail and the inner side surface of the groove.

4. The track rail mounting structure of the rectilinear guide apparatus according to claim 1, wherein the pressure member is a spherical body which is inserted with pressure into a plurality of holes opened at a predetermined interval on the inner side surface of one side of the groove, so that the spherical body presses the side surface of the track rail.

5. The track rail mounting structure of the rectilinear guide apparatus according to claim 4, wherein a pressing force of the spherical body is reinforced by a pressing force reinforcing member inserted into the hole where the spherical body is inserted with pressure.

6. The track rail mounting structure of the rectilinear guide apparatus according to claim 1, wherein the pressure member is a spherical body which is held by a holding metal member, and the metal member holding the spherical body is inserted with pressure into a plurality of holes opened at a predetermined interval on the inner side surface of the groove, so that the spherical body presses the side surface of the track rail.

(57) **ABSTRACT**

A seal device fixed to an end portion of a slider of a guide device includes: a casing; a plurality of seal members; and elastic members, wherein each seal member has a recess portion in which a rail penetrates. An inner circumferential face of the recess portion comes into contact with an outer surface of the rail when the seal member is pushed onto one side of the rail by the elastic members. The plurality of seal members are arranged in the casing in such a manner that when a seal portion of one seal member is pushed by the elastic member and contacted with one side of the rail, a seal portion of the next seal member is pushed by the elastic member and contacted with the other side of the rail.

SEAL DEVICE FOR A GUIDE DEVICE AND GUIDE DEVICE

BACKGROUND OF THE INVENTION

[0001] 1. Field of the Invention

[0002] The present invention relates to a seal device for a guide device used for a moving portion of various machine tools, industrial robots or various common machines. Particularly, the present invention relates to a seal device for a guide device in which a slider striding over a rail is guided along the rail. More particularly, the present invention relates to a seal device which effectively exhibits a sealing function even in a guide device in which the rail width is partially different. The present invention also relates to a guide device in which the seal device is used.

[0003] 2. Description of the Related Art

[0004] Conventionally, there is provided a seal device for a guide device shown in FIGS. 1(*a*) and 1(*b*). In the drawings, reference numeral **121** is referred to as an end seal attached to an end portion of the slider **120** arranged striding over the rail **130** and moved along the rail **130**. This end seal **121** is composed in such a manner that a rubber member **124** is coated on a plate-shaped core metal **123**. The core metal **123** has a recess portion **122** in which the rail **130** penetrates. A seal portion **125**, which is called a lip, is formed at the inner circumferential edge of the recess portion **122**. Since a forward end portion of the seal portion **125** closely comes into contact with the outer circumferential face of the rail **130** and moves together with the slider **120**, foreign objects such as dust does not get into the slider **120**. **FIG. 1**(*a*) is a front view of the slider **120** and end seal **121**, and **FIG. 1**(*b*) is a sectional view of the inner circumferential portion of the end seal **121**.

[0005] In the conventional seal device, the following problem may be encountered. The dimension t (interval between the inner circumferential face of the core metal **123** and the outer circumferential face of the rail **130**) of the seal portion **125** of the end seal **121** is 1 to 2 mm. In case where the width of the rail **130** is different as shown in **FIG. 2**, for example, a transport device described in Japanese Unexamined Patent Publication No. 2001-99152 in which the slider **120** moves on the rail **130**, the rail width of the curved portion **130**B of the rail **130** is smaller than that of the straight portion **130**A, it is impossible for the elastic extension and contraction of the seal portion **125** to absorb a change in the width of the rail **130**. That is, it is impossible for the elastic extension and contraction of the seal portion **125** to absorb a reduction of the width in the small width portion. Therefore, the forward end portion of the seal portion **125** is separated from the outer circumferential face of the rail **130**, which results in a defective sealing function.

[0006] In order to solve the above problem, Japanese Patent Publication No. 2939846 discloses a seal device as shown in **FIG. 3**. This seal device **110** includes a pair of end face plates **102**, **103** made of metal arranged at the end portions of the slider **100** in the moving direction. The end face plates **102**, **103** have an inside shape formed into the same profile as that of the outer face of the rail **101**. A small gap is formed between the inside of the end face plates **102**, **103** and the rail **101**. The seal device further includes a support member **104** interposed between the end plates **102**, **103**; two side seal members **105**, **106** and one upper seal member **107** made of bearing metal and arranged in a cut-out portion provided inside the support member **104**. The two side seal members **105**, **106** and one upper seal member **107** are formed in shapes that correspond to the profile of the outer face of the rail **101**. The two side seal members **105**, **106** and one upper seal member **107** are restricted to move by the pair of end face plates **102**, **103**. The seal device further includes compression springs **108** for elastically pushing the seal members **105**, **106**, **107** onto the outer face of the rail **101**.

[0007] However, even in the seal device **110** composed as described above, the following problems may be encountered. In case where the slider **100** is guided along the rail **101** in which a straight portion and curved portion are continuously connected with each other, a gap is caused between the rail **101** and the side seal members **105**, **106** by an inner wheel difference of the curved portion, which deteriorates the sealing function of the seal member. Further, since the seal member is divided into three pieces of the side seal members **105**, **106** and the upper seal member **107** so that the seal members do not come into contact with each other, a gap is caused at each of the intersections (opposing faces) of the divided seal members. Further, in case where the inner wheel difference is caused in the curved portion of the rail **101**, it is impossible to absorb the inner wheel difference. Further, this device is disadvantageous in that the number of parts is large and the structure becomes complicated. For example, when such a structure is adopted that the divided seal members come into contact with each other, a gap is formed by the abrasion caused between the divided seal members.

[0008] In the conventional guide device, the end seal **121** is arranged at the end of the slider **120**, and the seal device **110** is arranged at the end of the moving member (slider) **100** as described above. However, no seal devices are arranged in the side portions of the slider **120** and the moving member (slider) **100**, that is, no seal devices are arranged in the portions opposed to the side of the rail **130**. Therefore, problems may be encountered in which dust gets into the slider from the side portion. Therefore, it is impossible to apply the conventional guide device, for example, to a wood working machine used in a dusty place.

SUMMARY OF THE INVENTION

[0009] The present invention has been accomplished to solve the above problems. It is an object of the present invention to provide a seal device for a guide device and a guide device which enable a simple structure and exhibit not only a sealing function of the slider end portion but also a sealing function of the slider side portion even in case where the rail width is changed and the shape of the rail is changed from a straight line to a curved line.

[0010] According to a first aspect of the present invention, there is provided a seal device for a guide device which is fixed to an end portion of a slider of the guide device so as to prevent foreign objects such as dust from getting into the seal device, the slider being arranged striding over a straight and/or curved rail and guided along the rail, the seal device comprising: a casing; a plurality of plate-shaped seal members accommodated in the casing; and an elastic member for pushing the seal members onto the rail, wherein each seal member has a recess portion in which the rail penetrates, an inner circumferential face of the recess portion includes a seal portion which comes into contact with an outer surface of the rail, and wherein the plurality of seal members are arranged in the casing in such a manner that the seal members are pushed by the elastic member, the seal portion of one seal member comes into contact with one side of the rail, and the seal portion of the next seal member comes into contact with the other side of the rail.

[0011] As described above, when the seal portion formed in the recess portion of one seal member in a plurality of seal members provided in the casing is pushed by the elastic member and contacted with one side of the guide rail, the seal portion formed in the next seal member is pushed onto the other side of the guide rail, that is, the plurality of seal members are arranged in the casing while the phase of the seal portion formed in the recess portion of one seal member and the phase of the seal portion formed in the recess portion of the other seal member are alternately changed from each other. Due to the above structure, sealing is performed in such a manner that the seal portions of a plurality of seal members (at least two seal members) slide on the circumferential face of the rail on which the slider moves. Therefore, a perfect sealing function can be provided. Especially when the rail width is locally different, for example even when the width of a curved portion is smaller than that of a straight portion, a difference in the width can be absorbed when the seal member is moved while being pushed by the elastic member. Therefore, the seal portion can be always contacted with the outer circumferential face of the guide rail, and the sealing function is not impaired.

[0012] According to a second aspect of the present invention, the elastic members are integrally formed on the outer periphery of the seal members.

[0013] When the elastic member is integrally formed in the outer periphery of the seal member, the number of parts composing the seal device can be decreased, and the assembling work can be easily performed.

[0014] According to a third aspect of the present invention, an isolation plate is arranged between the seal members.

[0015] When the isolation plate is arranged between the seal members as described above, each seal member can be smoothly moved regardless of the rail width by the function of the elastic member without interfering with the other seal members, and the seal portion comes into contact with the outer circumferential face of the guide rail. Therefore, the sealing function is effectively performed.

[0016] According to a fourth aspect of the present invention, there is provided a seal device for a guide device which is fixed to a side portion of a slider of the guide device so as to prevent foreign objects such as dust from getting into the seal device, the slider being arranged striding over a straight and/or curved rail and guided along the rail, the seal device comprising: a casing; a plurality of plate-shaped seal members accommodated in the casing; and an elastic member for pushing the seal members onto the rail, wherein a side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex or concave shape of a predetermined radius of curvature, a side of at least one seal member slidably coming into contact with the side of the rail is formed into a straight shape, and wherein the seal members are pushed by the elastic member and at least one portion of the side of each seal member comes into contact with the side of the rail.

[0017] As described above, the side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex or concave shape of a predetermined radius of curvature, and the side of at least one seal member slidably coming into contact with the side of the rail is formed into the straight shape. Therefore, in the straight portion of the rail, the straight side of the seal member closely comes into contact with the side of the rail, and in the curved portion of the seal member, the side of the seal member, which is formed into a convex or concave of a predetermined radius of curvature, closely comes into contact with the side of the rail. Therefore, even if the rail profile is changed from a straight shape to a curved shape, no foreign objects get into the slider from the side portion.

[0018] According to a fifth aspect of the invention, there is provided a seal device for a guide device which is fixed to a side portion of a slider of the guide device so as to prevent foreign objects such as dust from getting into the seal device, the slider being arranged striding over a straight and/or curved rail and guided along the rail, the seal device comprising: a casing; a plurality of plate-shaped seal members accommodated in the casing; and an elastic member for pushing the seal members onto the rail, wherein a side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex shape of a predetermined radius of curvature, a side of at least one seal member slidably coming into contact with the side of the rail is formed into a concave shape of a predetermined radius of curvature, and a side of at least one seal member slidably coming into contact with the side of the rail is formed into a straight shape, and wherein the seal members are pushed by the elastic member and at least one portion of the side of each seal member comes into contact with the side of the rail.

[0019] As described above, the side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex shape of a predetermined radius of curvature, and the side of at least one seal member slidably coming into contact with the side of the rail is formed into a concave shape of a predetermined radius of curvature, and further the side of at least one seal member slidably coming into contact with the side of the rail is formed into a straight-line-shape. Due to the above structure, in the straight rail portion, the straight side of the seal member closely comes into contact with the rail side. In the curved rail portion, the convex side of the seal member of a predetermined radius of curvature or the concave side of the seal member closely comes into contact with the rail side. In the portion where the rail is curved in the other direction, the concave side of the seal member of a predetermined radius of curvature or the convex side of the seal member closely comes into contact with the rail side. Therefore, even if the rail is curved from a straight shape to a curved shape which is curved to either the right or the left, no foreign objects get into the slider from the side portion of the slider.

[0020] According to a sixth aspect of the present invention, the elastic members of a guide device according to the fourth or fifth aspect are integrally formed on the outer periphery of the seal members.

[0021] When the elastic member is integrally formed in the outer periphery of the seal member, the number of parts composing the seal device can be decreased, and the assembling work can be easily performed.

[0022] According to a seventh aspect of the present invention, an isolation plate is arranged between the seal members of a guide device according to one of the fourth to sixth aspects.

[0023] When the isolation plate is arranged between the seal members as described above, each seal member can be smoothly moved regardless of the rail width by the function of the elastic member without interfering with the other seal members, and the seal portion comes into contact with the outer circumferential face of the guide rail. Therefore, the sealing function is effectively performed.

[0024] According to a eighth aspect of the present invention, there is provided a guide device comprising: a straight and/or curved rail; and a slider arranged striding over the rail, the slider having seal devices arranged at both end portions and both side portions respectively for preventing foreign objects from getting into the slider, wherein the seal device attached to both end portions of the slider is the seal device according to one of the first to third aspects, and the seal device attached to both side portions is the seal device according to one of the fourth to seventh aspects.

[0025] As described above, when the seal device attached to both end portions of the slider is the seal device according to one of the first to third aspects, and the seal device attached to both side portions is the seal device according to one of the fourth to seventh aspects, both end portions and both side portions of the slider are sealed. Accordingly, no foreign objects get into the slider.

BRIEF DESCRIPTION OF THE DRAWINGS

[0026] **FIG. 1**(*a*) is a front view showing a conventional seal device and **FIG. 1**(*b*) is a sectional view of an inner circumferential portion of an end seal;

[0027] **FIG. 2** is a plan view showing a conventional guide device using a rail in which a straight portion and curved portion are combined with each other;

[0028] **FIG. 3** is an exploded perspective view showing the conventional guide device;

[0029] **FIG. 4** is an exploded perspective view showing a seal device of a guide device of the present invention;

[0030] **FIG. 5** is a front view showing a seal member of the seal device of the guide device;

[0043] **FIG. 18** is an exploded perspective view showing a seal device of a fifth embodiment of the present invention.

DETAILED DESCRIPTION OF THE PREFFERD EMBODIMENTS

[0044] Referring to the drawings, embodiments of the present invention will be described below. **FIG. 4** is an exploded perspective view showing an arrangement of a seal device of a guide device of the present invention. As shown in the drawing, this seal device includes: a casing **1**; a plurality of seal members **2-1**, **2-2** accommodated in the casing **1** (In the drawing, two seal members are shown.); and an isolation plate **3** interposed between the seal members **2-1**, **2-2**. In the casing **1**, there is formed a recess portion **5** in which the rail (shown in **FIG. 6**) penetrates. In the seal members **2-1**, **2-2**, there are respectively formed recess portions **6-1**, **6-2** in which the rail **4** penetrates. In the isolation plate **3**, there is formed a recess **7** in which the rail **4** penetrates.

[0045] At both side portions of each seal member **2-1**, **2-2**, there are integrally provided elastic members **8-1**, **8-1**. As shown in **FIG. 5**, the center line **16** of the recess portion **6-1** of the seal member **2-1** in the width direction is shifted from the center line **12** of the seal member **2-1** itself in the width direction by the distance d. The inner circumferential face **6-1***a* on one side and the inner circumferential face **6-1***b* on the upper side are formed into a shape closely coming into contact with the outer circumferential face of the rail **4**. Although not shown in the drawing, the structure of the seal member **2-2** is the same as that of the seal member **2-1**, and the inner circumferential face **6-2***a* on one side and the inner circumferential face **6-2***b* on the upper side are formed into a shape closely coming into contact with the outer circumferential face of the rail **4**.

[0046] **FIG. 6** is a view showing a positional relation of the seal member **2-1** with the rail **4** in the case where the seal member **2-1** is accommodated in the casing **1** and the rail **4** is inserted into its recess portion **6-1**. As shown in **FIG. 5**, the center line **16** of the recess portion **6-1** (not shown in **FIG. 6**) of the seal member **2-1** in the width direction is shifted from the center line **12** of the seal member **2-1** itself in the width direction by the distance d. Therefore, when the seal member **2-1** is accommodated in the casing **1** and the rail **4** is inserted into its recess portion **6-1**, the elastic member **8-1** on one side (on the left in the drawing) contracts and pushes the seal member **2-1** as shown by the arrow f, however, the elastic member **8-1** on the other side (on the right in the drawing) does not contract but extends. Due to the foregoing, the inner circumferential face **6-1***a* on one side of the recess portion **6-1** composing the seal portion closely comes into contact with the outer circumferential face on one side of the rail **4**, however, a gap g is formed between the inner circumferential face **6-1***c* on the opposite side of the recess portion **6-1** and the outer circumferential face on the opposite side of the rail **4**.

[0047] The seal member **2-2** is arranged in the casing **1** interposing the isolation plate **3** while the phase is shifted (inverted by 180°) as follows. On the contrary to the seal member **2-1**, the inner circumferential face **6-2***a* on one side of the recess portion **6-2** composing the seal portion closely comes into contact with the outer circumferential face on one side on the opposite side of the rail **4**, so that the gap g can be formed between the inner circumferential face **6-2***c* on one side of the recess portion **6-2** and the outer circumferential face on the opposite side of the rail **4**.

[0048] Due to the above structure, the inner circumferential faces **6-1***a*, **6-2***a* on one side composing the seal portion of the seal members **2-1**, **2-2**, which are arranged on both sides of the isolation plate **3** in the casing, are pushed by the elastic members **8-1**, **8-2** and respectively contacted with the opposed outer circumferential face of the rail **4**. Under the above condition, the inner circumferential faces **6-1***a*, **6-2***a* on one side composing the seal portion of the seal members **2-1**, **2-2** are moved on the rail **4** together with the slider. Therefore, foreign objects such as dust are removed from the outer circumferential face of the rail **4** by the seal portion of the seal members **2-1**, **2-2**. Accordingly, no foreign objects get into the slider. The inner circumferential faces **6-1***a*, **6-2***a* on side of the seal members **2-1**, **2-2** are contacted with the outer circumferential face of the rail **4** on the opposed side when they are pushed by the elastic members **8-1**, **8-2**. Therefore, even if the width of the rail **4** differs within the expansion and contraction range of the elastic members **8-1**, **8-2**, the width difference can be absorbed in this expansion and contraction range. Accordingly, no gaps are formed between the seal portion and the outer circumferential face of the rail **4**. Therefore, the sealing function is not impaired.

[0049] **FIG. 7** is a view to explain a sealing function in the case where the seal device of the present invention is applied to a guide device in which the rail width of a curved portion is smaller than the rail width of a straight portion like the transport device (shown in **FIG. 2**) described in Japanese Unexamined Patent Publication No. 2001-99152. In the drawing, two-dotted chain line A expresses an outer circumference of the rail **4** in the straight portion, and solid line B expresses an outer circumference of the rail **4** in the curved portion. As shown in the drawing, since the seal member **2-1** is pushed onto the rail side by the elastic member **8-1**, the inner circumferential face **6-1***a* on one side composing the seal portion always closely comes into contact with and slides on the outer circumferential face in either the straight portion (portion shown by two-dotted chain line A) in which the width of the rail **4** is large or the curved portion (portion shown by solid line B) in which the width of the rail **4** is small. Although not shown in the drawing, the seal member **2-2** is also pushed by the elastic member **8-2**, and the inner circumferential face **6-2***a* on one side always closely comes into contact with and slides on the outer circumferential face of the rail **4** in either the straight portion or the curved portion of the rail **4**.

[0050] Due to the foregoing, the inner circumferential faces **6-1***a*, **6-2***a* on one side of the seal members **2-1**, **2-2** and the upper side inner circumferential faces **6-1***b*, **6-2***b* always slidably come into contact with both the outer side faces and the upper face of the rail **4** irrespective of the width of the rail. Therefore, a sufficiently high sealing performance can be exhibited. In the above example, the width of the curved portion of the rail **4** is different from that of the straight portion. The seal device of the present invention is capable of exhibiting a sufficiently high sealing performance even in the case where the width is different within the curved portion and in the case where the width is different within the straight portion.

[0051] The seal members **2-1**, **2-2** are made of elastic material such as rubber or resin formed into a felt-shape, however, materials to compose the seal members **2-1**, **2-2** are not limited to the above specific examples. As far as the material is easily conformed to and seldom seized to and easily fitted to the rail **4**, any material such as resin or metal, for example, white metal used for a bearing metal may be used for the seal members **2-1**, **2-2**. In the above example, the cross sections of the inner circumferential faces **6-1***c*, **6-2***c* on one side of the seal members **2-1**, **2-2** which do not compose the seal portion are made to be similar to the cross section of the outer circumferential face of the rail **4**, however, the cross sections of the inner circumferential faces **6-1***c*, **6-2***c* are not limited to the above specific example.

[0052] **FIG. 8** is a view showing an appearance of the guide device to which the seal device of the present invention is applied. In the view, reference numeral **10** is a slider which is arranged striding over the rail. The slider **10** comprises a block **11**, the detail of which will be described later, and end plates **12**. The seal devices **13** of the present invention are arranged outside the end plates **12** which are attached to both ends of the slider **10**. The slider **10** is moved in the longitudinal direction of the rail **4**. When the slider **10** is moved, the inner circumferential faces **6-1***a*, **6-2***a* on one side of the seal members **2-1**, **2-2** (shown in **FIGS. 4 and 6**) and the inner circumferential faces **6-1***b*, **6-2***b* on the upper side of the seal members composing the seal device **13** closely come into contact with and slide on both the side faces and the upper face of the rail **4**. Due to the foregoing, foreign objects such as dust can be prevented from getting into the slider **10** from the surface of the rail **4**.

[0053] **FIGS. 9 and 10** are a partially cutaway perspective view and lateral sectional view showing a composition of the guide device from which the seal device **13** is removed. The cross section of the rail **4** is formed into a substantial rectangle. Four ball running grooves **4***a*, **4***b*, in which the balls **20** are running, are formed in the longitudinal direction. These ball running grooves **4***a*, **4***b* are formed on both side faces and at both edge portions on the upper face of the rail **4**. The ball running grooves **4***a* located on both side faces are formed downward by the angle of about 30 with respect to the lateral direction on the surface of **FIG. 9**. On the other hand, the ball running grooves **4***b* on the upper face are formed upward in the vertical direction.

[0054] The slider **10** includes: a block **11** having an attaching face **21**, onto which the movable body such as a table is attached, and tap holes **22** in which bolts for fixing the movable body are screwed; and a pair of end plates **12**, **12** attached (fixed) to both end portions of the block **11**. When the end plates **12**, **12** are attached, an infinite circulating path for the balls **20** is composed in the slider **10**.

[0055] The block **11** includes: a horizontal portion **11***a* on which the attaching face **21** is formed; and a pair of skirt portions **11***b*, lib which are hanging from the horizontal portion **11***a*. The cross section of the block **11** is substantially formed into a saddle. On the lower face side of the horizontal portion **11***a* and on the inside of each skirt portion **11***b*, four straight load running grooves **11***c*, **11***d*, which are opposed to the ball running grooves **4***a*, **4***b* of the rail **4**, are formed. In the horizontal portion **11***a* and each skirt portion **11***b*, the ball returning holes lie, **11***f* respectively corresponding to the load running grooves **11***c*, **11***d* are formed. By the U-shaped direction converting paths formed on the end plates **12**, **12**, the load running grooves **11***c*, **11***d* and the corresponding ball returning holes lie, **11***f* are connected with each other, so that the infinite circulating path of the balls can be formed.

[0056] Due to the foregoing, the balls **20** are running as follows. The balls **20**, which bear a load between the ball running grooves **4***a*, **4***b* of the rail **4** and the load running grooves **11***c*, **11***d* of the block **11**, run in the load running grooves **11***c*, **11***d* according to the movement of the slider **10** and are released from the load. Then the balls **20** get into the direction converting path formed on one end plate **12** and run in the opposite direction to the running direction of the load running grooves **11***c*, **11***d* while no load is being given to the balls **20**. In this way, the balls **20** run in the ball returning holes lie, **11***f* formed in the block **11**. After the balls **20** have run in the ball returning holes **11***e*, **11***f*, they get between the rail **4** and the block **11** again via the direction converting path formed on the other end plate **12**. Then, while the balls **20** are bearing a load, they run in the load running grooves **11***c*, **11***d*.

[0057] The above-described guide device is an example of the guide device into which the seal device of the present invention is incorporated. Therefore, the guide device of the present invention is not limited to the above specific example. After all, as far as the guide device is composed in such a manner that the slider is arranged striding over a straight and/or curved rail and guided along the rail and the seal device of the present invention is fixed to the end portion of the slider, it is possible to exhibit a sealing function by which foreign objects such as dust can be prevented from getting into the slider.

[0058] In the seal device of the above structure, two seal members **2-1**, **2-2** are arranged while the isolation plate **3** is being interposed between them. However, the number of the seal members is not limited to two, that is, not less than three seal members may be arranged. The isolation plate **3** is not necessarily required. In the case where each seal member can be smoothly moved even when the seal members **2-1**, **2-2** are contacted with each other, the isolation plate **3** may be omitted. In the above example, the elastic members **8-1**, **8-2** are respectively arranged on both side portions of the seal members **2-1**, **2-2** integrally with the seal members **2-1**, **2-2**. However, the elastic members **8-1**, **8-2** are not necessarily arranged integrally with the seal members **2-1**, **2-2**. As far as each seal member **2-1**, **2-2** can be individually pushed toward the rail **4**, the elastic members **8-1**, **8-2** may be composed separately from the seal members **2-1**, **2-2**.

[0059] The elastic members are not necessarily formed separately from the seal members **2-1**, **2-2**. The following structure may be adopted. When the seal members **2-1**, **2-2** are made of elastic material, the inner circumferential face **6-1***a*, **6-2***a* on one side can be always contacted with the outer circumferential face of the rail by the elastic extension and contraction caused between the one side of the seal members **2-1**, **2-2** and the inner circumferential faces **6-1***a*, **6-2***a* on one side even if the rail width is changed. Further, the following structure may be adopted. For example, as shown in **FIG. 11, a** predetermined shape of hole **23** is formed in the seal member **2-1**. Since the shape of the hole **23** can be deformed, the inner circumferential face **6-1***a* on one side composing the seal portion of the recess portion **6-1** can be always contacted with the outer circumferential face of the rail even if the rail width is changed. Although not shown in the drawing, the situations are the same in the case of the seal member **2-2**.

[0060] **FIG. 12** is an exploded perspective view showing an example of the arrangement of the seal device of the guide device of the present invention. As shown in the drawing, the seal device **30** includes: a casing **31**; a plurality of (three in the case shown in the drawing) plate-shaped seal members **32-1**, **32-2**, **32-3**; and two isolation plates **33-1**, **33-2** interposed between the seal member **32-1** and the seal member **32-2** and between the seal member **32-2** and the seal member **32-3**. The seal members **32-1**, **32-2**, **32-3** and the isolation plates **33-1**, **33-2** are superposed to each other and accommodated in the casing **31**. As shown in FIGS. **13**(*a*) and **13**(*b*), the seal members **32-1**, **32-2**, **32-3** and the isolation plates **33-1**, **33-2** are attached (fixed) to both side bottom portions of the block **11** of the slider **10** by screws **34**. The seal members **32-1**, **32-2**, **32-3** are pushed onto the sides of the rail **4** by the elastic members, and the sides are slidably contacted with the side faces of the rail **4** as described later. **FIG. 13**(*a*) is a lateral sectional view of the rail **4** and slider **10** of the guide device, and **FIG. 13**(*b*) is an enlarged sectional view of the neighborhood portion of the seal device **30**.

[0061] The side **32-1***a* of the seal member **32-1** slidably coming into contact with the side of the rail **4** is formed into a convex (an arcuate shape) of a predetermined radius of curvature, the side **32-2***a* of the seal member **32-2** slidably coming into contact with the side of the rail **4** is formed into a straight shape, and further the side **32-3***a* of the seal member **32-3** slidably coming into contact with the side of the rail **4** is formed into a concave (an arcuate shape) of a predetermined radius of curvature. On the sides of the seal members **32-1**, **32-2**, **32-3** arranged on the side opposite to the rail **4**, the elastic members **35-1**, **35-1**, **35-2**, **35-2**, **35-3**, **35-3** are respectively integrally arranged. When the thus composed seal device **30** is attached to both side bottom portions of the block **11** of the slider **10**, the seal members **32-1**, **32-2**, **32-3** are pushed by the elastic members **35-1**, **35-1**, **35-2**, **35-2**, **35-3**, **35-3**.

[0062] Since the side **32-1***a* of the seal member **32-1** is formed into a convex (an arcuate shape) of a predetermined radius of curvature, the side **32-2***a* of the seal member **32-2** is formed into a straight shape, and further the side **32-3***a* of the seal member **32-3** is formed into a concave (an arcuate shape) of a predetermined radius of curvature, in a portion where the rail **4** is curved convex by a predetermined radius of curvature as shown in **FIG. 14**(*a*), the side **32-1***a* of the seal member **32-1** closely comes into contact with the side of the rail **4** so as compose the seal portion. In a portion where the rail **4** is curved concave by a predetermined radius of curvature as shown in **FIG. 14**(*b*), the side **32-3***a* of the seal member **32-3** closely comes into contact with the side of the rail **4** so as compose the seal portion. In a portion where the rail **4** is straight as shown in **FIG. 14**(*c*), the side **32-2***a* of the seal member **32-2** closely comes into contact with the side of the rail **4** so as compose the seal portion.

[0063] In the case where the rail **4** snakes as shown in **FIG. 15**, the rail **4** is composed of curved portions **4-1**, **4-2** and a straight portion **4-3**, wherein the curved portions **4-1**, **4-2** are respectively formed into arcs, the radiuses of curvature of which are predetermined. Therefore, the convex (arcuate) side **32-1***a* of the seal member **32-1** and the concave (arcuate) side **32-3***a* of the seal member **32-3** are previously manufactured according to the radiuses of curvature of these curved portions **4-1**, **4-2**. Due to the foregoing, when the seal device **30** in which the seal members **32-1**, **32-2**, **32-3** are superposed as shown in **FIG. 12** is attached to both side bottom portions of the block **11** of the slider **10** as shown in **FIG. 13**, if the slider **10** is moved on the snaking rail **4**, either of the sides **32-1***a*, **32-2***a*, **32-3***a* of the seal members **32-1**, **32-2**, **32-3** closely comes into contact with the side of the rail **4**, so that the seal portion can be formed.

[0064] The seal members **32-1**, **32-2**, **32-3** can be made of the same material as that of the seal members **2-1**, **2-2**. The isolation plates **33-1**, **33-2** can be made of the same material as that of the above isolation plate **3**.

[0065] In the seal device **30** of the above structure, three seal members **32-1**, **32-2**, **32-3** are arranged while the isolation plates **33-1**, **33-2** are being interposed between them, however, the number of the seal members is not limited to three. That is, not less than three seal members maybe arranged. The isolation plates are not necessarily required. In the case where each seal member can be smoothly moved even when the seal members **32-1**, **32-2**, **32-3** are contacted with each other, the isolation plates may be omitted. In the above example, the elastic members **35-1**, **35-2**, **35-3** are respectively arranged on side portions of the seal members **32-1**, **32-2**, **32-3** integrally with the seal members **32-1**, **32-2**, **32-3**. However, the elastic members **35-1**, **35-2**, **35-3** are not necessarily arranged integrally with the seal members **32-1**, **32-2**, **32-3**. As far as each seal member **32-1**, **32-2**, **32-3** can be individually pushed toward the rail **4**, the elastic members **35-1**, **35-2**, **35-3** may be composed separately from the seal members **32-1**, **32-2**, **32-3**.

[0066] In the case of the guide device shown in **FIG. 15**, the rail **4** is snaking. However, for example, in the case where the rail **4** is annularly formed into an ellipse as shown in **FIG. 16**, the seal device located outside the annular rail **4** is the seal device **30** composed as shown in **FIG. 17**, and the seal device located inside the annular rail **4** is the seal device **30** composed as shown in **FIG. 18**. The seal device **30** shown in **FIG. 17** is composed in such a manner that the side **32-2***a* slidably coming into contact with the outer circumferential side face of the rail **4** is the straight seal member **32-2**, the isolation plate is the isolation plate **33-1**, and the side **32-3***a* slidably coming into contact with the outer circumferential side face of the rail **4** is the seal member **32-3** of a concave (arc) of a predetermined radius of curvature. The seal device **30** shown in **FIG. 18** is composed in such a manner that the side **32-2***a* slidably coming into contact with the inner circumferential side face of the rail **4** is the straight seal member **32-2**, the isolation plate is the isolation plate **33-1**, and the side **32-1***a* slidably coming into contact with the inner circumferential side face of the rail **4** is the seal member **32-1** of a convex (arc) of a predetermined radius of curvature.

[0067] As described above, the seal device **30** located outside the annular rail **4** is composed as shown in **FIG. 17**, and the seal device **30** located inside the annular rail **4** is composed as shown in **FIG. 18**. Due to the above structure, in the seal device **30** located outside, either the straight side **32-2***a* of the seal member **32-2** or the concave (arcuate) side **32-3***a* of the seal member **32-3** closely comes into contact with the outer circumferential side of the rail **4**, so that the seal portion can be formed. In the seal device **30** located inside, either the straight side **32-2***a* of the seal member **32-2** or the convex (arcuate) side **32-1***a* of the seal member **32-1** closely comes into contact with the inner circumferential side of the rail **4**, so that the seal portion can be formed. Accordingly, there is no possibility that foreign objects get into the slider **10** from the bottom side portion.

[0068] When the seal device **30** composed as shown in **FIG. 4** is arranged at both end portions of the slider **10** of the guide device and when the seal device **30** composed as shown in **FIG. 12** or the seal device **30** composed as shown in **FIGS. 17 and 18** is arranged at both side portions of the bottom portion of the slider **10**, it becomes possible to provide a guide device incorporated into a wood working machine used in a dusty environment in which both end portions and both side portions of the slider **10** are sealed so that no foreign objects can not get into the slider **10**.

[0069] As explained above, according to each aspects of the present invention, it is possible to provide the following excellent effects.

[0070] According to the first aspect of the invention, a plurality of seal members are arranged in the casing so that the phase of arranging the plurality of seal members can be alternately changed in such a manner that when a seal portion of one seal member is pushed by the elastic member and contacted with one side of the rail, a seal portion of the next seal member is pushed by the elastic member and contacted with the other side of the rail. Accordingly, the seal portions of the plurality of seal members (at least two seal members) conduct sealing while they are sliding on the outer circumferential face of the rail on which the slider moves. Therefore, it is possible to provide a perfect sealing function. Especially when the rail width is locally different, for example even when the width of a curved portion is smaller than the width of a straight portion, a difference in the width can be absorbed when the seal member is moved while being pushed by the elastic member. Therefore, the seal portion can be always contacted with the outer circumferential face of the guide rail. Accordingly, the sealing function is not impaired.

[0071] According to the second aspect of the invention, when the elastic member is formed in the outside portion of the seal member integrally with the seal member as described above, the number of parts composing the seal device can be decreased, and the assembling work can be easily performed.

[0072] According to the third aspect of the invention, the isolation plate is arranged between the seal members. Therefore, each seal member can be smoothly moved according to the rail width without interfering with the other seal members by the action of the elastic member, and the seal portion comes into contact with the outer circumferential face of the guide rail. Therefore, the sealing function can be effectively performed.

[0073] According to the fourth aspect of the invention, the side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex or concave of a predetermined radius of curvature, and the side of at least one seal member slidably coming into contact with the side of the rail is formed into the straight-line-shape. Therefore, in the straight portion of the rail, the straight side of the seal member closely comes into contact with the side of the rail, and in the curved portion of the seal member, the side of the seal member, which is formed into a convex or concave of a predetermined radius of curvature, closely comes into contact with the side of the rail, so that the seal portion can be formed. Therefore, even if the rail profile is changed from a straight shape to a curved shape, no foreign objects get into the slider from the side portion.

[0074] According to the fifth aspect of the invention, the side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex of a predetermined radius of curvature, and the side of at least one seal member slidably coming into contact with the side of the rail is formed into a concave of a predetermined radius of curvature, and further the side of at least one seal member slidably coming into contact with the side of the rail is formed into a straight shape. Due to the above structure, in the straight rail portion, the straight side of the seal member closely comes into contact with the rail side, so that the seal portion can be formed. In the curved rail portion, the convex side of the seal member of a predetermined radius of curvature or the concave side of the seal member closely comes into contact with the rail side, so that the seal portion can be formed. In the portion where the rail is curved in the other direction, the concave side of the seal member of a predetermined radius of curvature or the convex side of the seal member closely comes into contact with the rail side, so that the seal portion can be formed. Therefore, even if the rail is curved from a straight shape to a curved shape which is curved to either the right or the left, no foreign objects gets into the slider from the side portion of the slider.

[0075] According to the sixth aspect of the invention, the elastic members are formed on the outside of the seal members integrally with the seal members. Therefore, the number of parts composing the seal device can be reduced, and the assembling work can be easily performed.

[0076] According to the seventh aspect of the invention, the isolation plate is arranged between the seal members. Therefore, each seal member is pushed by the elastic member and smoothly moved according to the curved rail without interfering with the other seal members, and the side of the seal member comes into contact with the rail side. Therefore, the sealing function can be effectively performed.

[0077] According to the eighth aspect of the invention, when the seal device attached to both end portions of the slider is the seal device according to one of the first to third aspects and the seal device attached to both side portions is the seal device according to the fourth to seventh aspects, both end portions and both side portions of the slider are sealed. Accordingly, it becomes possible to provide a guide device, into the slider of which no foreign objects get.

What is claimed is:

1. A seal device for a guide device which is fixed to an end portion of a slider of the guide device so as to prevent foreign objects such as dust from getting into the seal device, the slider being arranged striding over a straight and/or curved rail and guided along the rail, the seal device comprising:

a casing;

a plurality of plate-shaped seal members accommodated in the casing; and

an elastic member for pushing the seal members onto the rail,

wherein each seal member has a recess portion in which the rail penetrates, an inner circumferential face of the recess portion includes a seal portion which comes into contact with an outer surface of the rail, and

wherein the plurality of seal members are arranged in the casing in such a manner that the seal members are pushed by the elastic member, the seal portion of one seal member comes into contact with one side of the rail, and the seal portion of the next seal member comes into contact with the other side of the rail.

2. A seal device for a guide device according to claim 1, wherein the elastic member is integrally formed on the outer periphery of each seal member.

3. A seal device for a guide device according to claim 1, further comprising an isolation plate arranged between the seal members.

4. A seal device for a guide device according to claim 2, further comprising an isolation plate arranged between the seal members.

5. A seal device for a guide device which is fixed to a side portion of a slider of the guide device so as to prevent foreign objects such as dust from getting into the seal device, the slider being arranged striding over a straight and/or curved rail and guided along the rail, the seal device comprising:

a casing;

a plurality of plate-shaped seal members accommodated in the casing; and

an elastic member for pushing the seal members onto the rail,

wherein a side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex or concave shape of a predetermined radius of curvature, a side of at least one seal member slidably coming into contact with the side of the rail is formed into a straight shape, and

wherein the seal members are pushed by the elastic member and at least one portion of the side of each seal member comes into contact with the side of the rail.

6. A seal device for a guide device which is fixed to a side portion of a slider of the guide device so as to prevent foreign objects such as dust from getting into the seal device,

the slider being arranged striding over a straight and/or curved rail and guided along the rail, the seal device comprising:

a casing;

a plurality of plate-shaped seal members accommodated in the casing; and

an elastic member for pushing the seal members onto the rail,

wherein a side of at least one seal member slidably coming into contact with the side of the rail is formed into a convex shape of a predetermined radius of curvature, a side of at least one seal member slidably coming into contact with the side of the rail is formed into a concave shape of a predetermined radius of curvature, and a side of at least one seal member slidably coming into contact with the side of the rail is formed into a straight shape, and

wherein the seal members are pushed by the elastic member and at least one portion of the side of each seal member comes into contact with the side of the rail.

7. A seal device for a guide device according to claim 5, wherein the elastic member is integrally formed on the outer periphery of each seal member.

8. A seal device for a guide device according to claim 6, wherein the elastic member is integrally formed on the outer periphery of each seal member.

9. A seal device for a guide device according to claim 5, further comprising an isolation plate arranged between the seal members.

10. A seal device for a guide device according to claim 6, further comprising an isolation plate arranged between the seal members.

11. A seal device for a guide device according to claim 7, further comprising an isolation plate arranged between the seal members.

12. A seal device for a guide device according to claim 8, further comprising an isolation plate arranged between the seal members.

13. A guide device comprising:

a straight and/or curved rail; and

a slider arranged striding over the rail, the slider having seal devices arranged at both end portions and both side portions respectively for preventing foreign objects from getting into the slider,

wherein the seal device attached to both end portions of the slider is the seal device described in one of claims 1 to 4, and the seal device attached to both side portions is the seal device described in one of claims 5 to 12.

(57) **ABSTRACT**

There is provided a rolling element spacer used in a rolling guide device having an endless circulation passage of balls, arranged alternately with many balls in the endless circulation passage, and circulating together with the balls in the endless circulation passage. It has a pair of ball holding seats each of which is formed in a concave spherical face form nearly approximating a spherical face of the ball and sliding-contacts with the ball and, around each ball holding seat, there is formed an annular dropout prevention portion protruding in a ball arranging direction than an edge portion of the ball holding seat and kept in non-contact with respect to the ball seated on the ball holding seat.

ROLLING ELEMENT SPACER IN ROLLING GUIDE DEVICE

BACKGROUND OF THE INVENTION

[0001] 1. Field of the Invention

[0002] The present invention relates to a rolling element spacer which, in various rolling guide devices each having an endless circulation passage for balls such as a linear guide device and a ball screw device, is interposed between the mutually adjoining balls in the endless circulation passage and reduces frictions between the balls and a heat generation to thereby smoothen the rolling thereof.

[0003] 2. Description of the Related Art

[0004] Hitherto, as a rolling guide device in which a pair of members continuously performing a relative motion through an endlessly circulating ball row, there have been known devices such as a linear guide device which is used in a linear guide portion in a machine tool, a carrying device and the like and which guides a movable body such as a table on a stationary portion such as a bed or a saddle, and a ball screw which is used together with this linear guide device and which gives a stroke of a linear motion corresponding to a rotation amount of a motor to the movable body.

[0005] The former linear guide device comprises a bearing rail which is disposed on the stationary portion and in which a rolling groove for the balls is formed along a longitudinal direction, and a sliding base which has a load rolling groove facing the rolling groove of the bearing rail through many balls and in which there is formed an endless circulation groove for the balls rolling on the load rolling groove, and it is constituted such that, in accompaniment with the endless circulation of the balls, the sliding base supporting the movable body continuously performs the linear motion along the bearing rail. Further, reversely to this, there is a case where it is constituted such that the bearing rail is moved relative to the fixed sliding base.

[0006] On the other hand, the latter ball screw comprises a screw shaft in which there is formed a spiral ball rolling groove with a predetermined lead, and a nut member which has a load rolling groove facing the ball rolling groove through many balls and in which there is formed an endless circulation passage for the balls rolling on the load rolling groove, and it is constituted such that, in accompaniment with a relative rotation motion between the screw shaft and the nut member, the balls circulate in the endless circulation passage, and the nut member and the screw shaft relatively move in an axial direction.

[0007] On the other hand, in such a rolling guide device, since the individual ball circulating in the endless circulation passage mutually contacts with the balls positioned before and after it, in case that it is used at a high speed, there have been such possibilities that, besides the fact that the balls are worn in relatively short time by a friction between the balls for instance, there arises a disadvantage such as the fact that the ball or the load rolling groove generates a seizure owing to a friction heat. Further, when reversing a motion direction, i.e., when reversing a circulation direction, an arrangement of the balls in the endless circulation passage is liable to be disturbed and, in an extreme case, there arises a so-called lock phenomenon in which the balls clog in the endless circulation passage, so that there has been a possibilities that the rolling guide device itself becomes impossible to operate. Therefore, as one for solving such drawbacks, in Japanese Patent Laid-Open No. 315835/1999 Gazette, there is disclosed a rolling guide device in which a rolling element spacer is interposed between the balls mutually adjoining in the endless circulation passage.

[0008] In the rolling guide device disclosed in the above Gazette, it is adapted such that a synthetic resin made rolling element spacer referred to as separator is arranged alternately with the ball in the endless circulation passage, thereby preventing the balls from mutually contacting. Such a separator is formed in a disk-like form whose outer diameter is smaller than a diameter of the ball and, in its both front/rear faces contacting with the balls, there are formed ball holding seats whose curvatures are larger than a curvature of a spherical face of the ball. By this, if the ball and the separator are alternately arranged without a gap in the endless circulation passage, each ball becomes a state of being sandwiched by a pair of separators adjoining before and after it, so that it circulates in the endless circulation passage together with the separators without disturbing a row even when reversing the circulation direction.

[0009] However, like the rolling element spacer shown in the Japanese Patent Laid-Open No. 315835/1999 Gazette, if the ball holding seat which sliding-contacts with the ball is formed in a concave curved face form whose curvature is larger than the spherical face of the ball, since a gap is formed between a peripheral edge portion of the ball holding seat and the ball, the ball rocks with respect to the rolling element spacer, so that there is a problem that it is impossible to completely eliminate a meander of the balls in the endless circulation passage.

[0010] On the other hand, from a viewpoint of preventing the meander of the balls in the endless circulation passage, it is necessary that the ball settles on the ball holding seat of the rolling element spacer without rocking, and therefor it is necessary that ball holding seat is formed in a concave spherical face form nearly approximating the spherical face of the ball. However, in case that the ball holding seat is formed in such a concave spherical face form, a contact area between the ball and the ball holding seat becomes large, so that there are possibilities of an increase in sliding contact resistance of the rolling element spacer with respect to the ball, a premature wear of the rolling element spacer, and the like.

[0011] Further, in case that the ball holding seat is designed such that its diameter is small in order to avoid the increase in sliding contact resistance with respect to the ball, there has been a disadvantage that the rolling element spacer falls out from between the mutually adjoining balls even if a slight gap is generated between the ball and the rolling element spacer.

SUMMARY OF THE INVENTION

[0012] The invention has been made in view of such a problem, and its object is to provide a rolling element spacer which makes a sitting of the ball with respect to the ball holding seat good to thereby intend to stabilize an alignment of the balls and the rolling element spacers in the endless circulation passage, can reduce the sliding contact resistance acting to the ball, and can effectively prevent the rolling element spacer from falling out from between the balls.

[0013] In order to achieve the above object, the invention provides a rolling element spacer used in a rolling guide device in which a pair of members perform a relative continuous motion through an endlessly circulating ball row, interposed between balls mutually adjoining in its endless circulation passage, and circulating together with the balls, characterized in that it has a pair of ball holding seats each of which is formed in a concave spherical face form nearly approximating a spherical face of the ball and sliding-contacts with the ball and, around each ball holding seat, there is formed an annular dropout prevention portion protruding in a ball arranging direction than an edge portion of the ball holding seat and kept in non-contact with respect to the ball seated on the ball holding seat.

[0014] According to such a technical means, since the ball folding seat with which the ball sliding-contacts is formed in the concave spherical face form nearly approximating the spherical face of the ball, a gap is scarcely formed between the spherical face of the ball and the ball holding seat, so that the siting of the ball with respect to the ball holding seat is stabilized. Therefore, in case that the rolling element spacers and the balls are alternately arranged in the endless circulation passage of the rolling guide device, it is intended to stabilize the alignment of the balls and the rolling element spacers, so that it become possible to prevent a meander of the balls in the endless circulation passage.

[0015] Further, since the annular dropout prevention portion kept in non-contact with respect to the ball is formed around the ball holding seat and the dropout prevention portion protrudes in the ball arranging direction than the edge portion of the ball holding seat, even if a gap is generated between the ball and the rolling element spacer and thus the rolling element spacer becomes likely to fall out from between the mutually adjoining balls, it becomes possible to prevent beforehand a dropout accident of the rolling element spacer by the fact that the dropout prevention portion engages with the ball. Accordingly, since a diameter of the ball holding seat can be determined irrespective of the dropout of the rolling element spacer and thus the ball holding seat can be formed in a size as minimum as necessary, it becomes possible to make a contact area between the ball holding seat and the ball small, thereby reducing the sliding contact resistance acting to the ball. Further, since the dropout prevention portion is kept in non-contact with respect to the ball under a state that the ball seats on the ball holding seat, there is no case that the sliding contact resistance acting to the ball increases, by the fact that the dropout prevention portion is provided.

[0016] In case that the ball holding seat is formed in the concave spherical face form nearly approximating the spherical face of the ball, since a peripheral edge portion of the ball holding seat contacts with the spherical face of the ball, a lubricant adhered on the ball is scraped by the peripheral edge portion, so that the ball is liable to come into a state of insufficient lubrication. However, according to the rolling element spacer of the invention, since the dropout prevention portion provided around the ball holding seat is kept in non-contact with the spherical face of the ball, the lubricant is liable to enter into the gap between the dropout prevention portion and the ball, so that a lubricating state of the ball can be maintained well even in case that the ball holding seat is formed in the concave spherical face form nearly approximating the spherical face of the ball. Accordingly, from a viewpoint of making a holding state of the lubricant in the rolling element spacer of the invention further good, it is preferable to form an annular groove between the ball holding seat and the dropout prevention portion surrounding it and utilize this annular groove as a lubricant sump. If constituted in this manner, since the lubricant flowing into the gap between the ball and the dropout prevention portion is stored in the annular groove, it becomes possible to always apply the lubricant to a surface of the ball.

[0017] On the other hand, in the endless circulation passage of the rolling guide device, since it is difficult to completely eliminate a gap between the ball and the rolling element spacer, it follows that the rolling element spacer and the ball are repeating collisions bit by bit during a circulation of the balls. Therefore, from a viewpoint of reducing a fatigue and decreasing a collision noise of the balls owing to such collisions, it is preferable that the ball holding seat with which the ball sliding-contacts is formed of a suitably soft material. In contrast to this, since the dropout prevention portion is one for preventing the rolling element spacer from falling out from between the mutually adjoining balls, it must not be easily deformed by being pushed by the ball in case that such a situation occurs, so that it is preferable that it is formed of a hard material. Accordingly, from such a viewpoint, it is preferable that the ball holding seat and the dropout prevention portion provided in the rolling element spacer of the invention are molded respectively by different resin materials, and the dropout prevention portion is molded by the resin material harder than the ball holding seat.

[0018] Incidentally, the dropout prevention portion may be formed in a continuous annular form, but the dropout prevention portion may be made by providing a protrusion separated by a slit in the annular form.

[0019] As explained above, according to the rolling element spacer of the invention, since each of a pair of ball holding seats with which the balls sliding-contact is formed in the concave spherical face form nearly approximating the spherical face of the ball and, around each ball holding seat, there is formed the annular dropout prevention portion protruding in the ball arranging direction than the edge portion of the ball holding seat and kept in non-contact with respect to the ball seated on the ball holding seat, it is possible to intend to stabilize the alignment of the balls and the rolling element spacers in the endless circulation passage while making the sitting of the ball with respect to the ball holding seat good and intend to decrease the sliding contact resistance acting to the ball, and additionally it becomes possible to effectively prevent the rolling element spacer from falling out from between the balls.

BRIEF DESCRIPTION OF THE DRAWINGS

[0020] **FIG. 1** is a side sectional view showing one embodiment of a ball screw device in which rolling element spacers of the invention are arranged together with balls in an endless circulation passage;

[0029] **FIG. 10** is an enlarged sectional view showing a relation between the dropout prevention portion of the rolling element spacer shown in **FIG. 9** and the ball; and

[0030] **FIG. 11** is a sectional view showing a 2nd embodiment of the rolling element spacer of the invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0031] Hereunder, a rolling element spacer of the invention is detailedly explained on the basis of the drawings.

[0032] **FIG. 1** and **FIG. 2** show one embodiment of a ball screw device in which the rolling element spacers of the invention are arranged together with balls in an endless circulation passage. In these drawings, the reference numeral i denotes a screw shaft, the reference numeral **2** a ball and the reference numeral **3** a nut member, and the nut member **3** meshes with the screw shaft **1** through many balls **2**.

[0033] A spiral ball rolling groove **10** is formed in an outer periphery face of the screw shaft **1**, while a spiral load rolling groove **30** facing the ball rolling groove **10** of the screw shaft **1** is formed in an inner periphery face of the nut member **3**, and the ball rolling groove **10** and the load rolling grove **30** form a spiral load ball passage between the screw shaft **1** and the nut member **3**. That is, if a relative rotary motion occurs between the screw shaft land the nut member **3**, the ball **2** spirally rolls in the load ball passage while bearing a load. Further, a return pipe **4** mutually communicating both ends of the load ball passage to thereby constitute the endless circulation passage for the balls **2** is attached to the nut member **3**, so that the ball **2** having finished rolling in the load ball passage and having been released from the load becomes a no-load state and rolls in the return pipe **4**, and is returned to an inlet of the load ball passage while jumping the ball rolling groove **10** by several turns. Accordingly, if the screw shaft **1** and the nut member **3** are relatively rotated, it follows that the ball **2** rolls from the load ball passage to the return pipe **4** and from the return pipe **4** to the load ball passage, and is circulated inside the endless circulation passage constituted by the load ball passage and the return pipe **4**.

[0034] In this ball screw device, in order to prevent the balls **2** incorporated in the endless circulation passage from mutually contacting, a rolling element spacer **5** is interposed between the mutually adjoining balls **2**, **2**. As shown in **FIG. 3** to **FIG. 5**, the rolling element spacer **5** is formed by deforming a synthetic resin into an approximately disk form and, in its both front/rear faces, there are respectively formed ball holding seats **50** with which the balls **2** sliding-contact. The ball **2** and the rolling element spacer **5** are alternately arranged in the endless circulation passage. By this, it is adapted such that the balls **2** rolling in the endless circulation passage are prevented from mutually contacting, a smooth circulation of the ball and, in turn, smoothening of the rotary motion of the nut member **3** relative to the screw shaft **1** are intended, and additionally a generation of noise owing to a collision between the balls during an operation of the ball screw device is reduced.

[0035] The ball holding seat **50** is formed in a concave spherical face form nearly approximating a spherical face of the ball **2**, and it is constituted such that the adjoining ball **2** contacts with the ball holding seat **50** almost without a gap. Further, an annular lubricating oil sump **51** is formed in the ball holding seat **50**, and it is adapted such that a lubrication between the ball holding seat **50** and the ball **2** is intended. Further an annular dropout prevention portion **52** is formed around the ball holding seat **50** so as to surround the ball holding seat **50**. A tip of the dropout prevention portion **52** protrudes than an edge portion of the ball holding seat **50** with respect to a arranging direction of the balls **2** (horizontal direction in **FIG. 5**). However, as shown in **FIG. 6**, it is adapted such that, under a state that the ball **2** seats on the ball holding seat **50**, a gap is formed between the ball **2** and the tip of the dropout prevention portion **52**. Additionally, between the dropout prevention portion **52** and the ball holding seat **50**, there is formed an annular groove **53** separating them, and it is adapted such that the annular groove **53** functions as a lubricating oil sump.

[0036] **FIG. 7** shows a state that the balls **2** seat on the ball holding seats **50** of the rolling element spacer **5**. As mentioned before, since the ball holding seat **50** is formed in the concave spherical face form nearly approximating the spherical face of the ball **2**, the seated ball **2** contacts with the ball holding seat **50** almost without the gap as shown in this drawing. By this, in case that the balls **2** and the rolling element spacers **50** are arranged without gaps in the endless circulation passage of the ball screw device, the balls **2** don't rock unstably on the ball holding seats **50** of the rolling element spacers **5**, so that the balls **2** and the rolling element spacers **5** can be circulated without meandering in the endless circulation passage.

[0037] Further, since the dropout prevention portion **52** formed around the ball holding seat **50** does not contact with the ball **2** seated on the ball holding seat **50**, it follows that a lubricant such as grease adhered on the ball **2** enters into the annular groove **53** from a gap between the dropout prevention portion **52** and the spherical face of the ball **2** and is collected in the annular groove **53**. Therefore, the lubricant is liable to be drawn between the ball **2** and the ball holding seat **50** which mutually sliding-contact, so that it is possible to surely lubricate between the ball **2** and the rolling element spacer **5** and, besides, the lubricant becomes liable to adhere also to a surface, of the ball **2**, moving outside after passing the annular groove **53**, so that it becomes possible to surely lubricate between the ball **2** and the rolling groove **10** of the ball screw device.

[0038] On the other hand, **FIG. 8** shows a state that a gap between the mutually adjoining balls **2** increases during circulating in the endless circulation passage, and thus the balls **2** float from the ball holding seats **50** of the rolling element spacer **5**. Such a state occurs somewhere in the endless circulation passage because it is difficult to arrange the balls **2** and the rolling element spacers **5** without gaps relative to the endless circulation passage of the ball screw device for instance, and the ball **2** and the rolling element spacer **5** wear during being used for a long time. And, if the balls **2** float from the ball holding seats **50** in the above manner, the rolling element spacer **5** sandwiched by the balls **2** from both sides loses its support and attempts to fall out from between the balls **2**. However, in the rolling element spacer **5** of this embodiment, since the tip of the dropout prevention portion **52** protrudes than the edge portion of the ball holding seat **50** with respect to the arranging direction of the balls **2**, if the rolling element spacer **5** becomes likely to drop out from between the mutually adjoining balls **2**, the dropout prevention portions **52** having been in a non-contacting state up to that time engage with the balls **2**, thereby acting so as to prevent the rolling element spacer **5** from falling out from between the balls **2**. Accordingly, in the rolling element spacer **5** of this embodiment, it is unnecessary to set a diameter of the ball holding seat **50** uselessly large for the purpose of dropout prevention from between the balls **2**, so that the ball holding seat **50** can be formed in a size as minimum as necessary. Therefore, a contact area between the ball **2** and the ball holding seat **50** can be made small, so that a sliding contact resistance of the ball **2** with respect to the rolling element spacer **5** can be reduced correspondingly. From a viewpoint of the ball screw device in which the rolling element spacers **5** are arranged in the endless circulation passage, this fact leads to an achievement of a motion whose torque fluctuation is little and which is smooth.

[0039] Incidentally, in the rolling element spacer **5** of the aforesaid 1st embodiment, the annular groove **53** is formed between the ball holding seat **50** and the dropout prevention portion **52**, and the annular lubricating oil sump **51** is formed in the ball holding seat **50** but, as shown in **FIG. 9**, the annular groove **53** and the lubricating oil sump **51** may be omitted in the invention. However, even in this case, as shown in **FIG. 10**, the dropout prevention portion **52** does not contact with the spherical face of the ball **2** seated on the ball holding seat **50**, and a gap is formed between the dropout prevention portion **52** and the spherical face of the ball **2**. By this, since the lubricant such as grease adhered on the ball **2** enters into the gap, the lubricant becomes liable to be drawn into between the ball **2** and the ball holding seat **50** which mutually sliding-contact although an amount of the lubricant held in the gap is reduced in comparison with a case in which the annular groove **53** is formed, so that it becomes possible to surely lubricate between the ball **2** and the rolling element spacer **5**.

[0040] **FIG. 11** shows a 2 nd embodiment of the rolling element spacer of the invention.

[0041] In the rolling element spacer **5** of the aforesaid 1st embodiment, the ball holding seat **50** and the dropout prevention portion **52** are injection-molded integrally from a single synthetic resin. However, in a rolling element spacer **6** of the 2nd embodiment, the ball holding seat **50** and the dropout prevention portion **52** are molded respectively by different synthetic resins. Incidentally, since other constitutions are common to the rolling element spacer **5** of the 1st embodiment, the same reference numerals as the 1st embodiment are affixed in **FIG. 11**, and detailed explanations thereof are omitted here.

[0042] Since the rolling element spacer performs a role of cushion between the mutually adjoining balls **2** to there by reduce generations of fatigue and noise of the balls **2** owing to a collision, it is preferable that the ball holding seat **50** is formed of a suitably soft material in order to be able to sufficiently exhibit this function. However, since the dropout prevention portion **52** is one which, in case that a spacing between the mutually adjoining balls **2** becomes increased, engages with the ball **2** to thereby prevent the rolling element spacer from falling out, it is preferable that it is formed of a hard material in order not to be deformed easily. Here, as an aim of selecting a resin material for molding the dropout prevention portion and the ball holding seat, a bending modulus of elasticity of such a synthetic resin can be made the aim. That is, this is because it is considered that a material whose bending modulus of elasticity is small deforms easily, while a material whose bending modulus of elasticity is large is difficult to deform.

[0043] Accordingly, according to the rolling element spacer **6** of the 2nd embodiment, the dropout prevention portion **52** can be molded by a hard synthetic resin in comparison with the ball holding seat **50**, so that it become possible to exhibit in maximum the functions of the respective portions.

What is claimed is:

1. A rolling element spacer used in a rolling guide device in which a pair of members perform a relative continuous motion through an endlessly circulating ball row, interposed between balls mutually adjoining in its endless circulation passage, and circulating together with the balls,

characterized in that it has a pair of ball holding seats each of which is formed in a concave spherical face form nearly approximating a spherical face of the ball and sliding-contacts with the ball, and

around each ball holding seat, there is formed an annular dropout prevention portion protruding in a ball arranging direction than an edge portion of the ball holding seat and kept in non-contact with respect to the ball seated on the ball holding seat.

2. A rolling element spacer set forth in claim 1, characterized in that an annular groove is formed between the ball holding seat and the dropout prevention portion, and the annular groove functions as a lubricating oil sump.

3. A rolling element spacer set forth in claim 1, characterized in that a lubricating oil sump is formed in the ball holding seat.

4. A rolling element spacer set forth in claim 1, characterized in that the ball holding seat and the dropout prevention portion are molded by different resin materials, and the dropout prevention portion is molded by the resin material harder than the ball holding seat.

LINEAR MOTION GUIDE DEVICE

FIELD OF THE INVENTION

[0001] The present invention relates to a motion guide device provided with a movable member having a body into which passage constituting members formed of resin material are assembled.

BACKGROUND ART

[0002] A motion guide device is provided with a track rail on which a rolling member rolling portion is formed and a movable block disposed to be movable along the track rail through a number of rolling members such as bolls or rollers. The movable block is formed with a loaded rolling member rolling portion corresponding to a rolling member rolling portion of the track rail, a rolling member escape passage formed in parallel to the loaded rolling member rolling portion with a predetermined space therefrom, and a pair of rolling member rolling direction changing passages each of which connects the loaded rolling member rolling portion and the rolling member escape passage to each other to thereby constitutes a rolling member circulation passage along which the rolling members circulate.

[0003] The applicant of the subject application has proposed a technology, such as Japanese Patent Laid-open Publication No. HEI 7-317762, in which support members (retainers) extending along both side edges of the rolling member rolling groove in a loaded area of the movable block, an escape passage constituting member constituting the escape passage of the rolling member, and inner periphery guide section constituting member constituting an inner periphery guide section of the rolling direction changing passage are integrally formed with a body of the movable block through a resin molding process.

[0004] However, in such movable block with which the resin portions or members are integrally formed, when the movable block body has a large size or scale, it is necessary to prepare a large-sized mold, which makes it difficult to manufacture such mold. Furthermore, the support members extending along both the side edges of the rolling member rolling groove have thin thickness and long length. Therefore, there may cause a case that resin may not sufficiently be supplied at the time of the molding, thus being also inconvenient.

[0005] In order to solve such problems or inconveniences mentioned above, the applicant of the subject application has also provided a motion guide device in which the support members, the escape passage constituting member and the inner periphery guide section constituting member, which are all formed of resin, were formed as separate units independent from the movable block body and then assembled with the movable block body to thereby make easy the molding process and constitute the movable block.

[0006] In such motion guide device, connecting portions of the support members, the escape passage constituting members and the inner periphery guide section constituting members are formed to be continuous so as to make smooth the circulation of the rolling members. That is, at least one of connecting portions of these members is integrally formed.

[0007] However, even in such structure, these support members, the escape passage constituting members and the inner periphery guide section constituting members have shapes different from each other and amounts (volumes) of resin shrinkage cavities thereof are also different from each other. Accordingly, in the case where the connecting portions of the support members, the escape passage constituting members and the inner periphery guide section constituting members are integrally formed, the thin and long support members and escape passage constituting members may be flexed and the inner periphery guide section constituting members may be opened, which constitutes a further problem. That is, since the rolling members circulate at high speed in the circulation passage constituted by such support members, escape passage constituting members and inner periphery guide section constituting members, such flexible structure of the support members and the escape passage constituting members and the opening (widening) of the inner periphery guide section constituting members will disturb the smooth circulation of the rolling members in the circulation passage.

DISCLOSURE OF THE INVENTION

[0008] The present invention has been conceived in consideration of the above matters, and an object of the present invention is to provide a motion guide device which can be easily manufactured even having a large scale and, moreover, in which the long and thin support members and escape passage constituting members are not flexed and the inner periphery guide section constituting members are not opened (widened).

[0009] Hereunder, the present invention will be described. Further, it is to be noted that although reference numerals used in the accompanying drawings are added to respective members or portions by applying ( ) for the sake of easy understanding of the present invention, the present invention is not limited to the embodiments shown in the drawings.

[0010] The above object can be achieved according to the present invention by providing a motion guide device which comprises a track member (**1**) provided with rolling member rolling portions (**1***b*, **1***b*) and a movable member (**2**) disposed to be movable along the track member (**1**) through a number of rolling members (**3** - - -) and in which the movable member (**2**) is provided with loaded rolling member rolling portions (**4***d*, **4***d*) corresponding to the rolling member rolling portions (**1***b*, **1***b*) of the track member (**1**), rolling member escape passages disposed in parallel to the loaded rolling member rolling portions (**4***d*, **4***d*) with a predetermined distance and a pair of direction changing passages connecting the loaded rolling member rolling portions (**4***d*, **4***d*) and the rolling member escape passages to thereby circulate the rolling members,

> [0011] wherein support members (**11**, **12**, **13**) extending along both side edges of the loaded rolling member rolling portions (**4***d*, **4***d*), escape passage constituting members (**14**, **14**) constituting the rolling member escape passages and a pair of inner periphery guide section constituting members (**15***a*, **15***a*) constituting the inner peripheral portions of the direction changing passages are formed to be independent from a body (**4**) of the movable member and also independent from each other and are assembled to the body (**4**) of the movable member.

[0012] According to this invention, since the support members, the escape passage constituting members and the inner periphery guide section constituting members are formed independently from the body of the movable member and from each other, these members can be manufactured by preliminarily calculating amounts of respective shrinkage cavities of the support members, the escape passage constituting members and the inner periphery guide section constituting members. As a result, the long and thin support members and escape passage constituting members can be prevented from being flexed, and the inner periphery guide section constituting members can be also prevented from being opened.

[0013] In one preferred embodiment of this invention, the support members act to prevent the rolling members **(3 - - -)** from coming off from the loaded rolling member rolling portions **(4*d*, 4*d*)** at a time when the movable member **(2)** is removed from the track member **(1)**.

[0014] In another preferred embodiment of this invention, either one of the inner periphery guide section constituting members **(15*a*, 15*a*)** and the body **(4)** of the movable member is formed with a positioning recess **(24)** for positioning the inner periphery guide section constituting members **(15*a*, 15*a*)** with respect to the body **(4)** of the movable member and the other one thereof is formed with a movable member body positioning protrusion **(23)** to be engaged with the movable member body positioning recess **(24)**; either one of the inner periphery guide section constituting members **(15*a*, 15*a*)** and the escape passage constituting members **(14, 14)** is formed with a positioning recess **(42)** for positioning the escape passage constituting members with respect to the inner periphery guide section constituting members **(15*a*, 15*a*)** and the other one thereof is formed with an escape passage constituting member positioning protrusion **(20)** to be engaged with the escape passage constituting member positioning recess **(42)**; and either one of the inner periphery guide section constituting members **(15*a*, 15*a*)** and the support members **(11, 12, 13)** are formed with positioning recesses **(11*b*, 13*b*, 25)** for positioning the support members **(11, 12, 13)** with respect to the inner periphery guide section constituting members **(15*a*, 15*a*)** and the other one thereof is formed with support member positioning protrusions **(26, 27, 12*b*)** to be engaged with the support member positioning recesses **(11*b*, 13*b*, 25)**.

[0015] According to the above embodiment, in the case where the support member, the escape passage constituting member and the inner periphery guide section constituting member are manufactured independently from the body of the movable member and also independently from each other, the number of constitutional members or parts increases and, hence, the assembling working may be made difficult. According to the present invention, however, since the support member and the escape passage constituting member are positioned with reference to the inner periphery guide section constituting member which is positioned to the body of the movable member, the working precision or performance of the support member, escape passage constituting member and inner periphery guide section constituting member can be improved. As a result, even in the case where the support member, the escape passage constituting member and the inner periphery guide section constituting member are manufactured independently from the body of the movable member and also independently from each other, these circulation passage constituting members never make worse the motion of the rolling members. Moreover, since the support member and the escape passage constituting member are positioned and assembled with the inner periphery guide section constituting member being one reference member, the support member, the escape passage constituting member and the inner periphery guide section constituting member can be easily assembled with high reproductivity.

[0016] Furthermore, in a further preferred embodiment of the present invention, a pair of side lids **(5, 5)** constituting outer periphery guide sections of the direction changing passages are mounted to both longitudinal end portions of the movable member body **(4)**, both the end portions of the support member **(11, 13)** are inserted into the side lids **(5, 5)**, and either one of the inner periphery guide section constituting members **(15*a*, 15*a*)** and the support members **(11, 13)** is formed with a positioning recess **(11*b*, 13*b*)** for positioning the support members with respect to the inner periphery guide section constituting members **(15*a*, 15*a*)** and the other one thereof is formed with support member positioning protrusions **(26, 27)** to be engaged with the support member positioning recesses **(11*b*, 13*b*)**.

[0017] According to this invention, since both the end portions of the support members are inserted into the paired side lids mounted to the body of the movable member, the support member can be firmly fixed thereto. Moreover, in the case where both the end portion of the support member are fitted into the side lids, when it is required to carry out the assembling working, it is necessary that the support member is once inserted into one of the side lids, the rolling members are fitted and, then, the other side lid is inserted into the other end portion of the support member. In the process that the other side lid is inserted, there is a fear that the support member falls down and, hence, the side lids may not be precisely fitted to the support member. According to this invention, however, the support member can be positioned by the inner periphery guide section and the side lids, so that the support member is supported at two portions, and accordingly, the fear of falling-down of the support member in the assembling process will be reduced. Thus, the side lids can be simultaneously inserted into a plurality of support members, enabling the assembling process to be easy.

[0018] Furthermore, in a preferred embodiment of this invention, a number of rolling members **(3, 3, - - -)** are held in series with predetermined distance by a rolling member support belt **(10)** having side edge portions **(10*d*)** projecting over both side end portions of the rolling members, and by assembling the support members **(11, 12, 13)** to the body **(4)** of the movable member, a guide section **(43)** for guiding the side edge portions **(10*d*)** of the rolling member support belt **(10)** is formed.

[0019] According to this invention, the rolling member support belt is held by the support member and the guide section formed by the body of the movable member, thus being prevented from coming off from the movable member. On the other hand, the rolling members can be held by the rolling member support belt, and accordingly, the rolling member support belt and the rolling members never come off from the movable member.

[0020] In a further preferred embodiment of the present invention, the track member is a track rail **(1)** and the movable member is a movable block **(2)** provided with a pair of sleeve portions disposed so as to oppose to both side surfaces of the track rail, the rolling member rolling portions are vertical two rows of rolling member rolling passages (**1**b, **1**b) formed on each of lateral side surfaces of the track rail (**1**), totally, four rows thereof, the loaded rolling member rolling portions are vertical two rows of loaded rolling member rolling passages (**4**d, **4**d) formed on each of inner side surfaces of the lateral sleeve portions (**2**b, **2**b) of the movable block (**2**), totally, four rows thereof, the escape passage constituting passage includes vertical two rows thereof formed on each of the lateral sleeve portions (**2**b, **2**b) of the movable block, totally, four rows thereof, the direction changing passages connect an upper loaded rolling member rolling passage and a lower rolling member escape passage (**14, 14**) and connect an lower loaded rolling member rolling passage and an upper rolling member escape passage so as to constitute grade separation structure, and the inner periphery guide section constituting member is composed of a pair of divided blocks (**15**a, **15**b) divided in the longitudinal direction of the track rail (**1**).

[**0021**] According to this invention, the inner periphery guide sections to which the direction changing passages in grade separation can be easily manufactured.

[**0022**] In a still further preferred embodiment of this invention, either one of the paired divided blocks (**15**a, **15**b) is formed with a positioning recess (**28**) for positioning the paired divided blocks and the other one thereof is formed with a divided block positioning protrusion (**33**) to be engaged with the divided block positioning recess (**28**).

[**0023**] According to this invention, even in the case of the divided inner periphery guide section, the inner periphery guide section can be assembled with high precision.

[**0024**] In a still further preferred embodiment of the present invention, the support members (**11, 12, 13**) include a first support member (**11**) disposed above the upper loaded rolling member rolling passage (**4**d), a second support member (**12**) disposed between the upper loaded rolling member rolling passage (**4**d) and the lower rolling member rolling passage (**4**d) and a third support member (**13**) disposed below the lower loaded rolling member rolling passage (**4**d).

[**0025**] According to this invention, the second support member is commonly utilized with the upper loaded rolling member rolling passage and the lower rolling member rolling passage, so that the number of the parts or members to be used can be reduced in comparison with the case where the second support members are disposed respectively to the upper loaded rolling member rolling passage and the lower rolling member rolling passage.

[**0026**] Still furthermore, the object of the present invention mentioned above can be also achieved by a motion guide device which comprises a track member (**1**) provided with rolling member rolling portions (**1**b, **1**b) and a movable member (**2**) disposed to be movable along the track member (**1**) through a number of rolling members (**3, 3**, - - -) and in which the movable member (**2**) is provided with loaded rolling member rolling portions (**4**d, **4**d) corresponding to the rolling member rolling portions (**1**b, **1**b) of the track member (**1**), rolling member escape passages disposed in parallel to the loaded rolling member rolling portions (**4**d, **4**d) with a predetermined distance and a pair of direction changing passages connecting the loaded rolling member rolling portions (**4**d, **4**d) and the rolling member escape passages to thereby circulate the rolling members,

[**0027**] wherein support members (**11, 12, 13**) extending along both side edges of the loaded rolling member rolling portions (**4**d, **4**d) and a pair of inner periphery guide section constituting members (**15**a, **15**b) constituting the inner peripheral portions of the direction changing passages are formed to be independent from a body (**4**) of the movable member and also independent from each other and are assembled to the body (**4**) of the movable member, and the rolling member escape passages are constituted by through holes perforated to the body (**4**) of the movable member.

[**0028**] According to this invention, since the support members and the inner periphery guide section constituting members are formed independently from the body of the movable member and from each other, these members can be manufactured by preliminarily calculating respective shrinkage cavities of the support members and the inner periphery guide section constituting members. As a result, the long and thin support members can be prevented from being flexed and the inner periphery guide section constituting members can be also prevented from being opened.

BRIEF DESCRIPTION OF THE DRAWINGS

[**0029**] In the accompanying drawings:

[**0030**] **FIG. 1** is a developed perspective view of a linear motion guide device according to a first embodiment of the present invention;

[**0031**] **FIG. 2** is a side (end) view, partially including a cross sectional area, of the linear motion guide device of **FIG. 1**;

[0062] **FIG. 20B** represents a state after the insertion; and

[0063] **FIG. 21** is a front view showing the inner periphery guide section constituting member to which the first and third support members are mounted.

[0064] **FIG. 22** is a disassembled view showing another example of the escape passage constituting members.

BEST MODE FOR EMBODYING THE INVENTION

[0065] **FIGS. 1 and 2** represent a linear motion guide device according to a first embodiment of a motion guide device of the present invention, and the linear motion guide device comprises a track rail **1** as a linearly extending track member and a movable block as a movable member assembled with the track rail **1** to be movable through a number of balls **3** as rolling members.

[0066] The track rail **1** has a longitudinally extending structure having approximately rectangular cross section, and the track rail **1** has both lateral side surfaces on which grooves **1***a* are respectively formed. The groove **1***a* has side wall sections **1***b*, **1***b* and bottom wall section **1***c*.

[0067] As shown in **FIG. 2**, the extensions of the side wall sections **1***b*, **1***b* of the groove **1***a* intersect each other at a right angle of 90° degrees, and in the illustration, upper and lower side wall sections **1***b*, **1***b* constitute roller rolling surfaces along which the rollers roll. That is, both the side surfaces of the track rail **1** are formed with two upper and lower roller rolling surfaces **1***b*, **1***b* as, totally, four rolling member rolling surfaces.

[0068] On the other hand, the movable block **2** is provided with a flat (horizontal) section **2***a* corresponding to the upper surface of the track rail **1** when assembled and a lateral pair of sleeve (skirt) sections **2***b*, **2***b* extending downward from both side ends of the flat section **2***a* so as to oppose to the side surfaces of the track rail **1**. The movable block **2** is composed of a block body **4** made of steel, a circulation passage forming structure made of resin (circulation passage structure, hereinlater) which is assembled with the block body **4** and a pair of side lids **5**, **5** with which the circulation passage structure is assembled. The side lids **5**, **5** may be called as end plates **5**, **5** which are mounted to both the longitudinal end portions of the block body **4**.

[0069] The sleeve sections **4***b*, **4***b* of the block body **4** are formed with projections **4***c*, **4***c* each having an outer shape substantially in conformity with the shape of the groove **1***a* formed on each side surface of the track rail. The projections **4***c* are formed with two loaded roller rolling surfaces **4***d*, **4***d*, as loaded rolling member rolling surfaces, corresponding to the roller rolling surfaces **1***b*, **1***b* of the track rail **1**. That is, upper and lower (two) loaded roller rolling surfaces **4***d*, **4***d* are formed on each of the lateral sleeve sections **4***b*, **4***b* of the block body **4**. (Totally, four surfaces **4***d*, **4***d* are formed).

[0070] Furthermore, each of the sleeve sections **2***b*, **2***b* of the movable block **4** is formed with upper and lower (two) roller escape passages **7**, **7** in parallel to the upper and lower loaded roller rolling surfaces **4***d,* **4***d,* respectively with a predetermined space and U-pipe-shaped direction changing passages **8, 8** connecting both end portions of the loaded roller rolling surfaces **4***d,* **4***d* and the roller escape passages **7, 7**, respectively, so as to circulate the rollers **3, 3**, - - - , **3**, as shown in **FIG. 3**. That is, these loaded roller rolling surfaces **4***d,* **4***d,* the paired rolling direction changing passages **8, 8** and the roller escape passages **7, 7** constitute a roller circulation passage.

[0071] The four, each two, rows of the upper and lower roller escape passages **7, 7** are formed on each of the lateral sleeve sections **2***b,* **2***b,* and the rolling direction changing passages **8, 8** are formed so as to connect the upper loaded roller rolling surface **4***b* and the lower roller escape passage **7** and connect the lower loaded roller rolling surface **4***b* and the upper roller escape passage **7** in the illustrated state, in which the flat section **2***a* of the movable member **2** is disposed upward, to thereby establish a grade separation arrangement.

[0072] Four, respectively two, roller circulation passages are formed on the lateral sleeve sections **2***b*, **2***b* of the block body **4**, and each of the roller circulation passages is formed in one plane so that the rollers **3, 3**, - - - , **3** circulate two-dimensionally along the roller circulation passages. A plane in which one of the roller circulation passages is positioned and another plane in which the other one of the roller circulation passages is arranged are crossed each other at the right angle, so that one of the roller circulation passages is positioned on the inner peripheral side of the other one.

[0073] With reference to **FIG. 3**, the rollers **3, 3**, - - - , **3** are arranged in series through a roller support (holding) belt **10**, as rolling member support belt, and the rollers **3, 3**, - - - , **3** circulate in the state held (retained) by the roller support belt **10**. The roller support belt **10** is composed of a flexible belt member **10***a* formed with roller holes into which the rollers are accommodated and held, respectively, and spacers **10***b,* **10***b* each disposed between the rollers in the roller holes. The flexible belt member **10***a* has side edge portions **10***d,* **10***d* positioned outside the axial ends of the rollers **3, 3**, - - - , **3**.

[0074] The resin circulation passage structure comprises: support members **11, 12** and **13** extending along both side edges of the loaded roller rolling surfaces **4***d*, **4***d* and preventing the rollers, **3, 3**, - - - , **3** from coming off from the loaded roller rolling surfaces **4***d*, **4***d* at a time when the movable block **2** is removed from the track rail **1**; escape passage constituting members **14, 14** constituting the roller escape passages; and a pair of inner periphery guide section constituting members **15***a* and **15***b* constituting the inner periphery guide sections of the rolling direction changing passages. The support members **11, 12, 13**, the escape passage constituting members **14, 14** and the paired inner periphery guide section constituting members **15***a*, **15***b* are formed respectively of resin independent from the block body **4**, and these members are assembled to the block body **4** after the molding processes thereof.

[0075] According to this first embodiment of the present invention mentioned above, the support members **11, 12, 13**, the escape passage constituting members **14, 14** and the paired inner periphery guide section constituting members **15***a,* **15***b* are formed of resin independently (separately) from the block body **4**, shrinkage cavities (shrinkage amounts) of these members can be preliminarily calculated and then manufactured through the molding process. As a result, the support members **11, 12** and **13** having thin and long extensions and the escape passage constituting members **14, 14** are not flexed or adversely bent, and moreover, the inner periphery guide section constituting members **15***a* and **15***b* are also not opened (widened).

[0076] In the support members **11, 12** and **13**, as shown in **FIGS. 1 and 2**, the first support member **11** supports the lower sides of the lower rollers **3, 3**, - - - , **3**, the second support member **12** supports the upper sides of the lower rollers **3, 3**, - - - , **3** and the lower sides of the upper rollers **3, 3**, - - - , **3** and the third support member **13** supports the upper sides of the upper rollers **3, 3**, - - - , **3**.

[0077] **FIG. 4** shows the first support member **11**. The first support member **11** is formed of a resin material so as to provide a thin structure having a long scale. By incorporating the first support member **11** into the block body **4**, a guide groove for guiding the side edge portion of the roller support belt is formed. This first support member **11** is mounted to the movable block **2** in a state that the first support member **11** is disposed between both the side lids **5, 5** and supported thereby at both longitudinal ends thereof. The first support member **11** is formed, at both end portions thereof, with protruded portions **11***a,* **11***a,* which are to be fitted into the side lids **5, 5**. Furthermore, the side surface portions of the first support member **11** are formed with recessed portions such as slots **11***b,* **11***b* for positioning the first support member **11** with respect to the inner periphery guide section constituting members **15***a* and **15***b*.

[0078] **FIG. 5** shows the second support member **12**. The second support member **12** is also formed of a resin material so as to provide a thin structure having a long scale. The second support member **12** has both side portions on which guide grooves **12***a,* **12***a* are formed for guiding the side edge portions of the roller support belt **10**. This second support member **12** is mounted to the movable block **2** in a state that the second support member **12** is disposed between the paired inner periphery guide section constituting members **15***a*, **15***a* and supported thereby at both longitudinal ends thereof. The second support member **12** is formed, at both end portions thereof, with protruded portions (protrusion) **12***b,* **12***b,* which are to be fitted into the inner periphery guide section constituting members **15***a,* **15***a*. Each of the protrusions **12***b,* **12***b* has a portion of rectangular section and a portion of circular section.

[0079] **FIG. 6** shows the third support member **13**. The third support member **13** is also formed of a resin material so as to provide a thin structure having a long scale. By incorporating the third support member **13** into the block body **4**, a guide groove for guiding the side edge portions of the roller support belt **10** is formed. This third support member **13**, like the first support member **11**, is mounted to the movable block **2** in a state of being disposed between both the side lids **5, 5** and supported thereby at both longitudinal ends thereof. The third support member **13** is formed, at both end portions thereof, with protruded portions **13***a,* **13***a,* which are to be fitted into the side lids **5, 5**. Furthermore, the side surface portions of the third support member **13** are formed with recessed portions such as slots

13*b*, **13***b* for positioning the third support member **13** with respect to the inner periphery guide section constituting member **15***a*, **15***a*.

[**0080**] As shown in **FIG. 1**, the escape passage constituting members **14**, **14** are composed of a pair of pipe halves **14***a*, **14***b* formed by dividing a pipe along the axial direction of the pipe. Each of these pipe halves **14***a*, **14***b* is provided with a groove conformed with the shape of the roller **3** in the axial direction, a guide groove guiding a belt side edge portion **10***d* and a flange **19** extending in the longitudinal direction along both the side edges of the grooves. Each of these pipe halves **14***a*, **14***b* has a length slightly longer than the length of the block body **4**. The escape passage constituting members **14**, **14**, each being formed by assembling the pipe halves **14***a*, **14***b*, are positioned at their both end portions to recessed portions **42**, **42** (mentioned hereinlater) of the inner periphery guide section constituting members **15***a*, **15***a*, and, in a state that both the end portions of the escape passage constituting members are supported, are fixed to the movable block **2** through the inner periphery guide section constituting members **15***a*, **15***a*. To both the end portions of the escape passage constituting members **14**, **14** are formed positioning protrusion (protruded portions) **20** for positioning the escape passage constituting members **14**, **14** with respect to the inner periphery guide section constituting members **15***a*, **15***a*.

[**0081**] **FIGS. 7 and 8** represent the inner periphery guide section constituting members **15***a* and **15***b*, respectively. Each of the inner periphery guide section constituting members **15***a* and **15***b* is composed of a divided blocks divided into tow parts along the longitudinal direction of the track rail **1**. These two divided blocks are combined, and the U-shaped direction changing passages, which have grade separation structures, are formed. The grade separation direction changing passages have rectangular shapes in cross sections. Furthermore, The direction changing passage is formed with a guide groove for guiding the side edge portions **10***d*, **10***d* of the roller support belt **10**.

[**0082**] **FIG. 7** shows an inner side divided block (i.e., the inner periphery guide section constituting member). The divided block **15***a* on the side of the movable block **2** (i.e., inner side divided block) is formed with an inner periphery guide section **21** of the inner peripheral side roller circulation passage. This inner periphery guide section **21** is formed to provide approximately semicircular shape. The inner side divided block **15***a* has a front surface portion **22** abutting against the block body **4** and the front surface portion **22** is formed with positioning protrusions (protruded portions) **23** for positioning the divided block with respect to the block body **4**. The block body **4** is formed with positioning recessed portions for positioning the block body to be fitted to the positioning protrusions **23** (see **FIG. 1**). Further, there are also formed, on the front surface portion **22**, positioning recessed portions **42**, **42** for positioning escape passage groove constituting members **14**, **14**, to which are fitted the positioning protrusions **20**, **20**, mentioned hereinbefore, for positioning the escape passage section constituting members **14**, **14**. The positioning protrusions **20**, **20** for positioning the escape passage groove constituting members **14**, **14** have flanged portions which are fitted to expanded portions **42***a*, **42***a* of the recessed portions for positioning the escape passage section constituting members, whereby the escape passage section constituting members **14**, **14** are prevented from being rotated. Furthermore, the front surface portion **22** is further formed with a positioning recess **25** for positioning a second support member **12** with respect to the divided block **15***a*, and this second support member positioning recess **25** is fitted with the second support member positioning protrusion **12***b* mentioned hereinbefore. The divided block **15***a* is formed, at its side surface, with a first support member positioning protrusion **26** for positioning the first support member **11** and a third support member positioning protrusion **27** for positioning the third support member **13** with respect to the divided block **15***a*. These first and third support member positioning protrusions **26** and **27** are fitted to the first and third support member positioning recesses **11***b* and **13***b*, respectively. Further, divided block positioning recesses **28**, **28** for positioning the other, i.e. outer divided block **15***b* with respect to the inner divided block **15***a* are formed on the back surface of the divided block **15***a*.

[**0083**] **FIG. 8** represents the outer (side lid side) divided block **15***b*. The outer divided block **15***b* is formed with an outer periphery guide section **31** of the inner side roller circulation passage and an inner periphery guide section **32** of the outer side roller circulation passage. These inner and outer periphery guide sections **32** and **31** have substantially semi-circular shapes. Further, the outer divided block **15***b* is formed with divided block positioning protrusions **33**, **33** fitted to the divided block positioning recesses **28**, **28** formed on the inner side divided block **15***a*. Furthermore, side lid positioning protrusions **34**, **34** for positioning the outer divided block **15***b* with respect to the side lids **5**, **5** are formed on the back surface of the outer divided block **15***b*.

[**0084**] **FIG. 9** represents the side lid (i.e., longitudinal endplate) **5** having a sectional shape corresponding to that of the block body **4** and provided with horizontal flat portion **5***a* and a sleeve, i.e. side skirt, portions **5***b*, **5***b*, on which outer periphery guide section **36**, **36** of the outer peripheral side roller circulation passage is formed. Furthermore, the inner periphery guide section constituting members **15***a* and **15***b* in the state assembled together are fitted to these sleeve portions **5***b*, **5***b*. The sleeve portions **5***b*, **5***b* are formed with side lid positioning recesses **37**, **37** for positioning the side lid **5** which are fitted with the side lid positioning protrusions **34**, **34** formed on the outer divided block **15***b*. Still furthermore, the sleeve portions **5***b*, **5***b* are formed with recesses **39** and **40** into which the protrusions **11***a* and **13***a* of the first and third support members **11** and **13** are forcibly inserted.

[**0085**] As shown in **FIG. 1**, the side lids **5**, **5** are mounted to both longitudinal ends of the block body **4**. Bolts are inserted into bolt insertion holes formed on the side lids **5**, **5** and the bolts are screwed into screw holes formed on the end surfaces of the block body **4**, whereby the side lids **5**, **5** are fastened and fixed to the block body **4**, and accordingly, the inner periphery guide section constituting members **15***a*, **15***b* are fixed to the block body **4**. Further, decorative plates **38**, **38** are attached to the outer side portions of the side lids **5**, **5**.

[**0086**] Incidentally, in a case where the support members **11**, **12**, **13**, the escape passage constituting members **14**, **14**, and the inner periphery guide section constituting members **15***a*, **15***b* are formed out of resin material independently from the block body **4** and also independently from each other, there may cause fears such that the number of constitutional members or parts for constituting the motion guide device is increased and the assembling working thereof will be made difficult and troublesome. On the other hand, according to the present invention, as mentioned above, the support members **11**, **12**, **13** and the escape passage constituting members **14**, **14** are positioned with reference to the inner periphery guide section constituting member **15***a* which is positioned to the block body **4**, so that the support members **11**, **12**, **13** and the escape passage constituting members **14**, **14** can be positioned with high precision to the block body **4**. As a result, even in the case where the support members **11**, **12**, **13**, the escape passage constituting members **14**, **14**, and the inner periphery guide section constituting members **15***a*, **15***b* are formed independently from the block body **4** and from each other, these circulation passage forming members do not interfere the motion of the rollers. Furthermore, the support members **11**, **12**, **13** and the escape passage constituting members **14**, **14** are positioned and assembled with the inner periphery guide section constituting member **15***a* being as one reference member, so that the inner periphery guide section constituting members **15***a*, **15***b*, the support members **11**, **12**, **13** and the escape passage constituting members **14**, **14** can be easily assembled with high reproductivity.

[0087] The roller support belt **10** is supported by guide grooves **43** (**FIG. 21**) formed by the support members **11**, **12**, **13** and the block body **14** so as to prevent rollers **3**, **3**, - - - , **3** from coming of f from the movable block **2**. The rollers **3**, **3**, - - - , **3** are supported by the roller support belt **10**. Accordingly, the roller support belt **10** and the rollers **3**, **3**, - - - , **3** never come off from the movable block **2**. Further, the rollers **3**, **3**, - - - , **3** are guided in the predetermined track by the contact of the support members **11**, **12**, **13** at the axial end surfaces of the rollers **3**, and hence, the generation of inclination of the rollers **3** with respect to their rotation axes, so-called, the generation of skew can be prevented.

[0088] Next, the method of assembling such motion guide device will be described hereunder. The assembling of the motion guide device is performed along the steps or processes represented by FIGS. **10** to **16**.

[0089] First, as shown in **FIG. 10**, the inner divided blocks **15***a*-**1**L and **15***a*-**1**R of the inner periphery guide section constituting member are fixed to one end side, and to left and right sides, of the block body **4**. Further, it is to be noted, for the sake of easy understanding of the explanation, that references "-**1**" and "-**2**" are additionally applied to the reference numerals of the respective members or elements which are disposed to one and the other end sides of the block body **4** and, furthermore, the capitals "L" and "R" are further added to "-**1**" and "-**2**" to elements or members disposed on left and right sides of the block body **4**, for example, as shown in **FIG. 10**, such as **15***a*-**1**L or **15***a*-**1**R.

[0090] The mounting of these divided blocks **15***a*-**1**L and **15***a*-**1**R with respect to the block body **4** will be completed by fitting the positioning protrusions **23** formed on the divided blocks **15***a*-**1**L and **15***a*-**1**R into the positioning recesses **24** formed on the end surfaces of the block body **4**.

[0091] In the next step shown in **FIG. 11**, the escape passage constituting members **14** are inserted respectively into four slots (long holes) of the block body **4** from the side opposite to the other side of the block body **4**, i.e., mounting side of the divided blocks **15***a*-**1**L and **15**-**1**R. These escape passage constituting members **14** are each composed of pipe members **14***a*, **14***b* in combination thereof, and the positioning protrusions **20** for positioning the escape passage constituting members **14** are engaged with the positioning recesses **42** for positioning the escape passage constituting members of the divided blocks **15***a*-**1**L and **15***a*-**1**R with the positioning protrusions **20** being disposed upper side.

[0092] Further, as shown in **FIG. 11, a** pair of second support members **12** are mounted. More in detail, as shown in **FIG. 17**, the positioning protrusions **12***b* for positioning the second support members on one end side of the second support members **12** are engaged with the second positioning recesses **25** formed on the divided blocks **15***a*-**1**L and **15***a*-**1**R with the positioning protrusions **12***b* being disposed upper side.

[0093] Next, with reference to **FIG. 12**, the inner divided blocks **15***a*-**2**L and **15***a*-**2**R of the other side lateral inner periphery guide section constituting members are mounted to the other side end portions of the block body **4**. These divided blocks **15***a*-**2**L and **15***a*-**2**R are also positioned to the block body **4**, as like as the divided blocks **15***a*-**1**L and **15***a*-**1**R mentioned before, by fitting the positioning protrusions **23** formed on the divided blocks into the positioning recesses **24** formed on the block body **4**. Furthermore, the positioning recesses **42** for the escape passage constituting members of the divided blocks **15***a*-**2**L and **15***a*-**2**R are then engaged with the positioning protrusions **20** of the other end side escape passage constituting members **14** which have already been mounted to the block body **4**, respectively, and at the same time, the positioning recesses **25** of the-respective second support members of the divided blocks **15***a*-**2**L and **15***a*-**2**R are engaged with the protrusions for positioning the second support member on the other side thereof. According to the described manner, the respective inner divided blocks **15***a*-**1**L, **15***a*-**1**R, **15***a*-**2**L, **15***a*-**2**R, the escape passage constituting members **14** and the second support members **12** are united with respect to the block body **4** in the firm engaging state requiring no pressing force of, for example, finger pressing to thereby prevent them from coming off from the block body **4**.

[0094] Under the state mentioned above, as shown in **FIG. 13**, the first support member **11** and the third support member **13** are mounted to the block body **4**. Specifically, for example, with respect to the first support member **11**, as shown in FIGS. **18**(*a*) and (*b*), the positioning recesses **11***b* for positioning the first support member formed on both end portions of the first support member **11** are engaged with the positioning protrusions **26** for positioning the first support member of the divided block **15***a*-**1**L (further, since substantially the same is applicable to the other divided blocks **15***a*-**1**R, **15***a*-**2**L and **15***a*-**2**R, only the case of the divided block **15***a*-**1**L will be discussed herein).

[0095] Furthermore, as shown in **FIG. 19**, substantially the same matter as that mentioned above will be described with respect to the third support member **13**. That is, the positioning recesses **13***b* for positioning the third support member formed on both end portions of the third support member **13** are engaged with the positioning protrusions **27** for positioning the third support member of the divided block **15***a*-**1**L (further, substantially the same is applicable to the other divided blocks **15***a*-**1**R, **15***a*-**2**L and **15***a*-**2**R).

[0096] Further, the engagements between the recesses **11***b* for positioning the first support member and the positioning protrusions **26** for positioning the first support member and between the recesses **13***b* for positioning the third support member and the positioning protrusions **27** for positioning the third support member are made with a little close fit state, and after the fitting, these support members never come off from the block body, with no support, by means of, for example, fingers.

[0097] Next, as shown in **FIG. 14**, the outer divided blocks **15***b*-**1**L, **15***b*-**1**R of the inner periphery guide section constituting members are mounted to bilateral both sides on one end side portion of the block body **4**, and the side lid **5-1** is further attached to this one end side portion. More in detail, with reference to the divided blocks **15***b*-**1**L and **15***b*-**1**R, the divided block positioning protrusions **33** formed thereto are engaged with the divided block positioning recesses **28** formed on the inner divided blocks **15***a*-**1**L and **15***a*-**1**R, respectively. On the other hand, with reference to the side lid **5-1**, as shown in FIGS. **20**(*a*) and (*b*), the protrusions **11***a* and **13***a* formed on the first and third support members **11** and **13** are inserted into and then mounted to the recesses **39** and **40**, respectively, formed on the divided blocks **15***a*-**1**L and **15***a*-**1**R, and then, fastened to the block body **4** by means of bolts.

[0098] Thereafter, as shown in **FIG. 15**, the rollers **3**, **3**, - - - , **3** (four rows) aligned and supported by the roller support belts **10** are inserted into the respective roller circulation passages from the other side of the block body **4**, i.e. the side opposite to the side lid mounting side.

[0099] Then, as shown in **FIG. 16**, the outer periphery divided blocks **15***b*-**2**L, **15***b*-**2**R and the side lid **5-2** are mounted to the other side end portion of the block body **4**. The mounting of these outer periphery divided blocks **15***b*-**2**L, **15***b*-**2**R and the side lid **5-2** is performed by substantially the same manner as that performed for the mounting of the outer periphery divided blocks **15***b*-**1**L, **15***b*-**1**R and the side lid **5-1** on the one side of the block body **4** mentioned before. Now, since the support members **11** and **13** are positioned by the inner divided blocks **15***a*-**1**L, **15***a*-**1**R and the side lid **5-1**, the support members are positioned at two portions in the longitudinal direction thereof. Accordingly, in the assembling process, there is no fear of tilting (falling) and the side lid **5-2** can be simultaneously inserted into a plurality of support members **11** and **13**, thus making easy the assembling process.

[0100] **FIG. 21** represents the inner periphery guide section constituting member **15***a* mounted with the first, second and third support members **11**, **12** and **13**. By assembling the inner periphery guide section constituting member **15***a* mounted with the first, second and third support members **11**, **12** and **13**, the guide grooves **43**, **43**,—guiding the side edge portions **10***d* of the belt portions **10***a* of the roller support belts **10** in the loaded area are formed. The guide groove **43** can attain the functions of preventing the roller support belt **10** from being swung at the time of rolling motion of the rollers **3**, **3**, - - - , **3** and preventing the belt portion **10***a* from coming off through engagement of the side edge portion **10***d* of the belt portion **10** at the time of removing the movable block **2** from the track rail **1**. The rollers **3** are held by the roller support belt **10** so as not to come off therefrom to thereby support without coming off from the movable block **2** by way of the roller support belt **10**.

[0101] **FIG. 22** shows a disassembled view of another example of the escape passage constituting member. This escape passage constituting member **50** is composed, as like as the escape passage constituting member **14** mentioned hereinbefore, by assembling a pair of pipe halves **50***a*, **50***b* divided in a direction perpendicular to the axial direction of a pipe. The respective pipe halves **50***a*, **50***b* have flanged portions **53**, **53** on which positioning protrusion and recess **51** and **52** are formed, respectively. The flanged portions **53**, **53** constituting the divided surfaces of the pipe halves **50***a*, **50***b* intersect at right angle with respect to the axial line RC of the roller **3** so as to be parallel to a plane including the circulation passage. The escape passage constituting member **50** is formed bilaterally asymmetrically with respect to the axial line RC of the roller **3**. According to such structure, the escape passage constituting member **50** has a shape different on the inner peripheral side **55** and the outer peripheral side **54** of the circulation passage. As shown in **FIG. 11** mentioned before, the escape passage constituting member **50** is inserted into four slots **4***a* of the block body **4**. The positioning recesses **42** for positioning the escape passage constituting member, in conformity with the sectional shape thereof, are formed on the inner divided blocks **15***a*-**1**L and **15***a*-**1**R so as to be fitted with the positioning protrusions formed on both the axial end portions of the escape passage constituting member **50**.

[0102] As shown in **FIG. 22**, according to the structure in which the inner peripheral side **55** and the outer peripheral side **54** of the circulation passage of the escape passage constituting member **50** are made different in shapes from each other, there is no fear of causing the erroneous insertion of the inner peripheral side **55** and the outer peripheral side **54** of the escape passage constituting member **50** during the insertion working thereof into the block body **4**. On the other hand, in an arrangement in which the escape passage constituting member **50** is formed laterally symmetrically with respect to the axial line RC of the roller **3**, it is inevitable to cause a fear of erroneous insertion of the inner peripheral side **55** and the outer peripheral side **54** of the escape passage constituting member **50** during the insertion working thereof into the block body **4**.

[0103] Further, in the described embodiment, although four rows of the roller rolling surfaces **1***b*, **1***b* and the loaded roller rolling surfaces **4***d*, **4***d* are formed (two in each lateral side), the number of these rows may be variously set on the basis of kinds of rolling motion guide devices. Furthermore, although the inner periphery guide section constituting members **15***a*, **15***b* are divided into two blocks and the direction changing passages are formed on the inner periphery guide section constituting members **15***a*, **15***b* so as to intersect as grade separation structure, it is not necessary to divide the inner periphery guide section constituting members **15***a*, **15***b* in accordance with the form of the circulation passage. Still furthermore, balls may be also utilized as rolling members in place of the rollers **3**.

[0104] Moreover, in the described embodiment, although the linear motion guide device was described, the present invention may be applied to a curvilinear motion guide device guiding a curved motion.

[0105] Furthermore, in the described embodiment, although the escape passage is composed of a pipe-shaped escape passage constituting member, the escape passage may be formed by a through-hole perforated in the block body.

[0106] As mentioned hereinbefore, according to the present invention, the support members, the escape passage constituting members and the inner periphery guide section constituting members constituting the rolling member circulation passages are formed respectively of resin material independent (separately) from the body of the movable member and these members are assembled with the body of the movable member. Accordingly, the respective shrinkage cavity amounts of the support members, the escape passage constituting members and the direction changing passages are preliminarily calculated and manufactured according thereto. As a result, the thin and long-scale support members and escape passage constituting members can be prevented from being bent or flexed and the inner periphery guide section constituting members can be also prevented from being opened.

1. A motion guide device which comprises a track member provided with a rolling member rolling portion and a movable member disposed to be movable along the track member through a number of rolling members and in which said movable member is provided with a loaded rolling member rolling portion corresponding to the rolling member rolling portion of the track member, a rolling member escape passage disposed in parallel to the loaded rolling member rolling portion with a predetermined distance and a pair of direction changing passages connecting the loaded rolling member rolling portion and the rolling member escape passage to thereby circulate the rolling members,

wherein support members extending along both side edges of the loaded rolling member rolling portion, escape passage constituting members constituting the rolling member escape passages and a pair of inner periphery guide section constituting members constituting the inner peripheral portions of the direction changing passages are formed to be independent from a body of the movable member and also independent from each other and are assembled to the body of the movable member.

2. A motion guide device according to claim 1, wherein said support members act to prevent the rolling members from coming off from the loaded rolling member rolling portion at a time when the movable member is removed from the track member.

3. A motion guide device according to claim 1 or **2**, wherein:

either one of the inner periphery guide section constituting member and the body of the movable member is formed with a positioning recess for positioning the inner periphery guide section constituting member with respect to the body of the movable member and the other one thereof is formed with a movable member body positioning protrusion to be engaged with said movable member body positioning recess;

either one of the inner periphery guide section constituting member and the escape passage constituting member is formed with a positioning recess for positioning the escape passage constituting member with respect to the inner periphery guide section constituting member and the other one thereof is formed with an escape passage constituting member positioning protrusion to be engaged with said escape passage constituting member positioning recess; and

either one of the inner periphery guide section constituting member and the support member is formed with a positioning recess for positioning the support member with respect to the inner periphery guide section constituting member and the other one thereof is formed with a support member positioning protrusion to be engaged with said support member positioning recess.

4. A motion guide device according to claim 1 or **2**, wherein a pair of side lids constituting outer periphery guide sections of the direction changing passages are mounted to both longitudinal end portions of the movable member body, both the end portions of said support member are inserted into said side lids, and either one of the inner periphery guide section constituting member and the support member is formed with a positioning recess for positioning the support member with respect to the inner periphery guide section constituting member and the other one thereof is formed with a support member positioning protrusion to be engaged with said support member positioning recess.

5. A motion guide device according to any one of claims 1 to 4, wherein a number of rolling members are held in series with predetermined distance by a rolling member support belt having side edge portions projecting over both side end portions of the rolling members, and by assembling the support member to the body of the movable member, a guide section for guiding the side edge portions of the rolling member support belt is formed.

6. A motion guide device according to claim 1 to **5**, wherein said track member is a track rail and said movable member is a movable block provided with a pair of sleeve portions disposed so as to oppose to both side surfaces of the track rail, said rolling member rolling portion includes vertical two rows of rolling member rolling passages formed on each of lateral side surfaces of the track rail, totally, four rows thereof, said loaded rolling member rolling portion includes vertical two rows of loaded rolling member rolling passages formed on each of inner side surfaces of the lateral sleeve portions of the movable block, totally, four rows thereof, said escape passage constituting passage includes vertical two rows thereof formed on each of the lateral sleeve portions of the movable block, totally, four rows thereof, said direction changing passages connect an upper loaded rolling member rolling passage and a lower rolling member escape passage and connect an lower loaded rolling member rolling passage and an upper rolling member escape passage so as to provide a grade separation structure, and said inner periphery guide section constituting member is composed of a pair of divided blocks divided in the longitudinal direction of the track rail.

7. A motion guide device according to claim 6, wherein either one of said paired divided blocks is formed with a divided block positioning recess and the other one thereof is formed with a divided block positioning protrusion to be engaged with the divided block positioning recess.

8. A motion guide device according to claim 6 or **7**, wherein said support members include a first support member disposed above the upper loaded rolling member rolling passage, a second support member disposed between the upper loaded rolling member rolling passage and the lower rolling member rolling passage and a third support member disposed below the lower loaded rolling member rolling passage.

9. A motion guide device which comprises a track member provided with a rolling member rolling portion and a movable member disposed to be movable along the track member through a number of rolling members and in which said movable member is provided with a loaded rolling member rolling portion corresponding to the rolling member rolling portion of the track member, a rolling member escape passage disposed in parallel to the loaded rolling member rolling portion with a predetermined distance and a pair of direction changing passages connecting the loaded rolling member rolling portion and the rolling member escape passage to thereby circulate the rolling members,

wherein support members extending along both side edges of the loaded rolling member rolling portion and a pair of inner periphery guide section constituting members constituting the inner peripheral portions of the direction changing passages are formed to be independent from a body of the movable member and also independent from each other and are assembled to the body of the movable member, and said rolling member escape passage is constituted by a through hole perforated to the body of the movable member.

(57) **ABSTRACT**

This invention relates to a dust preventing structure of a guide unit comprising a track shaft and a sliding member engaging the track shaft via a plurality of rolling bodies such that it is capable of reciprocating in a length direction thereof. Elastic members in firm contact with the track shaft are overlaid in the length direction of the track shaft. A lubricant pocket forming member having a concave groove portion for forming a lubricant pocket constituted of the elastic members and filled with lubricant by a help of the surface of the track shaft as well is provided so as to achieve a smooth reciprocating motion of the sliding member with respect to the track shaft with less sliding friction. Particularly, under even a severe use condition in which use of coolant is required or dust, dirt, wooden pieces, cutting powder or the like falls on the guide unit, a smooth reciprocating motion of the sliding member with respect to the track shaft can be maintained in a long period.

DUST PREVENTING STRUCTURE OF GUIDE UNIT

BACKGROUND OF THE INVENTION

[0001] The present invention relates to a guide unit in which a track shaft and a sliding member are engaged with each other such that they are capable of relatively reciprocating via rolling bodies such as balls or rollers of ball bearing, ball bushing, ball screw, ball spline, roller bearing or the like for linear sliding and curved sliding, and more particularly to a dust preventing structure of a guide unit for removing foreign matter adhering to the surface of the track shaft and applying lubricating performance between the track shaft and sliding member.

[0002] This kind of the guide units are used in various fields requiring a linear motion, rotary motion, a curved motion and the like and their use conditions are diversified. For example, a guide unit of linear sliding type ball bearing for use in semiconductor manufacturing apparatus is used under a very clean environment, a guide unit of machine tool is used under an environment in which coolant is used and further, a guide unit of timber processing unit is used under a condition in which dust, dirt, wooden pieces, cutting powder and the like falls thereon.

[0003] In such a guide unit, if foreign matter such as coolant and dust invades into a gap between the track shaft and sliding member, the coolant repels lubricant or foreign matter absorbs lubricant, so that lubricity between the track shaft and sliding member drops considerably. As a result, rolling bodies such as balls or rollers bearing a load between the track shaft and sliding member or the track shaft in which the rolling bodies roll and the rolling groove in the sliding member side are worn abnormally thereby the service life of the unit dropping remarkably.

[0004] Thus, in a conventional linear sliding motion ball bearing comprising a track rail (track shaft) in which a ball rolling groove is formed in the length direction thereof and a sliding base (sliding member) in which a ball infinite circulation path constituted of a load rolling groove opposing the ball rolling groove in the aforementioned track rail via a plurality of balls, a direction changing path disposed at beginning and terminal ends of the load rolling groove and a ball return path connecting these direction changing paths is formed, sealing members made of rubber or the like are attached to both ends in the traveling direction of the sliding base so that they are in firm contact with the track rail, thereby removing coolant, dust and the like adhering to the surface of the track rail in the accordance the movement of the sliding base to prevent them from invading into the interior of the sliding base.

[0005] In case where, in this kind of the guide unit, foreign matter such as welding spatter or the like adheres to the track rail, if the aforementioned sealing member makes contact with the spatter, it may be caught thereby and damaged. To avoid such an inconvenience, according to another known structure of the guide unit, a scraper member made of metal or the like is attached outside of the sealing member of the sliding base with a slight gap with respect to the track rail, so that the foreign matter such as welding spatter adhering to the track rail is scraped out by this scraper member before the sealing member comes into contact with the spatter.

[0006] Because this kind of the sealing member keeps a firm contact with the track shaft (track rail in the previous example), lubricant such as lubricating oil and grease supplied inside the sliding member (sliding base in the previous example) and adhering to the surface of the track shaft is wiped off by a sealing member at the rear side of the sliding member in the advancement direction so as to prevent the lubricant from leaking out of the sliding member (lubricant leakage preventing function).

[0007] This lubricant leakage preventing function of this sealing member exerts an effect of using lubricant supplied inside the sliding member effectively. If an attention is paid to a sealing member located at the front side in the advancement direction when the sliding member reciprocates, it comes that this sealing member moves with a firm contact with the surface of the track shaft after lubricant is wiped off, so that friction resistance increases as compared to the sealing member located at the rear side in the advancement direction. As a result, a smooth reciprocation of the sliding member is prevented and if a reciprocating stroke is extremely long, the sealing member located at the front side in the advancement direction may be damaged by a friction caused between the sealing member and the track shaft or the service life of the sealing member may be shortened extremely.

[0008] This problem occurs like a case in which a scraper member made of metal, plastics or the like is used with the sealing member. Although the scraper member is capable of removing a large foreign matter such as spatter, because it cannot be mounted in a firm contact with the surface of the track shaft, it is not capable of removing small dust or dirt and when the sliding member reciprocates, the sealing member located at the front side in the advancement direction comes into contact with the small dust or dirt, so that friction resistance increases thereby the service life being reduced.

[0009] If the guide unit is used under a condition in which use of coolant is required or under an environment in which dust, dirt, wooden pieces, cutting powder or the like falls, this problem is very conceivable because after the sealing member wipes off, a slight amount of lubricant remaining on the surface of the track shaft is washed off by those foreign matters or absorbed. This problem needs to be solved to accelerate maintenance free about lubricant in a guide unit for use under such a severe condition.

OBJECT AND SUMMARY OF THE INVENTION

[0010] Accordingly, the inventor of the present invention considered a solution of this problem earnestly. As a result, the inventor of the present invention has completed a dust preventing structure of a guide unit capable of achieving a smooth reciprocation with less friction resistance of the sliding member with respect to the track shaft, preventing foreign matter from invading inside of the sliding member even if use of the sealing member is omitted if it is not used under a severe environment and further maintaining a smooth reciprocation of the sliding member with respect to the track shaft in a long period even under a severe condition in which use of coolant is required or dust, dirt, wooden pieces, cutting powder or the like falls on the guide unit, by using the sealing member at the same time.

[0011] Therefore, an object of the present invention is to provide a dust preventing structure of a guide unit capable of achieving a smooth reciprocation of the sliding member with respect to the track shaft with less friction resistance.

[0012] Further, another object of the present invention is to provide a dust preventing structure of a guide unit capable of maintaining a smooth reciprocation of the sliding member with respect to the track shaft in a long period even under a severe condition in which use of coolant is required or dust, dirt, wooden pieces, cutting powder or the like falls on the guide unit.

[0013] To achieve the above object, according to an aspect of the invention, there is provided a dust preventing structure of a guide unit comprising a track shaft and a sliding member engaging the track shaft via a plurality of rolling bodies so that it is capable of reciprocating in a length direction thereof, wherein elastic members in firm contact with the track shaft are overlaid in the length direction of the track shaft.

[0014] Further, according to another aspect of the invention, there is provided a dust preventing structure of a guide unit comprising a track shaft and a sliding member engaging the track shaft via a plurality of rolling bodies so that it is capable of reciprocating in a length direction thereof, the dust preventing structure further comprising a lubricant pocket forming member having a concave groove portion made of elastic material for forming a lubricant pocket filled with lubricant together with the surface of the track shaft.

[0015] Then, according to a preferred embodiment of the present invention, there is provided a dust preventing structure of a guide unit comprising a track shaft and a sliding member engaging the track shaft via a plurality of rolling bodies so that it is capable of reciprocating in a length direction thereof, the dust preventing structure further comprising a lubricant pocket forming member made of elastic material, including a lubricant supplying portion which is in firm contact with the track shaft holding lubricant for supplying lubricant to the surface of the track shaft upon use and a concave groove portion for forming a lubricant pocket filled with lubricant together with the surface of the track shaft.

[0016] According to the present invention, basically, the aforementioned lubricant pocket forming member is made of elastic material and includes the lubricant supplying portion which is in firm contact with the track shaft holding lubricant for supplying lubricant to the surface of the track shaft upon use and the concave groove portion for forming the lubricant pocket to be filled with lubricant together with the surface of the track shaft. If the lubricant supplying portion made of elastic material is capable of coating the surface of the track shaft with lubricant loaded in the lubricant pocket, with some extent of stiffness and holding a sufficient amount of lubricant, this lubricant pocket forming member can be formed with only the elastic material for forming the lubricant supplying portion. In this case, the lubricant pocket forming member may be formed with a single component member having a single or plural stripes of the concave groove portions or may be formed with plural component members when a single or plural stripes of the concave groove portions are formed when they are combined.

[0017] However, if as lubricant to be loaded in the lubricant pocket, for example, grease or solid lubricant is used, coating resistance which is generated when each of these lubricants is applied to the surface of the track shaft increases, so that an elastic material capable of holding a sufficient amount of lubricant considering a durable period of the dust preventing structure of the present invention may not be capable of bearing this coating resistance. Preferably, this lubricant pocket forming member comprises a plurality of elastic members constituting the lubricant supplying portion holding lubricant and spacer members which are made of stiff material and sandwiched between the plural elastic members so as to form a single or plural stripes of concave groove portions with the elastic members.

[0018] The size and quantity of the concave groove portion formed in the lubricant pocket forming member are not restricted to any particular ones, requirement for the lubricant pocket is satisfied if at least one stripe of the concave groove portion is formed and a sufficient amount of lubricant can be loaded in the lubricant pocket formed by this concave groove portion and the surface of the track shaft considering the durable period of the dust preventing structure of the present invention. Further, this concave groove portion needs to extend over an entire range in the direction of an outside periphery in which the sliding member covers the track shaft, so that lubricant can be applied to a substantially entire range in which the sliding member covers the track shaft.

[0019] The elastic material for forming at least the lubricant supplying portion of the aforementioned lubricant pocket forming member is continuously foamed body such as a continuously foamed polyurethanefoam and sintered resin or fiber entangled body such as wool felt, having physical properties including a tensile strength of 30-50 kg/cm^3, degree of elongation of 300-500%, and impact resilience of 30-60% and made to absorb and hold lubricant after it is formed to a predetermined shape. If the elastic member is formed of rubber or synthetic resin, lubricant is mixed with the rubber or synthetic resin preliminarily and formed to a predetermined shape. Alternatively, lubricant is mixed with monomer at a stage where monomer is polymerized so as to produce rubber or synthetic resin and an obtained rubber or synthetic resin containing lubricant is formed to a predetermined shape. Meanwhile, in case where the aforementioned polyurethanefoam is soaked with lubricant, preferably, the lubricant should be 30-50 weight % in terms of weight ratio.

[0020] The lubricant to be loaded in the aforementioned lubricant pocket may be in any condition of fluid, solid or gelatinous as long as it has a lubricating performance and can be loaded in the lubricant pocket. Although fluid lubricant having a relatively low viscosity can be used, the lubricant is preferred to have a high viscosity of more than 200 cst because such a lubricant is not likely to leak out of the lubricant pocket or in the form of paste, solid state or gelatinous state. More specifically, grease, high viscosity lubricant, solid lubricant, or gelatinous or solid state wax, or the like can be mentioned. Particularly, grease is preferred because it forms a lubricant coating film having an excellent durability (that is, lubricant coating film having an excellent anti-coolant performance) under a condition in which coolant is used.

[0021] In case where the lubricant pocket forming member is composed of a plurality of the elastic members and spacer members, the same elastic members as those for forming the lubricant supplying portion can be used and the spacer members may be formed of metallic plate or synthetic resin plate. Preferably, the spacer member is made of a metallic plate such as stainless plate because its mechanical characteristic value is excellent.

[0022] Further, according to the present invention, it is preferable to provide a scraper member which holds the aforementioned lubricant pocket forming member by sandwiching it between the scraper member and the sliding member. This scraper member needs to have such a strength that it is never deformed or damaged when it removes foreign matter adhering to the surface of the track shaft such as welding spatter and it is attached to the sliding member with a slight gap with respect to the surface of the track shaft, for example, a gap of 0.05-0.3 mm.

[0023] Preferably, this scraper member is formed into a shape capable of covering substantially entirely the lubricant pocket forming member with both ends of the sliding member in the advancement direction and the surface of the track shaft so as to protect the lubricant pocket forming member having the lubricant supplying portion formed of the elastic material from an impact given from outside, and foreign matter such as coolant, dust, cutting powder and the like.

[0024] The dust preventing structure of the present invention having the lubricant pocket forming member is accommodated in various guide units in diversified patterns.

[0025] The guide unit to which the dust preventing structure of the present invention is applied basically comprises the track shaft and the sliding member engaging this track shaft via a plurality of the rolling bodies such that it is capable of reciprocating in the length direction thereof and this dust preventing structure is mounted on each of both ends of the sliding member of the guide unit in the advancement direction thereof.

[0026] The guide unit to which the dust preventing structure of the present invention is applicable includes not only the linear sliding type ball bearing comprising the track rail (track shaft) having the ball rolling grooves and the sliding base (sliding member) engaging the track rail via a plurality of balls such that it is capable of reciprocating in the length direction thereof and having an infinite circulation path for the balls, but also a ball screw comprising a screw shaft (track shaft) having a spiral ball rolling groove and a nut member (sliding member) engaging the screw shaft via a plurality of balls such that it is capable of reciprocating and having an infinite circulation path for the balls, curved sliding type ball bearing, ball bushing, ball spline and roller bearings for linear sliding and curved sliding and the like.

[0027] The sliding member of the guide unit to which the dust preventing structure of the present invention is mounted may be or may not be provided with a sealing member for sealing between inside and outside of this sliding member at both end portions in the advancement direction and this is selectable depending on use condition of the guide unit.

[0028] Although the lubricant supplying member is disposed as required between the sliding member and sealing member, the dust preventing structure of the present invention may be or may not be provided with that lubricant supplying member. This is also selectable depending on use condition of the guide unit.

[0029] Regardless of it that the sliding member of the guide unit is provided with the sealing member and the lubricant supplying member, the dust preventing structure of the present invention is disposed most outside of both ends in the advancement direction of the sliding member and the lubricant supplying portion of the lubricant pocket forming member slides in firm contact with the surface of the track shaft to remove relatively small foreign matter and further lubricant loaded in the lubricant pocket formed by the lubricant pocket forming member is applied to the surface of the track shaft.

[0030] In case where the aforementioned scraper member is disposed outside of the lubricant pocket forming member, this scraper member exerts a function of scraping out a relatively large foreign matter adhering to the surface of the track shaft ahead of the lubricant pocket forming member.

[0031] Thus, according to the dust preventing structure of the present invention, it is used with, for example, the sealing member and lubricant supplying member, and even if the guide unit is used under a severe condition in which use of coolant is required or dust, dirt, wooden pieces, cutting powder or the like falls thereon, it can remove foreign matter on the surface of the track shaft securely and apply lubricant to the surface of the track shaft to form lubricant coating film before the sealing member comes into contact with the surface of the track shaft or lubricant is supplied to the surface of the track shaft by the lubricant supplying member. As a result, such an event that the sealing member is damaged or supplied lubricant is repelled by foreign matter remaining on the surface of the track shaft, particularly coolant so that it is not supplied uniformly to the entire surface of the track shaft never occurs, so that a smooth reciprocation of the sliding member with respect to the track shaft can be maintained in a long period.

[0032] Of course, if the guide unit is not used under such a severe condition, the dust preventing structure of the present invention may be mounted directly on both ends in the advancement direction of the sliding member without using the sealing member or lubricant supplying member, thereby achieving two roles of removing foreign matter from the surface of the track shaft and supplying lubricant to the surface of the track shaft at the same time.

[0033] According to the present invention, it is possible to provide a dust preventing structure of a guide unit capable of not only achieving a smooth reciprocation of the sliding member with respect to the track shaft with less friction resistance but also maintaining a smooth reciprocation of the sliding member with respect to the track shaft in a long period even under a severe condition in which use of coolant is required or dust, dirt, wooden pieces, cutting powder falls on the guide unit.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0042] Hereinafter, the preferred embodiments of the present invention will be described in detail with reference to the accompanying drawings.

[0043] **FIGS. 1, 2** show a ball bearing for linear sliding provided with a dust preventing structure according to the embodiment of the present invention.

[0044] This ball bearing for linear sliding comprises a track rail (track shaft) **1** in which a ball rolling groove **1***a* is formed in the length direction thereof and a sliding base (sliding member) **2** in which an infinite circulation path for balls **3** including a load rolling groove **5** opposing the ball rolling groove **1***a* in the aforementioned track rail **1** via a plurality of balls **3**, direction changing paths (not shown) disposed at beginning and terminal ends of the load rolling groove **5** and a ball return path **6** for connecting between these direction changing paths is formed. Lubricant supplying members **7**, end seal (sealing member) **8** and a dust preventing member **9** of the present invention are disposed on both end portions back and forth in the advancement direction of the sliding base **2**.

[0045] The sliding base **2** comprises sliding base main body **2***a* composing a main body thereof and end plates **2***b* attached to both ends portions back and forth in the advancement direction. The load rolling path **5** and ball return path **6** which constitute the infinite circulation path for the balls **3** are formed in the sliding base main body **2***a* and the direction changing path constituting the infinite circulation path for the balls **3** is formed in the end plates **2***b*.

[0046] Mounting holes **11***a*, **11***b*, **11***c* through which a pair of fixing bolts **10** are inserted are formed in each top portion of the aforementioned lubricant supplying member **7**, end seal **8** and dust preventing member **9**. The lubricant supplying member **7**, end seal **8** and dust preventing member **9** are mounted on each of both ends portions back and forth of the sliding base **2** in the advancement direction with the fixing bolts **10** which pass through the mounting holes **11***a*, **11***b*, **11***c* and engage the end plate **2***b* of the sliding base **2**.

[0047] Reference numeral **12** denotes a supplying nipple for supplying lubricant or grease to the infinite circulation path for the balls **3** formed in the sliding base **2**, the supplying nipple being inserted through holes **13** provided in the lubricant supplying member **7**, end seal **8** and dust preventing member **9** and engaging a mounting hole **14** in the end plate **2***b*. Reference numerals **15***a*, **15***b*, **15***c* denote collars each having a dimension corresponding to thickness of the lubricant supplying member **7**, end seal **8** and dust preventing member **9** so as to prevent the lubricant supplying member **7**, end seal **8** and dust preventing member **9** from being crushed when the fixing bolts **10** are tightened firmly.

[0048] The dust preventing member **9** of the present invention which is applied by this embodiment is made of continuously foamed urethanefoam as shown in FIGS. **2**, **3**, comprising lubricant pocket forming portion **16** including three elastic members **16***a*, **16***b*, **16***c* soaked cheld with lubricant for constituting the lubricant supplying portion and spacer members **16***x*, **16***y* made of metallic plates, which are interposed between the elastic members **16***a*, **16***b*, **16***c* for forming concave groove portion **18** with the elastic members **16***a*, **16***b*, **16***c* and a scraper member **17** made of metal plates, having a shape capable of covering a substantially entire lubricant pocket forming member **16** together with the both end portions back and forth (correspond to the end seal **8** mounted on both end portions back and forth in the advancement direction of the sliding base **2** in this embodiment) in the advancement direction of the sliding base **2** and the surface of the track rail **1**, in other words, a shape capable of covering all surface substantially completely except faces of the lubricant pocket forming member **16** which contact the end seal **8** and track rail **1**, the scraper member **17** being mounted on the sliding base **2** with a slight gapd (0.1 mm in this embodiment) relative to the track rail **1** while the lubricant pocket forming member **16** being sandwiched and held between the scraper member **17** and the sliding base **2** together with the lubricant supplying member **7** and end seal **8**.

[0049] Meanwhile, the aforementioned scraper **17** may be formed of resin in the form of a case. In this case, it is recommendable to attach a metallic scraper for removing foreign matter on the track rail **1** on an outside face thereof.

[0050] An inside size (dimension in a plane perpendicular to the length direction of the track rail **1**) of this case is set so as to be smaller than an outside size (size in the same plane) of each of the elastic members **16***a*, **16***b*, **16***c*. As a result, the respective elastic members **16***a*, **16***b*, **16***c* are fit within the case by tightening so that the outside peripheries of the elastic members **16***a*, **16***b*, **16***c* are fixed. By setting the inside size of the case appropriately, the tightening amount of the respective elastic members **16***a*, **16***b*, **16***c* can be adjusted. The size of the spacers **16***x*, **16***y* to be disposed between the elastic members **16***a*, **16***b*, **16***c* is set such that they are fit with the case with a gap because they are made of stiff material.

[0051] Although according to the above embodiment, the respective elastic members **16***a*, **16***b*, **16***c* are fit within the case by tightening, these elastic members **16***a*, **16***b*, **16***c* may be fit such that they are tightened by the track rail **1**. In this case, preferably the above case has no gap with respect to the elastic members **16***a*, **16***b*, **16***c*.

[0052] Further, by forming the case of resin, the collars **15***a*, **15***b*, **15***c* for preventing the lubricant supplying member **7**, end seal **8** and dust preventing member **9** from being crushed can be molded integrally with this case, thereby the number of parts being reduced.

[0053] Further, by extending this case such that it covers not only the respective elastic members **16***x*, **16***b*, **16***c* and spacers **16***a*, **16***y* but also the end seal **8** and lubricant supplying member **7** disposed backward thereof, the elastic members **16***a*, **16***b*, **16***c*, spacers **16***x*, **16***y*, end seal **8** and lubricant supplying member **7** can be molded integrally with the case, thereby assembly efficiency and appearance of the case being improved.

[0054] The sealed space lubricant pocket (corresponding to the concave groove portion **18**) formed by the concave groove portion **18** formed in the lubricant pocket forming member **16** with the surface of the track rail **1** is filled with paste like grease

[0055] According to this embodiment, the respective elastic members **16***a*, **16***b*, **16***c* made of continuously foamed urethanefoam have tensile strength of 43 kg/cm^3, elongation degree of 360%, density of 0.5 g/cm^3 and impact resilience of 53% and is soaked with lubricant of more than 50 weight %. Further, a supply possible period of the lubricant which is absorbed by these elastic members **16***a*, **16***b*, **16***c* and supplied to the track rail **1** is designed so as to be equal to a coating possible period of grease **19** which is loaded in the lubricant pocket (corresponds to the concave groove portion **18**) and applied to the track rail **1**.

[0056] As shown in **FIG. 4**, the lubricant supplying member **7** used in this embodiment comprises a casing **20** including a main body **20***a* and a lid portion **20***b*, an oil absorptive body **21** made of rayon mixed wool felt having a percentage of void of 81%, which is accommodated in the casing **20** and soaked with lubricant a coating body **22** made of wool felt having a percentage of void 54%, which receives lubricant from the oil absorptive body **21** for coating the ball rolling groove **1***a* the track rail **1** with lubricant and an oil amount adjusting plate **23** which partitions between the oil absorptive body **21** and coating body **22** for supplying lubricant of a predetermined amount from the oil absorptive body **21** to the coating body **22**. Reference numeral **24** denotes a collar.

[0057] As shown in **FIG. 5**, the end seal **8** used for this embodiment comprises a stiff main body **8***a* made of a metallic plate having a stiffness, an elastic main body **8***b* bonded to the surface of the main body **8***a* and made of a rubber plate having an elasticity, and a seal lip portion **8***c* formed integrally of the same material as the elastic main body **8***b* and to be in firm contact with the surface of the track rail **1**.

[0058] Thus, according to the dust preventing structure (dust preventing member **9**) of this embodiment, even if use of coolant is required or this is used under a severe condition in which dirt, dust, wooden pieces, cutting powder or the like falls thereon, before the end seal **8** comes into a contact with the surface of the track rail **1** or lubricant is supplied to the ball rolling groove **1***a* of the track rail **1** by the lubricant supplying member **7**, foreign matter such as coolant and dust adhering to the surface of the track rail **1** is removed securely by the scraper member **17** and the three elastic members **16***a*, **16***b*, **16***c* constituting the lubricant supplying portion. Further, grease **19** loaded in the lubricant pocket (corresponds to the concave groove portion **18**) is applied to the track rail **1** so as to form lubricant film having an excellent anti-coolant performance. As a result, a friction between the surface of the track rail **1** and the seal lip portion **8***c* of the end seal **8** can be reduced as much as possible. Thus, air tightness between the surface of the track rail **1** and seal lip portion **8***c* of the end seal **8** can be maintained in a long term. Consequently, a reduction of lubricity caused due to a shortage of lubricant supplied from the lubricant supplying member **7** to the ball rolling groove **1***a* of the track rail **1** or lubricant or grease supplied to the infinite circulation path for the balls **3** via the supply nipple **12** can be prevented in a long term.

[0059] About this point, durability test was performed under a condition in which coolant was used regarding the embodiment in which the lubricant pocket (corresponds to the concave groove portion **18**) was filled with grease **19** and a comparative example in which no grease **19** is loaded in the lubricant pocket (corresponds to the concave groove portion **18**). As a result, in this embodiment, at an end portion of each of three the elastic members **16***a*, **16***b*, **16***c* constituting the lubricant supplying portion while in firm contact with the surface of the track rail **1**, a durability seven times the comparative example was indicated and even if an impact applied to the seal lip portion **8***c* of the end seal **8** in firm contact with the surface of the track rail **1** exceeds seven times the comparative example, any damage was not noticed, thereby indicating that a durability seven times the comparative example was exerted.

[0060] **FIG. 6** shows a modification of the dust preventing structure (dust preventing member **9**) of the present invention. Different from the above embodiment, the lubricant pocket forming member **16** comprises three elastic members **16***a*, **16***b*, **16***c* made of continuously foamed polyurethanefoam and soaked with lubricant so as to form a lubricant supplying portion. A cutout portion **18***a* is formed in the two elastic members **16***b*, **16***c* of them and when three elastic members **16***a*, **16***b*, **16***c* are overlaid, a predetermined concave groove portion **18** is formed.

[0061] In this modification, the lubricant pocket forming member **16** is entirely formed of continuously foamed polyurethanefoam, so that the amount of lubricant which it can be soaked with increases thereby lubricant being supplied in a longer term.

[0062] **FIG. 7** shows other modification of the dust preventing structure (dust preventing member **9**) of the present invention. Different from the above embodiment, a cutout portion **18***a* having a triangular section is formed on a single side of a bottom of each of the two elastic members **16***a*, **16***b* located on both sides and a cutout portion **18***a* having a triangular section is formed on each of both sides of a bottom of the elastic member **16***b* located in the center. When the spacer members **16***x*, **16***y* are overlaid and sandwiched between the elastic members **16***a*, **16***b*, **16***c*, the concave groove portions **18** each having a section of inverse trapezoidal shape are formed with the elastic members **16***a*, **16***b*, **16***c* and the spacer members **16***x*, **16***y*.

[0063] In this modification, the formed concave groove portion **18** has a section of inverse trapezoidal shape and therefore the shape of a section of the lubricant pocket formed with the surface of the track rail **1** is inverse trapezoidal. As a result, the capacity of the lubricant pocket relative to the size of a coating surface (that is, opening portion of the concave groove portion **18**) of lubricant can be increased, so that the amount of lubricant which can be loaded in this lubricant pocket increases thereby making it possible to supply the lubricant in a longer period.

[0064] **FIG. 8** shows other modification of the dust preventing structure (dust preventing member **9**) of the present invention. In this modification, the dust preventing member **9** comprises three elastic members **16***d*, **16***e*, **16***f* made of elastic materials not soaked with lubricant unlike the aforementioned elastic members **16***a*, **16***b*, **16***c* soaked with lubricant and the scraper member **17** mounted on the sliding base **2** such that it holds these three elastic members **16***d*, **16***e*, **16***f* between the scraper member **17** and the sliding base **2** with the lubricant supplying member **7** and end seal **8** while maintaining a slight gap with respect to the track rail **1**.

[**0065**] In this modification also, the dust preventing member **9** prevents an invasion of dust or dirt into the sliding base **2** because the elastic members **16***d*, **16***e*, **16***f* are overlaid on the track shaft **1** in the length direction thereof such that they are in firm contact with the track shaft **1**, thereby achieving a smooth reciprocating motion of the sliding base **2** relative to the track rail **1**. Further, lubricant supplied to the track rail **1** by the aforementioned lubricant supplying member **7** or other means is held effectively, thereby maintaining a smooth reciprocating motion of the sliding base **2** with respect to the track rail **1** in a long period.

[**0066**] Although in the modification of **FIG. 8**, all the three elastic members **16***d*, **16***e*, **16***f* constituting the dust preventing member **9** are composed of elastic members not soaked with lubricant, it is permissible to replace one or two of them with the aforementioned elastic members **16***a*, **16***b*, **16***c* soaked with lubricant so that the elastic members soaked with lubricant and not soaked with lubricant are combined, considering a use environment of a guide unit to which the dust preventing structure of the present invention is applied.

What is claimed is:

1. A guide unit comprising:

a track shaft having a rolling groove of a rolling body,

a sliding member engaged with the track shaft via the rolling body and moved relative to the track shaft,

a pair of end seals mounted to both ends in traveling direction of the sliding member, having a seal lip portion being in firm contact with a surface of the track shaft, and

a pair of dust preventing members mounted to both ends in traveling direction of the sliding member and being on outer side of the end seals, for removing foreign matters adhering to the track shaft forwardly to the end seal,

wherein the dust preventing member comprises elastic members holding lubricant, in firm contact with a surface of said track shaft, said elastic members are overlaid in the length direction of said track shaft, and a spacer member interposed between the elastic members, and the spacer member is in no contact with the surface of the track shaft.

2. A guide unit according to claim 1, wherein the elastic members are made of continuously foamed urethane foam.

3. A guide unit according to claim 1, wherein the spacer member is made of a metallic plate.

4. A guide unit according to claim 1, wherein a scraper member is mounted on the sliding member with a predetermined gap relative to the track shaft for scraping off foreign matters adhering to the track shaft in accordance with a relative movement between the sliding member and the track shaft, and the elastic members are sandwiched and held between the scraper member and the sliding member.

5. A guide unit according to claim 2, wherein a scraper member is mounted on the sliding member with a predetermined gap relative to the track shaft for scraping off foreign matters adhering to the track shaft in accordance with a relative movement between the sliding member and the track shaft, and the elastic members are sandwiched and held between the scraper member and the sliding member.

(57) **ABSTRACT**

The present invention relates to a ball chain used by being integrated to, for example, a ball endless track of a linear guide device for endless sliding in which a number of balls are arranged in one row and rollably held, particularly to a ball chain which is most pertinent to a linear guide device having a ball rolling groove in a shape of a Gothic arch. According to the ball chain, the number of balls are arranged in one row and the balls are held rollably, each of the balls is pinched by a pair of spherical seats and the spherical seats are connected to each other by flange portions to thereby constitute a ball holding unit and a plurality of the ball holding units are connected in a shape of a rosary by a flexible connecting portion. Further, the spherical seats and the flange portions are molded by a resin material whereas the connecting portion is formed by a material having a tensile strength larger than that of the resin material.

BALL CHAIN

TECHNICAL FIELD

[0001] The present invention relates to a ball chain used by being integrated, for example, to a ball endless track of a linear guide device for endless sliding in which a number of balls are arranged in one row and are held rollably, particularly to a ball chain which is most pertinent in a linear guide device having a ball rolling groove in a shape of a Gothic arch.

BACKGROUND ART

[0002] There has conventionally been known a linear guide device for guiding a movable body of a table or the like along a fixed unit of a bed or the like, which is constituted by a track rail having a ball rolling groove, a slider having a load rolling groove opposed to the ball rolling groove, having a no load rolling path for circulating balls from one end to other end of the load rolling groove and moved along the track rail and a number of the balls rolling between the slider and the track rail while carrying a load and circulating an endless track constituted by the load rolling groove of the slider and the no load rolling path.

[0003] According to the conventional linear guide device constituted in this way, the endless track of the slider is filled with the balls and accordingly, when the slider is moved along the track rail, the balls contiguous to each other are circulated in the endless track while colliding or sliding with each other by which there poses a problem in which the balls are worn at an early stage and the life of the device is shortened.

[0004] Hence, in order to resolve such a problem, there has been proposed a linear guide device in which a ball chain aligning and holding a number of balls is integrated to the endless track (Japanese Unexamined Patent Publication No. JP-A-5-52217). As shown by **FIG. 16** and **FIG. 17**, according to such a ball chain **100**, spacers **102** are interposed among respective balls **101** contiguous to each other, the balls **101** are connected in a shape of a rosary by connecting the respective spacers **102** by connecting portions **103** in a strip-like shape and the balls **101** are fabricated by injection molding of flexible resin where balls **101** are arranged in a mold as cores.

[0005] The conventional ball chain **100** constituted in this way, is integrated in an endless track **105** of a slider **104** and circulated in the endless track as shown by **FIG. 18**, in this case, the spacers **102** are interposed among the balls **101** contiguous to each other and therefore, mutual friction or collision among the balls is prevented and wear of the balls **101** can be prevented as less as possible.

[0006] However, according to such a conventional ball chain **100**, one of the spacers **102** supports two of the balls **101** disposed on both sides thereof and therefore, when an angle of contact of the spacer **102** in respect of the ball **101** is changed by bending or twisting the ball chain **100**, there poses a problem in which the balls **101** drop off among the spacers **102**.

[0007] Accordingly, although the conventional ball chain sufficiently achieves a function as a ball retainer for preventing mutual contact of balls, a function thereof as a so-called ball case for preventing detachment of balls is not sufficient. Therefore, according to a conventional linear guide device integrated with such a ball chain, in order to completely prevent accident of detachment of balls when a slider is removed from a track rail, as shown by **FIG. 19**, ball retainers **107** are installed on both sides of a load rolling groove **106** of a slider **104**.

[0008] However, when a ball rolling groove **109** of a track rail **108** and the load rolling groove **106** of the slider **104** are formed in a shape of a so-called circular arc comprising a single ball rolling face, depths of the rolling grooves **106** and **109** are comparatively small relative to the radius of the ball **101** and therefore, although as shown by **FIG. 19**, the ball retainers **107** can be formed on the both sides of the load rolling groove **106** of the slider **104**, when the ball rolling groove **109** and the load rolling groove **106** are formed in a shape of a Gothic arch, that is, in a shape where a pair of ball rolling faces are intersected with each other, as shown by **FIG. 20**, the depths of the rolling grooves **106** and **109** are near to the radius of the ball **101** and accordingly, it is almost impossible to install the ball retainers **107** on the both sides of the load rolling groove **106**.

[0009] Therefore, in integrating a ball chain to a linear guide device having ball rolling grooves in a shape of a Gothic arch, it is necessary to ensure sufficiently the function of the ball chain for retaining the balls and it is problematic to integrate a conventional ball chain having a such a weak function as it is.

[0010] Meanwhile, such a ball chain **100** is used by being circulated in an endless track and accordingly, it is preferable to make the connecting portion **103** for connecting the respective spacers **102** as thin as possible and make a sectional area thereof as small as possible to flexibly bend the ball chain **100** in the endless track.

[0011] Meanwhile, considering that the respective spacers **102** are brought into sliding contact with the balls **101**, the resin material used in molding the ball chain **100** needs to be provided with lubrication performance, wear resistance and the like in respect of rolling of the balls **101** and therefore, there is a constant restriction in selecting resin for molding the ball chain **100** and mechanical strength of the mold resin per se is difficult to provide.

[0012] Therefore, according to the conventional ball chain **100**, the tensile strength of the connecting portion **103** is obliged to lower and there caused a trouble in which the connecting portion **103** is broken between the respective spacers **102** when the ball chain is being used in an endless circulating path.

DISCLOSURE OF THE INVENTION

[0013] The present invention has been carried out in view of such a problem and it is a first object thereof to provide a ball chain capable of firmly holding balls even when the ball chain is bent or twisted or the like and which is most pertinent to a linear guide device having a ball rolling groove in a shape of a Gothic arch.

[0014] Further, it is a second object of the present invention to provide a ball chain in which lubrication performance and wear resistance in respect of rolling of balls are excellent, arranged balls are rolled excellently and which is provided with sufficient tensile strength and capable of preventing accident of breaking the ball chain while it is being used.

[0015] According to an aspect of the present invention achieving the first object, there is provided a ball chain arranged with a number of balls in one row and rollably holding the balls wherein each of the balls are pinched by a pair of spherical seats and the spherical seats are connected to each other by flange portions to thereby constitute a ball holding unit and a plurality of the ball holding units are connected in a shape of a rosary by a flexible connecting portion.

[0016] According to such a technical means, each of the balls is pinched by the pair of spherical seats connected by the flange portions, the ball holding unit is constituted for each of the balls and the ball chain is constituted by connecting the ball holding units in a shape of a rosary by the flexible connecting portion and accordingly, even when the ball chain is bent or twisted or the like, an angle of contact of the spherical seat in respect of the ball remains unchanged and the ball can be held at each of the ball holding unit with certainty.

[0017] In this case, the ball chain according to the present invention can be fabricated by injection molding of synthetic resin in which the balls are inserted into a mold as cores and in view of reducing a minimum radius in bending the ball chain in a shape of a circular arc, it is preferable that the connecting portion is softer and the sectional area is preferably small.

[0018] Further, according to another aspect of the present invention achieving the second object mentioned above, there is provided a ball chain comprising a number of balls arranged in one row, a plurality of ball holding members arranged among the balls contiguous to each other for rotatably holding the balls and a connecting portion for connecting the ball holding members wherein a tensile strength of the connecting portions is larger than a tensile strength of the ball holding members.

[0019] According to such a technical means, the ball holding members for rotatably holding the balls are interposed among the balls contiguous to each other, the ball holding members are connected to each other by the connecting portion having a tensile strength larger than a tensile strength of the ball holding member and accordingly, even when a material for molding the ball holding member which is provided with a low mechanical strength is used, a sufficient tensile strength can be ensured for the ball chain as a whole. Further, the mechanical strength of the material per se for molding the ball holding member does not pose any problem and the tensile strength of the ball chain as a whole can be ensured and accordingly, such a molding material can be selected only in view of lubrication performance, wear resistance or the like in respect of rolling of the balls and excellent rolling of the arranged balls can be expected.

[0020] In this case, although the ball chain according to the present invention can be integrated by penetrating the connecting portion such as wire or the like through the ball holding members molded by resin, the integrating operation is troublesome when the ball holding members are penetrated one by one by the connecting portion and in view of reducing time and labor of integration, it is preferable to pad the ball holding members to the connecting portion by injection molding of synthetic resin.

[0021] Further, in padding the ball holding members by such an injection molding, it is preferable to form recesses and protrusions at the connecting portion in correspondence with portions for padding the ball holding members such that the ball holding members do not drop off the connecting portion after molding.

BRIEF DESCRIPTION OF THE DRAWINGS

[0022] **FIG. 1** is a perspective view showing a first embodiment of a linear guide device using a ball chain according to the present invention;

[0023] **FIG. 2** illustrates a front view and a sectional view showing the first embodiment of the linear guide device according to the present invention;

[0024] **FIG. 3** is a sectional view showing an endless track of balls provided to a slider according to the first embodiment;

[0025] **FIG. 4** is a view disassembling a moving block and a lid constituting the endless track of balls;

[0026] **FIG. 5** illustrates a plane view and a front view showing the first embodiment of the ball chain according to the present invention;

[0027] **FIG. 6** is an enlarged view showing a section of the endless track of balls according to the first embodiment of a linear guide device;

[0028] **FIG. 7** is a plane view showing a second embodiment of a ball chain according to the present invention;

[0029] **FIG. 8** is a plane view showing a third embodiment of a ball chain according to the present invention;

[0030] **FIG. 9** is a plane view showing a fourth embodiment of a ball chain according to the present invention;

[0031] **FIG. 10** illustrates a front view and a sectional view showing a fifth embodiment of a ball chain according to the present invention;

[0032] **FIGS. 11***a* and *b* are front views showing connecting portions according to the fifth embodiment; formed in a shape of a Gothic arch.

BEST MODE FOR CARRYING OUT THE INVENTION

[0035] A detailed explanation will be given of a ball chain according to the present invention in reference to attached drawings as follows.

⊙ First Embodiment

[0036] **FIG. 1** and **FIG. 2** show an embodiment of a linear guide device integrated with a ball chain according to the present invention.

[0037] In the drawings, notation **1** designates a track rail arranged at a fixed unit of a bed of a machine tool or the like, notation **2** designates a slider for guiding a movable body of a table or the like along the track rail **1**, notation **3** designates a ball rolling between the track rail **1** and the slider **2** while carrying a load and is endlessly circulated in the slider **2**.

[0038] First, a section of the track rail **1** is formed substantially in a rectangular shape and a total of two streaks of ball rolling grooves **11** where the balls **3** roll are formed on both side faces thereof along a longitudinal direction (direction orthogonal to paper face of **FIG. 2**). The track rail **1** is formed with bolt attaching holes **12** at pertinent intervals in the longitudinal direction and the track rail **1** is fixed to the fixed unit by fixing bolts, not illustrated, which are inserted into the bolt attaching holes **12**.

[0039] Further, the slider **2** is constituted by a moving block **4** having attaching faces **41** for a movable body of a table or the like and tap holes **42** into which fixing bolts of the movable body are screwed and a pair of lids **5** which are fixed to both front and rear end faces of the moving block **4** and endless tracks of the balls **3** are provided in the slider by fixing the lids **5** to the moving block **4**.

[0040] A section of the moving block **4** is formed substantially in a shape of a saddle having a horizontal portion **4***a* formed with the attaching faces **41** and a pair of skirt portions **4***b* hung from the horizontal portion **4***a* and a load rolling groove **43** opposed to the ball rolling groove **11** of the track rail **1** is formed on an inner face side of each of the skirt portions **4***b*. Further, a ball return hole **44** in correspondence with each of the load rolling groove **43** is formed at each of the skirt portions **4***b* in which the balls **3** finished with rolling on the load rolling groove **43** and relieved of the load are rolled in a direction reverse to a direction of rolling on the load rolling groove **43**.

[0041] The moving block **4** is fabricated by utilizing injection molding of synthetic resin. That is, the moving block **4** is formed by padding synthetic resin by injection molding to a block main body **40** made of metal and formed by machining, portions requiring mechanical strength such as the movable body attaching face **41**, the load rolling face **43** of the ball **3** and the like mentioned above, are formed at the block main body **40** and in the meantime, portions where mechanical strength is not important such as the ball return hole **44** an the like are formed by synthetic resin and light weight formation of the moving block **4** is achieved as light as possible.

[0042] **FIG. 3** is a sectional view showing an endless track of the balls **3** provided to the slider **2** and as shown by **FIG. 4**, the endless track is completed by fixing the lids **5** to end faces of the moving block **4**. That is, when the lid **5** is fixed to the moving block **4**, a ball guide portion **46** on the side of the moving block **4** is fitted into a U-shape groove **51** on the side of the lid **5** by which a direction change path **54** in a U-like shape is completed and the load rolling face **43** of the moving block **4** is connected to the ball return hole **44** by the direction change path **54**.

[0043] Thereby, when the balls **3** carrying a load between the ball rolling groove **11** of the track rail **1** and a load rolling groove **43** of the moving block **4**, finishes rolling on the load rolling groove **43** in accordance with movement of the slider **2**, the balls are relieved of the load, enter the direction change path **54** of one of the lids **5** and are rolled in the ball return hole **44** of the moving block **4** in a no load state as they are in a direction reverse to a direction of rolling on the load rolling groove **43**. Further, the balls **3** which have finished rolling in the ball return hole **44**, enter again between the track rail **1** and the moving block **4** via the direction change path **54** of other of the lids **5** and roll on the load rolling groove **43** while carrying the load.

[0044] Meanwhile, the balls **3** are integrated to the endless track of the slider **2** in a state where they are held in one row by the ball chain **6** and the ball chain **6** is circulated in the endless track in accordance with rolling of the balls **3**. As shown by **FIG. 5**, the ball chain **6** is formed by connecting a plurality of ball holding units **61** each holding a single piece of the ball **3** in a shape of a rosary by a flexible connecting portion **62** and each of the ball holding units **61** is constituted by a pair of spherical seats **63** pinching the ball **3** from left and from right and flange portions **64** connecting the spherical seats **63** to each other.

[0045] The connecting portion **62** connects only side ends on one side of the ball holding units **61** arranged in one row to each other and when the connecting portion **62** is flexed as shown by **FIG. 3**, slit-like spaces among the ball holding units **61** contiguous to each other are expanded and the ball chain **6** per se can be bent in a ring-like shape in a state where the flange portions **64** are disposed on an inner peripheral side or an outer peripheral side.

[0046] Further, the ball chain **6** is formed by injection molding of synthetic resin inserted with the balls **3** as cores in a mold and the connecting portions **62**, the spherical seats **63** and the flange portions **64** are integrally molded by such an injection molding and the balls **3** are incorporated by the spherical seats **63**.

[0047] **FIG. 6** is an enlarged sectional view showing a state of rolling the balls **3** in the endless track.

[0048] The load rolling groove **43** of the slider **2** and the ball rolling groove **11** of the track rail **1** are formed in a shape of a Gothic arch formed by intersecting two of ball rolling faces **10** to each other and each of the balls **3** is brought into contact with two points of each of the load rolling groove **43** and the ball rolling groove **11**. Further, escape grooves **31** are respectively formed at deepest portions of the ball rolling groove **11** and the load rolling groove **43** which are formed in a shape of a Gothic arch, that is, positions in each of which the two ball rolling faces **10** are intersected with each other and the flange portions **64** of the ball chain **6** are contained in the escape grooves **31** while the balls **3** are rolling in the rolling grooves **43** and **11**.

[0049] Further, guide grooves **32** are formed in the ball return hole **44** of the slider **2** along the longitudinal direction, the flange portions **64** of the ball chain **6** under a no load state are guided by the guide grooves **32** and the ball chain **6** is prevented from meandering in the ball return hole **44**.

[0050] Further, according to the linear guide device of the embodiment constituted as described above, when the slider **2** is moved on the track rail **1**, the balls **3** roll on the load rolling groove **43** of the slider **2** and the ball rolling groove **11** of the track rail **1** and the ball chain **6** is circulated at inside of the endless track formed in the slider **2**. In this case, according to the respective ball holding units **61** constituting the ball chain **6**, regardless of a state of flexing or extending the ball chain **6**, pairs of the spherical seats **63** always pinch the balls **3** with certainty and therefore, the balls **3** can be prevented from dropping off the ball chain **6** as less as possible.

[0051] Further, the ball chain **6** in the endless track is circulated while disposing the flange portions **64** on the outer peripheral side or the inner peripheral side and accordingly, for example, even when the slider **2** is drawn from the track rail **1** (state where track rail **1** is removed in **FIG. 6**), the balls **3** are brought into a state where they are pinched from three directions by the load rolling groove **43** of the slider **2** and the flange portions **64** of the ball chain **6** and the balls **3** can be prevented from dropping off the endless track of the slider **2** with certainty.

◎ Second Embodiment

[0052] **FIG. 7** shows a second embodiment of a ball chain according to the present invention. Although the ball chain **7** is provided with a constitution substantially similar to that of the ball chain **6** of the first embodiment shown by **FIG. 5**, the constitution is different therefrom only in that the flange portions **64** connecting pairs of the spherical seats **63** are arranged to divide in four the surroundings of the balls **3**. Therefore, according to the ball chain **7** of the second embodiment, the balls **3** are completely constrained at insides of the ball holding units **61** and the balls **3** can be completely prevented from dropping off the ball chain **7**.

◎ Third Embodiment

[0053] **FIG. 8** shows a third embodiment of a ball chain according to the present invention.

[0054] According to the ball chain **6** of the first embodiment, the connecting portion **62** for connecting the respective ball holding units **61** are also molded by resin and therefore, when the ball chain **6** is circulated in the endless track and flexing and extending thereof are repeated, there is a concern that the ball chain **6** is cut at the connecting portion **62**.

[0055] Hence, according to a ball chain **8** of the embodiment, a wire **80** penetrating the respective ball holding units **61** is installed and the connecting portion **62** is constituted by the wire **80**. Although a method of fabricating such a ball chain **8** is substantially the same as that of the ball chain **6** according to the first embodiment, a single piece of the wire **80** is inserted in a mold along with the balls **3** and the respective ball holding units **61** are padded to the wire **80** at an equal interval by injection molding of synthetic resin.

[0056] Further, according to the ball chain **8** of the embodiment where the connecting portion **62** is reinforced by the wire **80**, the connecting portion **62** is not broken even by repeated flexing and extending and trouble of breaking the ball chain **8** in the midst of use can be avoided.

◎ Fourth Embodiment

[0057] **FIG. 9** shows a fourth embodiment of a ball chain according to the present invention.

[0058] A ball chain **9** of the embodiment of constituted such that the connecting portion **62** for coupling the respective ball holding units **61** is formed at centers of the spherical seats **63** and a contiguous pair of the ball holding units **61** can be flexed in any direction centering on the connecting portion **62**. Therefore, different from the ball chains described above, there is no specific flexing direction in the ball chain **9** and the ball chain **9** can be integrated to the endless track without taking any special consideration in the flexing direction in the endless track of the slider **2**.

[0059] Further, although according to the linear guide devices mentioned above, the slider is provided with a total of two streaks of the ball endless tracks in which respective streaks are in correspondence with both left and right side faces of the track rail, the linear guide device according to the present invention is not limited thereto but the slider **2** may be provided with a total of four streaks of the ball endless tracks in which respective two streaks are in correspondence with each of both left and right side faces of the track rail **1**.

◎ Fifth Embodiment

[0060] **FIG. 10** shows a fifth embodiment of a ball chain according to the present invention.

[0061] According to a ball chain **71**, the plurality of balls **3** are arranged in a connector belt **72** in one row at a predetermined interval and the balls **3** are rotatable in a state where they are held by the connector belt **72**.

[0062] The connector belt **72** is constituted by a plurality of ball holding members **74** interposed among the respective balls **3** and a strip-like connecting portion **75** for connecting contiguous ones of the ball holding members **74** to each other and spherical seats **74***a* for embracing the spherical face of the ball **3** are formed at each of the ball holding members **74**. Thereby, the respective balls **3** are brought into a state where they are embraced from left and from right by the contiguous ball holding members **74** and are held by such a connector belt **72**.

[0063] As shown by FIGS. **11**(*a*) and **11**(*b*), according to the connecting portion **75**, through holes **75***a* each having a diameter more or less larger than the diameter of the ball, are formed in a stainless steel sheet (SUS **304** or the like) having a thickness of 0.05 through 0.2 mm which is formed in a strip-like shape and the balls **3** are contained in such through holes **75***a*. Meanwhile, the ball holding member **74** is molded by synthetic resin of polyamide-base elastomer, polyester-base elastomer or the like and is padded to the connecting portion **75** by injection molding. That is, as shown by **FIG. 11**(*a*), ball dies **91** each having a diameter larger than the diameter or the ball **3** are projected at a predetermined interval in a forming mold **90** and as shown by **FIG. 11**(*b*), the ball dies **91** are contained in the through holes **75***a* of the connecting portion **75** and under the state, the ball holding members **74** are padded to the connecting portion **75** by injection molding. Thereafter, the ball dies **91** are forcibly detached from among the ball holding members **74** and the balls **3** are pushed in portions detached of the ball dies **91** by which the ball chain **71** in which the balls **3** are contained in the through holes **75***a* of the connecting portion **75** by the ball holding members **74** is completed.

[0064] Further, the ball chain **71** of the embodiment constituted as described above, is used by being integrated to an endless track of a slider constituting a linear guide device or the like, the tensile strength of the connecting portion **75** formed by a stainless steel sheet is considerably larger than that of the ball holding member **74** made of synthetic resin and accordingly, even when large tensile force is exerted on the ball chain **71** during circulation in the endless track, the ball chain **71** is not broken between the ball holding members **74** contiguous to each other and smooth circulation of the ball chain **71** can always be expected.

[0065] Further, the tensile strength of the ball chain **71** per se is dependent on that of the connecting portion **75** and accordingly, it is not necessary to expect mechanical strength such as tensile strength or the like in resin material molding the ball holding members **74** and resin material used in injection molding can be selected only in view of lubrication performance, wear resistance or the like in respect of rolling of the balls **3**. Accordingly, smooth rolling of the balls **3** can also be expected.

◎ Sixth Embodiment

[0066] **FIG. 12** shows a sixth embodiment of a ball chain according to the present invention.

[0067] Although according to the above-described fifth embodiment, the connecting portion **75** is installed along both sides of a row of the balls which are arranged in one row, according to the embodiment, a connecting portion **76** is installed only on one side of the ball row. The other points as well as the constitution and the method of fabrication are the same as those in the fifth embodiment.

[0068] Accordingly, as shown in **FIG. 13**, according to the connecting portion **76** of the embodiment, notched portions **76***a* each in a shape of an arch are arranged in the longitudinal direction at a predetermined interval and the balls **3** are contained in the notched portions **76***a*.

◎ Seventh Embodiment

[0069] **FIG. 14** shows a seventh embodiment of a ball chain according to the present invention.

[0070] Although according to the above-described fifth and sixth embodiments, a stainless steel sheet in a strip-like shape is used as the connecting portion, according to the embodiment, wires **77** each having a slender wire diameter are used as a connecting portion and ball holding members **78** are padded to the wires **77** by using injection molding of synthetic resin.

[0071] Each of the ball holding members **78** is arranged to be brought into contact with a single one of the ball and an independent ball holding unit is constituted by a pair of the ball holding members disposed on both sides of the ball. Therefore, even in the case where such a ball chain is used by being flexed extremely, according to each of the ball holding units, a pair of the ball holding members **78** hold the balls **3** with certainly and prevention of detachment of the ball **3** is achieved.

◎ Eighth Embodiment

[0072] **FIG. 15** shows an eighth embodiment of a ball chain according to the present invention.

[0073] Although according to the above-described ball chains of the respective embodiments, the ball holding members **74** interposed among the respective balls **3** are integrated with the connecting portion **75** (or **76**) in a strip-like shape by utilizing injection molding of synthetic resin, according to the embodiment, the connecting portion is constituted by a wire **79** having a slender wire diameter and ball holding members **80** previously formed by injection molding of synthetic resin which are penetrated by the wire **79** at a later stage.

[0074] That is, the ball holding members **80** are formed with through holes for inserting the wire **79** and by passing the wire **79** through the through holes, the respective ball holding members **80** are connected to each other. Such a wire **79** is folded back by a ball holding member **80***a* disposed at an end portion of the ball chain and is inserted through the respective ball holding members **80** at both sides of the ball row. Further, a stopper plate for fixedly engaging both end portions of the wire **79** is installed at an end portion of the ball chain, not illustrated, and a detachment preventive processing is carried out on the both end portions of the wire **79** which has passed through all of the ball holding members **80** after they are passed through the stopper plate.

[0075] Further, also in the ball chain of the eighth embodiment, the ball holding members **80** made of synthetic resin are connected by the wire **79** having large tensile strength by which the balls **3** are rotatably held and accordingly, even when large tensile force is exerted on the ball chain, the ball chain is not broken between the ball holding members **80** contiguous to each other and by using a resin material excellent in lubrication of the balls **3** for the ball holding members **80**, smooth formation of rolling of the balls **3** can be expected.

Industrial Applicability

[0076] As has been explained, according to a ball chain of the present invention, a ball holding unit pinching a ball is formed by a pair of spherical seats, the ball chain is constituted by connecting a plurality of the ball holding units and accordingly, even when the ball chain is bent or twisted while it is being used, the balls do not drop off among the spherical seats and the balls can be held by the ball chain with certainty.

[0077] Further, according to a ball chain of the present invention, ball holding members interposed among balls contiguous to each other are connected to each other by a connecting portion having a tensile strength higher than that of the ball holding member and accordingly, even when a material for molding the ball holding member which is provided with a low mechanical strength is used, a sufficient tensile strength can be ensured for the ball chain as a whole and accordingly, occurrence of accident of breaking the ball chain while it is being used can be prevented beforehand.

[0078] Further, even in the case where the material for molding the ball holding member which is provided with low mechanical strength is used, the tensile strength of the ball chain can be ensured and occurrence of breaking the ball chain can be prevented and accordingly, in selecting a material for molding the ball holding member, consideration is given only in view of lubrication performance, wear resistance or the like in respect of rolling of the balls by which excellent rolling of the balls arranged thereby can be expected.

1. A ball chain arranged with a number of balls in one row and rollably holding the balls:

wherein each of the balls are pinched by a pair of spherical seats and the spherical seats are connected to each other by flange portions to thereby constitute a ball holding unit and a plurality of the ball holding units are connected in a shape of a rosary by a flexible connecting portion.

2. The ball chain according to claim **1**:

wherein the spherical seats and the flange portions are molded by a resin material and the connecting portion is formed by a material having a tensile strength larger than a tensile strength of the resin material.

3. A linear guide device comprising a track rail having ball rolling grooves each in a shape of a Gothic arch formed by intersecting a pair of ball rolling faces with each other, a slider having load rolling grooves each in a similar shape of a Gothic arch opposed to the ball rolling grooves and no load rolling paths for circulating the balls from one end to other end of each of the load rolling grooves for moving along the track rail and a number of balls rolling between the slider and the track rail while carrying a load and circulating endless tracks constituted by the load rolling grooves and the no load rolling paths of the slider:

wherein the ball chain according to claim 1 are integrated to each of the endless tracks of the slider such that the flange portions of the ball chain are disposed on an inner peripheral side or an outer peripheral side thereof and escape grooves by which the flange portions of the ball chains are contained and guided are formed at deepest portions of the ball rolling grooves of the track rail and the load rolling grooves of the slider both formed in the shape of the Gothic arch.

4. A ball chain comprising a number of balls arranged in one row, a plurality of ball holding members arranged among the balls contiguous to each other for rotatably holding the balls and a connecting portion for connecting the ball holding members:

wherein a tensile strength of the connecting portion is larger than a tensile strength of the ball holding members.

5. The ball chain according to claim **4**:

wherein the connecting portion is made of a metal material whereas the ball holding members are made of a resin material.

6. The ball chain according to claim **4**:

wherein the connecting portion and the ball holding members are made of a resin material.

7. The ball chain according to claim 5 or **6**:

wherein the ball holding members are padded to the connecting portion by injection molding.

8. The ball chain according to claim **7**:

wherein the connecting portion is formed with recesses and protrusions in correspondence with portions thereof for padding the ball holding members.

(57) **ABSTRACT**

The present invention offers a universal guide device capable of using the sliders of conventional straight guide devices intact. The universal guide device does not need a different slider for each different radius of track rail. The universal guide device can be manufactured at lower cost than heretofore. This universal guide device in accordance with the invention comprises a track rail and sliders mounted to the rail via balls circulating through endless circular paths. The rail has at least one straight region and at least one curved region shaped in an arc with a given radius of curvature. Each of the sliders is of saddlelike cross section. The sliders span the rail. The sliders have ball-rolling surfaces shaped linearly. The curved region of the rail is set narrower than the straight region of the rail.

UNIVERSAL GUIDE DEVICE AND MOVING TABLE DEVICE USING SAME

FIELD OF THE INVENTION AND RELATED ART STATEMENT

[0001] 1. Field of the Invention

[0002] The present invention relates to a universal guide device that is used in sliding portions of various machine tools, part-conveying systems, and so on and is capable of guiding a movable object or material over a conveyance path containing both straight and curved regions.

[0003] 2. Related Art

[0004] For example, on a product line or the like in a plant, if all processing stations are arranged linearly, then no problems will take place. However, depending on the space of the plant in which a machine is installed or on the contents of the processing performed in processing stations, it may be necessary to change the direction of conveyance of materials to be processed between two adjacent processing stations. In this case, it is customary to use a pallet changer or the like to achieve a change in the direction of conveyance. Unfortunately, additional space and cost for installing the pallet changer or the like are necessary.

[0005] Known means for modifying the direction of conveyance of materials or objects without using a pallet changer include universal guide devices (as described in Laid-open, unexamined Japanese patent application Nos. 293319/1988 and 50333/1994) capable of guiding materials continuously along a path including both straight and curved lines and curved guide devices (as described in Laid-open, unexamined Japanese patent application No. 186028/1988) capable of guiding materials continuously along an annular path.

[0006] These universal guide devices and curved guide devices each comprise a track rail, a slider, and a number of balls. The rail forms longitudinally extending surfaces on which the balls roll. The slider is mounted to span the rail. Load-rolling surfaces opposite to the rolling surfaces of the rail and an endless circular path for the balls are formed on and in the slider. The endless circular path includes the load-rolling surfaces. The balls roll in the endless circular path of the slider and between the rolling surfaces of the rail and the load-rolling surfaces of the slider carry a load. The slider moves along the rail in response to rolling movement of the balls.

[0007] In the former universal guide device, each load-rolling surface of the slider is partitioned into straight load regions formed linearly and curved load regions shaped into an arc in conformity with the curvature of the rail. In each straight load region of the rail, the load acting on the slider is carried by the balls rolling in the straight load region. In each curved region, the load is carried by the balls rolling in the curved region. As a result, even if straight and curved regions are intermingled on the track rail, the slider can move along the rail through the straight and curved regions continuously.

[0008] In the latter curved guide device, the track rail is shaped into an arc having a given curvature. The load-rolling surface of the slider is shaped into an arc in conformity with the curvature of the rail. All the balls interposed between the load-rolling surface of the slider and the rolling surface of the rail roll on while carrying the load acting on the slider. In consequence, the slider can make a curved motion along the rail.

[0009] In these conventional universal guide devices and curved guide devices, the load-rolling groove or race in the slider is shaped into an arc in conformity with the curvature of the track rail to permit movement of the slider through the curved region of the rail. Therefore, it has been necessary to machine the load-rolling surface in conformity with the curvature of the rail. Consequently, it has been impossible to directly use the sliders of conventional mass-produced linear guide devices that are available in the market. Hence, the production cost is increased. Furthermore, a different slider is necessary for each different curvature of track rail. Therefore, it is laborious to machine the sliders and to manage finished products.

[0010] Where the load-rolling surface of a slider is machined into an arc, the direction of bending of the curved region of a track rail is limited to one direction, left or right. Although it is possible to transport materials and objects annularly, it is impossible to convey materials along a track including two curved regions bent in different directions such as an S-shaped track.

[0011] On the other hand, in a path between two adjacent machining stations on a product line, if materials can be transported, no problems take place. It is considered that capability to carry very large loads is not necessary in curved regions of the rail. However, during a machining process, a machining force acting on a material needs to be sustained reliably by a guide device. Straight regions of the rail are required to have ability to carry a larger load than curved regions. In the aforementioned conventional universal guide device, the load-rolling surface formed on the slider is divided into straight and curved load regions. Therefore, the straight regions of the rail have decreased ability to sustain loads. Consequently, a machining force acting on materials cannot be sufficiently sustained.

[0012] Where materials are actually transported using such universal guide devices, it is necessary to construct a moving table device from two or more universal guide devices in order to transport such materials stably. In particular, two track rails are placed parallel to each other. Plural sliders are mounted to each track rail. A table is mounted so as to span all of these sliders. The materials to be transported are placed on this table.

[0013] Where the table is moved only through a linear region or only through a curved region, if all the sliders are mounted directly to the table, no problems take place. The table can be smoothly moved. However, where the table is moved from a curved region to a straight region or vice versa continuously, if all the sliders are directly mounted to the same table, the configuration of one slider relative to the track rail is restricted by other sliders. This makes it difficult to move the table smoothly. Accordingly, where plural universal guide devices of the construction described above are used to construct the moving table device, it has been impossible to mount the sliders directly to the table.

OBJECTS AND SUMMARY OF THE INVENTION

[0014] In view of the foregoing problem, the present invention has been made. It is an object of the present invention to provide a universal guide device which can directly use sliders heretofore employed in linear guide devices and which do not need different sliders for each different radius of track rail and thus can be fabricated at lower cost than conventionally.

[0015] It is another object of the invention to provide a universal guide device in which sliders can move through two curved regions of a track rail continuously along the rail even if the two curved regions are bent in different directions and in which the sliders can move from a straight region to a curved region or vice versa continuously without sacrificing the ability of the rail to sustain a load in the straight region even if the rail contains both straight and curved regions.

[0016] It is a further object of the invention to provide a moving table device comprising plural parallel track rails and plural sliders mounted to each track rail, the moving table device being characterized in that smooth movement of the sliders is assured even if a table is supported by the sliders that are four or more in number.

[0017] To achieve the objects described above, a universal guide device in accordance with the present invention comprises: a track rail including a straight region and a curved region shaped into an arc with a given radius of curvature and having ball-rolling surfaces on both its side surfaces, the ball-rolling surfaces extending longitudinally; a slider having a saddlelike cross section and mounted to span the track rail; load-rolling surfaces formed on the slider and located opposite to the rolling surfaces, respectively, of the rail; and an endless circular path for a number of balls. The circular path is formed on the slider and includes the load-rolling surfaces. The numerous balls sustain a load between each rolling surface of the track rail and each load-rolling surface of the slider. The load-rolling surfaces formed on the slider are formed linearly. The width of the curved region of the track rail is set narrower than the straight region of the rail.

[0018] In this universal guide device in accordance with the present invention, the load-rolling surfaces formed on the slider are not shaped into an arc corresponding to the curvature of the curved region of the track rail. Rather, the load-rolling surfaces are formed linearly in conformity with the rolling surfaces of the straight region of the track rail. In the present invention, however, the curved region of the rail is set narrower than the straight region of the rail. Therefore, if the rolling surfaces of the rail assume the form of an arc, and if the load-rolling surfaces of the slider are linear, the slider can engage the curved region of the rail and can move along the curved region without trouble.

[0019] When the slider is moving through the curved region of the track rail, the balls are squeezed in between the arc-shaped rolling surfaces formed longitudinally of the rail and the linear load-rolling surfaces formed on the slider and roll along the load-rolling surfaces while carrying the load. Therefore, with respect to the numerous balls rolling on the load-rolling surfaces, only some of the balls carry the load between the rolling surfaces of the rail and the load-rolling surfaces of the slider.

[0020] In this universal guide device in accordance with the present invention, the load-rolling surfaces formed on the slider are shaped linearly rather than into an arc. Therefore, the sliders of linear guide devices can be used intact. Furthermore, an operation for machining the load-rolling surface into an arc in conformity with the curvature of the track rail is dispensed with. Therefore, it is possible to fabricate a universal guide device at quite low cost. Furthermore, the linearly formed load-rolling surfaces have no directivity. Consequently, even if two curved regions bent in different directions are contained in the rail, the slider can move through these curved regions continuously.

[0021] In addition, in the universal guide device in accordance with the present invention as described above, all the balls rolling on the load-rolling surfaces of the slider bear against the rolling surfaces of the track rail within the straight region of the rail. Therefore, the ability of the slider to sustain a load is not impaired, unlike the case in which only some balls bear against the rolling surfaces in a curved region. If large loads act on the slider, the loads can be sufficiently sustained.

[0022] In the present invention, as long as the ball-rolling surfaces on the track rail side are formed on the surfaces of the rail, balls forming a row and rolling on the load-rolling surface of the slider do not simultaneously touch the arc-shaped rolling surface on the rail side. Therefore, this rolling surface may be shaped in the same way as the rolling surface of the prior art curved guide device without needing any special machining operation. Furthermore, this track rail can be easily fabricated, because one surface of the rail and the arc-shaped rolling surface formed on it can be simultaneously ground. However, where an upward facing rolling surface is formed on the top surface of a track rail, this rolling surface needs to be machined in a special manner. In particular, a downward facing load-rolling surface is linearly formed on the slider in an opposite orientation to the upward facing rolling surface of the track rail. Consequently, this upward facing rolling surface needs to have such a width that balls forming a row and rolling on the downward facing rolling surface of the slider simultaneously touch the upward facing surface.

[0023] In the universal guide device in accordance with the present invention, the slider can move through both straight and curved regions of the track rail freely. Therefore, if this rail is composed of only curved regions, the slider can move along the annular rail. That is, where attention is paid to only the curved region of the rail, the universal guide device in accordance with the invention can be regarded as a curved guide device.

[0024] As mentioned previously, in the universal guide device in accordance with the present invention, the straight and curved regions of the track rail differ in width. Therefore, it is desired to provide an intermediate rail portion connecting the straight and curved regions of the rail such that the width of the rail varies continuously in this intermediate rail portion.

[0025] Moreover, a moving table device can be built using universal guide devices of the construction in accordance with the invention as described above. Specifically, plural track rails are mounted parallel to each other on a fixed portion such as a pedestal or a base. A table is mounted to span sliders that move on these rails. However, if two or more sliders are mounted to each rail, and if all of the sliders are directly mounted to the same table, it will be difficult to move the table smoothly between the straight and curved regions of the rail, as mentioned previously.

[0026] In view of this, first and second track rails are mounted parallel to each other. Plural sliders are mounted to each of these rails. A fixed plate is made to span one slider mounted to the first rail and one slider mounted to the second rail such that these two sliders are coupled. Another fixed plate is bridged across another slider mounted to the first rail and another slider mounted to the second rail, and so on. Preferably, the table is mounted so as to be rotatable relative to the fixed plates. Where the moving table device is constructed in this way, even if the table is supported by the sliders that are four in number, the first fixed plate bridged over the first row of sliders that is the forerunner in the direction of movement and the second fixed plate bridged over the second row of sliders rotate in such a way that the sliders are oriented in the tangential direction of the rails. The distance between the sliders on the rails is made variable. Hence, the sliders can move smoothly.

[0027] Additionally, the table can be smoothly moved between the straight and curved regions of the rail by mounting the first and second rails parallel to each other, mounting plural sliders to each of the rails, and mounting the table so as to be rotatable relative to the sliders. That is, in this structure, when the sliders move through the curved region of the rail, they rotate to arbitrary directions so as to orient themselves to the tangential direction of the rails. This permits smooth movement of the sliders.

[0028] As described thus far, in the universal guide device in accordance with the present invention, the load-rolling surfaces formed on the sliders are only required to be shaped linearly rather than into an arc. Therefore, the sliders of numerous linear guide devices available on the market can be used intact. Moreover, it is not necessary to machine the load-rolling surfaces in conformity with the curvature of the rails. In consequence, the sliders can be manufactured easily and inexpensively.

[0029] Since the load-rolling surfaces formed on the sliders have no directivity, if each track rail has two curved regions bent in different directions, the sliders can move through the curved regions continuously along the rail. For example, materials can be guided freely along a track having a high degree of freedom (e.g., consisting of a combination of straight lines and curved lines such as an S-shaped track).

[0030] Because the load-rolling surfaces formed on the sliders are linear, all the balls rolling on the load-rolling surfaces of the sliders bear against the rail in the straight regions and sustain the load. Therefore, the sliders can exhibit sufficient ability to sustain the load within these straight regions. If straight and curved lines are intermingled on the rail, the sliders can move through the straight and curved regions continuously without sacrificing the ability of the rail in the straight regions to sustain the load.

[0031] Other objects and features of the invention will appear in the course of the description thereof, which follows.

BRIEF DESCRIPTION OF THE DRAWINGS

[0032] **FIG. 1** is a plan view of a universal guide device in accordance with a first embodiment of the present invention;

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0054] Referring to FIG. 1, there is shown a universal guide device in accordance with a first embodiment of the present invention. A track rail 1 is mounted to a fixed portion such as a pedestal or a base. Sliders 2 can move along the rail 1. This rail 1 is composed of a straight guide rail portion 1A, a curved guide rail portion 1B shaped into an arc with a given radius, and an intermediate rail portion 1C connecting these rail portions 1A and 1B. The sliders 2 can move on these rail portions 1A, 1B, and 1C freely.

[0055] FIG. 2 is a perspective view of the straight guide rail portion 1A and one slider 2 mounted on this rail portion 1A. FIG. 3 is a front view in cross section taken axially of the straight guide rail portion 1A. The straight rail portion 1A has a substantially rectangular cross section. Two side ball-rolling surfaces 10*a* and two top ball-rolling surfaces 10*b* extend longitudinally. Balls 3 roll on these four rolling surfaces 10*a*, 10*b*. The two side ball-rolling surfaces 10*a* are formed on the opposite side surfaces of the straight guide rail portion 1A, while the two top ball-rolling surfaces 10*b* are formed around the opposite edges, respectively, of the top surface of the guide rail portion 1A. The side ball-rolling surfaces 10*a* are tilted at an angle of 30° downwardly from the horizontal in the paper. The top ball-rolling surfaces 10*b* face vertically upward. Bolt-mounting holes 11 are formed in the straight guide rail portion 1A and spaced regularly from each other longitudinally along the rail portion 1A. Anchoring bolts (not shown) are inserted in the bolt-mounting holes 11 to mount the rail portion 1A fixedly to the fixed portion.

[0056] Referring particularly to FIGS. 2 and 3, each of the sliders 2 described above comprises a movable block 4 and two covers 5 mounted to the front and rear end surfaces, respectively, of the block 4. The movable block 4 is provided with tapped holes 42 into which the anchoring bolts are screwed. The movable block 4 has a mounting surface 41 on which a movable body such as a table is mounted. An endless circular path for the balls 3 is formed inside the slider by mounting the covers 5 to the movable block 4. Seal members 6 that make a sliding contact with the track rail 1 are mounted to the covers 5, respectively, to prevent dust adhering to the rail 1 from entering the slider 2 during movement of the slider.

[0057] Referring particularly to FIG. 3, the aforementioned movable block 4 has a horizontal portion 4*a* and a pair of skirt portions 4*b* descending from the horizontal portion 4*a*. The block 4 has a saddlelike cross section. The above-described mounting portion 41 is formed in the horizontal portion 4*a*. Two straight load-rolling surfaces 43*a* are formed on the inner surfaces of the skirt portions 4*b* of the horizontal portion 4*a* and located opposite to side ball-rolling surfaces 10*a* of the straight guide rail portion 1A. Two straight load-rolling surfaces 43*b* are formed on the bottom surface of the horizontal portion 4*a* and located opposite to the top ball-rolling surfaces lob of the straight guide rail portion 1A. Ball return holes 44*a* corresponding to the load-rolling surfaces 43*a* are formed in the skirt portions 4*b*, respectively. Ball return holes 44*b* corresponding to the load-rolling surfaces 43*b* are formed in the horizontal portion 4*a*. U-shaped direction change paths 51 (FIG. 4) are formed in the covers 5, respectively, to connect the load-rolling surfaces 43*a* and 43*b* with the ball return holes 44*a* and 44*b*, respectively, thus forming an endless circular path for balls.

[0058] Some of the balls 3 sustain a load between the ball-rolling surface 10*a* of the straight guide rail portion 1A and the load-rolling surface 43*a* of the movable block 4. The other balls 3 sustain a load between the top ball-rolling surface 10*b* of the straight guide rail portion 1A and the load-rolling surface 43*b* of the movable block 4. As each slider 2 moves, the balls 3 finish rolling over the load-rolling surfaces 43*a* and 43*b*. Then, the balls 3 are relieved of the load and enter the direction change path 51 in one cover 5. The balls then roll through the ball return holes 44*a* and 44*b* in the movable block 4 in a direction opposite to the direction of rolling motion on the load-rolling surfaces 43*a* and 43*b* while maintained in an unloaded state. After finishing rolling through the ball return holes 44*a* and 44*b*, the balls 3 enter again into the gap between the straight guide rail 1A and the movable block 4 through the direction change path 51 in the other cover 5, and roll on the load-rolling surfaces 43*a* and 43*b* while sustaining a load.

[0059] Ball-holding plates 45 and 46 are mounted to the bottom ends of the skirt portions 4*b* and the horizontal portion 4*a*, respectively, of the movable block 4. The ball-holding plates 45 and 46 are stamped from a metal plate or formed from a hard synthetic resin by injection molding or other method. The ball-holding plates 45 and 46 prevent the balls 3 rolling on the ball-rolling surfaces 10*a*, 10*b* from coming off the slider 2 when the slider 2 is removed from the track rail 1.

[0060] FIG. 4 shows the manner in which the balls 3 are rolling on the side rolling surfaces 10*a* formed on the side surfaces of the straight guide rail portion 1A and circulating through the path when each slider 2 is moving along the straight guide rail portion 1A. The balls 3 rolling on the top ball-rolling surfaces lob formed on the top surface of the straight guide rail portion 1A make similar rolling and circulating motion.

[0061] As mentioned previously, the direction change paths 51 corresponding to the load-rolling surfaces 43*a* and 43*b* are formed in the two covers 5 mounted to the opposite end surfaces, respectively, of the movable block 4. By mounting the covers 5 to the movable block 4, the slider 2 forms an endless circular path for the balls 3 as shown. The rolling surfaces 10*a* and 10*b* extend linearly and longitudinally along the straight guide rail portion 1A. Also, the load-rolling surfaces 43*a* and 43*b* of the slider 2 opposite to the rolling surfaces 10*a* and 10*b*, respectively, are formed linearly. Therefore, all the balls 3 simultaneously rolling on the load-rolling surfaces 43*a* and 43*b* are in contact with the rolling surfaces 10*a* and 10*b*, respectively, of the straight guide rail portion 1A, as shown in FIG. 4. That is, when the slider 2 is moving along the straight guide rail portion 1A, none of the balls 3 are idling without sustaining a load between the rolling surface **10**a or **10**b on the side of the track rail **1** and the load-rolling surface **43**a or **43**b on the side of the slider **4**. If a large load is applied to the slider **2**, the load is sustained reliably, and the slider **2** can be moved smoothly.

[0062] **FIG. 5** is a front view in cross section of the curved guide rail portion **1**B and one slider **2** mounted on it. This curved guide rail portion **1**B is shaped into a cross-sectional shape similar to that of the above-described straight guide rail portion. This curved guide rail portion **1**B is shaped into an arc having a given curvature R in the longitudinal direction. Side rolling surfaces **12**a continuous with the side rolling surfaces **10**a, respectively, formed on the opposite side surfaces of the straight guide rail portion **1**A are formed on the opposite side surfaces of the curved guide rail portion **1**B. Top rolling surfaces **12**b continuous with the top rolling surfaces **10**b, respectively, formed on the top surface of the straight guide rail portion **1**A are formed on the top surface of the curved guide rail portion **1**B.

[0063] Since the curved guide rail portion **1**B is formed to have a given curvature, if the width L_2 of the curved guide rail portion **1**B is set equal to the width L_1 of the straight guide rail portion **1**A, then the inner side surface of the curved guide rail portion **1**B may be hindered by the skirt portions **4**b or with the covers **5**. Therefore, the width L_2 of the curved guide rail portion **1**B is set smaller than the width L_1 of the straight guide rail portion **1**A. For comparison, the cross section of the straight guide rail portion **1**A is indicated by the dot-and-dash line. When the width L_2 of the curved guide rail portion **1**B is set smaller than the width L_1 of the straight guide rail portion **1**A, only the inner side surface of the curved guide rail portion **1**B needs to be ground, as shown in **FIG. 5**. Alternatively, both inner and outer side surfaces may be ground, as shown in **FIG. 16**.

[0064] **FIG. 6** shows the manner in which the balls **3** are rolling and circulating through a circular path when the slider **2** is moving along the curved guide rail portion **1**B. The balls **3** are shown to roll on the rolling surfaces **12**a formed on the opposite side surfaces of the curved guide rail portion **1**B. The rolling surfaces **12**a are shaped into arcs longitudinally of the curved guide rail portion **1**B. On the other hand, the load-rolling surfaces **43**a of the slider **2** opposite to the rolling surfaces **12**a are shaped linearly. Thus, as shown in **FIG. 6**, inside of the curved guide rail portion **1**B, only those of the balls **3** which are rolling close to both ends of the load-rolling surfaces **43**a bear against the rolling surfaces **12**a. Outside of the curved guide rail portion **1**B, only those of the balls **3** which roll across the centers of the load-rolling surfaces **43**a bear against the rolling surfaces **12**a. That is, when the slider **2** is moving along the curved guide rail portion **1**B, only parts of the balls **3** rolling on the load-rolling surfaces **43**a of the slider **2** sustain a load, whereas the other balls **3** idle without sustaining a load. It may be considered that all the balls **3** rolling on the load-rolling surfaces **43**a bear against the rolling surfaces **12**a of the curved guide rail portion **1**B, depending on the curvature of the curved guide rail portion **1**B. Even in this case, some of the balls **3** hardly sustain a load and idle. Even if some of the balls **3** idle without bearing against the rolling surfaces **12**a of the curved guide rail portion **1**B in this way, these balls **3** do not disengage from between the load-rolling surfaces **43**a and the rolling surfaces **12**, because the ball-holding plate **46** is mounted to the slider **2**.

[0065] **FIG. 7** shows the manner in which the balls **3** are rolling on the load-rolling surfaces **43**b formed on the horizontal portion **4**a of the slider **2**. That is, **FIG. 7** is a perspective of the slider **2** as taken from above the curved guide rail portion **1**B. Since the load-rolling surface **43**b of the slider **2** is straight while the opposite rolling surface **12**b of the curved guide rail portion **1**B is shaped into an arc, if the width of the rolling surfaces **12**b is set equal to the width of the side rolling surfaces **12**a on the curved guide rail portion and the width of the load-rolling surfaces **43**b, some of the balls **3** rolling on the load-rolling surface **43**b on the side of the slider **2** bear against the inner surface of the rolling surface **12**b. The others come off the rolling surface **12**b and bear against the top surface of the curved guide rail portion **1**B. Consequently, the balls **3** cannot smoothly circulate through the endless circular path in the slider **2**.

[0066] Therefore, the rolling surface **12**b formed on the top surface of the curved guide rail portion **1**B is shaped to have a larger groove width d than the load-rolling surfaces **43**b such that all the balls **3** which roll on the load-rolling surfaces **43**b can simultaneously bear against the rolling surface **12**b, as shown in **FIG. 7**. **FIG. 8** is an enlarged view showing the manner in which the balls **3** touch rolling surfaces between the load-rolling surface **43**b on the side of the slider **2** and the rolling surface **12**b on the side of the curved guide rail portion **1**B. The solid line indicates the manner in which the balls touch the rolling surfaces in cross section α-α of **FIG. 7**. The dot-and-dash line indicates the manner in which the balls touch the rolling surfaces in cross section B-B. The rolling surfaces **12**b are set wider than the load-rolling surfaces **43**b. Furthermore, the rolling surfaces **12**b are shaped into an arc having a curvature in the horizontal direction in the plane of **FIG. 8**. Therefore, as the balls **3** roll on the straight load-rolling surfaces **43**b, the positions at which the balls touch the rolling surfaces **12**b move right and left. The balls roll on the load-rolling surfaces **43**b while sustaining a load between the slider and the curved guide rail portion at all times.

[0067] In the universal guide device in the present invention in this way, the curved guide rail portion **1**B is set narrower than the straight guide rail portion **1**A. Where the top surface of the track rail **1** needs a rolling surface for the balls **3**, only the rolling surface **12**b on the top surface of the curved guide rail portion **1**B is set wider than the load-rolling surface **43**b on the side of the slider **2**. Hence, the slider **2** can be moved freely between the straight guide rail portion **1**A and the curved guide rail portion **1**B, though the slider **2** is the same as the prior art linear guide device structure.

[0068] However, when the slider **2** moves along the curved guide rail portion **1**B, the number of the balls **3** bearing against the side rolling surfaces **12**a of the curved guide rail portion **1**B is fewer than the number of the balls **3** bearing against the side rolling surfaces **10**a of the straight guide rail portion **1**A. Therefore, it cannot be denied that the ability of the slider **2** to sustain a load in the curved region of the track rail **1** decreases. However, the ability of the straight region to sustain a load is not sacrificed for the sake of the curved region. If a large load acts on the slider **2** in the straight region, the load can be sufficiently sustained.

[0069] In the universal guide device in accordance with the present invention as described above, the load-rolling surfaces **43**_a_ and **43**_b_ of the slider **2** are shaped linearly and have no directivity. Therefore, the slider **2** can move along the curved guide rail portion **1**B without trouble, irrespective of whether the curved guide rail portion **1**B is bent right or left. For this reason, as shown in **FIG. 9**, the slider **2** can be moved along an S-shaped track rail **1** built by combining two curved guide rail portions **1**B bent in different directions. Furthermore, it is not always necessary that all the successive curved guide rail portions **1**B within the continuous track rail **1** be shaped into arcs with uniform radius. The slider can be moved freely even if curved rail portions having different radii are combined.

[0070] As shown in **FIG. 10**, the curved guide rail portion **1**B formed at uniform curvature is cut into two rail pieces **16** and **17**. Then, one rail piece **17** is rotated through 180° and combined with the other rail piece **16**, thus forming an S-shaped track rail **1**. Even in this case, the slider **2** can be moved along the track rail **1** freely.

[0071] Referring next to **FIG. 11**, there is shown the intermediate rail portion **1**C connecting the straight guide rail portion **1**A and the curved guide rail portion **1**B. It may be possible to construct the track rail **1** by connecting the straight guide rail portion **1**A and curved guide rail portion **1**B without using the intermediate rail portion **1**C. As mentioned previously, the curved guide rail portion **1**B is set narrower than the straight guide rail portion **1**A. In addition, the rolling surface **12**_b_ of the curved guide rail portion **1**B is set wider than the top rolling surface **10**_b_ of the straight guide rail portion **1**A. Therefore, if the straight guide rail portion **1**A and curved guide rail portion **1**B are connected directly, then smooth movement of the slider **2** may be somewhat hindered. Consequently, in the present invention, the intermediate rail portion **1**C is interposed between the straight guide rail portion **1**A and the curved guide rail portion **1**B to transport the slider **2** from the straight guide rail portion **1**A to the curved guide rail portion **1**B and vice versa smoothly.

[0072] This intermediate rail portion **1**C assumes a cross-sectional shape similar to that of the straight guide rail portion **1**A, and extends linearly. The intermediate rail portion **1**C has ball-rolling surfaces that continuously connect with the rolling surfaces **10**_a_ and **10**_b_ of the straight guide rail portion **1**A and with the rolling surfaces **12**_a_ and **12**_b_ of the curved guide rail portion **1**B. Since the curved guide rail portion **1**B is set narrower than the straight guide rail portion **1**A, the side surface **14** of the intermediate rail portion **1**C that is continuous with the inner side surface of the curved guide rail portion **1**B is cut out obliquely on the side at the end of the curved guide rail portion **1**B as indicated by the dot-and-dash line of **FIG. 13**. The width decreases gradually from the straight guide rail portion **1**A toward the curved guide rail portion **1**B. Thus, the side rolling surface **10**_a_ formed on the side of the straight guide rail portion **1**A is continuous with the rolling surface **12**_a_ formed on the side surface of the curved guide rail portion **1**B, without step-wise changes. The balls can roll smoothly between the rolling surfaces **10**_a_ and **12**_a_.

[0073] As shown in **FIG. 11, a** ball-rolling surface **13**_b_ that is continuous with the rolling surface **10**_b_ of the straight guide rail portion **1**A and with the rolling surface **12**_b_ of the curved guide rail portion **1**B is formed on the top surface of the intermediate rail portion **1**C. As shown in **FIGS. 12 and 13**, the width of the ball-rolling surface **13**_b_ gradually increases on the side at the end of the curved guide rail portion **1**B. This connects the rolling surfaces **10**_b_ and **12**_b_ having different widths without any step-wise changes. Consequently, balls that have rolled on the rolling surface **12**_b_ of the curved guide rail portion roll into the top rolling surface **10**_b_ of the straight guide rail portion that is narrower than the rolling surface **12**_b_ without being caught. In this way, the slider can be smoothly moved from the curved region to the straight region of the track rail.

[0074] Referring next to **FIG. 14**, there is shown a universal guide device in accordance with a second embodiment of the present invention. A track rail **7** and a slider **8** are similar in fundamental structure with their respective counterparts of the first embodiment described above. However, the rail **7** has two ball-rolling surfaces **71**_a_ and two ball rolling surfaces **71**_b_ on opposite sides, one pair above the other. The upper rolling surfaces **71**_a_ are tilted at an angle of 45° upwardly. The lower rolling surfaces **71**_b_ are tilted at an angle of 45° downwardly. The slider **8** has load-rolling surfaces **81**_a_ and **81**_b_ that are tilted at angles corresponding to the ball rolling surfaces **71**_a_ and **71**_b_, respectively.

[0075] This **FIG. 14** shows the manner in which the slider **8** is mounted to the straight region of the track rail **7**, i.e., the straight guide rail portion **7**A. A curved guide rail portion **7**B continuous with this straight guide rail portion **7**A is set narrower than the straight guide rail portion **7**A, in the same way as in the first embodiment. **FIG. 15** is a front view in cross section of the curved guide rail portion **7**B, and in which the contour of the straight guide rail portion **7**A is also indicated by the dot-and-dash line.

[0076] In the universal guide device in accordance with the second embodiment constructed in this manner, the curved guide rail portion **7**B is set narrower than the straight guide rail portion **7**A in the same way as in the first embodiment. In consequence, the slider **8** can freely move between the straight guide rail portion **7**A and the curved guide rail portion **7**B.

[0077] In the embodiments given above, the present invention is applied to universal guide devices. If an annular track rail is composed by combining plural curved guide rail portions of the structure described above, the slider can be moved along this rail. A curved guide device can be easily constructed.

[0078] In the present invention, the load-rolling surfaces **43**_a_ and **43**_b_ formed on the slider **2** are shaped linearly. Therefore, a universal guide device can be fabricated by making direct use of sliders of the existing linear guide devices. Accordingly, in the embodiments described above, the curved guide rail portion **1**B is set narrower than the straight guide rail portion **1**A to permit the slider of the straight guide device to move along the curved guide rail portion **1**B as it is. However, due to the degree of curvature of the curved guide rail portion **1**B, it may be impossible to adapt the structure sufficiently only with a decrease in the width of the curved guide rail portion **1**B. The curved guide rail portion **1**B may be hindered in its movement by the skirt portions **4**_b_ of the slider **2** or with the covers **5**. Accordingly, in this case, the length of the slider **2** taken longitudinally with regard to the track rail **1** is reduced, thus preventing interference between the curved guide rail portion **1**B and the slider **2**.

[0079] Referring to **FIGS. 17 and 18**, there is shown a moving table device using a universal guide device in accordance with the present invention, the moving table device forming a third embodiment of the invention. Track rails **1** and **1'** are mounted to a fixed portion such as a pedestal or a base. Sliders **2** can move along the rails **1** and **1'**. A table **92** is mounted to the sliders.

[0080] The track rails **1** and **1'** are composed of the first rail **1** and the second rail **1'** that extend in parallel and are uniformly spaced from each other. The rail **1** comprises a straight guide rail portion **1A**, a curved guide rail portion **1B** shaped into an arc with a given curvature, and an intermediate rail portion **1C** connecting the straight guide rail portion **1A** and the curved guide rail portion **1B**. Similarly, the rail **1'** comprises a straight guide rail portion **1'A**, a curved guide rail portion **1'B** shaped into an arc with a given curvature, and an intermediate rail portion **1'C** connecting the straight guide rail portion **1'A** and the curved guide rail portion **1'B**. The radii of curvature of the curved guide rail portions **1B** and **1'B** are set to R1 and R2, respectively. The centers O of their radii of curvature are coincident.

[0081] Plural (e.g., 2) sliders **2** are mounted to each of the rails **1** and **1'**. Four sliders in total support the table. The sliders **2** can move freely on the first rail **1** (1A, 1B, 1C) and on the second rail **1'** (1'A, 1'B, 1'C). A pair of fixed plates **91** is mounted across the first and second rows of the sliders **2** as viewed in the direction of motion on the rails **1** and **1'**. The fixed plates **91** assume an elongated rectangular form and are mounted to the top surfaces of the sliders **2** with fixing means such as screws. That is, the fixed plates **91** are bridged across the sliders **2** that are adjacent to each other looking down the longitudinal direction of the rails **1** and **1'** (i.e., in the direction of the array of the rail portions).

[0082] The table **92** is mounted so as to be rotatable relative to the fixed plates. A shaft **93** is mounted to the bottom surface of the table **92**. Rotary bearings **90** for rotatably holding the shaft **93** are mounted to the top surfaces of the fixed plates **91**. The rotary bearings **90** permit the table **92** to rotate relative to the fixed plates while the bearings receive a load from the table **92**. The rotary bearings **90** are mounted in housings **94**, which in turn are mounted to the fixed plates **91**. Each of the rotary bearings **90** has an outer race **90*a*** mounted to the housing and an inner race **90*b*** mounted to the shaft **93**.

[0083] **FIG. 19** shows one of the rotary bearings **90**. A V-shaped rolling surface is formed in both the outer race **90*a*** and inner race **90*b***. A roller-rolling path of substantially rectangular cross section is formed between these rolling surfaces. Plural rollers **95** are arranged in the roller-rolling path and tilted alternately in directions at right angles to each other. The rollers **95** roll in the roller-rolling path while receiving a load. Spacers **96** are interposed between adjacent rollers **95** to maintain the rollers **95** in a given disposition.

[0084] In the roller-rolling path, the two rollers **95** horizontally adjacent to the same spacer **96** have axes that are perpendicular to each other. These rollers **95** are classified as outward facing rollers **95*a*** and inward facing rollers **95*b***. The spacers **96** maintain the outward facing rollers **95*a*** in such a disposition that their axes C face toward the center of rotation B lying at the center of rotation of the outer race **90*a*** and the inner race **90*b***.

[0085] **FIG. 20** shows the manner in which the track rails **1** and **1'** consisting of the rail portions **1A**, **1B**, **1C** and rail portions **1'A**, **1'B**, **1'C**, respectively, are combined into an S-shaped form. The fixed plates **91** and the table **92** move on this S-shaped rail. When moving on the curved rail portions **1B** and **1'B**, the sliders **2** are directed in the tangential direction of the curved rail portions **1B** and **1'B**. Therefore, the fixed plates **91** mounted to the sliders **2** rotate about the center O of the radius of curvature. As a result, the distance between the sliders **2** moving on the inner track rail **1** decreases, while the distance between the sliders **2** moving on the outer track rail **1'** increases. Since the fixed plates **91** are rotatably mounted to the table **92**, the plates permit such variations in the distances between the sliders **2** and enable smooth motion of the sliders **2**.

[0086] **FIGS. 21 and 22** show a moving table device using a universal guide device in accordance with the present invention, the moving table device forming a fourth embodiment of the present invention. In this fourth embodiment, the first track rail **1** and the second track rail **1'** are mounted in parallel, and two sliders **2** are mounted to both of the rails **1** and **1'**. These four sliders **2** support the table **92**, in the same way as in the third embodiment described above. However, the moving table device in accordance with the fourth embodiment differs from the moving table device in accordance with the third embodiment in that the four sliders **2** have their respective rotary bearings **90** and that the table **92** is rotatably held by the rotary bearings **90**. The rotary bearings **90** are similar in structure to the rotary bearings used in the third embodiment. Shafts mounted at the four corners of the table **92** are rotatably held.

[0087] In the moving table device in accordance with this embodiment, the sliders **2** support the four corners of the table **92** and so the table **92** can be held more stably than in the third embodiment. Since the four sliders **2** are rotatably held to the table, the sliders **2** moving on the curved guide rail portions **1B** and **1'B** rotate arbitrarily and independently and are directed in tangential directions $\theta 1$, $\theta 2$, $\theta 3$, and $\theta 4$ of the curved guide rail portions **1B**, **1'B**, as shown in **FIG. 22**. This permits smooth motion of the sliders **2**.

[0088] When the table **92** moves between the track rails **1** and **1'** having different radii of curvature as encountered when moving from the straight regions **1A**, **1'A** of the rails **1**, **1'** to the curved regions **1B**, **1'B**, if the distance between the sliders **2** is kept constant, the sliders **2** will be hindered in their movement by the rails **1** and **1'**, hindering smooth movement of the table **92**. However, gaps are provided between the sliders **2** and the rails **1**, **1'** by setting the width of rails **1** and **1'** narrower as mentioned above. The gaps eliminate the interference between the sliders **2** and the rails **1**, **1'**, assuring smooth movement of the sliders **2**.

What is claimed is:

1. A universal guide device comprising:

a track rail including a straight region and at least one curved region shaped into an arc having a given radius of curvature, and having ball-rolling surfaces formed on the two opposite side surfaces along a longitudinally direction of said track rail;

a slider formed a saddlelike shape and mounted on said track rail, having load-rolling surfaces which located opposite to said ball-rolling surfaces of said track rail, and having endless circular paths which including said load-rolling surfaces;

a number of balls rolling in said endless circular path formed in said slider, sustaining a load between said ball-rolling surfaces of said track rail and said load-rolling surfaces of said slider; and

wherein said load-rolling surfaces are shaped linearly and said curved region of said track rail is set narrower than said straight region of said track rail.

2. The universal guide device of claim 1, wherein the balls sustain a load between the arc-shaped ball-rolling surfaces along a longitudinally direction of said track rail and the straight load-rolling surfaces formed on said slider, when said slider moves through the curved region of said track rail.

3. The universal guide device of claim 1, wherein some of said balls rolling on said load-rolling surfaces on said slider sustain a load between the ball-rolling surfaces on said track rail and the load-rolling surfaces on said slider, when said slider moves through the curved region of said track rail.

4. The universal guide device of claim 1, wherein said track rail has a upward ball-rolling surface which formed on a top surface of said track rail, said slider has a downward load-rolling surface opposite to said upward ball-rolling surface of said track rail, and said upward ball-rolling surface in said curved region of said track rail is set to such a width that all the balls rolling on the downward load-rolling surface of said slider simultaneously touch said upward ball-rolling surface.

5. The universal guide device of claim 1, wherein said track rail has two curved regions bent in different directions, right and left.

6. The universal guide device of claim 1, wherein said track rail is constructed by combining a straight guide rail and a curved guide rail.

7. The universal guide device of claim 6, wherein said track rail has a intermediate rail that connects said straight guide rail with said curved guide rail, and wherein said intermediate rail has a width that continuously varies from the end of said straight guide rail to the end of said curved guide rail.

8. A moving table device comprising plural universal guide devices mounted parallel to each other and a table guided said universal guide devices, each of said universal guide devices comprising:

a track rail including a straight region and at least one curved region shaped into an arc having a given radius of curvature, and having ball-rolling surfaces formed on the two opposite side surfaces along a longitudinally direction of said track rail;

a slider formed a saddlelike shape and mounted on said track rail, having load-rolling surfaces which located opposite to said ball-rolling surfaces of said track rail, and having endless circular paths which including said load-rolling surfaces;

a number of balls rolling in said endless circular path formed in said slider, sustaining a load between said ball-rolling surfaces of said track rail and said load-rolling surfaces of said slider; and

wherein said load-rolling surfaces are shaped linearly and said curved region of said track rail is set narrower than said straight region of said track rail.

9. The moving table device of claim 8, wherein plurality of said track rails are mounted parallel to each other, plurality of said sliders are mounted to each of said track rails, the sliders adjacent each other on different said rails are connected by fixed plates, and said table is mounted so as to be rotatable relative to said fixed plates.

10. The moving table device of claim 8, wherein plurality of said track rails are mounted parallel to each other, plurality of said sliders are mounted to each of said track rails, said table is mounted so as to be rotatable relative to said sliders.

11. A moving table device comprising plural universal guide devices mounted parallel to each other and a table guided said universal guide devices, each of said universal guide devices comprising:

a track rail including a straight region and at least one curved region shaped into an arc having a given radius of curvature, and having ball-rolling surfaces formed on the two opposite side surfaces along a longitudinally direction of said track rail;

a slider formed a saddlelike shape and mounted on said track rail, having load-rolling surfaces which located opposite to said ball-rolling surfaces of said track rail, and having endless circular paths which including said load-rolling surfaces;

a number of balls rolling in said endless circular path formed in said slider, sustaining a load between said ball-rolling surfaces of said track rail and said load-rolling surfaces of said slider; and

wherein plurality of said track rails are mounted parallel to each other, plurality of said sliders are mounted to each of said track rails, the sliders adjacent each other on different said rails are connected by fixed plates, and said table is mounted so as to be rotatable relative to said fixed plates.

(57) **ABSTRACT**

A roller retainer **11** encloses an outer periphery of the roller **9** situated on a diagonal **20** when the roller **9** is viewed from the side surface thereof. Whether the rollers **9** are arranged in a parallel manner or in a cross manner, the roller retainer **11** is able to keep a constant position and thus the disposition of the roller retainer **11** is free from the influence of the direction the roller **9**. Also, since the roller retainer **11** restricts a corner portion **9***a* of the roller **9**, the roller **9** is difficult to slip off the roller retainer **11** and thus the roller **9** can be restricted positively, thereby being able to control the skew of the roller **9**.

ROLLER RETAINER, ROLLER SCREW USING ROLLER RETAINER AND ROLLING GUIDE APPARATUS USING ROLLER RETAINER

BACKGROUND OF THE INVENTION

[0001] 1. Field of the Invention

[0002] The present invention relates to a roller retainer which is used in a rolling guide apparatus and a roller screw and also which is used to hold rollers rolling through a circulation passage in such a manner that the rollers can be freely rotated and slid.

[0003] 2. Description of the Related Art

[0004] Conventionally, there is known a roller screw structured such that a plurality of rollers are interposed between a screw shaft and a nut member. In case where the screw shaft is rotated with respect to the nut member, the nut member is moved linearly in the axial direction of the screw shaft. In the screw shaft, there is formed a spiral-shaped roller rolling groove. On the other hand, in the nut member, there is formed a roller circulation passage including a spiral-shaped load rolling groove which is so formed as to correspond to the roller rolling groove of the screw shaft. The rollers roll in such a manner that they move along the outer periphery of a screw groove between the screw shaft and nut member, thereby circulating through the roller circulation passage. In such roller screw, the plurality of rollers are, in some cases, arranged parallel in the roller circulation passage in order that the axes of the mutually adjoining rollers can be held almost parallel to each other; and, in other cases, they are cross arranged in such a manner that the axes of the mutually adjoining rollers cross each other.

[0005] Generally, in a roller screw in which only the rollers are arranged in the roller circulation passage, the movements of the respective rollers can vary from one another, and the rollers can fall down in a plane including the axes of the rollers and the advancing direction of the rollers to thereby cause a so called skew. Such skew interferes with the lined-up circulation of the rollers. To prevent the skews of the rollers, there is proposed use of a roller retainer which can hold the rollers in such a manner that the rollers can be freely rotated and slid. As shown in **FIG. 13**, the roller retainer **2** encloses the outer periphery of a roller **1** that is situated on the center line **1***a* of the roller **1** when the roller **1** is viewed from the side surface thereof, and thus restricts the roller **1** to thereby prevent the roller **1** against skew.

[0006] However, in the conventional roller retainers **2**, when the rollers **1** are arranged in a crossing manner, the roller retainers **2** are also arranged in a crossing manner that the roller retainers **2** cross each other, which makes it impossible to obtain a large contact area between the roller retainers **2**. For this reason, the conventional roller retainers **2** cannot be applied to the rollers **1** which are cross arranged.

[0007] Also, since the conventional roller retainer **2** encloses the outer periphery of the roller **1** that is situated on the center line **1***a* of the roller **1** when the roller **1** is viewed from the side surface thereof, the roller **1** is easy to slip off the roller retainer **2** and the roller retainer **2** is not be able to provide a sufficient force to hold the roller **1**, thereby raising a fear that the skew of the roller cannot be controlled.

SUMMARY OF THE INVENTION

[0008] The present invention aims at eliminating the above drawbacks found in the conventional roller retainer, and therefore an object of the invention is to provide a roller retainer which can be applied to both of cross arranged rollers and parallel arranged rollers and can restrict the rollers more positively in such a manner the skews of the rollers can be controlled, as well as a linear guide apparatus and a roller screw respectively using such roller retainers.

[0009] Now, description will be given below of the invention. By the way, for easy understanding of the invention, reference numerals shown in the accompanying drawings are stated herein while putting them in parentheses; however, the invention is not limited to the illustrated embodiments thereof. In attaining the above object, according to the invention, the outer periphery of a roller situated on a diagonal when the roller is viewed from the side surface thereof is enclosed by a roller retainer, and the corner portion and cylindrical portion of the roller are restricted.

[0010] In other words, according to a first aspect of the invention, there is provided a roller retainer (**11**) for holding a roller (**9**) circulating through a roller circulation passage, wherein the roller retainer (**11**) encloses the outer periphery of the roller (**9**) situated on a diagonal (**20**) when the roller (**9**) is viewed from the side surface thereof. Here, the roller retainer may hold a plurality of rollers, which respectively circulate through the roller circulation passage, in a series manner, or the roller retainer may hold the plurality of rollers individually.

[0011] According to the first aspect of the invention, since the roller retainer encloses the outer periphery of the roller that is situated on the diagonal when the roller is viewed from the side surface thereof, the roller retainer is allowed to keep a constant position whether the rollers are arranged in a parallel manner or in a cross manner and thus the disposition of the roller retainer is free from the influence of the direction of the roller. Therefore, there can be obtained a roller retainer which can be applied not only to a structure in which rollers are parallel arranged but also to a structure in which rollers are cross arranged. Also, because the roller retainer restricts the corner portion of the roller, the roller is difficult to slip off the roller retainer, thereby being able to restrict the roller positively, so that the skew of the roller can be controlled.

[0012] Also, according to a second aspect of the invention, in a roller retainer according to the first aspect of the invention, the roller retainer (**11**) holds individually a plurality of rollers (**9**) which are respectively allowed to circulate through the roller circulation passage.

[0013] In the case of a roller screw, the circulation path of a roller draws a spiral shape. In case where a roller retainer is formed in a band shape so that it can hold a plurality of rollers in a series manner, the roller retainer is spirally twisted and a load is thereby applied to the roller retainer, which raises a fear that the roller retainer can be damaged or broken. However, according to the second aspect of the invention, since the roller retainer holds the plurality of rollers individually, even in case where the circulation path of the roller is formed in a spiral shape, the roller retainer can be prevented against damage or breakage.

[0014] Further, according to a third aspect of the invention, in a roller retainer according to the first or second aspect of the invention, the roller retainer (**11**) is molded with the roller (**9**) inserted therein. As the molding method, for example, there can be employed a method in which molten resin is injection molded into a metal mold in which the roller has been installed.

[0015] According to the third aspect of the invention, a clearance between the roller retainer and roller can be made small to thereby be able to restrict the roller positively.

[0016] Also, according to a fourth aspect of the invention, there is provided a roller screw comprising: a track shaft (**5**) including a spiral-shaped roller rolling groove (**5*a***) having a V-shaped section; a slide member (**6**) comprising a roller circulation passage including a spiral-shaped load rolling groove (**6*a***) having a V-shaped section and assembled to the track shaft (**5**) in such a manner that it can be moved with respect to the track shaft (**5**), the load rolling groove (**6*a***) being so formed as to correspond to the roller rolling groove (**5*a***); a plurality of rollers (**9**) respectively arranged and stored in the roller circulation passage and allowed to circulate through the roller circulation passage in linking with the relative motion of the slide member (**6**) with respect to the track shaft (**5**); and a plurality of retainers (**11**) for holding the plurality of rollers (**9**) individually in such a manner that the rollers (**9**) can be rotated and slid, wherein each of the roller retainers (**11**) encloses the outer periphery of its associated one of the rollers (**9**) that is situated on a diagonal (**20**) when the roller (**9**) is viewed from the side surface thereof, and also wherein, in at least one of the roller rolling groove (**5*a***) and load rolling groove (**6*a***), there is formed a guide groove (**10, 14**) for guiding the roller retainer (**11**).

[0017] According to the fourth aspect of the invention, not only there can be obtained the above-mentioned operation effects, but also, since the roller retainer is guided by the guide groove, the fall-down of the roller retainer as well as the skew of the roller can be controlled.

[0018] Further, according to a fifth aspect of the invention, there is provided a rolling guide apparatus comprising: a track shaft (**31**) including a roller rolling groove (**31*a***) having a V-shaped section; a slide member (**32**) comprising a roller circulation passage including a load rolling groove (**32*a***) having a V-shaped section and assembled to the track shaft (**31**) in such a manner that it can be moved with respect to the track shaft (**31**), the load rolling groove (**32*a***) being so formed as to correspond to the roller rolling groove (**31*a***); a plurality of rollers (**9**) respectively arranged and stored in the roller circulation passage and allowed to circulate through the roller circulation passage in linking with the relative motion of the slide member (**32**) with respect to the track shaft (**31**); and, a plurality of retainers (**11**) for holding the plurality of rollers (**9**) individually in such a manner that the rollers can be rotated and slid, wherein each of the roller retainers (**11**) encloses the outer periphery of its associated one of the rollers (**9**) that is situated on a diagonal (**20**) when the roller (**9**) is viewed from the side surface thereof, and also wherein, in at least one of the roller rolling groove (**31*a***) and load rolling groove (**32*a***), there is formed a guide groove (**38**) for guiding the roller retainer (**11**).

[0019] According to the fifth aspect of the invention, not only there can be obtained the above-mentioned operation effects, but also, since the roller retainer is guided by the guide groove, the fall-down of the roller retainer as well as the skew of the roller can be controlled.

BRIEF DESCRIPTION OF THE DRAWINGS

[0020] **FIG. 1** is a perspective view of a roller screw incorporating therein a roller retainer according to a first embodiment of the invention;

[0021] **FIG. 2** is a section view of the above roller screw in the axial direction thereof;

[0022] **FIG. 3** is a side view of a roller retainer and a roller;

[0023] **FIG. 4** is a perspective view of the roller retainer and roller;

[0024] **FIGS. 5A and 5B** are views of roller retainers and rollers, showing a state thereof in which they are respectively arranged in line; specifically, **FIG. 5A** shows a state thereof in which they are parallel arranged and **FIG. 5B** shows a state thereof in which they are cross arranged;

[0025] **FIG. 6** is atypical view of rollers and roller retainers rolling on the periphery of a screw shaft (that is, **FIG. 6** is a section view of the rollers and roller retainers in a direction crossing the screw shaft at right angles);

[0026] **FIG. 7** is a perspective view of rollers and roller retainers which are parallel arranged in a roller screw;

[0027] **FIG. 8** is a perspective view of rollers and roller retainers which are cross arranged in a roller screw;

[0028] **FIG. 9** is a section view of another example of a roller retainer;

[0029] **FIG. 10** is a plan view of a linear guide incorporating a roller retainer according to the first embodiment of the invention;

[0030] **FIG. 11** is a side view of the above linear guide;

[0031] **FIG. 12** is a section view of the linear guide, taken along the direction thereof to cross the axial direction thereof; and

[0032] **FIG. 13** is a side view of a roller retainer and a roller according to the prior art.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0033] Hereinafter, a description will be given in more detail of preferred embodiments of the invention with reference to the accompanying drawings.

[0034] Now, **FIG. 1** shows a roller screw into which a roller retainer according to a first embodiment of the invention is incorporated. This roller screw comprises a screw shaft **5** with a spiral-shaped roller rolling groove **5*a*** formed on the outer peripheral surface thereof, a nut member **6** (slide member), in which a roller circulation passage (rolling body circulation passage) including a spiral-shaped load rolling groove **6*a*** formed on the inner peripheral surface thereof in such a manner to correspond to the spiral-shaped roller rolling groove **5*a*** is formed and which is assembled to the screw shaft **5** in such a manner that it can be moved with respect to the screw shaft **5**, and a plurality of rollers which are arranged and stored in the roller circulation passage and are allowed to circulate in linking with the relative movement of the nut member **6** with respect to the screw shaft **5**. A load rolling passage of the roller circulation passage is formed by and between the roller rolling groove **5*a*** of the screw shaft **5** and the load rolling groove **6***a* of the nut member **6**. The nut member **6** includes a return pipe **7**. A no-load return passage, which allows one end of the load rolling passage to communicate with the other end thereof, is formed by the return pipe **7**. With the relative rotation of the screw shaft **5** with respect to the nut member **6**, the roller is allowed to roll between the roller rolling groove **5***a* of the screw shaft **5** and the load rolling groove **6***a* of the nut member **6**, while the nut member **6** is moved linearly with respect to the screw shaft **5**.

[0035] Now, **FIG. 2** shows the section of the above roller screw in the axial direction thereof. On the outer peripheral surface of the screw shaft **5**, there is formed a roller rolling groove **5***a* having a given lead. The roller rolling groove **5***a* has a V-shaped section and the angle of the inclined wall surface of the V-shaped roller rolling groove **5***a* is set substantially at 90°.. A roller **9** is allowed to roll on the wall surface **8***a* or **8***b* of the roller rolling groove **5***a*. In the bottom portion of the roller rolling groove **5***a*, there is formed a guide groove **10** which is used to guide a roller retainer **11** along the roller rolling groove **5***a*. This guide groove **10** is formed slightly wider than the width W of the roller retainer **11** and slightly deeper than the end face **11***a* of the roller retainer **11**, in order to be able to avoid interference with the roller retainer **11** (see **FIG. 3**).

[0036] The nut member **6** is fitted with the screw shaft **5** with a clearance between them. The nut member **6** is formed substantially in a cylindrical shape and includes, in the end portion thereof, a flange **12** which is used to connect the nut member **6** to a member to be guided. On the inner peripheral surface of the nut member **6**, there is formed a spiral-shaped load rolling groove **6***a* having a lead equal to the lead of the screw shaft **5**. The load rolling groove **6***a* also has a V-shaped section and the angle of the inclined wall surface of the V-shaped load rolling groove **6***a* is set substantially at 90°. The roller **9** is allowed to roll on the wall surface **13***a* or **13***b* of the roller rolling groove **6***a*. Between the load rolling groove **6***a* and roller rolling groove **5***a* that adjoin each other, there is formed a substantially square-shaped load rolling passage. In the bottom portion of the load rolling groove **6***a*, there is formed a spiral-shaped guide groove **14** which extends along the load rolling groove **6***a*. This guide groove **14** is also formed slightly wider than the width W of the roller retainer **11** and slightly deeper than the end face **11***a* of the roller retainer **11**, in order to be able to avoid interference with the roller retainer **11** (see **FIG. 3**). As shown in **FIG. 1**, in the nut member **6**, there are opened up return pipe fit holes into which the two side portions of a return pipe **7** can be inserted. The return pipe fit holes are so formed as to extend into the load rolling groove **6***a*. The return pipe **7** is fixed to the nut member **6** by a pipe holder **15**.

[0037] As shown in **FIG. 2**, between the load rolling groove **6***a* of the nut member **6** and the roller rolling groove **5***a* of the screw shaft **5**, there are arranged and stored a plurality of rollers **9**. The plurality of rollers **9**, in some cases, are parallel arranged such that the axes of the mutually adjoining rollers **9** are kept almost parallel to each other and, in other cases, they are cross arranged such that the axes of the mutually adjoining rollers **9** cross each other almost at right angles. The manner of arrangement of the rollers **9** is decided according to a ratio of axial-direction loads applied to the roller screw during the reciprocating motion thereof.

[0038] **FIGS. 3 and 4** respectively show the roller retainer **11** and roller **9** which are incorporated into the above-mentioned roller screw. Specifically, **FIG. 3** is a view of the roller **9** and roller retainer **11** when they are viewed from the side surfaces thereof; and, **FIG. 4** is a perspective view of the roller **9** and roller retainer **11**.

[0039] The roller **9** is formed in a cylindrical shape and the side surface thereof has a substantially square shape. The roller **9** is allowed to roll between the wall surfaces **8***a* and **13***a* or between the wall surface **8***b* and **13***b* which respectively provide the mutually opposing sides of the load running passage (see **FIG. 2**). The outside diameter of the roller **9** is set almost the same as the distance between the wall surfaces, while the axial-direction length of the roller **9** is set slightly smaller than the distance between the wall surfaces. By the way, a pre-load may be given to the roller **9** or may not.

[0040] The roller retainers **11** are disposed in the same number as that of the rollers **9** in order that they are able to hold the plurality number of rollers **9** individually. Also, the roller retainer **11** is formed in a frame shape so that it can enclose the outer periphery of the roller **9** situated on the diagonal **20** when it is viewed from the side surface thereof. And, the corner portion **9***a* of the roller **9** is fitted into a fit groove **21** which is formed in the interior portion of the frame-shaped roller retainer **11** and has a V-shaped section. The roller retainer **11** restricts the corner portion **9***a* and cylindrical portion **9***b* of the roller **9**. The roller retainer **11** is formed of synthetic resin and is manufactured by injection molding with the roller **9** inserted therein.

[0041] Now, **FIGS. 5A and 5B** show examples where the rollers **9** and roller retainers **11** are arranged linearly in a line. Specifically, **FIG. 5A** shows an example where the mutually adjoining rollers are arranged in such a manner that their axes are kept substantially parallel to each other, whereas **FIG. 5B** shows an example where the mutually adjoining rollers are arranged in such a manner that their axes cross each other substantially at right angles. In the case of the roller screw, within the return pipe **7**, the rollers **9** and roller retainers **11** are arranged linearly in this manner. Also, in the case of a rolling guide apparatus which will be discussed later, within a load rolling passage and a no-load return passage, rollers **9** and roller retainers **11** are arranged linearly.

[0042] Now, **FIG. 6** is a typical view of a roller allowed to roll along the outer periphery of the screw shaft and a roller retainer for holding this roller. In case where, the screw shaft **5** is rotated, the rollers **9** and roller retainers **11** are respectively allowed to roll in the peripheral direction of the screw shaft **5** within the load rolling passage while receiving loads. In this rolling operation, there is produced a speed difference between the inner and outer peripheral sides of the screw shaft **5** and thus the roller **9** is going to fall down in a plane including the axis of the roller **9** and advancing direction thereof, thereby causing a skew in the roller **9**. However, since the roller retainer **11** restricts the corner portion **9***a* and cylindrical portion **9***b* of the roller **9**, the roller **9** can be restricted positively and the skew of the roller **9** can be thereby controlled. Also, because the two end portions **11***b* and **11***b* of the roller retainer **11** are guided to the guide groove **10** formed in the bottom portion of the roller rolling groove **5***a* and to the guide groove **14** formed in the bottom portion of the load rolling groove **6***a*, the smooth circulation of the roller retainer **11** and roller **9** can be assured. Also, as shown in **FIG. 6**, the two end portions **11***b* and **11***b* of the roller retainer **11** are contacted with the guide grooves **10** and **14**. That is, the roller retainer **11** itself is also restricted by the guide grooves **10** and **14**. This can prevent the roller retainer **11** from falling down and thus the roller **9** from falling down.

[0043] The roller **9** and roller retainer **11** rolling on the outer periphery of the screw shaft **5** are picked up by the return pipe **7**. The thus picked-up roller **9** and roller retainer **11** are then allowed to pass through the interior portion of the return pipe **7**. And, the roller **9** and roller retainer **11** are returned again to the load rolling passage at intervals of several pitches. In case where the direction of rotation of the screw shaft **5** is reversed, the roller **9** and roller retainer **11** are allowed to circulate reversely along the above passage. By the way, in case where the screw shaft **5** is fixed and the nut member **6** can be rotated, the roller **9** and roller retainer **11** are also allowed to circulate similarly.

[0044] Now, **FIG. 7** shows an example where a plurality of rollers **9** are parallel arranged in the roller circulation passage in such a manner that the axes of the mutually adjoining rollers **9** are kept substantially parallel to each other; and, **FIG. 8** shows an example where a plurality of rollers **9** are cross arranged in such a manner that the axes of the mutually adjoining rollers **9** are made to cross each other substantially at right angles. As shown in these figures, whether the rollers **9** are parallel arranged or cross arranged, the roller retainers **11** are always allowed to keep a constant position, that is, the disposition of the roller retainers **11** is free from the influence of the directions of the rollers **9**. Also, since the disposition of the roller retainers **11** is free from the influence of the directions of the rollers **9**, the guide grooves **10** and **14** may be formed only in the bottom portions of the roller rolling groove **5***a* and load rolling groove **6***a*, so that the guide grooves **10** and **14** can be formed easily.

[0045] Now, **FIG. 9** shows another example of a roller retainer according to the invention. The present roller retainer **11** is not molded with the roller **9** inserted therein but the roller retainer **11** is formed as a single body. And, after molded as a single body, the roller **9** is fitted into the roller retainer **11**. The corner portions **9***a* of the roller **9** are inserted into a fit groove **21** formed in the roller retainer **11**. Between the roller **9** and roller retainer **11**, there is provided an interference and thus the roller **9** and roller retainer **11** are interference fitted with each other. Even in case where the roller retainer **11** is formed in this manner, the clearance between the roller **9** and roller retainer **11** can be made small.

[0046] By the way, in the present roller screw, the roller **9** rolling on the roller rolling groove **5***a* of the screw shaft **5** is picked up by the return pipe **7** and is returned by an amount equivalent to several windings. However, alternatively, there can also be employed a structure in which a deflector for picking up the roller **9** is disposed in the nut member **6**. That is, the roller **9** rolling on the roller rolling groove **5***a* of the screw shaft **5** may be removed from the roller rolling groove **5***a* by this deflector and may be then returned beyond the outside diameter portion of the screw shaft **5** to the roller rolling groove **5***a* that is situated by one lead ahead. Also, although not shown, there can also be employed a roller screw of a so called side cover type in which a nut member **6** is composed of a nut main body with a load rolling groove formed therein and two side covers respectively mounted on the two ends of the nut main body, in the nut main body, there is formed a roller return passage, and, in the two side covers, there are formed communication passages allowing the load rolling groove and return passage to communicate with each other.

[0047] Now, **FIGS. 10 and 12** respectively show a linear guide serving as a rolling guide apparatus incorporating therein the roller retainer **11** according to the first embodiment of the invention. This is a known linear guide which is used to guide a movable body such as a table set on a fixed portion such as a bed or a saddle. And, this linear guide comprises a guide rail **31** (a track shaft) which is disposed on the fixed portion and includes roller rolling grooves **31***a* formed along the longitudinal direction of the guide rail **31** and serving as rolling body rolling surfaces, a moving block (a slide member) **32** in which there is formed a roller circulation passage (rolling body circulation passage) including load rolling grooves serving as load rolling surfaces corresponding to the roller rolling grooves **31***a* of the guide rail **31** and also which is assembled to the guide rail **31** in such a manner that it can be freely moved with respect to the guide rail **31**, and a plurality of rollers **9** which are respectively arranged and stored in the roller circulation passage and are allowed to circulate through the roller circulation passage in linking with the relative movement of the moving block **32** with respect to the guide rail **31**. The plurality of rollers **9** are held by the roller retainers **11** individually (see **FIG. 12**). The rollers **9** are arranged and stored in the roller circulation passage in such a manner that the axes thereof are kept substantially parallel to each other. With the endless circulation of the plurality of rollers **9**, the moving block **32** supporting the movable body is allowed to move linearly along the guide rail **31**. By the way, the roller retainer **11** may also be formed in a band shape so that the plurality of rollers **9** circulating through the roller circulation passage can be held in a series manner.

[0048] The guide rail **31** is long and narrow and has a substantially square-shaped section. On the two right and left side surfaces of the guide rail **31**, there are formed the roller rolling grooves **31***a* having a V-shaped section, which respectively extend along the whole length of the guide rail **31** in the longitudinal direction and provide a track when the rollers **9** roll. By the way, although the shown guide rail is linear, in some cases, a curved rail is also used as the guide rail. Also, while the number of the roller rolling grooves **31***a* is two in the illustrated embodiment, the number of the roller rolling grooves can also be changed according to the uses of the linear guide.

[0049] The moving block **32** can be substantially structured in such a manner that a moving block main body **34** and a pair of side covers **35** respectively disposed on the two ends of the main body **34** are combined together. In the moving block main body **34**, there are formed two load rolling grooves **32***a* with a V-shaped section which are respectively opposed to the roller rolling grooves **31***a* (see **FIG. 12**). Due to the combinations of the load rolling grooves **32***a* and roller rolling grooves **31***a*, between the guide rail **31** and moving block **32**, there are formed two load rolling passages C. Further, in the moving block main body **34**, there are formed two return passages D which respectively extend in parallel to their associated load rolling passages C, and a pair of direction switch passages which respectively connect the respective return passages D to their associated load rolling passages C. Combination of the return passages D and load rolling passages C with the pair of direction switch passages connecting them together forms a roller circulation passage.

[0050] As shown in **FIG. 12**, the moving block main body **34** includes a main body block **39** and a molded body **36**. The main body block **39** is a high-rigidity structure body which is made of steel in such a manner that it can stand a load to be applied to the moving block **32** and, in the upper surface of the main body block **39**, there is formed a screw hole for fixing a member to be guided by the present linear guide. The molded body **36** is molded integrally with the main body block **39** according to a so called insert molding method in which molten resin is injected into a metal mold storing the main body block **39** therein. By the way, in some cases, the molded body **36** is die-cast molded using metal such as aluminum instead of the resin. Also, the invention is not limited to the above-mentioned insert molding method. For example, the main body block **39** and molded body may be formed separately and, after then, they may be combined together. Also, the main body block **39** and molded body **36** may be molded integrally according to an MIM (Metal Injection Mold) method.

[0051] The above-mentioned load rolling grooves **32***a* are respectively formed in the main body block **39**. And, on the other hand, the return passages D are respectively formed in the molded body **36**. In the main body block **39**, there are formed two through holes which respectively extend in parallel to their associated load rolling grooves **32***a*, and the pipe-shaped portion of the molded body **36** is molded integrally with the through holes of the main body block **39**. And, in the interior portion of the pipe-shaped portion of the molded body **36**, there are formed the return passages D for return of the rollers as well as guide grooves **37** which are used to guide the roller retainer **11** in their associated return passages D. Also, in the main body block **39**, there are formed guide grooves **38** respectively extending along their associated load rolling grooves **32***a*. These guide grooves **37** and **38** are respectively formed slightly wider than the width of the roller retainer **11** and slightly deeper than the end face of the roller retainer **11**, in order to be able to avoid interference with the roller retainer **11**. These guide grooves **37** and **38** guide the roller retainer **11** as well as, when the moving block **32** is pulled out from the guide rail **31**, prevent the rollers **9** from slipping off the load rolling passages C. By the way, the guide grooves **38** may not be formed in the main body block **39** but guide grooves may be formed in the molded body that is formed integrally with the main body block **39**.

[0052] As the moving block **32** is moved along the guide rail **31**, the roller **9** rolls from one end of the load rolling passage C to the other end thereof while receiving a load from the moving block **32**, after then, the roller **9** is picked up into one direction switch passage and is then guided to the return passage D and, further, the roller **9** is returned to one end of the load rolling passage C through the other direction switch passage. During circulation of the roller **9**, the roller **9** is going to fall down in a plane including the axis of the roller **9** and the advancing direction thereof, thereby causing a skew in the roller **9**. However, since the roller retainer **11** restricts the corner portion **9***a* of the roller **9**, the roller **9** can be restricted positively to thereby be able to control the skew of the roller **9**. Also, because the end portions **11***b* and **11***b* of the roller retainer **11** are guided by the guide grooves **38** respectively formed in their associated load rolling grooves **32***a*, the smooth circulation of the roller retainer **11** and roller **9** can be assured. Further, since the roller retainer **11** according to the present embodiment encloses the outer periphery of the roller **9** that is situated on the diagonal thereof when the roller **9** is viewed from the side surface thereof, whether the rollers **9** are parallel arranged or cross arranged, the roller retainer **11** is able to always keep a constant position and thus the disposition of the roller retainer **11** is free from the influence of the direction of the roller **9**. Therefore, the guide grooves **37** and **38** may be formed only at the diagonal positions of the roller **9**, which can facilitate the formation of the guide grooves **37** and **38**.

[0053] By the way, in the present embodiment, the relative motion of the moving block **32** and guide rail **31** is linear; however, the invention can also apply suitably to a guide apparatus in which the relative motion is curved.

[0054] Also, the roller retainer according to the invention can also apply to a roller spline which is used as a rolling guide apparatus and further can apply to a bearing such as a swing bearing, provided it uses rollers.

[0055] As has been described heretofore, according to the invention, since each roller retainer encloses the outer periphery of its associated roller that is situated on the diagonal when the roller is viewed from the side surface thereof, the roller retainer is allowed to keep a constant position whether the rollers are arranged in a parallel manner or in a cross manner and thus the disposition of the roller retainer is free from the influence of the direction of the roller. Therefore, there can be obtained a roller retainer which can be applied not only to a structure in which rollers are parallel arranged but also to a structure in which rollers are cross arranged. Also, because the roller retainer restricts the corner portion of the roller, the roller is difficult to slip off the roller retainer, thereby being able to restrict the roller positively, so that the skew of the roller can be controlled.

What is claimed is:

1. A roller retainer for holding a roller circulating through a roller circulation passage,

wherein said roller retainer encloses the outer periphery of said roller situated on a diagonal when said roller is viewed from the side surface thereof.

2. A roller retainer as set forth in claim 1, wherein said roller retainer holds a plurality of rollers circulating through said roller circulation passage, individually.

3. A roller retainer as set forth in claim 1, wherein said roller retainer is molded with said roller inserted therein.

4. A roller screw comprising:

a track shaft including a spiral-shaped roller rolling groove having a V-shaped section;

a slide member including a roller circulation passage including a spiral-shaped load rolling groove having a V-shaped section and assembled to said track shaft so as to move with respect to said track shaft, said load rolling groove corresponding to said roller rolling groove;

a plurality of rollers arranged and stored in said roller circulation passage and allowed to circulate through said roller circulation passage in linking with the relative motion of said slide member with respect to said track shaft; and

a plurality of retainers for holding said plurality of rollers individually so that said rollers are rotated and slid;

wherein each of said roller retainers encloses the outer periphery of its associated one of said rollers that is situated on a diagonal when said roller is viewed from the side surface thereof, and also wherein, in at least one of said roller rolling groove and said load rolling groove, there is formed a guide groove for guiding said roller retainer.

5. A rolling guide apparatus comprising:

a track shaft including a roller rolling groove having a V-shaped section;

a slide member including a roller circulation passage with a load rolling groove having a V-shaped section and assembled to said track shaft so as to move with respect to said track shaft, said load rolling groove corresponding to said roller rolling groove;

a plurality of rollers arranged and stored in said roller circulation passage and allowed to circulate through said roller circulation passage in linking with the relative motion of said slide member with respect to said track shaft; and

a plurality of retainers for holding said plurality of rollers individually so that said rollers are rotated and slid;

wherein each of said roller retainers encloses the outer periphery of its associated one of said rollers that is situated on a diagonal when said roller is viewed from the side surface thereof, and also wherein, in at least one of said roller rolling groove and said load rolling groove, there is formed a guide groove for guiding said roller retainer.

(57) **ABSTRACT**

A linear motion guiding apparatus comprises a guide rail provided with a ball running groove, and a movable block movably arranged along the guide rail through balls. The movable block is provided with a ball running counter-groove, a ball returning passage arranged away from the ball running counter-groove and direction changing passages for connecting these members. A resin-formed body for forming a ball circulation passage comprises a pair of ball passage forming portions, a returning passage forming portion and a pail of direction changing passage-inner guide forming portions. The resin-formed body is separately formed from a body of the movable block. At least two portions of (a) the ball passage forming portions, (b) the returning passage forming portion, (c) one of the direction changing passage-inner guide forming portions and (d) another of the of direction changing passage-inner guide forming portions are connected with each other through integral forming so that the resin-formed body can be built in the body of the movable block.

LINEAR MOTION GUIDING APPARATUS

BACKGROUND OF THE INVENTION

[0001] 1. Field Of The Invention

[0002] The present invention relates to a linear motion guiding apparatus in which a passage forming member formed of resin is built into a body of movable member.

[0003] 2. Description Of The Related Art

[0004] The applicant has already proposed a technical idea that, in a movable block of a linear motion guiding apparatus, a pair of ball passage forming portions extending along the opposite longitudinal sides of a loaded-ball running groove, a ball returning passage forming portion and a pair of direction changing passage-inner guide forming portions were integrally formed of resin with a body of the movable block (refer to Japanese Patent Provisional Publication No. H7-317,762).

[0005] More specifically, when a resin forming is carried out, the body of the movable block is inserted in a die, and the ball passage forming portions, the direction changing passage-inner guide forming portions or the ball returning passage forming portion is integrally formed with the block body.

[0006] In the conventional movable block obtained by the integral forming, the block body is inserted in the die, as mentioned above. When the block body has a large size, a large-scaled die is required to be used. It is not easy to prepare such a large-scaled die, and there is actual restriction in size. The ball passage forming portions located at the opposite longitudinal sides of the ball running groove extending along the longitudinal direction of the block body are thin and long, with the result that molten resin may not reach every part of the space for forming the ball passage forming portions during the resin forming treatment.

[0007] Increase in number of gates formed on the die may solve the above-mentioned problem of misrun of the molten resin. However, when the block body is inserted in the die, the block body may deteriorate the run of the molten resin.

[0008] When the movable block has a pair of wing portions, which face right and left-hand side portions of the guide rail so that the guide rail is held between the wing portions, and there are four trains of balls between the right and left-hand side portions of the guide rail and the right and left-hand wing portions of the moving block, and more specifically, the upper and lower trains of balls are arranged at each of a gap between the right-hand side portion of the guide rail and the corresponding right-hand wing portion of the moving block and another gap between the left-hand side portion of the guide rail and the corresponding left-hand wing portion of the moving block, the block body inserted in the die may deteriorate the run of the molten resin in the width direction of the moving block.

SUMMARY OF THE INVENTION

[0009] An object of the present invention is therefore to provide a linear motion guiding apparatus in which a resin-formed body for forming a rolling member circulation passage is formed separately from a body of a movable member so as to permit easy formation of the resin-formed body, and such a resin-formed body is able to be built in the body of the movable member, ensuring integral formability of the maximum number of unit parts for defining the rolling member circulation passage.

[0010] In order to attain the aforementioned object, a linear motion guiding apparatus comprises:

[0011] a guide member provided with a rolling member running track, and

[0012] a movable member arranged so as to be movable along the guide member through a large number of rolling members, said movable member being provided with (i) a rolling member running counter-track corresponding to the rolling member running track of said guide member, (ii) a rolling member returning passage arranged away from said rolling member running counter-track by a prescribed distance and in parallel therewith and (iii) a pair of direction changing passages for connecting the rolling member running counter-track and the rolling member returning passage to permit circulation of the rolling members,

[0013] characterized in that:

[0014] a resin-formed body for forming a rolling member circulation passage comprises a pair of rolling member passage forming portions extending along both longitudinal sides of said rolling member running counter-track, a returning passage forming portion for forming the rolling member returning passage and a pair of direction changing passage-inner guide forming portions for forming inner peripheral guide portions of **129** said direction changing passages, said resin-formed body being separately formed from a body of said movable member; and

[0015] at least two portions of (a) said pair of rolling member passage forming portions, (b) said returning passage forming portion, (c) one of said pair of direction changing passage-inner guide forming portions and (d) another of said pair of direction changing passage-inner guide forming portions are connected with each other through integral forming so that said resin-formed body can be built in the body of said movable member.

[0016] Embodiments of the combination of these portions (a) to (d) for the resin-formed body for forming the rolling member circulation passage may include the following three examples:

[0017] the first example in which the resin-formed body comprises (i) an integral body of the pair of rolling member passage forming portions and the pair of direction changing passage-inner guide forming portions, and (ii) the returning passage forming portion separately formed from the integral body the second example in which the resin-formed body comprises (i) an integral body of the pair of rolling member passage forming portions, the returning passage forming portion and one of the pair of direction changing passage-inner guide forming portions, and (ii) another of the pair of direction changing passage-inner guide forming portions separately formed from the integral body; and

[0018] the third example in which the resin-formed body is manufactured by preparing an integral body of the pair of rolling member passage forming portions, the returning passage forming portion and the pair of direction changing passage-inner guide forming portions, and then dividing the pair of rolling member passage forming portions and the returning passage forming portion in longitudinal intermediate portions thereof into respective two parts.

[0019] According to the present invention, the resin-formed body for forming the rolling member circulation passage is separately formed from the body of the movable member. Even if the movable member has a large size, the flow of molten resin is not therefore restricted by the body of the movable member unlike the conventional prior art in which the body of the movable member and the resin-formed body are integrally formed with each other, and it is possible to ensure proper run of molten resin through increase in a number of gates in the die, thus leading to an excellent formability. In general, it is hard to achieve proper run of molten resin especially at the rolling member passage forming portions extending along the longitudinal sides of the rolling member running counter-track, and it is therefore effective to separately form the resin-formed body from the body of the movable member in the same manner as the present invention.

[0020] The rolling member circulation passage is formed by the resin-formed body. Therefore, the direct positioning can be achieved in the relative positional relationship between the direction changing passage-inner guide forming portions and the rolling member passage forming portion, as well as the relative positional relationship between the direction changing passageinner guide forming portions and the returning passage forming portion, and the continuity of the rolling member circulation passage is properly ensured, thus leading to smooth run of the rolling members.

[0021] Since the rolling member passage forming portions are located along the both longitudinal sides of the rolling member running counter-track, the direction changing passage-inner guide forming portions having a proper relative positional relationship with the rolling member passage forming portions are accurately set on the both ends of the rolling member running counter-track.

[0022] Maintenance of a proper relative positional relationship of the direction changing passage-inner guide forming portions with the rolling member returning passage causes the direction changing passage-inner guide forming portions to be accurately connected to the inner surface of the rolling member returning passage.

[0023] Especially, change in a running direction of the rolling members takes place in the connection area of the rolling member passage forming portions with the direction changing passage-inner guide forming portions as well as in the connection area of the direction changing passage-inner guide forming portions with returning passage forming portion. When two portions in such a connection area are connected with each other by integral forming, a step for assembling these two portions is not required, thus making it possible to ensure a smooth continuity of these two portions without being affected by accuracy of assembly.

[0024] The rolling member returning passage may be a through-hole formed in the body of the movable member, the resin formed-body may comprise the pair of direction changing passage-inner guide forming portions and the rolling member passage forming portions extending along the both longitudinal sides of the rolling member running counter-track, and the rolling member passage forming portions and at least one of the pair of direction changing passage-inner guide forming portions may be connected with each other through integral forming.

[0025] When the rolling member passage forming portions and the direction changing passage-inner guide forming portions are integrally formed with each other so as to provide the smooth connection area in this manner, it is possible to achieve the smooth run of the rolling members in the connection area of these portions, thus improving circulation property of the rolling member without providing any returning passage forming portion made of resin. Such a construction causes easy manufacture of the apparatus due to no existence of the returning passage forming portion.

[0026] The present invention may have additional features that a rolling member retainer is provided, the rolling member retainer being able to retain the rolling members in a train with a prescribed distance kept between adjacent two of the rolling members, and the rolling member retainer having side edge portions projecting from both sides of each of the rolling members; and guide grooves for guiding the side edge portions of the rolling member retainer are formed on an entire periphery of the rolling member circulation passage.

[0027] The present invention may have additional features that a retaining portion is provided on the rolling member passage forming portion, for preventing the rolling member retainer being out of place, when the movable member is removed from the guide member, and a guide portion is continuously formed on the entire periphery of the rolling member circulation passage, for guiding the side edge portions of the rolling member retainer.

[0028] Such provision of the rolling member retainer permits the smooth run of the rolling members by means of the rolling member retainer, due to proper maintenance of continuity of the guide portion for the rolling member retainer.

[0029] Since the guide portion for the rolling member retainer having a small thickness is not formed by inserting the body of the movable member in a die and then injecting molten resin into the die, but is separately formed from the body of the movable member, position of gates can freely be determined without being restricted by the body of the movable member, with the result that molten resin can reach, during formation of the guide portion, the entire space therefor, which is formed in the die.

[0030] The present invention may have additional features that each of the direction changing passage-inner guide forming portions has a thin sheet portion, which is to be brought into contact with the end face of the body of the movable member, and each of the direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions or the returning passage forming portion by means of the thin sheet portion.

[0031] When each of the direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions by means of the thin sheet portion, deformation of the thin sheet portion can absorb distortion, which occurs between the direction changing passage-inner guide forming portion and the rolling member passage forming portion, or between the direction changing passage-inner guide forming portion and the returning passage forming portion. Accordingly, it is possible to maintain an accurate positional relationship between the end of the direction changing passage-inner guide forming portion and the rolling member passage forming portion or between the direction changing passage-inner guide forming portion and the returning passage forming portion.

[0032] The thin sheet portion is urged against the flat end face of the body of the movable member by a clamping force, which is applied to the side cover plate. The position of the direction changing passage-inner guide forming portion can therefore be corrected through deformation of the thin sheet portion, even when the direction changing passage-inner guide forming portion is not correctly positioned relative to the end face of the body of the movable member. In addition, the thin sheet portion can firmly be secured between the side cover plate and the body of the movable member by the clamping force, which is applied to the side cover plate, thus preventing the direction changing passage-inner guide forming portion from being incorrectly placed.

[0033] The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member comprises a movable block, which is provided with a horizontal portion, which faces an upper surface of the guide rail and a pair of wing portions, between which the guide rail is held at right and left-hand side surfaces thereof; two trains of the rolling members are arranged in a gap between the upper surface of the guide rail and a lower surface of the movable block, and a single train of the rolling members is arranged in each of gaps between the right and left-hand side surfaces of the guide rail and both of the wing portions, so as to provide a total number of trains of four.

[0034] The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member comprises a movable block, which is provided with a pair of wing portions, between which the guide rail is held at right and left-hand side surfaces thereof; and two trains of the rolling members are arranged in each of gaps between the right and left-hand side surfaces of the guide rail and both of the wing portions, so as to provide a total number of trains of four.

[0035] In these cases, the respective four direction changing passage-inner guide forming portions may be formed into an integral body, or the respective two direction changing passage-inner guide forming portions at each of the right and left-hand sides of the movable block may be formed into an integral body.

[0036] The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member is provided with a horizontal portion, which faces an upper surface of the guide rail and a single wing portion, which faces one side surface of the guide rail; a single train of the rolling members is arranged in a gap between the one side surface of the guide rail and the single wing portion, and another single train of the rolling members is arranged in a gap between the upper surface of the guide rail and a lower surface of the horizontal portion in a vicinity of a corner of the guide rail.

[0037] The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member comprises a movable block, which is provided with a pair of wing portions, between which the guide rail is held at right and left-hand side surfaces thereof; and a single train of the rolling members is arranged in each of gaps between the right and left-hand side surfaces of the guide rail and both of the wing portions, so as to provide a total number of trains of two.

[0038] The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member comprises a movable block arranged along one side surface of the guide rail; and two trains of the rolling members are arranged in a gap between the one side surface of the guide rail and the movable block.

[0039] The apparatus of the present invention may have the construction that the guide member comprises a spline shaft; and the movable member comprises an outer tube, which is movably supported on the spline shaft through a plurality of trains of the rolling members.

[0040] In addition, according to the present invention, there is also provided a linear motion guiding apparatus comprising:

[0041] a guide rail provided with two rolling member running tracks on each of right and left-hand side surfaces of the guide rail, so as to provide a total number of the rolling member running tracks of four; and

[0042] a movable block provided with a pair of wing portions, between which the guide rail is held at the right and left-hand side surfaces thereof, each of said wing portions having on an inner surface thereof two rolling member running counter-tracks corresponding to said two rolling member running tracks of the guide rail, so as to provide a total number of the rolling member running counter-tracks of four, said movable block having four endless circulation passages, which are formed by four rolling member returning passages arranged in parallel with said four rolling member running countertracks, respectively, and rolling member returning passages for connecting both ends of each of said four rolling member running counter-tracks with both ends of each of said four rolling member returning passages, respectively

[0043] characterized in that:

[0044] a resin-formed body comprises, for each of said endless circulation passages, a pair of rolling member passage forming portions extending along both longitudinal sides of said rolling member running counter-track, a returning passage forming portion for forming the rolling member returning passage and a pair of direction changing passage-inner guide forming portions for forming inner peripheral guide portions of said direction changing passages, said resin-formed body being separately formed from a body of said movable block;

[0045] said resin-formed body is divided into two body-parts, which are arranged on the wing portions of the movable block, respectively, so as to form the two endless circulation passages at an inner side of each of the wing portions; and

[0046] in each of the two body-parts, the rolling member running counter-track and the pair of direction changing passage-inner guide forming portions are formed into an integral body, and the returning passage forming portion is separately formed from said integral body.

[0047] According to the present invention, the resin-formed body for forming the rolling member circulation passage is separately formed from the body of the movable block. Even if the movable block has a large size, the flow of molten resin is not therefore restricted by the body of the movable block unlike the conventional prior art in which the body of the movable block and the resin-formed body are integrally formed with each other, and it is possible to ensure proper run of molten resin through increase in a number of gates in the die, thus leading to an excellent formability. In general, it is hard to achieve proper run of molten resin especially at the rolling member passage forming portions extending along the longitudinal sides of the rolling member running counter-track, and it is therefore effective to separately form the resin-formed body from the body of the movable block in the same manner as the present invention.

[0048] Especially, since the resin-formed body is divided into the two body-parts, each of which forms two endless circulation passages, a proper run of molten resin can be ensured, even when the block of the movable block has a larger width.

[0049] The rolling member circulation passage is formed by the resin-formed body. Therefore, the direct positioning can be achieved in the relative positional relationship between the direction changing passage-inner guide forming portions and the rolling member passage forming portion, as well as the relative positional relationship between the direction changing passage-inner guide forming portions and the returning passage forming portion, and the continuity of the rolling member circulation passage is properly ensured, thus leading to smooth run of the rolling members.

[0050] Since the rolling member passage forming portions are located along the both longitudinal sides of the rolling member running counter-track, the direction changing passage-inner guide forming portions having a proper relative positional relationship with the rolling member passage forming portions are accurately set on the both ends of the rolling member running counter-track.

[0051] Maintenance of a proper relative positional relationship of the direction changing passage-inner guide forming portions with the rolling member returning passage causes the direction changing passage-inner guide forming portions to be accurately connected to the inner surface of the rolling member returning passage.

[0052] Especially, change in a running direction of the rolling members takes place in the connection area of the rolling member passage forming portions with the direction changing passage-inner guide forming portions. When these two portions in such a connection area are connected with each other by integral forming, a step for assembling these two portions is not required, thus making it possible to ensure a smooth continuity of these two portions without being affected by accuracy of assembly.

[0053] The present invention may have additional features that a rolling member retainer is provided, the rolling member retainer being able to retain the rolling members in a train with a prescribed distance kept between adjacent two of the rolling members, and the rolling member retainer having side edge portions projecting from both sides of each of the rolling members; and guide grooves for guiding the side edge portions of the rolling member retainer are formed on an entire periphery of the rolling member circulation passage.

[0054] Such provision of the rolling member retainer permits the smooth run of the rolling members by means of the rolling member retainer, due to proper maintenance of continuity of the guide portion for the rolling member retainer.

[0055] Since the guide portion for the rolling member retainer having a small thickness is not formed by inserting the body of the movable block in a die and then injecting molten resin into the die, but is separately formed from the body of the movable block, position of gates can freely be determined without being restricted by the body of the movable block, with the result that molten resin can reach, during formation of the guide portion, the entire space therefor, which is formed in the die.

[0056] The present invention may have additional features that each of the direction changing passage-inner guide forming portions has a thin sheet portion, which is to be brought into contact with the end face of the body of the movable block, and each of the direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions or the returning passage forming portion by means of the thin sheet portion.

[0057] When each of the direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions by means of the thin sheet portion, deformation of the thin sheet portion can absorb distortion, which occurs between the direction changing passage-inner guide forming portion and the rolling member passage forming portion, or between the direction changing passage-inner guide forming portion and the returning passage forming portion. Accordingly, it is possible to maintain an accurate positional relationship between the end of the direction changing passage-inner guide forming portion and the rolling member passage forming portion or between the direction changing passage-inner guide forming portion and the returning passage forming portion.

[0058] The thin sheet portion is urged against the flat end face of the body of the movable member by a clamping force, which is applied to the side cover plate. The position of the direction changing passage-inner guide forming portion can therefore be corrected through deformation of the thin sheet portion, even when the direction changing passage-inner guide forming portion is not correctly positioned relative to the end face of the body of the movable block. In addition, the thin sheet portion can firmly be secured between the side cover plate and the body of the movable block by the clamping force, which is applied to the side cover plate, thus preventing the direction changing passage-inner guide forming portion from being incorrectly placed.

BRIEF DESCRIPTION OF THE DRAWINGS

[0059] **FIG. 1** is a schematic disassembling perspective view illustrating a movable block of a linear motion guiding apparatus of the first embodiment of the present invention;

[0060] **FIG. 2** shows a resin frame member as shown in **FIG. 1**, as one of resin-formed bodies for forming a ball circulation passage, and more specifically, **FIG. 2**(*a*) is a front view of the resin frame member, **FIG. 2**(*b*) is a side view thereof, **FIG. 2**(*c*) is a cross-sectional view cut along the line C-C as indicated in **FIG. 2**(*a*), **FIG. 2**(*d*) is a cross-sectional view cut along the line D-D as indicated in **FIG. 2**(*b*), **FIG. 2**(*e*) is an enlarged cross-sectional view cut along the line E-E as indicated in **FIG. 2**(*a*) and **FIG. 2**(*f*) is an enlarged cross-sectional view cut along the line F-F as indicated in **FIG. 2**(*a*);

[0061] **FIG. 3**(*a*) is a front view having a cross-section, illustrating the linear motion guiding apparatus of the first embodiment of the present invention as shown in **FIG. 1**, **FIG. 3**(*b*) is a front view of the apparatus as shown in **FIG. 3**(*a*), in which a half portion of a side cover plate is omitted, and FIGS. **3**(*c*) to (*f*) are partially cross-sectional views illustrating embodiments of the structure of a ball passage forming portion and the vicinity thereof, as shown in **FIG. 3**(*a*);

[0062] **FIG. 4**(*a*) is a side view having a partial cross section, of the linear motion guiding apparatus of the first embodiment of the present invention, **FIG. 4**(*b*) is a cross-sectional view of a ball circulation passage of the movable block as shown in **FIG. 4**(A), from which a ball retainer is removed, **FIG. 4**(*c*) is a partial side view of the ball retainer, **FIG. 4**(*d*) is a plan view of the ball retainer as shown in **FIG. 4**(*c*) and **FIG. 4**(*e*) is a view of the ball retainer, with sight being placed in a direction of an arrow of "a" as indicated in **FIG. 4**(*d*);

[0063] **FIG. 5** shows a side cover plate of the movable block, and more specifically, **FIG. 5**(*a*) is a front view of the side cover plate, **FIG. 5**(*b*) is a back view thereof and **FIG. 5**(*c*) is a transverse sectional view thereof at its central portion;

[0064] FIGS. **6**(*a*) to **6**(*i*) are descriptive views illustrating steps for assembling the movable block as shown in **FIG. 1**;

[0065] **FIG. 7**(*a*) is an enlarged partial view of the direction changing passage as shown in **FIG. 4**(*b*), **FIG. 7**(*b*) is a partial side view of the direction changing passage as shown in **FIG.4***b*(*b*), in which the side cover plate is removed, **FIG. 7**(*c*) is a partial side view illustrating a recess portion, which forms the direction changing passage in the side cover plate as shown in **FIG. 7**(*a*), **FIG. 7**(*d*) is a partial cross-sectional view of an outer peripheral side-half pipe member for forming a part of a resin pipe as shown in **FIG. 7**(*a*), **FIG. 7**(*e*) is a side view of the outer peripheral side-half pipe member as shown in **FIG. 7**(*d*), **FIG. 7**(*f*) is a partial cross-sectional view of an inner peripheral side-half pipe member for forming another part of the resin pipe as shown in **FIG. 7**(*a*), **FIG. 7**(*g*) is a side view of the inner peripheral side-half pipe member as shown in **FIG. 7**(*f*);

[0066] **FIG. 8** is a schematic disassembling perspective view illustrating the first modification of the resin-formed body for forming the ball circulation passage in the first embodiment of the present invention;

[0067] **FIG. 9**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in **FIG. 8**, **FIG. 9**(*b*) is a view illustrating the first resin frame of the resin-formed body, **FIG. 9**(*c*) is a view illustrating the second resin frame thereof, **FIG. 9**(*d*) is a back view of the first resin frame and **FIG. 9**(*e*) is a back view of the second resin frame;

[0068] **FIG. 10** is a schematic disassembling perspective view illustrating the second modification of the resin-formed body for forming the ball circulation passage in the first embodiment of the present invention;

[0069] **FIG. 11**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in **FIG. 10**, **FIG. 11**(*b*) is a side view illustrating the connecting end of one of divided resin frames, as shown in **FIG. 11**(*a*) and **FIG. 11**(*c*) is an enlarged cross-sectional view illustrating the connecting portion of the resin frames;

[0070] **FIG. 12** is a schematic disassembling perspective view illustrating the third modification of the resin-formed body for forming the ball circulation passage in the first embodiment of the present invention;

[0071] **FIG. 13**(*a*) is a side view having a partial cross section, illustrating the linear motion guiding apparatus, in which the movable block as shown in **FIG. 12** is used, and **FIG. 13**(*b*) is a cross-sectional view of the resin-formed body for forming the ball circulation passage as shown in **FIG. 13**(*a*);

[0072] **FIG. 14**(*a*) is an enlarged partial cross-sectional view of the direction changing passage as shown in **FIG. 13**(*b*), which is formed in the side cover plate removed from the ball passage forming portion, **FIG. 14**(*b*) is a partial cross-sectional view illustrating the side cover as shown in **FIG. 14**(*a*), which is secured to the ball passage forming portion, **FIG. 14**(*c*) is a partial side view illustrating the ball passage forming portion, in which the side cover plate as shown in **FIG. 14**(*a*) is removed, and **FIG. 14**(*d*) is a partial side view illustrating a recess portion, which forms the direction changing passage in the side cover plate as shown in **FIG. 14**(*a*);

[0073] **FIG. 15** is a schematic disassembling perspective view illustrating the fourth modification of the resin-formed body for forming the ball circulation passage in the first embodiment of the present invention;

[0074] FIGS. **16**(*a*) to **16**(*h*) are descriptive views illustrating the other embodiments of arrangement of the trains of balls in the linear motion guiding apparatus of the first embodiment of the present invention;

[0075] **FIG. 17** is a perspective view illustrating the constructional elements other than the resin-formed body for forming the ball circulation passage of the linear motion guiding apparatus as shown in **FIG. 16**(*a*), which is provided with two trains of balls at each of the both sides;

[0076] **FIG. 18** is a schematic disassembling perspective view illustrating a movable block of a linear motion guiding apparatus of the second embodiment of the present invention;

[0077] **FIG. 19**(*a*) is a front view illustrating the linear motion guiding apparatus of the second embodiment of the present invention as shown in **FIG. 18**, **FIG. 19**(*b*) is a partial cross-sectional view illustrating one ball circulation passage of the apparatus as shown in **FIG. 19**(*a*), **FIG. 19**(*c*) is a partial plan view of a roller retainer as shown in **FIG. 19**(*b*) and **FIG. 19**(*d*) is a view of the roller retainer, with sight being placed in a direction of an arrow of "d" as indicated in **FIG. 19**(*c*);

[0078] **FIG. 20** shows the resin-formed body for forming the ball circulation passage as shown in **FIG. 18**, and more specifically, **FIG. 20**(*a*) is a cross-sectional view cut along the line a-a as indicated in **FIG. 20**(*b*), **FIG. 20**(*b*) is a front view of the resin-formed body for forming the ball circulation passage as shown in **FIG. 20**(*a*), **FIG. 20**(*c*) is a partial side view of the resin-formed body for forming the ball circulation passage, in which the resin pipe as shown in **FIG. 20**(*a*) is removed, **FIG. 20**(*d*) is a cross-sectional view of an outer peripheral side-half pipe member for forming a part of a resin pipe as shown in **FIG. 20**(*a*), **FIG. 20**(*e*) is a side view of the outer peripheral side-half pipe member as shown in **FIG. 20**(*d*), **FIG. 20**(*f*) is a cross-sectional view of an inner peripheral side-half pipe member for forming another part of the resin pipe as shown in **FIG. 20**(*a*), **FIG. 20**(*g*) is a side view of the inner peripheral side-half pipe member as shown in **FIG. 20**(*f*) and **FIG. 20**(*h*) is a partial cross-sectional view illustrating the constructional example of the roller passage forming portion, in which the roller retainer is not used;

[0079] **FIG. 21** is a schematic disassembling perspective view illustrating the first modification of the resin-formed body for forming the ball circulation passage in the second embodiment of the present invention;

[0080] **FIG. 22**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in **FIG. 21**, **FIG. 22**(*b*) is a view illustrating the first resin frame as shown in **FIG. 22**(*a*), with sight being placed on the divided end side thereof and **FIG. 22**(*c*) is a view illustrating the second resin frame as shown in **FIG. 22**(*a*), with sight being placed on the divided end side thereof;

[0081] **FIG. 23** is a schematic disassembling perspective view illustrating the second modification of the resin-formed body for forming the ball circulation passage in the second embodiment of the present invention;

[0082] **FIG. 24**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in **FIG. 23**, **FIG. 24**(*b*) is a view illustrating one resin frame as shown in **FIG. 24**(*a*), with sight being placed on the divided end side thereof and **FIG. 24**(*c*) is a view illustrating the other resin frame as shown in **FIG. 24**(*a*), with sight being placed on the divided end side thereof;

[0083] **FIG. 25** is a schematic disassembling perspective view illustrating the third modification of the resin-formed body for forming the ball circulation passage in the second embodiment of the present invention;

[0084] **FIG. 26** is a schematic disassembling perspective view illustrating the fourth modification of the resin-formed body for forming the ball circulation passage in the second embodiment of the present invention;

[0085] **FIG. 27** is a front view having a cross-sectional half portion, illustrating the other embodiment of arrangement of the trains of balls in the linear motion guiding apparatus of the second embodiment of the present invention;

[0086] **FIG. 28** is a schematic disassembling perspective view of an outer tube of a ball-spline as a linear motion guiding apparatus of the third embodiment of the present invention;

[0087] **FIG. 29**(*a*) is a front view having a cross-section, illustrating the ball spline of the third embodiment of the present invention, in which the outer tube as shown in **FIG. 28** is used, **FIG. 29**(*b*) is a partial cross-sectional view illustrating one ball circulation passage of the apparatus as shown in **FIG. 29**(*a*) and **FIG. 29**(*c*) is a disassembling cross-sectional view illustrating the construction of the ball circulation passage, in which the roller retainer as shown in **FIG. 29**(*b*) is removed;

[0088] **FIG. 30** shows the resin-formed body for forming the ball circulation passage as shown in **FIG. 29**, and more specifically, **FIG. 30**(*a*) is a cross-sectional view cut along the line a-a as indicated in **FIG. 30**(*b*), **FIG. 30**(*b*) is a front view of the resin-formed body for forming the ball circulation passage as shown in **FIG. 30**(*a*), **FIG. 30**(*c*) is a partial side view of the resin-formed body for forming the ball circulation passage, in which the resin pipe as shown in **FIG. 30**(*a*) is removed, **FIG. 30**(*d*) is a cross-sectional view of an outer peripheral side-half pipe member for forming a part of a resin pipe as shown in **FIG. 30**(*a*), **FIG. 30**(*e*) is a side view of the outer peripheral side-half pipe member as shown in **FIG. 30**(*d*), **FIG. 30**(*f*) is a cross-sectional view of an inner peripheral side-half pipe member for forming another part of the resin pipe as shown in **FIG. 30**(*a*) and **FIG. 30**(*g*) is a side view of the inner peripheral side-half pipe member as shown in **FIG. 30**(*f*)

[0089] **FIG. 31** is a schematic disassembling perspective view illustrating the first modification of the resin-formed body for forming the ball circulation passage in the third embodiment of the present invention;

[0090] **FIG. 32**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in **FIG. 31**, **FIG. 32**(*b*) is a view illustrating the first resin frame as shown in **FIG. 32**(*a*), with sight being placed on the divided end side thereof and **FIG. 32**(*c*) is a view illustrating the second resin frame as shown in **FIG. 32**(*a*), with sight being placed on the divided end side thereof;

[0091] **FIG. 33** is a schematic disassembling perspective view illustrating the second modification of the resin-formed body for forming the ball circulation passage in the third embodiment of the present invention;

[0092] **FIG. 34**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in **FIG. 33**, **FIG. 34**(*b*) is a view illustrating one resin frame as shown in **FIG. 34**(*a*), with sight being placed on the divided end side thereof and **FIG. 34**(*c*) is a view illustrating the other resin frame as shown in **FIG. 34**(*a*), with sight being placed on the divided end side thereof;

[0093] **FIG. 35** is a schematic disassembling perspective view illustrating the third modification of the resin-formed body for forming the ball circulation passage in the third embodiment of the present invention;

[0094] **FIG. 36** is a schematic disassembling perspective view illustrating the fourth modification of the resin-formed body for forming the ball circulation passage in the third embodiment of the present invention;

[0095] **FIG. 37** is a front view having a partial cross-section, illustrating the another embodiment of arrangement of the trains of balls in the ball spline as the linear motion guiding apparatus of the third embodiment of the present invention;

[0096] **FIG. 38**(*a*) is a front view having a partial cross-section, illustrating a roller-spline as the linear motion guiding apparatus of the fourth embodiment of the present invention, in which a side cover plate is removed, and **FIG. 38**(*b*) is a longitudinal partial cross-sectional view of one roller circulation passage as shown in **FIG. 38**(*b*);

[0097] **FIG. 39**(*a*) is a partial cross-sectional view illustrating the constructional example of the resin-formed body for forming the roller circulation passage of the roller spline as shown in **FIG. 38**, and FIGS. **39**(*b*) to **39**(*e*) are views illustrating the first to fourth modifications of the resin-formed body for forming the roller circulation passage;

[0098] **FIG. 40**(*a*) is a front view of the movable block of the linear motion guiding apparatus of the fourth embodiment of the present invention, in which the side cover plate is removed, and **FIG. 40**(*b*) is a perspective view of the movable block as shown in **FIG. 40**(*a*);

[0099] **FIG. 41** is a schematic disassembling perspective view of the resin-formed bodies for forming the ball circulation passage as shown in **FIG. 40**;

[0100] **FIG. 42** is a front view of the resin frame composing the resin-formed body for forming the ball circulation passage, as shown in **FIG. 41**, **FIG. 42**(*b*) is a left-hand side view of the resin-formed body as shown in **FIG. 42**(*a*) and **FIG. 42**(*c*) is a right-hand side view of the resin-formed body as shown in **FIG. 42**(*a*);

[0101] **FIG. 43** shows a resin pipe for forming a part of the resin-formed body for forming the ball circulation passage, as shown in **FIG. 41**, and more specifically, **FIG. 43**(*a*) is a front view of an outer peripheral side-half pipe member, **FIG. 43**(*b*) is a side view of the outer peripheral side-half pipe member as shown in **FIG. 43**(*a*), **FIG. 43**(*c*) is a front view of an inner peripheral side-half pipe member, **FIG. 43**(*d*) is a side view of the inner peripheral side-half pipe member as shown in **FIG. 43**(*c*); and

[0102] **FIG. 44**(*a*) is a cross-sectional view of one ball circulation passage, in which the ball retainer is removed from the movable block as shown in **FIG. 40**(*a*), **FIG. 44**(*b*) is an enlarged partial view of the direction changing passage as shown in **FIG. 44**(*a*), **FIG. 44**(*c*) is a partial side view of the ball retainer, **FIG. 44**(*d*) is a plan view of the ball retainer as shown in **FIG. 44**(*c*), **FIG. 44**(*e*) is a view of the ball retainer, with sight being placed in a direction of an arrow of "a" as indicated in **FIG. 44**(*d*), **FIG. 44**(*f*) is a partial side view of the direction changing passage as shown in **FIG. 44**(*b*), in which the side cover plate is removed, and **FIG. 44**(*g*) is a partial side view illustrating a recess portion, which forms the direction changing passage in the side cover plate as shown in **FIG. 44**(*b*).

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0103] Now, embodiments of a linear motion guiding apparatus the present invention will be described in detail below with reference to the accompanying drawings.

[0104] First Embodiment

[0105] FIGS. **1** to **7** show a linear motion guiding apparatus of the first embodiment of the present invention.

[0106] The linear motion guiding apparatus **1** is provided with a guide rail **2** as a guide member, which extends linearly, and a movable block **4** as a movable member, which is arranged so as to be movable along the guide rail **2** through a large number of balls **3** as rolling members.

[0107] The guide rail **2** is formed into a long bar shape having a rectangular cross-section. Two ball running grooves **5**, **5** as a rolling member running track are formed on the horizontal upper surface of the guide rail **2**, and a single ball running groove **5** as the rolling member running track is formed on each of the right and left-hand vertical surfaces of the guide rail **2**, so as to provide a total number of grooves **5** of four.

[0108] The movable block **4** is formed as a block body having an inverse U-shaped cross-section, with its opening end being directed downwardly. The block body is provided with a horizontal portion **6**, which faces the upper surface of the guide rail **2** and with a pair of wing portions **7**, **7**, which extend downwardly from the right and left ends of the horizontal portion **6** and face the right and left-hand side surfaces of the guide rail **2**, respectively. The horizontal portion **6** has on its lower surface two ball running counter-grooves **8**, **8** as a rolling member running counter-track, which correspond to the ball running grooves **5**, **5** formed on the upper surface of the guide rail **2**. Each of the wing portions **7**, **7** has on its inner surface a single ball running counter-groove **8** as the rolling member running counter-track, which corresponds to the respective ball running grooves **5**, **5** formed on the right and left-hand side surfaces of the guide rail **2**.

[0109] In addition, in the movable block **4**, there are formed four ball returning passages **9**, **9**, **9**, **9** as a rolling member returning passage, which are provided in parallel with the four ball running counter-grooves **8**, **8**, **8**, **8**, respectively, as well as four pairs of direction changing passages **10**, **10**, **10**, **10** each having a U-shape, for connecting the respective both ends of the ball running counter-grooves **8**, **8**, **8**, **8** with the respective both ends of the ball returning passages **9**, **9**, **9**, **9**, so as to form four endless circulation passages. The ball returning passages **9**, **9** respectively corresponding to the ball running grooves **5**, **5** formed on the upper side of the guide rail **2** are formed in the horizontal portion **6**. The other ball returning passages **9**, **9** respectively corresponding to the ball running grooves **5**, **5** formed on the right and left hand vertical surfaces of the guide rail **2** are formed in the wing portions **7**, **7** of the movable block **4**, respectively.

[0110] In each of the four endless circulation passages in this embodiment, the balls **3** are retained in the form of train by means a ball retainer **12** as a rolling member retainer, as shown in **FIG. 4** so that the balls **3** can be circulated while being guided by the ball retainer **12**.

[0111] The ball retainer **12** comprises a flexible belt portion **12***b*, which is provided with ball holes **12***a* for respectively receiving the balls **3**, and spacing portions **12***c* provided between the adjacent two balls **3**, **3**. The belt portion **12***b* has a width longer than the diameter of the ball **3** so that the both side edges of the belt portion **12***b* extend outwardly from the ball **3**.

[0112] The spacing portion **12***c* is provided with a ball supporting spherical recess **12***d* corresponding to the spherical surface of the ball **3**. The ball **3** is supported on its both sides by a pair of supporting spherical recesses **12***d* so as to prevent the ball **3** from coming off the belt portion **12***b*. In this embodiment, the one end of the belt portion **12***b* is not connected to the other end thereof, thus forming a strip-shaped belt having the both ends. The one end of the belt portion **12***b* may be connected to the other end thereof so as to form an endless belt.

[0113] The movable block **4** is composed of a block body **13** having ball running counter-grooves **8**, **8**, **8**, **8**, a resin-formed body **20** for forming ball circulation passages, which is inserted in the block body **13**, and a pair of side cover plates **40**, **40** secured to the both end surfaces of the block body **13**, in which the resin-formed body **20** is inserted.

[0114] Each of the ball circulation passages of the resin-formed body **20** comprises a pair of ball passage forming portions **21**, **21** extending along both longitudinal sides of the ball running counter-groove **8**, a pair of direction changing passage-inner guide forming portions **22**, **22** provided on the both side faces of the block body **13**, and a resin pipe **23** as a returning passage forming portion, which is inserted into a through-hole formed in the block body **13**. In this embodiment, the ball passage forming portions **21**, **21** and the pair of direction changing passage-inner guide forming portions **22**, **22** are integrally formed with each other into an integral body, and the resin pipe **23** is separately formed from the above-mentioned integral body. More specifically, there is used a construction that the ball passage forming portions **21**, **21** and the pair of direction changing passage-inner guide forming portions **22**, **22** are integrally connected with each other through integral forming to form an integral resin frame **24**, and the four resin pipes **23** can respectively be inserted into the block body **13**.

[0115] The ball passage forming portions **21**, **21** are provided with guide grooves for guiding the both side edges of the belt portion **12***b* of the ball retainer **12** in a loaded area. The guide grooves can prevent the ball retainer **12** not only from being swung during run of the ball, but also from being sagged by engaging the side edges of the belt portion **12***b* with the guide groove **21***a,* when the movable block **4** is removed from the guide rail **2**. The balls **3** are supported by the ball retainer **12**. More specifically, the ball retainer **12** is supported by a jaw portion of the guide groove **21***a,* with the result that the balls **3** are kept in its proper position so as not to come off the movable block **4**.

[0116] In this embodiment, a distance between the pair of ball passage forming portions **21**, **21** arranged in parallel with each other on the both longitudinal sides of the ball running counter-groove **8** is slightly larger than the diameter of the ball **3**. The balls **3** come off the ball running counter-groove **8**, if the ball retainer **12** is not used. When an amount of projection of the jaw portion **21***b* is predetermined so that a distance between the pair of ball passage forming portions **21**, **21** is slightly smaller than the diameter of the ball **3** as shown in FIG: **3**(*d*), it is however possible to prevent the balls **3** from coming off the ball running counter-groove **8** even without the ball retainer **12**. Such a construction can apply not only to the case where the balls **3** are inserted into the ball circulation passage with the use of the ball retainer **12**, but also to the case where the balls are inserted therein without the ball retainer **12**. The distance between the pair of ball passage forming portions **21**, **21** may be slightly smaller than the diameter of the ball **3** so that the ball passage forming portions **21**, **21** directly hold the ball **3** without the use of the ball retainer **12** as shown in **FIG. 3**(*e*).

[0117] Guide grooves **9***c,* **10***c* are also formed in the ball returning passage **9** and the direction changing passage **10** as non-loaded areas, in order to guide the side edges of the belt portion **12***b*. The guide grooves **9***c,* **10***c* are connected to the above-mentioned guide groove **21***a* in the loaded area so as to form an endless groove on the entire periphery.

[0118] When the ball retainer **12** is not used as shown in **FIG. 3**(*f*), the distance between the pair of ball passage forming portions **21**, **21** arranged on the both longitudinal sides of the ball running counter-groove **8**, which portions do not have any jaw portions **21**, may be slightly smaller than the diameter of the ball **3**, thus preventing the balls **3** from coming off the ball running counter-groove **8**.

[0119] The four sets of ball passage forming portions **21**, **21** are composed of the first thin connecting plate portion **25** extending longitudinally along the under surface of the horizontal portion **6** of the block body **13**, a pair of second connecting plate portions **26**, **26**, which have an L-shaped cross section and extend in the longitudinal direction of the block body **13** along the corner portions between the horizontal portion **6** and the wing portions **7**, **7** of the block body **13**, and a pair of third connecting plate portions **27**, **27**, which extend in the longitudinal direction of the block body **13** along the lower surfaces of the wing portions **7**, **7** of the block body **13**.

[0120] More specifically, the right and left-hand side edges of the first connecting plate portion **25** and the upper edges of the pair of right and left-hand second connecting plate portions **26**, **26** are located at the both sides of the respective ball running counter-grooves **8**, **8** provided on the under surface of the horizontal portion **6**, so as to form the ball passage forming portions **21**, **21**; **21**, **21**. The lower edges of the second connecting plate portions **26**, **26** and the inner edges of the third connecting plate portions **27**, **27** are located at the both sides of the respective ball running counter-grooves **8**, **8** provided on the respective inner surface of the wing portions **7**, **7**, so as to form the other ball passage forming portions **21**, **21**; **21**, **21**.

[0121] The direction changing passage-inner guide forming portion **22** has a thin sheet portion **29**, which is to be connected to the end surface of the block body **13**. The ball passage forming portions **21**, **21** and the resin pipe **23** are connected through the above-mentioned thin sheet portion **29**. In this embodiment, the direction changing passage-inner guide forming portions **22**, **22** and the ball passage forming portions **21**, **21** are connected by means of the thin sheet portion **29** through integral forming. The resin pipe **23** is inserted in a hole **34** formed on the thin sheet portion **29** so as to make a faucet joint, and fixed to the thin sheet portion **29**.

[0122] The thin sheet portion **29** has the first end plate portion **30** corresponding to the end surface of the horizontal portion **6** of the block body **13**, a pair of third end plate portions **32**, **32** corresponding to the end surfaces of the wing portions **7**, **7** and the second end plate portions **31**, **31** for connecting the first end plate portion **30** and the respective third end plate portions **32**, **32**. The first end plate portion **30** has the direction changing passage-inner guide forming portions **22**, **22**, which are formed so as to project corresponding to the two trains of balls **3**, **3** on the upper surface side of the guide rail **2**. Each of the third end plate portions **32**, **32** has the direction changing passage-inner guide forming portion **22**, which is formed so as to project corresponding to the single train of balls **3** on the side surface of the guide rail **2**

[0123] The first end plate portions **30**, **30**, which are to be placed respectively on the both ends of the block body **13** are connected at its lower portion with the both ends of the first connecting plate portion **25** extending longitudinally between the first end plate portions **30**, **30**. The second end plate portions **31**, **31**, which are to be placed respectively on the both ends of the block body **13** are connected at its inner edge portion with the both ends of the second connecting plate portion **26** extending longitudinally between the second end plate portions **31**, **31**. The other second end plate portions **31**, **31** have the same connecting structure. The third end plate portions **32**, **32**, which are to be placed respectively on the both ends of the block body **13** are connected at its inner edge portion with the both ends of the third connecting plate portion **27** extending longitudinally between the third end plate portions **32**, **32**. The other third end plate portions **32**, **32** have the same connecting structure. A single resin frame **24** is formed in this way.

[0124] Each of the direction changing passage-inner guide forming portions **22** has a semi-cylindrical shape. On the outer periphery of the direction changing passage-inner guide forming portion **22**, there is formed an inner guide groove **10***a* having a semicircular cross section so as to form the inner guide portion for the direction changing passage **10**. The one end of the inner guide groove **10***a* is connected to the end of the ball running counter-groove **8**. Accordingly, the one end of the inner guide groove **10***a* has the same crosssectional shape as the ball running counter-groove **8** so as to make an alignment of the one end of the inner guide groove **10***a* with the end of the ball running counter-groove **8**. The other end of the inner guide groove **10***a* of the direction changing passage **10** is connected to the end of the ball returning passage **9**. Accordingly, the other end of the inner guide groove **10***a* has the same cross-sectional shape as the ball returning passage **9** so as to make an alignment of the other end of the inner guide groove **10***a* with the end of the ball returning passage **9**.

[0125] Cylindrical flange portions **33**, **33** are formed on the both ends of the inner guide groove **10***a*. The distance between the respective outer surfaces of the cylindrical flange portions **33**, **33** is larger than the width of the belt portion **12***b*. The cylindrical flange portions **33**, **33** form a retainer-guide groove **10***c* for the ball retainer **12** in cooperation with a semi-circular recess portion having cutouts, which is formed on the inner periphery of the recess of the side cover plate **40** described later.

[0126] The both ends of the inner guide groove **10***a* for the direction changing passage **10** extend to the contacting surface of the first and third end plate portions **30**, **32** with the end surface of the block body **13** so as to be connected to the respective ends of the ball running counter-groove **8** and the ball returning passage **9**. Pipe inserting holes **34**, **34**, **34**, **34** having a semicircular shape, in which the ends of the resin pipes **23** are to be inserted are formed on the first and third end plate portions **30**, **32**. As shown in **FIG. 7**, the resin pipe **23** is composed of an inner peripheral side-half pipe member **23***a* located in the inner peripheral side of the ball circulation passage, which is continuously connected to the inner guide groove **10***a* for the direction changing passage, and an outer peripheral side-half pipe member **23***b* located in the outer peripheral side of the ball circulation passage, which is continuously connected to an outer guide groove **10***b* for the direction changing passage **10**, which is formed on the side cover plate **40**. The inner peripheral side-half pipe member **23***a* has a groove portion **9***a* having a semi-circular cross section, and side edge portions **23***c* extending longitudinally along the groove portion **9***a*.

[0127] The outer peripheral side-half pipe member **23***b* is formed into a linear member having the same circular cross section as the outer guide groove **10***b* for the direction changing passage, which is formed on the side cover plate **40**. The outer peripheral side-half pipe member **23***b* has a groove portion **9***b*, which is continuously connected to the outer guide groove **10***b*, and side edge portions **23***d* extending longitudinally along the groove portion **9***b* . The side edge portions **23***d* is provided on its outer edges with projections **23***e*, which are to be brought into contact with the outer edges of the side edge portions **23***c* of the inner peripheral side-half pipe member **23***a* to form the retainer-guide groove **9***c* for the ball retainer **12**.

[0128] The inner peripheral side-half pipe member **23***a* of the resin pipe **23** has the same length of the block body **13**. The inner peripheral side-half pipe member **23***a* is positioned so as to be brought into contact with the back surface of the direction changing passage-inner guide forming portion **22**.

[0129] The outer peripheral side-half pipe member **23***b* of the resin pipe **23** has on the other hand a longer length than the block body **13** by a length corresponding to the thickness of the thin sheet portion **29**. The outer peripheral side-half pipe members **23***b* are inserted in the inserting holes **34** of the first and third end plate portions **30**, **32**. Longitudinal positional determination of the outer peripheral side-half pipe member **23***b* is made by bringing the both ends of the outer peripheral side-half pipe member **23***b* inserted in the inserting holes **34** into contact with the peripheral edge of the end portion of the outer guide grooves **10***b* for the direction changing passage, which are formed on the side cover plate **40**. The projections **23***e* formed on the both side edges of the outer peripheral side-half pipe member **23***b* come into contact with the outer edges of the cylindrical flange portions **33** formed on the direction changing passage-inner guide forming portion **22** to form a part of the guide groove **10***c*, and the outer peripheral side-half pipe member **23***b* and the inner peripheral side-half pipe member **23***a* are restricted to be turned in the inserting hole **14**.

[0130] The resin pipes **23** and the direction changing passage-inner guide forming portions **22** are accurately positioned through the inserting holes **34** formed on the first and third end plate portions **30**, **32** of the thin sheet portion **29** and a proper assembling is carried out in this manner.

[0131] As shown in **FIG. 5**, the side cover plate **40** is provided with an inserting recess portion **40***a*, in which the thin sheet portion **29** is inserted, four recess portions **41** having the outer guide grooves **10***b* for the direction changing passage, into which portions the direction changing passage-inner guide forming portions **22** are fitted, and screw-fixing portions for securing the side cover plate **40** to the block body **13**. In the screw-fixing portions, the side cover plate **40** is fixed to the block body **13** by inserting bolts **44** into holes **43** formed on the side cover plate **40** and engaging the bolts with screwed holes **45** formed on the end surface of the block body **13**. The holes **43** are located between the first and third end plate portions **30**, **32** of the thin sheet portion

[0132] As shown in **FIG. 7**, the outer guide groove **10***b* for the direction changing passage in the recess portion **41** has on its side edges larger-diameter arcuate recesses **46**, which form the retainer-guide groove **10***c* in cooperation with the cylindrical flange portions **33** of the direction changing passage-inner guide forming portions **22**, and a smaller-diameter arcuate recesses **47**, in which the cylindrical flange portions **33** are inserted. The direction changing passage-inner guide forming portion **22** provided with the inner guide groove **10***a* for the direction changing passage is fitted into the recess portion **41** of the side cover plate **40**, and the thin sheet portion **29** is received in the inserting recess portion **40***a* of the side cover plate **40**. The thin sheet portion **29** is held between the side cover plate **40** and the end surface of the block body **13** through a clamping force so as to be firmly fixed therebetween.

[0133] The direction changing passage-inner guide forming portions **22** and the ball passage forming portion **21** are connected through the thin sheet portion **29**, thus making it possible to maintain an accurate positional relationship of the end of the inner guide groove **10***a* for the direction changing passage formed in the direction changing passage-inner guide forming portion **22** relative to the ball passage forming portions **21**, **21**, as well as an accurate positional relationship of the inner guide groove **10***a* for the direction changing passage relative to the ball returning passage **9**.

[0134] The thin sheet portion **29** located in the vicinity of the direction changing passage-inner guide forming portion **22** is uniformly urged against the flat end surface of the block body **13** through a clamping force applied to the side cover plate **40** (see **FIG. 7**). Even when the direction changing passage-inner guide forming portion **22** is not located in a correct position, the thin sheet portion **29** changes its shape on the end surface of the block body **13**, thus permitting the correct positioning of the direction changing passage-inner guide forming portion **22**. The thin sheet portion **29** is firmly clamped and fixed through a clamping force, which is applied to the side cover plate **40**, and frictional force caused by such a clamping step may prevent an unfavorable movement of the inner guide groove **10***a* for the direction changing passage.

[0135] The side cover plate **40** is secured to the block body **13** so that the direction changing passage-inner guide forming portion **22** assembled to the block body **13** is fitted into the recess portion **41** of the side cover plate **40**. Such a fitting step permits to make an accurate positioning of the side cover plate **40** relative to the block body **13**.

[0136] **FIG. 6** shows assembling steps for the above-described resin-formed body for forming the ball circulation passage.

[0137] First, the inner peripheral side-half pipe member **23***a* of the resin pipe **23** is inserted in the through-hole **14** of the block body **13** (see FIGS. **6**(*a*) and **6**(*b*)).

[0138] Then, the resin frame **24** obtained by integral forming is inserted in the recess of the block body **13**, while causing the thin sheet portions **29** at the both ends of the resin frame **24** to slide on the respective end surfaces of the block body **13** (see FIGS. **6**(*c*) and **6**(*d*)). The first connecting plate portion **25** of the resin frame **24** comes into contact with the under surface of the horizontal portion **6**, thus making positional determination in the vertical direction of the resin frame **24**. The second connecting plate portion **26** and the third connecting plate portion **27** of the resin frame **24** come into contact with the respective inner surfaces of the wing portions **7**, **7** of the block body **13**, thus making positional determination of the ball passage forming portions **21**, **21** and the direction changing passage-inner guide forming portion **22** (see FIGS. **6**(*e*) and **6**(*f*)). At this time, the inserting hole **34** of the thin sheet portion **29** is aligned with the through-hole **14** of the block body **13**.

[0139] Then, the outer peripheral side-half pipe member **23***b* is inserted in the through-hole **14** from the inserting hole **34**, thus completing the assembling step of the resin-formed body **20** for forming the ball circulation passage (see FIGS. **6**(*g*) and **6**(*h*)).

[0140] Then, the one side cover plate **40** is secured to the one end surface of the block body **13** by a clamping step, the ball retainer **12** holding the balls is inserted, and the other side cover plate **40** is secured to the other end surface of the block body **13** by the same clamping step, thus completing the assembling step of the movable block **4**.

[0141] According to the present invention, the resin-formed body **20** for forming the ball circulation passage is separately formed from the block body **13**. Even when the movable block **4** has a larger size, there is no restriction of flow of molten resin by the block body **13**, unlike the case where the block body **13** is integrally formed with the resin-formed body **20**. Increase in number of gates formed on a die may ensure proper run of the molten resin, thus improving the formability. Especially, the ball passage forming portions **21**, **21** located at the opposite longitudinal sides of the ball running groove **8** are thin, with the result that molten resin may not reach every part of the space for forming the ball passage forming portions **21**, **21**. It is therefore effective to form the resin-formed body **20** separately from the block body **13** in accordance with the embodiment of the present invention.

[0142] The continuous circulation passage is formed by the resin-formed body **20**, and it is therefore possible to make positional determination of the inner guide groove **10***a* for the direction changing passage relative to the ball passage forming portions **21**, **21**, as well as positional determination of the inner guide groove **10***a* for the direction changing passage relative to the ball returning passage **9**, thus ensuring continuity of the circulation passage so as to make smooth circulation of the balls **3**.

[0143] When the proper positional relationship of the inner guide groove **10***a* for the direction changing passage relative to the ball passage forming portions **21**, **21**, is maintained, the ball passage forming portions **21**, **21** are located at the longitudinal both sides of the ball running groove **8** so as to be aligned with the ends of the inner guide groove **10***a* for the direction changing passage.

[0144] When the proper positional relationship of the inner guide groove **10***a* for the direction changing passage relative to the ball returning passage **9** is maintained, the inner guide groove **10***a* for the direction changing passage can be aligned with the inner groove **23***a* of the ball returning passage **9**.

[0145] The connecting portion of the ball passage forming portions **21**, **21** and the direction changing passage-inner guide forming portion **22** is obtained by integral forming, thus permitting omission of an assembling step of the connecting portion. Although the running direction of the balls **3** is changed in such a connecting portion, the above-mentioned integral structure may ensure continuity of the circulation passage, without being affected by assembling accuracy. It is therefore possible to make smooth run of the balls **3** from the ball running passage between the ball running groove **5** and the ball running counter-groove **8** to the direction changing passage **10**, as well as from the direction changing passage **10** to the ball returning passage **9**.

[0146] Description will be given of modifications of the resin-formed body **20** for forming the ball circulation passage, which is divided into parts In the description of the modifications, modified features will only be explained in comparison with the first embodiment of the present invention. The same reference numerals will be given to the same components as those in the first embodiment of the present invention, and description thereof will be omitted.

[0147] First Modification

[0148] **FIGS. 8 and 9** show the first modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the first embodiment.

[0149] In the first modification, the resin-formed body **20** for forming the ball circulation passage is composed of the first resin-formed frame **20**A, which is obtained by integrally connecting both of the ball passage forming portions **21**, **21** and the resin pipes **23** at their ends with the direction changing passage-inner guide forming portions **22**A for one side, and the second resin-formed frame **20**B, which is provided with the direction changing passage-inner guide forming portions **22**B for the other side and separately formed from the first resin-formed frame **20**A.

[0150] In this case, the ball passage forming portions **21**, **21** are integrally connected with the direction changing passage-inner guide forming portions **22**A through the thin sheet portion **29**A as in the first embodiment.

[0151] The direction changing passage-inner guide forming portions **22**A are also integrally connected with the resin pipes **23** through the thin sheet portion **29**A. In this case, the resin pipe **23** is formed into a tubular integral body, although the half pipe members are used in the first embodiment. Accordingly, there exists no inserting hole **34** in the thin sheet portion **29**A, and the ball returning passage **9** is exposed on the thin sheet portion **29**A.

[0152] The first resin-formed frame **20**A and the second resin-formed frame **20**B are connected, as shown in **FIG. 9**, by means of a joint method using the combination of a recess and a projection to be inserted therein, such as a faucet joint method. In the illustrated example, a recess portion **36** of a dove-tail groove is formed in the second resin-formed frame **20**B, and an engaging projection **35** to be engaged with the recess portion **36** is formed, on the other hand, in the ball passage forming portions **21**, **21**.

[0153] In this case, the resin pipe **23** of the first resin-formed frame **20**A is inserted in the through-hole **14** of the block body **13**, and the first, second and third connecting plate portions **25**, **26**, **27** are inserted along the under surface of the horizontal portion **6** of the block body **13** and the inner surfaces of the wing portions **7**,.**7**.

[0154] Then, the engaging projections **35** formed at the respective free end portions of the first, second and third connecting plate portions **25**, **26**, **27** are engaged with the recess portions **36** formed on the thin sheet portion **29**B of the second resin-formed frame **24**B, which is arranged on the other end surface of the block body **13**.

[0155] The recess portions **36** may be formed on the first resin-formed frame **20**A and the engaging projections **35** may be formed on the second resin-formed frame **20**B. The connecting method is not limited to the method described above, and there may be used any conventional connecting method, in which the ends of the divided parts can be maintained in a proper connecting position and connected.

[0156] Second Modification

[0157] **FIGS. 10 and 11** show the second modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the first embodiment.

[0158] In the second modification, the resin-formed body **20** for forming the ball circulation passage, which has been obtained by integrally forming both of the ball passage forming portions **21**, **21** and the resin pipes **23** as a returning passage forming portion with a pair of direction changing passageinner guide forming portions **22**, **22**, is divided at the middle portion of each of the ball passage forming portions **21**, **21** and the resin pipes **23** into two parts. More specifically, the ball passage forming portions **21**, **21** and the resin pipes **23** are divided at their middle portion into the respective two half parts, and each of the thus divided two half parts is integrally formed with the direction changing passage-inner guide forming portions **22**, **22**, thus forming two resin-formed frames **20**C, **20**D having substantially the same shape.

[0159] Four sets of the ball passage forming portions **21**, **21** are formed on the first, second and third connecting plate portions **25**, **26**, **27**. Recess portions **38** and engaging projections **37** to be inserted therein are formed on the divided ends of the first, second and third connecting plate portions **25**, **26**, **27** and the divided ends of the resin pipes **23**.

[0160] Third Modification

[0161] FIGS. **12** to **14** show the third modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the first embodiment.

[0162] In the third modification, there is not used the resin pipe **23** as a returning passage forming portion described in the first embodiment, and a resin-formed frame **20**E is obtained by integrally forming the first, second and third connecting plate portions **25**, **26**, **27** having the ball passage forming portions **21**, **21** with the thin sheet portions **29**, **29** each having the pair of direction changing passage-inner guide forming portions **22**, **22**. The ball returning passage **9** is composed as a through-hole formed in the block body **13**.

[0163] In this case, an engaging projection **39***a*, which is engageable with a tapered portion **15** formed in the opening end of the ball returning passage **9** may be formed in the opening end of the ball hole **39** of the thin sheet portion **29**. Such a construction permits to make a proper connection of the end of the ball returning passage **9** and the direction changing passage-inner guide forming portion **22**.

[0164] In the illustrated example, an arcuate engaging projection **48** is additionally formed on the connection portion of the outer guide groove **10***b* for the direction changing passage with the ball returning passage **9**. The engaging projection **48** can be fitted into the ball hole **39** of the thin sheet portion **29** and engaged with the tapered portion **15** of the opening end of the ball returning passage **9**.

[0165] Fourth Modification

[0166] **FIG. 15** shows the fourth modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the first embodiment.

[0167] In the fourth modification, there is not used the resin pipe **23** described in the third modification, a resin-formed frame **24**B is obtained by integrally forming the ball passage forming portions **21** with the direction changing passage-inner guide forming portions **22** for the one side, the other resin-formed frame **24**C provided with the direction changing passage-inner guide forming portions **22** for the other side is separately formed from the above-mentioned resin-formed frame **24**B, and the resin-formed frames **24**B, **24**C are connected with each other by engagement of the engaging projection **35** with the recess **36**. The structure other than the above-mentioned construction is the same as that of the third modification.

[0168] Modifications of the ball train

[0169] In the first embodiment and the first to fourth modifications, there is described that two trains of the balls are provided on the upper surface of the guide rail **2** and the single train of the balls is provided on each of the side surfaces of the guide rail **2**, so as to provide the total number of trains of four. In the present invention, the other type of ball trains can however be applied as shown in **FIG. 16**. With respect to the division of the resin-formed body **20** for forming the ball circulation passage, all the modifications as shown in **FIG. 16** are based on the divisional pattern of the first embodiment. All the divisional patterns of the first to fourth modifications may however be applied to the modifications of the ball train as shown in **FIG. 16**.

[0170] In the example as shown in FIGS. **16**(*a*) and **16**(*b*), two lower and upper trains of the balls as rolling members are provided on each of the gaps between the right and left-hand side surfaces of the guide rail **2** and the inner surfaces of the right and left-hand wing portions **7**, **7** of the movable block **13**, so as to provide the total number of trains of four.

[0171] **FIG. 16**(*b*) shows the resin-formed body **20** in which all the ball passage forming portions for the four trains of the balls are integrally formed with each other. The resin-formed body **20** may however be divided into two resin-formed bodies **20**, **20**, which correspond to two trains of the balls for each of the right and left-hand sides of the guide rail **2**, as shown in **FIG. 18**.

[0172] In the example as shown in FIGS. **16**(*c*) and **16**(*d*), the movable block **4** is provided with the horizontal portion **6** facing the upper surface of the guide rail **2** and a single wing portion **7** facing the one side surface of the guide rail **2**. The single train of the balls **3** as rolling members is provided between the one side surface of the guide rail **2** and the single wing portion **7** of the movable block **4**, and the other single train of the balls **3** is provided between the upper surface of the guide rail **2** and the lower surface of the horizontal portion in the vicinity of the corner of the guide rail **2**, so as to provide the total number of trains of two.

[0173] In the example as shown in FIGS. **16**(*e*) and **16**(*f*), the movable block **4** is provided with a pair of wing portions **7**, **7** between which the guide rail **2** is held at its right and left-hand surfaces. The single train of the balls **3** is provided in each of the gaps between the right and left-hand surfaces of the guide rail **2** and the inner surfaces of the right and left-hand wing portions **7**, **7** of the movable block **4**, so as to provide the total number of trains of two.

[0174] In the example as shown in FIGS. **16**(*g*) and **16**(*h*), the movable block **4** is arranged along the one side surface of the guide rail **2**. Two upper and lower trains of the balls **3** are provided between the one side surface of the guide rail **2** and the movable block **4**.

[0175] Second Embodiment

[0176] FIGS. **18** to **20** show a linear motion guiding apparatus of the second embodiment of the present invention.

[0177] In the second embodiment, rollers are used as rolling members. More specifically, the linear motion guiding apparatus comprises a guide rail **202** as a guide member, extending linearly, and a movable block **204** arranged so as to be movable along the guide rail **202** through a large number of rollers **203** as rolling members.

[0178] The guide rail **202** is formed into a long bar shape having a rectangular cross-section. Two roller running surfaces **205**, **205** as a rolling member running track are formed on the horizontal upper surface of the guide rail **2**, and a single roller running surface **205** as the rolling member running track is formed on each of the right and left-hand vertical surfaces of the guide rail **2**, so as to provide a total number of surfaces **5** of four.

[0179] The movable block **204** is formed as a block body having an inverse U-shaped cross-section, with its opening end being directed downwardly. The block body is provided with a horizontal portion **206**, which faces the upper surface of the guide rail **202** and with a pair of wing portions **207**, **207**, which extend downwardly from the right and left ends of the horizontal portion **206** and face the right and left-hand side surfaces of the guide rail **202**, respectively. The horizontal portion **206** has on its lower surface two roller running counter-surfaces **208**, **208** as a rolling member running counter-track, which correspond to the roller running surfaces **205, 205** formed on the upper surface of the guide rail **202**. Each of the wing portions **207, 207** has on its inner surface a single roller running counter-surface **208** as the rolling member running counter-track, which corresponds to the respective roller running surfaces **205, 205** formed on the right and left-hand side surfaces of the guide rail **202**.

[0180] In addition, in the movable block **204**, there are formed four roller returning passages **209, 209, 209, 209** as a rolling member returning passage, which are provided in parallel with the four roller running counter-surfaces **208, 208, 208, 208**, respectively, as well as four pairs of direction changing passages **210, 210, 210, 210** each having a U-shape, for connecting the respective both ends of the roller running counter-surfaces **208, 208, 208, 208** with the respective both ends of the roller returning passages **209, 209, 209, 209**, so as to form four endless circulation passages.

[0181] The roller returning passages **209, 209** respectively corresponding to the roller running surfaces **205, 205** formed on the upper side of the guide rail **202** are formed in the horizontal portion **206**. The other roller returning passages **209, 209** respectively corresponding to the roller running surfaces **205, 205** formed on the right and left-hand vertical surfaces of the guide rail **202** are formed in the wing portions **207, 207** of the movable block **204**, respectively.

[0182] In each of the endless circulation passages in this embodiment, the rollers **3** are retained in the form of train by means a roller retainer **212** as a rolling member retainer so that the rollers **203** can be circulated while being guided by the roller retainer **212**.

[0183] As shown in FIGS. **19**(*b*) to **19**(*d*), the roller retainer **212** comprises a flexible belt portion **212***b*, which is provided with roller holes **212***a* for respectively receiving the rollers **203**, and spacing portions **212***c* provided between the adjacent two rollers **203, 203**. The belt portion **212***b* has a width longer than the diameter of the roller **203** so that the both side edges of the belt portion **212***b* extend outwardly from the roller **203**.

[0184] The spacing portion **212***c* is provided with a roller supporting recess **212***d* corresponding to the cylindrical surface of the roller **203**. The roller **203** is supported on its both sides by a pair of supporting recesses **212***d* so as to prevent the roller **203** from coming off the belt portion **212***b*. In this embodiment, the one end of the belt portion **212***b* is not connected to the other end thereof, thus forming a strip-shaped belt having the both ends. The one end of the belt portion **212***b* may be connected to the other end thereof so as to form an endless belt.

[0185] As shown in **FIGS. 18 and 20**, the movable block **204** is composed of a metallic block body **213** having roller running counter-surfaces **208, 208, 208, 208**, a resin-formed body **220** for forming roller circulation passages, which is inserted in the block body **213**, and a pair of side cover plates **214, 214** secured to the both end surfaces of the block body **213**, in which the resin-formed body **220** is inserted.

[0186] In the second embodiment, four circulation passages are formed by two resin-formed bodies **220, 220** for forming the roller circulation passage, which are arranged at the right and left-hand sides.

[0187] Each of the roller circulation passages of the resin-formed bodies **220** comprises a pair of roller passage forming portions **221, 221** extending along both longitudinal sides of the roller running counter-surface **208**, a pair of direction changing passage-inner guide forming portions **222, 222** provided on the both side surfaces of the block body **213**, and a resin pipe **223** as a returning passage forming portion, which is inserted into a through-hole formed in the block body **213**.

[0188] The roller passage forming portions **221, 221** are provided with guide surfaces for guiding the both side edges of the belt portion **212***b* of the roller retainer **212** in a loaded area as illustrated in detain in **FIG. 20**. The guide grooves can prevent the roller retainer **212** not only from being swung during run of the roller, but also from being sagged by engaging the side edges of the belt portion **212***b* with the guide groove **221***a*. The rollers **203** are supported by the roller retainer **212**. More specifically, the roller retainer **212** is supported by a jaw portion of the guide groove **221***a*, with the result that the rollers **203** are kept-in its proper position so as not to come off the movable block **204**.

[0189] In this embodiment, the one end of the belt portion **212***b* is not connected to the other end thereof, thus forming a strip-shaped belt having the both ends. The one end of the belt portion **212***b* may be connected to the other end thereof so as to form an endless belt.

[0190] Guide grooves **209***c*, **210***c* are also formed in the roller returning passage **209** and the direction changing passage **210** as non-loaded areas, in order to guide the side edges of the belt portion **212***b*. The guide grooves **209***c*, **210***c* are connected to the above-mentioned guide groove **221***a* in the loaded area so as to form an endless groove on the entire periphery.

[0191] In each of the resin-formed bodies **220, 220** for forming the roller circulation passage, the roller passage forming portions **221, 221** and the pair of the direction changing passage-inner guide forming portions **222, 222** are integrally formed with each other. The resin pipe **223** for forming the roller returning passage **209** is separately formed from the resin-formed bodies **220, 220**. More specifically, the one ends of the two pairs of the roller passage forming portions **221, 221** are integrally connected with the ends of the pair of direction changing passage-inner guide forming portions **222, 222** to form a single resin frame **220A** so that the thus formed resin frame **220A** can be inserted into the block body **213**. The other resin frame **220A** has the same construction.

[0192] The roller passage forming portions **221, 221** to be arranged on the upper surface of the guide rail **202** are integrally connected with the other roller passage forming portions **221, 221** to be arranged on the side surface of the guide rail **202** by means of a thin connecting plate portion **226**.

[0193] The direction changing passage-inner guide forming portion **222** is integrally formed with a thin sheet portion **229**, which is to be brought into contact with the end surface of the block body **213**.

[0194] The thin sheet portion **229** has the first end plate portion **230**, which is to be brought into contact with the end surface of the horizontal portion **206** of the block body **213**, the third end plate portion **232**, which is to be brought into contact with the end surface of the wing portion **207**, and the second end plate portion **231**, which is arranged at the corner between the horizontal portion **206** and the wing portion **207** on the end surface of the block body **213**, and connects the first end plate portion **230** with the third end plate portion **232**.

[0195] The pair of roller passage forming portions **221**, **221**, which are arranged on the both longitudinal sides of the roller running surface **208** are integrally formed on the inside edge of the first end plate portion **230** and the inside edge of the third end plate portion **232**, respectively. The both ends of the connecting plate portion **226** are integrally connected with the inside edges of the second plate portions **231**, **231**.

[0196] Each of the direction changing passage-inner guide forming portions **222** has a semi-cylindrical shape. On the outer periphery of the direction changing passage-inner guide forming portion **222**, there is formed an inner guide groove **210***a* having a rectangular cross section so as to form the inner guide portion for the direction changing passage **210**. The one end of the bottom of the inner guide groove **210***a* is connected to the end of the roller running counter-surface **208**. Accordingly, the one end of the inner guide groove **210***a* has the same cross-sectional shape as the roller running counter-surface **208** so as to make an alignment of the one end of the inner guide groove **210***a* with the end of the roller running counter-surface **208**. The other end of the inner guide groove **210***a* of the direction changing passage **210** is connected to the end of the roller returning passage **229**. Accordingly, the other end of the inner guide groove **210***a* has the same cross-sectional shape as the roller returning passage **209** so as to make an alignment of the other end of the inner guide groove **210***a* with the end of the roller returning passage **209**.

[0197] Cylindrical flange portions **233**, **233** are formed on the both ends of the inner guide groove **210***a*. The distance between the respective outer surfaces of the cylindrical flange portions **233**, **233** is larger than the width of the belt portion **212***b*. The cylindrical flange portions **233**, **233** form a guide groove **210***c* for the roller retainer **212** in cooperation with the side cover plate **240** described later.

[0198] The one end of the inner guide groove **210***a* for the direction changing passage **210** extends to the contacting surface of the first and third end plate portions **230**, **232** with the end surface of the block body **213** so as to be connected to the end of the roller running counter-surface **208**. The other end of the inner guide groove **210***a* for the direction changing passage **210** extends to the end surface of the thin sheet portion **229**, which the block body **213**. A step portion **222***a* having a depth identical to the thickness of the thin sheet portion **229** is formed at the other end of the inner guide groove **210***a*. The inner peripheral side-half pipe member for the resin pipe **223** projects from the end surface of the block body **13** by a length identical to the thickness of the thin sheet portion **229**. The projected end of the half pipe member **223***a* is fitted into the step portion **222***a* of the thin sheet portion **229**.

[0199] Pipe inserting holes **234**, **234** having a semi-circular shape, in which the ends of for the outer peripheral side-half pipe member **223***a*for the resin pipes **223** for forming the roller returning passage **209** are to be inserted are formed on the first and third end plate portions **230**, **232** of the thin sheet portion **229**. The resin pipe **223** is inserted into the circular through-hole **214** formed in the block body **213** so that the inner peripheral surface of the resin pipe **223** form the roller returning passage **209**.

[0200] As shown in **FIG. 20**, the resin pipe **223** is composed of the inner peripheral side-half pipe member **223***a*, which is continuously connected to the inner guide groove **210***a* for the direction changing passage, and the outer peripheral side-half pipe member **223***b*, which is continuously connected to the outer guide groove **210***b* for the direction changing passage **210**, which is formed on the side cover plate **240**. The inner peripheral side-half pipe member **223***a* has an inner groove portion **209***a* having a rectangular cross section, and side edge portions **223***b* extending longitudinally along the inner groove portion **209***a*. The longitudinal edge portions **223***c* of the inner peripheral side-half pipe member **223***a* has the same width as the flange portion **233** of the portion **228**.

[0201] The outer peripheral side-half pipe member **223***b* is formed into a linear member having the same rectangular cross section as the outer guide groove **210***b* for the direction changing passage, which is formed on the side cover plate **240**. The outer peripheral side-half pipe member **223***b* has a outer groove portion **209***b*, which is continuously connected to the outer guide groove **210***b*, and side edge portions **223***d* extending longitudinally along the outer groove portion **209***b*. The side edge portions **223***d* is provided on its outer edges with projections **223***e*, which are to be brought into contact with the side edge portions **223***c* of the inner peripheral side-half pipe member **223***a* to form the guide groove for the belt portion **212** of the roller retainer **212**.

[0202] The inner peripheral side-half pipe member **223***a* of the resin pipe **223** has the same length of the block body **213**. The inner peripheral side half pipe member **223***a* is positioned so as to be brought into contact with the end surface of the direction changing passage-inner guide forming portion **222**, which is arranged on the side of the block body **213**.

[0203] The outer peripheral side-half pipe member **223***b* of the resin pipe **223** has on the other hand a longer length than the block body **213** by a length corresponding to the thickness of the first and third end plate portions of the thin sheet portion **229**, which are arranged on the both ends of the block body **213**. The outer peripheral side-half pipe members **223***b* are inserted in the inserting holes **234** of the first and third end plate portions **230**, **232**. Longitudinal positional determination of the outer peripheral side-half pipe member **223***b* is made by bringing the both ends of the outer peripheral side-half pipe member **223***b* inserted in the inserting holes **234** into contact with the peripheral edge of the end portion of the outer guide grooves **210***b* for the direction changing passage, which are formed on the side cover plate **240** The projections **223***e* formed on the both longitudinal side edges **223** of the outer peripheral side-half pipe member **223***b* come into contact with the cylindrical flange portions **233** at the side edges of the inner guide groove **210***a* of the direction changing passage-inner guide forming portion **222**, and the outer peripheral side-half pipe member **223***b* and the inner peripheral side-half pipe member **223***a* are restricted to be turned in the inserting hole **214**.

[0204] The resin pipes **223** and the direction changing passage-inner guide forming portions **222** are accurately positioned through the inserting holes **234** formed on the first and third end plate portions **230**, **232** of the thin sheet portion **229** and a proper assembling is carried out in this manner.

[0205] The side cover plate **240** is provided with four recess portions **241** having the outer guide grooves **210***b* for the direction changing passage, into which the portions **228** of the direction changing passage-inner guide forming portions **222** are fitted, and screw-fixing portions for securing the side cover plate **240** to the block body **213**. In the screw-fixing portions, the side cover plate **240** is fixed to the block body **213** by inserting bolts **244** into holes **243** formed on the side cover plate **240** and engaging the bolts **244** with screwed holes **245** formed on the end surface of the block body **213**. The holes **243** are located between the first and third end plate portions **230**, **232** of the thin sheet portion **229**.

[0206] The direction changing passage-inner guide forming portion **222** provided with the inner guide groove **210***a* for the direction changing passage is fitted into the recess portion **241** of the side cover plate **240**. The thin sheet portion **229** is held between the side cover plate **240** and the end surface of the block body **213** through a clamping force so as to be firmly fixed therebetween.

[0207] The direction changing passage-inner guide forming portions **222** and the roller passage forming portion **221** are connected through the thin sheet portion **229**, thus making it possible to maintain an accurate positional relationship of the end of the inner guide groove **210***a* for the direction changing passage relative to the roller passage forming portions **221**, as well as an accurate positional relationship of the inner guide groove **210***a* for the direction changing passage relative to the roller returning passage **209**.

[0208] The thin sheet portion **229** is uniformly urged against the flat end surface of the block body **213** through a clamping force applied to the side cover plate **240**. Even when the direction changing passage-inner guide forming portion **222** is not located in a correct position, the thin sheet portion **229** changes its shape, thus permitting the correct positioning of the direction changing passage-inner guide forming portion **222**. The thin sheet portion **229** is firmly clamped and fixed through a clamping force, which is applied to the side cover plate **240**, and frictional force caused by such a clamping step may prevent an unfavorable movement of the inner guide groove **210***a* for the direction changing passage.

[0209] Description will be given of modifications of the resin-formed body **220** for forming the roller circulation passage, which is divided into parts In the description of the modifications, modified features will only be explained in comparison with the second embodiment of the present invention. The same reference numerals will be given to the same components as those in the second embodiment of the present invention, and description thereof will be omitted.

[0210] First Modification

[0211] **FIGS. 21 and 22** show the first modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the second embodiment.

[0212] In the first modification, the resin-formed body **220** for forming the ball circulation passage is composed of the first resin-formed frame **220**A, which is obtained by integrally connecting both of the roller passage forming portions **221**, **221** and the resin pipes **223** at their ends with the direction changing passage-inner guide forming portions **222**A for one side, and the second resin-formed frame **220**B, which is provided with the direction changing passage-inner guide forming portions **222**B for the other side and separately formed from the first resin-formed frame **220**A.

[0213] In this case, the roller passage forming portions **221**, **221** are integrally connected with the direction changing passage-inner guide forming portions **222**A through the thin sheet portion **229**A as in the second embodiment.

[0214] The direction changing passage-inner guide forming portions **222** are also integrally connected with the resin pipes **223** through the thin sheet portion **229**A. In this case, the resin pipe **223** is formed into a tubular integral body, although the half pipe members are used in the second embodiment. Accordingly, there exists no inserting hole **234** in the thin sheet portion **229**A, and the roller returning passage **209** is exposed on the thin sheet portion **229**A.

[0215] The first resin-formed frame **220**A and the second resin-formed frame **220**B are connected, as shown in **FIG. 22**, by means of a joint method using the combination of a recess and a projection to be inserted therein, such as a faucet joint method. In the illustrated example, a recess portion **236** of a dove-tail groove is formed in the second resin-formed frame **220**B, and an engaging projection **235** to be engaged with the recess portion **236** is formed, on the other hand, in the roller passage forming portions **221**, **221**.

[0216] In this case, the resin pipe **223** of the first resin-formed frame **220**A is inserted in the through-hole **214** of the block body **213**, and the roller passage forming portions **221**, **221** and the connecting plate portion **226** are inserted along the under surface of the horizontal portion **206** of the block body **213** and the inner surfaces of the wing portions **207**,.**207**.

[0217] Then, the engaging projections **235** formed at the roller passage forming portions **221**, **221** and the connecting plate portion **226** are engaged with the recess portions **236** formed on the thin sheet portion **229**B of the second resin-formed frame **224**B, which is arranged on the other end surface of the block body **213**.

[0218] The recess portions **236** may be formed on the first resin-formed frame **220**A and the engaging projections **235** may be formed on the second resin-formed frame **220**B. The connecting method is not limited to the method described above, and there may be used any conventional connecting method in which the ends of the divided parts can be maintained in a proper connecting position and connected.

[0219] Second Modification

[0220] **FIGS. 23 and 24** show the second modification of the resin-formed body **220** for forming the ball circulation passage, which is described in the second embodiment.

[0221] In the second modification, the resin-formed body **220** for forming the roller circulation passage, which has been obtained by integrally forming both of the roller passage forming portions **221**, **221** and the resin pipes **223** as a returning passage forming portion with a pair of direction changing passage-inner guide forming portions **222**, **222**, is divided at the middle portion of each of the roller passage forming portions **221**, **221** and the resin pipes **223** into two parts. More specifically, the roller passage forming portions **221**, **221** and the resin pipes **223** are divided at their middle portion into the respective two half parts, and each of the thus divided two half parts is integrally formed with the direction changing passage-inner guide forming portions **222**, **222**, thus forming two resin-formed frames **220**C, **220**D having substantially the same shape.

[**0222**] Recess portions **238** and engaging projections **237** to be inserted therein are formed on the divided ends of the roller passage forming portions **221**, **221** and the divided ends of the connecting plate portion **226** and the divided ends of the resin pipes **223**.

[**0223**] Third Modification

[**0224**] FIGS. **25** to **26** show the third modification of the resin-formed body **220** for forming the roller circulation passage, which is described in the second embodiment.

[**0225**] In the third modification, there is not used the resin pipe **223** as a returning passage forming portion described in the second embodiment, and a resin-formed frame **220**E is obtained by integrally forming the both of the roller passage forming portions and the connecting plate portion **226** with the thin sheet portions **229**, **229** each having the pair of direction changing passage-inner guide forming portions **222**, **222**. The roller returning passage **209** is composed as a through-hole formed in the block body **213**.

[**0226**] In this case, an engaging projection **239***a*, which is engageable with a tapered portion **215** formed in the opening end of the roller returning passage **209** may be formed in the opening end of the roller hole **239** of the thin sheet portion **229**. Such a construction permits to make a proper connection of the end of the roller returning passage **209** and the direction changing passage-inner guide forming portion **222**.

[**0227**] In the illustrated example, an arcuate engaging projection **248** is additionally formed on the connection portion of the outer guide groove **210***b* for the direction changing passage with the roller returning passage **209**. The engaging projection **248** can be fitted into the roller hole **239** of the thin sheet portion **229** and engaged with the tapered portion **215** of the opening end of the roller returning passage **209**.

[**0228**] Fourth Modification

[**0229**] **FIG. 26** shows the fourth modification of the resin-formed body **220** for forming the roller circulation passage, which is described in the second embodiment.

[**0230**] In the fourth modification, there is not used the resin pipe **223** described in the third modification, a resin-formed frame **220**F is obtained by integrally forming the roller passage forming portions **221** with the direction changing passage-inner guide forming portions **222** for the one side, the other resin-formed frame **220**F provided with the direction changing passage-inner guide forming portions **222** for the other side is separately formed from the above-mentioned resin-formed frame **220**F, and the resin-formed frames **220**F, **220**F are connected with each other by engagement of the engaging projection **235** with the recess **236**. The structure other than the above-mentioned construction is the same as that of the third modification.

[**0231**] Modifications Of The Roller Train

[**0232**] In the second embodiment and the first to fourth modifications, there is described that two trains of the rollers are provided on the upper surface of the guide rail **2** and the single train of the rollers is provided on each of the side surfaces of the guide rail **2**, so as to provide the total number of trains of four. In the present invention, the other type of roller trains can however be applied as shown in the figures. With respect to the division of the resin-formed body **220** for forming the roller circulation passage, all the modifications are based on the divisional pattern of the first embodiment. All the divisional patterns of the first to fourth modifications may however be applied to the modifications of the roller train.

[**0233**] In the example as shown in **FIG. 27**, two lower and upper trains of the rollers as rolling members are provided on each of the gaps between the right and left-hand side surfaces of the guide rail **202** and the inner surfaces of the right and left-hand wing portions **207**, **207** of the movable block **204**, so as to provide the total number of trains of four.

[**0234**] In this case, four inner guide portions **210***a* corresponding to the four trains of the rollers **203** are integrally formed with each other in the direction changing passage-inner guide forming portions **222**.

[**0235**] In the above description, the present invention is applied to the linear motion guiding apparatus, in which the movable block is arranged on the guide rail as a track shaft through the rolling members. The present invention may however be applied to a so-called ball-spline, in which an outer tube as a movable member is fitted on a spline shaft as a track shaft, as described below.

[**0236**] Third Embodiment

[**0237**] A ball spline **301** as shown in FIGS. **28** to **30** is of a so-called "angular contact" ball spline, and has a spline shaft **302** as a guide member extending linearly and an outer tube **304** arranged so as to be movable along the spline shaft **302** through balls **303** as a large number of rolling members.

[**0238**] The spline shaft **304** is formed into a long bar shape having a circular cross-section. The spline shaft **304** has on its outer periphery three projections **306**. Two ball running grooves **305**, **305** are formed on the both sides of each of the projections **306**, so as to provide the total number of groove of six.

[**0239**] The outer tube **304** has on its inner periphery three recesses **307** corresponding to the projections **306** of the spline shaft **302**, respectively. Ball running counter-grooves **308**, **308** are formed at the both corners of each of the recesses **307**, so as to correspond to the above-mentioned ball running In addition, the outer tube **304** has six ball returning passage **309**, **309**; **309**, **309**; **309**, **309**, which are in parallel with the six ball running counter-grooves **308**, **308**; **308**, **308**; **308**, **308**, and six direction changing passages **310**, **310**; **310**, **310**; **310**, **310** formed into a U-shaped tube, which connect the ends of the above-mentioned ball running counter-grooves **308**, **308**; **308**, **308**; **308**, **308** with the ends of the above-mentioned ball returning passage **309**, **309**; **309**, **309**; **309**, **309**. The outer tube **304** has six circulation passages in this manner.

[**0240**] The ball arranged at each of the both side surfaces of the projection **306** of the spline shaft **302** comes in contact, at its opposite points, with the ball running groove

305 and the ball running counter-groove **308**, respectively. A line connecting the above-mentioned contact points is referred to as the "contact angle line". A contact angle α, i.e., an angle between the contact angle line and the radius line, which connects the center of the spline shaft **302** and the central portion of the projection **306** is relatively large. The ball returning passage **309** is located on the contact angle line.

[0241] In this third embodiment, the balls **303** inserted in each of the circulation passages are connected with each other by means of a ball retainer **312** so as to form the train of the balls **303**. The balls **303** are guided by means of the ball retainer **312** and circulated in each of the circulation passages. The ball retainer **312** has the same structure as shown in **FIG. 14** and the description thereof is therefore omitted.

[0242] The outer tube **304** is composed of a tubular main body **313** having the ball running counter-grooves **308, 308**; **308, 308**; **308, 308**, three resin-formed bodies **320, 320, 320** for forming the ball circulation passage, which are to be inserted in the main body **313**, and a pair of side cover plates **314, 314** secured on the both ends of the main body **313** after the insertion of the resin-formed bodies **320, 320, 320** in the main body **313**.

[0243] In the third embodiment, the six circulation passages are formed by the three resin-formed bodies **320, 320, 320**.

[0244] Each of the circulation passages **311** of the resin-formed bodies **320** for forming the ball circulation passage has a pair of the ball passage forming portions **321, 321** extending along the longitudinal side edges of the ball running counter-groove **308**, a pair of direction changing passage-inner guide forming portions **322, 322** provided on the both ends of the main body **313**, and resin pipes **323** as a returning passage forming portion, which are inserted in through-holes formed in the main body **313**.

[0245] The ball passage forming portions **321, 321** are provided with guide grooves for guiding the both side edges of the belt portion **312***b* of the ball retainer **312** in a loaded area. The guide grooves can prevent the ball retainer **312** not only from being swung during run of the ball, but also from being sagged by engaging the side edges of the belt portion **312***b* with the guide groove **321***a*, when the outer tube **304** is removed from the spline shaft **302**. The balls **303** are supported by the ball retainer **312**. More specifically, the ball retainer **312** is supported by a jaw portion of the guide groove **321***a*, with the result that the balls **303** are kept in its proper position so as not to come off the outer tube **304**.

[0246] Guide grooves **309***c*, **310***c* are also formed in the ball returning passage **309** and the direction changing passage **310** as non-loaded areas, in order to guide the side edges of the belt portion **312***b*. The guide grooves **309***c*, **310***c* are connected to the above-mentioned guide groove **321***a* in the loaded area so as to form an endless groove on the entire periphery.

[0247] In each of the resin-formed bodies **320** for forming the ball circulation passage, the ball passage forming portions **321, 321** and the pair of the direction changing passage-inner guide forming portions **322, 322** are integrally connected with each other. The resin-formed body **320** is divided at the other portions into separate parts so as to be able to be inserted in the main body **313**. In the third embodiment, a single resin frame **324** is obtained by integrally connecting the ends of the four sets of ball passage forming portions **321, 321** with the end of the pair of direction changing passage-inner guide forming portions **322, 322**, and the thus obtained resin frame **324** is divided at the connecting portion of the returning passage forming portion **323** with the direction changing passage-inner guide forming portions **322, 322** into the separate parts so as to be able to be inserted in the main body **313**.

[0248] The adjacent two of the roller passage forming portions **321, 321, 321, 321** are integrally connected with each other by means of a thin connecting sheet portion **326**. The direction changing passage-inner guide forming portion **322** is integrally formed with the thin sheet portion **329**, which is to be brought into contact with the end surface of the main body **313**.

[0249] The thin sheet portion **329** is provided with the first end plate portions **330, 330** and the second end plate portion **231** for connecting the first end plate portions **330, 330** with each other. Each of the pair of ball passage forming portions **321, 321** is integrally connected with the inner edge of the first end plate portion **230**. The both ends of the connecting plate portion **326** are integrally connected with the inner edge of the second end plate portion **331**.

[0250] Each of the direction changing passage-inner guide forming portions **322** has a semi-cylindrical shape. On the outer periphery of the direction changing passage-inner guide forming portion **322**, there is formed an inner guide groove **310***a* having a semi-circular cross section so as to form the inner guide portion for the direction changing passage **310**. The one end of the inner guide groove **310***a* is connected to the end of the ball running counter-groove **308**. Accordingly, the one end of the inner guide groove **310***a* has the same cross-sectional shape as the ball running counter-groove **308** so as to make an alignment of the one end of the inner guide groove **310***a* with the end of the ball running counter-groove **308**. The other end of the inner guide groove **310***a* of the direction changing passage **310** is connected to the end of the ball returning passage **309**. Accordingly, the other end of the inner guide groove **310***a* has the same cross-sectional shape as the ball returning passage **309** so as to make an alignment of the other end of the inner guide groove **310***a* with the end of the ball returning passage **309**.

[0251] Cylindrical flange portions **333, 333** are formed on the both ends of the inner guide groove **310***a*. The distance between the respective outer surfaces of the cylindrical flange portions **333, 333** is larger than the width of the belt portion **312***b*. The cylindrical flange portions **333, 333** form a retainer-guide groove **310***c* for the ball retainer **312** in cooperation with the side cover plate **340** described later.

[0252] The both ends of the inner guide groove **310***a* for the direction changing passage **310** extend to the contacting surface of the first end plate portion **330** with the end surface of the main body **313** so as to be connected to the respective ends of the ball running counter-groove **308** and the ball returning passage **309**.

[0253] Pipe inserting holes **334, 334** having a semi-circular shape, in which the ends of for the outer peripheral side-half pipe member **323***a* for the resin pipes **323** for forming the roller returning passage **309** are to be inserted are formed on the first and third end plate portions **330, 332** of the thin sheet portion **329**. The resin pipe **323** is inserted into the circular through-hole **314** formed in the main body **313** so that the inner peripheral surface of the resin pipe **323** form the ball returning passage **309**.

[**0254**] The resin pipe **323** is composed of the inner peripheral side-half pipe member **323***a*, which is continuously connected to the inner guide groove **310***a* for the direction changing passage, and the outer peripheral side-half pipe member **323***b*, which is continuously connected to the outer guide groove **310***b* for the direction changing passage **310**, which is formed on the side cover plate **340**. The inner peripheral side-half pipe member **323***a* has an inner groove portion **309***a* having a rectangular cross section, and side edge portions **323***b* extending longitudinally along the inner groove portion **309***a*. The longitudinal edge portions **323***c* of the inner peripheral side-half pipe member **323***a* has the same width as the flange portion **333** of the direction changing passage-inner guide forming portion **322**.

[**0255**] The outer peripheral side-half pipe member **323***b* is formed into a linear member having the same rectangular cross section as the outer guide groove **310***b* for the direction changing passage, which is formed on the side cover plate **340**. The outer peripheral side-half pipe member **323***b* has a outer groove portion **309***b*, which is continuously connected to the outer guide groove **310***b*, and side edge portions **323***d* extending longitudinally along the outer groove portion **309***b*. The side edge portions **323***d* is provided on its outer edges with projections **323***e*, which are to be brought into contact with the side edge portions **323***c* of the inner peripheral side-half pipe member **323***a* to form the guide groove for the belt portion **312** of the ball retainer **312**.

[**0256**] The inner peripheral side-half pipe member **323***a* of the resin pipe **323** has the same length of the main body **313**. The inner peripheral side-half pipe member **323***a* is positioned so as to be brought into contact with the end surface of the direction changing passage-inner guide forming portion **322**, which is arranged on the side of the main body **313**.

[**0257**] The outer peripheral side-half pipe member **323***b* of the resin pipe **323** has on the other hand a longer length than the main body **313** by a length corresponding to the thickness of the first end plate portions **330, 330** of the thin sheet portion **329**, which are arranged on the both ends of the main body **313**. The outer peripheral side-half pipe members **323***b* are inserted in the inserting holes **334** of the first end plate portions **330, 332**. Longitudinal positional determination of the outer peripheral side-half pipe member **323***b* is made by bringing the both ends of the outer peripheral side-half pipe member **323***b* inserted in the inserting holes **334** into contact with the peripheral edge of the end portion of the outer guide grooves **310***b* for the direction changing passage, which are formed on the side cover plate **340**. The projections **323***e* formed on the both longitudinal side edges **323** of the outer peripheral side-half pipe member **323***b* come into contact with the outer edges of the cylindrical flange portions of the direction changing passage-inner guide forming portion **322** to form a guide groove, and the outer peripheral side-half pipe member **323***b* and the inner peripheral side-half pipe member **323***a* are restricted to be turned in the inserting hole **314**.

[**0258**] The resin pipes **323** and the direction changing passage-inner guide forming portions **322** as the ball returning passage forming portions are accurately positioned through the inserting holes **334** formed on the first end plate portion **330, 330** of the thin sheet portion **329** and a proper assembling is carried out in this manner.

[**0259**] The side cover plate **340** is provided with four recess portions **341** having the outer guide grooves **310***b* for the direction changing passage, into which the direction changing passage-inner guide forming portions **322** are fitted, and screw-fixing portions for securing the side cover plate **340** to the main body **313**. In the screw-fixing portions, the side cover plate **340** is fixed to the main body **313** by inserting bolts **344** into holes **343** formed on the side cover plate **340** and engaging the bolts **344** with screwed holes **345** formed on the end surface of the main body **313**. The holes **343** are located between the first end plate portions **330, 330** of the thin sheet portion **329**.

[**0260**] The direction changing passage-inner guide forming portion **322** is fitted, into the recess portion **341** of the side cover plate **340**. The thin sheet portion **329** is held between the side cover plate **340** and the end surface of the main body **313** through a clamping force so as to be firmly fixed therebetween.

[**0261**] The direction changing passage-inner guide forming portions **322** and the ball passage forming portion **321** are connected through the thin sheet portion **329**, thus making it possible to maintain an accurate positional relationship of the end of the inner guide groove **310***a* for the direction changing passage relative to the ball passage forming portions **321**, as well as an accurate positional relationship of the inner guide groove **310***a* for the direction changing passage relative to the ball returning passage **309**.

[**0262**] The thin sheet portion **329** is uniformly urged against the flat end surface of the main body **313** through a clamping force applied to the side cover plate **340**. Even when the direction changing passage-inner guide forming portion **322** is not located in a correct position, the thin sheet portion **329** changes its shape, thus permitting the correct positioning of the direction changing passage-inner guide forming portion **322**. The thin sheet portion **329** is firmly clamped and fixed through a clamping force, which is applied to the side cover plate **340**, and frictional force caused by such a clamping step may prevent an unfavorable movement of the inner guide groove **310***a* for the direction changing passage.

[**0263**] According to the present invention, only the ball running counter-groove **308** for the circulation passage **311** is formed of the main body **313** having high rigidity, and the other portions are formed of the resin-formed bodies **320** for forming the ball circulation passage. Precision working of the ball running counter-groove **308** of the main body **313** suffices, thus permitting reduction in steps for working and decrease in the production cost.

[**0264**] The resin-formed body **320** for forming the ball circulation passage is separately formed from the main body **313**. Even when the outer tube **304** has a larger size, there is no restriction of flow of molten resin by the main body **313**, unlike the case where the main body **313** is integrally formed with the resin-formed body **320**. Increase in number of gates formed on a die may ensure proper run of the molten resin, thus improving the formability. Especially, the ball passage forming portions **321, 321** located at the opposite longitudinal sides of the ball running groove **308** are thin, with the result that molten resin may not reach every part of the space for forming the ball passage forming portions **321**, **321**. It is therefore effective to form the resin-formed body **320** separately from the main body **313** in accordance with the embodiment of the present invention.

[**0265**] The ball passage forming portions **321**, **321** are continuously and integrally connected with the direction changing passage-inner guide forming portions **322**, and the divided parts are jointed so as to make alignment of them to make a faucet Joint. It is therefore possible to ensure a proper continuity of the connecting portion of the circulation passage and to make a smooth run of the balls **303** from the ball running passage between the ball running groove **305** and the ball running counter-groove **308** to the direction changing passage **310**, as well as from the direction changing passage **310** to the ball returning passage **309**.

[**0266**] Description will be given of modifications of the resin-formed body **320** for forming the ball circulation passage, which is divided into parts In the description of the modifications, modified features will only be explained in comparison with the third embodiment of the present invention. The same reference numerals will be given to the same components as those in the third embodiment of the present invention, and description thereof will be omitted.

[**0267**] First Modification

[**0268**] **FIGS. 31 and 32** show the first modification of the resin-formed body **320** for forming the ball circulation passage, which is described in the third embodiment.

[**0269**] In the first modification, the resin-formed body **320** for forming the ball circulation passage is composed of the first resin-formed frame **320**A, which is obtained by integrally connecting both of the ball passage forming portions **321**, **321** and the resin pipes **323** at their ends with the direction changing passage-inner guide forming portions **322**A for one side, and the second resin-formed frame **320**B, which is provided with the direction changing passage-inner guide forming portions **322**B for the other side and separately formed from the first resin-formed frame **320**A.

[**0270**] In this case, the ball passage forming portions **321**, **321** are integrally connected with the direction changing passage-inner guide forming portions **322**A through the thin sheet portion **329**A as in the first embodiment.

[**0271**] The direction changing passage-inner guide forming portions **322**A are also integrally connected with the resin pipes **323** through the thin sheet portion **329**A. In this case, the resin pipe **323** is formed into a tubular integral body, although the half pipe members are used in the third embodiment. Accordingly, there exists no inserting hole s**34** in the thin sheet portion **329**A, and the ball returning passage **309** is exposed on the thin sheet portion **329**A.

[**0272**] The first resin-formed frame **320**A and the second resin-formed frame **320**B are connected, as shown in **FIG. 32**, by means of a joint method using the combination of a recess and a projection to be inserted therein, such as a faucet joint method. In the illustrated example, a recess portion **336** of a dove-tail groove is formed in the second resin-formed frame **320**B, and an engaging projection **335** to be engaged with the recess portion **336** is formed, on the other hand, in the ball passage forming portions **321**, **321**.

[**0273**] In this case, the resin pipe **323** of the first resin-formed frame **320**A is inserted in the through-hole **314** of the main body **313**, and the ball passage forming portions **321**, **321** and the connecting plate portion **236** are inserted along the inner surface of the recess **307** of the main body **313**.

[**0274**] Then, the engaging projetions **335** formed at the respective free end portions of the ball passage forming portions **321**, **321** and the connecting plate portion **326** are engaged with the recess portions **336** formed on the thin sheet portion **329**B of the second resin-formed frame **324**B, which is arranged on the other end surface of the main body **313**.

[**0275**] The recess portions **336** may be formed on the first resin-formed frame **320**A and the engaging projections **335** may be formed on the second resin-formed frame **320**B. The connecting method is not limited to the method described above, and there may be used any conventional connecting method, in which the ends of the divided parts can be maintained in a proper connecting position and connected.

[**0276**] Second Modification

[**0277**] **FIGS. 33 and 34** show the second modification of the resin-formed body **320** for forming the ball circulation passage, which is described in the third embodiment.

[**0278**] In the second modification, the resin-formed body **320** for forming the ball circulation passage, which has been obtained by integrally forming both of the ball passage forming portions **321**, **321** and the resin pipes **323** as a returning passage forming portion with a pair of direction changing passage-inner guide forming portions **322**, **322**, is divided at the middle portion of each of the ball passage forming portions **321**, **321** and the ball returning passage forming portions **323** into two parts. More specifically, the ball passage forming portions **321**, **321** and the ball returning passage forming portions **323** are divided at their middle portion into the respective two half parts, and each of the thus divided two half parts is integrally formed with the direction changing passage-inner guide forming portions **322**, **322** thus forming two resin-formed frames **320**C, **320**D having substantially the same shape.

[**0279**] Recess portions **338** and engaging projections **337** to be inserted therein are formed on the divided ends of the ball passage forming portions **321**, **321**, the divided ends of the central connecting plate portion **326** and the divided ends of the resin pipes **323**.

[**0280**] Third Modification

[**0281**] **FIG. 35** shows the third modification of the resin-formed body **320** for forming the ball circulation passage, which is described in the third embodiment.

[**0282**] In the third modification, there is not used the resin pipe **323** as a returning passage forming portion described in the first embodiment, and a resin-formed frame **320**E is obtained by integrally forming the ball passage forming portions, the connecting plate portions **326** with the thin sheet portions **329**, **329** each having the pair of direction changing passage-inner guide forming portions **322**, **322**. The ball returning passage **309** is composed as a through-hole formed in the main body **313**.

[**0283**] In this case, an engaging projection **339***a*, which is engageable with a tapered portion **315** formed in the opening end of the ball returning passage **309** may be formed in the opening end of the ball hole **339** of the thin sheet portion **329**. Such a construction permits to make a proper connection of the end of the ball returning passage **309** and the direction changing passage inner guide forming portion **322**. In the illustrated example, an arcuate engaging projection **348** is additionally formed on the connection portion of the outer guide groove **310***b* formed on the side cover plate **340** with the ball returning passage **309**. The engaging projection **48** can be engaged with the thin sheet portion **329**.

[0284] Fourth Modification

[0285] **FIG. 36** shows the fourth modification of the resin-formed body **320** for forming the ball circulation passage, which is described in the third embodiment.

[0286] In the fourth modification, there is not used the resin pipe **323** described in the third modification, a resin-formed frame **320**F is obtained by integrally forming the ball passage forming portions **321** with the direction changing passage-inner guide forming portions **322** for the one side, the other resin-formed frame **320**G provided with the direction changing passage-inner guide forming portions **322** for the other side is separately formed from the above-mentioned resin-formed frame **320**F, and the resin-formed frames **320**F, **320**G are connected with each other by engagement of the engaging projection **335** with the recess **336**. The structure other than the above-mentioned construction is the same as that of the third modification.

[0287] In the third embodiment described above, there are used three sets of resin-formed bodies for forming the ball circulation passage, each of which is divided into two parts. Six sets of resin-formed bodies may however be used for the respective circulation passages. The single set of resin-formed body may also be used. In this case, the divisional method of the resin-formed body should be based on the first, second and fourth modifications described above, taking into consideration the difficulty of insertion of the resin-formed body into the main body of the outer tube.

[0288] Modifications Of The Ball Train

[0289] In the third embodiment and the first to fourth modifications thereof, the ball spline has the angular contact type ball train. The present invention may also be applied to the ball spline having the radial contact type ball train as shown in **FIG. 37**. In such a radial contact type ball train, the spline shaft has no projections on the outer periphery so as to reveal the circular crosssection, and the outer tube has no recesses on the inner periphery so as to reveal the hollow cylindrical shape. The radial contact type ball train has the smaller contact angle a than that of the angular contact type ball train. With respect to the divisional method of the resin-formed body **320** for forming the ball circulation passage, all the patterns described in the third embodiment and the first to fourth modifications thereof may be used.

[0290] In the example illustrated in **FIG. 37**, six resin-formed bodies **320** for forming the ball circulation passage are separately provided from each other for the respective six ball trains. The two sets of resin-formed bodies **320** mentioned above may be integrally formed with each other so as to prepare three sets of resin-formed bodies **320** having the six ball circulation passages. The single resin-formed body having the six ball circulation passages may also be used.

[0291] Fourth Embodiment

[0292] **FIGS. 38 and 39** illustrate the forth embodiment of the present invention. In the fourth embodiment, the present invention is applied to a roller spline, in which rollers are used as the rolling members.

[0293] The roller spline **401** as shown in **FIG. 38** is composed of a spline shaft **402** as a guide member extending linearly, and an outer tube **404** arranged so as to be movable along the spline shaft **402** through the rollers **403** as the rolling members.

[0294] The spline shaft **402** is formed into a long bar shape having a modified cross-section. The spline shaft **402** has on its outer periphery three projections **406**. Two roller running surfaces **405, 405** are formed on the both sides of each of the projections **406**, so as to provide the total number of running surfaces of six.

[0295] The outer tube **404** has on its inner periphery three recesses **407** corresponding to the projections **406** of the spline shaft **402**, respectively. Roller running counter-surfaces **408, 408** are formed at the both corners of each Of the recesses **407**, so as to correspond to the above-mentioned roller running surfaces **405, 405**.

[0296] In addition, the outer tube **404** has six roller returning passage **409, 409; 409, 409; 409, 409**, which are in parallel with the six roller running counter-surfaces **408, 408; 408, 408; 408, 408**, and six direction changing passages **410, 410; 410, 410; 410, 410** formed into a U-shaped tube, which connect the ends of the above-mentioned roller running counter-surfaces **408, 408; 408, 408; 408, 408** with the ends of the above-mentioned roller returning passage **409, 409; 409, 409; 409, 409**. The outer tube **404** has six circulation passages in this manner.

[0297] The rollers **403** inserted in each of the circulation passages are connected with each other by means of the same roller retainer **412** as the roller retainer **212** shown in **FIG. 19**, so as to form the train of the rollers **403**. The rollers **403** are guided by means of the roller retainer **412** and circulated in each of the circulation passages.

[0298] The outer tube **404** is composed of a tubular main body **413** having the roller running counter-grooves **408, 408; 408, 408; 408, 408**, three resin-formed bodies **420, 420, 420** for forming the ball circulation passage, which are to be inserted in the main body **413**, and a pair of side cover plates **440, 440** secured on the both ends of the main body **413** after the insertion of the resin-formed bodies **420, 420, 420** in the main body **413**.

[0299] In the fourth embodiment, the six circulation passages are formed by the three resin-formed bodies **420, 420, 420** as in the third embodiment.

[0300] Each of the resin-formed bodies **420** for forming the ball circulation passage has a pair of the roller passage forming portions **421, 421** extending along the longitudinal side edges of the roller running counter-groove **408**, a pair of direction changing passage-inner guide forming portions **422, 422** provided on the both ends of the main body **413**, and resin pipes **423** as a returning passage forming portion, which are inserted in through-holes formed in the main body **413**.

[0301] The roller passage forming portions **421, 421** are provided with guide grooves for guiding the both side edges of the belt portion **412***b* of the roller retainer **412** in a loaded area. The guide grooves can prevent the roller retainer **412** not only from being swung during run of the roller, but also from being sagged by engaging the side edges of the belt portion **412***b* with the guide groove **421***a*, when the outer tube **404** is removed from the spline shaft **402**. The rollers **403** are supported by the roller retainer **412**. More specifically, the roller retainer **412** is supported by a jaw portion of the guide groove **421***a*, with the result that the rollers **403** are kept in its proper position so as not to come off the outer tube **404**.

[**0302**] Guide grooves **409***c*, **410***c* are also formed in the roller returning passage **409** and the direction changing passage **410** as non-loaded areas, in order to guide the side edges of the belt portion **412***b*. The guide grooves **409***c*, **410***c* are connected to the above-mentioned guide groove **421***a* in the loaded area so as to form an endless groove on the entire periphery.

[**0303**] When the roller retainer **412** is not used, the guide grooves **421***a*, **410***a* , **409***a* are not needed, and the jaw portions as shown in **FIG. 20**(*h*) for supporting the ends of the roller are formed on the roller passage forming portions **421**.

[**0304**] In each of the resin-formed bodies **420** for forming the roller circulation passage, at least one of four connecting portions of the roller passage forming portions **421, 421** with the pair of the direction changing passage-inner guide forming portions **422, 422** are integrally connected with each other. The resin-formed body **420** is divided at the other portions into separate parts so as to be able to be inserted in the main body **413**.

[**0305**] The fundamental embodiment of the resin-formed body for forming the roller circulation passage, which is to be used for the spline unit is described in detail in the third embodiment. The structure of the resin-formed body for forming the roller circulation passage is described in detail in the second embodiment. Here, only the fundamental divisional pattern of the resin-formed body **420** for forming the roller circulation passage will be briefly described below with reference to **FIG. 39**.

[**0306**] In **FIG. 39**(*a*), the both ends of the four sets of roller passage forming portions **421, 421** are integrally connected with the respective one end of the pair of direction changing passage-inner guide forming portions **422, 422** to form a single resin frame **424**, and the both ends of each of the returning passage forming portions **423** are not connected with the other end of the direction changing passage-inner guide forming portion **422** so that these parts can be assembled into the main body **413**.

[**0307**] In **FIG. 39**(*b*), the resin-formed body **420** for forming the roller circulation passage is composed of the first resin-formed frame **420**A, which is obtained by integrally connecting both of the roller passage forming portions **421, 421** and the resin pipes **423** as a returning passage forming portion at their ends with the direction changing passage-inner guide forming portions **422**A for one side, and the second resin-formed frame **420**B, which is provided with the direction changing passage-inner guide forming portions **422**B for the other side and separately formed from the first resin-formed frame **420**A.

[**0308**] In **FIG. 39**(*c*), the resin-formed body **420** for forming the roller circulation passage, which has been obtained by integrally forming both of the roller passage forming portions **421, 421** and the resin pipes **423** as a returning passage forming portion with a pair of direction changing passage-inner guide forming portions **422, 422**, is divided at the middle portion of each of the roller passage forming portions **421, 421** and the returning passage forming portions **423** into two parts. More specifically, the roller passage forming portions **421, 421** and the resin pipes **423** are divided at their middle portion into the respective two half parts, and each of the thus divided two half parts is integrally formed with the direction changing passage-inner guide forming portions **422, 422**, thus forming two resin-formed frames **420**C, **420**D having substantially the same shape.

[**0309**] In **FIG. 39**(*d*), there is not used the resin pipe **423** as shown in **FIG. 39**(*a*), and a resin-formed frame **420**E is obtained by integrally forming both of the roller passage forming portions and the connecting plate portion **326** with the thin sheet portions **429, 429** each having the pair of direction changing passage-inner guide forming portions **422, 422**. The roller returning passage **409** is composed as a through-hole formed in the main body **413**.

[**0310**] In **FIG. 39**(*e*), there is not used the resin pipe **423** as shown in **FIG. 39**(*b*), and a resin-formed frame **420**F is obtained by integrally forming the roller passage forming portions **421** with the direction changing passage-inner guide forming portions **422** for the one side, the other resin-formed frame **420**G provided with the direction changing passage-inner guide forming portions **422** for the other side is separately formed from the above-mentioned resin-formed frame **420**F.

[**0311**] In FIGS. **39**(*a*) to **29**(*e*), the resin-formed frames are connected with each other by means of the conventional joint method such as a faucet joint, which uses engagement of the engaging projection with the recess.

[**0312**] Fifth Embodiment

[**0313**] FIGS. **40** to **44** show a linear motion guiding apparatus of the fifth embodiment of the present invention.

[**0314**] The linear motion guiding apparatus **501** is provided with a guide rail **502** as a guide member, which extends linearly, and a movable block **504** as a movable member, which is arranged so as to be movable along the guide rail **502** through a large number of balls **503** as rolling members.

[**0315**] The guide rail **502** is formed into a long bar shape having a rectangular cross-section. Two ball running grooves **505, 505** as a rolling member running track are formed on each of the right and left-hand side surfaces of the guide rail **502**, so as to provide a total number of grooves **505** of four. The guide rail **502** has on each of its side surfaces a projection **502***a*, on the upper and lower positions of which the ball running grooves **505, 505** are arranged.

[**0316**] The movable block **504** is formed as a block body having an inverse U-shaped cross-section, with its opening end being directed downwardly. The block body is provided with a horizontal portion **506**, which faces the upper surface of the guide rail **502** and with a pair of wing portions **507, 507**, which extend downwardly from the right and left ends of the horizontal portion **506** and face the right and left-hand side surfaces of the guide rail **502**, respectively. Each of the wing portions **507**, **507** has on its inner surface two ball running counter-grooves **508**, **508** as a rolling member running counter track, which correspond to the ball running grooves **505**, **505** formed on the right and left-hand side surfaces of the guide rail **502**.

[0317] Each of the right and left-hand wing portions **507**, **507** of the movable block **504** has two ball returning passage forming portions **509**, **509** formed therein, which extend in parallel with the ball running counter-grooves **508**, **508**. At both the longitudinal ends of each of the wing portions **507**, **507**, there are arranged direction changing passages **510**, **510**; **510**, **510** for connecting the ends of the ball running counter-grooves **508**, **508**; **508**, **508** with the ends of the ball returning passage **509**, **509**; **509**, **509**. In summary, each of the wing portions **507**, **507** of the movable block **504** has two endless circulation passages, in which the balls **503** are circulated, so as to provide the total number of passage of four.

[0318] In each of the four endless circulation passages in this embodiment, the balls **503** are retained in the form of train by means a ball retainer **512** as a rolling member retainer so that the balls **503** can be circulated while being guided by the ball retainer **512**.

[0319] As shown in FIGS. **44**(*c*) to **44**(*e*), the ball retainer **512** comprises a flexible belt portion **512***b*, which is provided with ball holes **512***a*for respectively receiving the balls **503**, and spacing portions **512***c*provided between the adjacent two balls **503**, **503**. The belt portion **512***b*has a width longer than the diameter of the ball **503** so that the both side edges of the belt portion **512***b* extend outwardly from the ball **503**.

[0320] The spacing portion **512***c* is provided with a ball supporting spherical recess **512***d* corresponding to the spherical surface of the ball **503**. The ball **503** is supported on its both sides by a pair of supporting spherical recesses **512***d* so as to prevent the ball **503** from coming off the belt portion **512***b*. In this embodiment, the one end of the belt portion **512***b* is not connected to the other end thereof, thus forming a strip-shaped belt having the both ends. The one end of the belt portion **512***b* may be connected to the other end thereof so as to form an endless belt.

[0321] As shown in **FIG. 41**, the movable block **504** is composed of a block body **513** having ball running counter-grooves **508**, **508**, **508**, **508**, a pair of right and left-hand resin-formed bodies **520**, **520** for forming ball circulation passages, which is inserted in the block body **513**, and a pair of side cover plates **540** (only one cover plate **540** is illustrated) secured to the both end surfaces of the block body **13**, in which the resin-formed bodied **520**, **520** are inserted.

[0322] Each of the right and left-hand resin-formed bodies **520**, **520** for forming the ball circulation passage forms two endless circulation passages. The right and left-hand resin-formed bodies **520**, **520** have the symmetrical shape. One of them will be described below and the description of other thereof will be omitted.

[0323] More specifically, the resin-formed body **520** for forming the ball circulation passage is composed of a resin frame **524** obtained by integrally forming the ball passage forming portions **521**, **521** extending along both longitudinal sides of the ball running counter-groove **508** with the pair of direction changing passage-inner guide forming portions **522**, **522** (see **FIG. 42**); and a pair of resin pipes **523**, **523** as a returning passage forming portion, which are to be inserted in through-holes **514**, **514** formed in the block body **513** (see **FIG. 43**). The ball passage forming portions **521**, **521** are integrally formed with the pair of direction changing passage-inner guide forming portions **522**, **522** to form the resin frame **524** as an integral body, and the pair of resin pipes **523**, **523** are separately formed from such an integral body, so that these parts can be assembled into the block body **513**.

[0324] As shown in **FIG. 42**, the ball passage forming portions **521**, **521** are provided with guide grooves for guiding the both side edges of the belt portion **512***b* of the ball retainer **512** in a loaded area. The guide grooves can prevent the ball retainer **512** not only from being swung during run of the ball, but also from being sagged by engaging the side edges of the belt portion **512***b* with the guide groove **521***a*, when the movable block **504** is removed from the guide rail **502**. The balls **503** are supported by the ball retainer **512**. More specifically, the ball retainer **512** is supported by a jaw portion of the guide groove **521***a*, with the result that the balls **503** are kept in its proper position so as not to come off the movable block **504**.

[0325] The distance between the pair of ball passage forming portions **521**, **521** arranged in parallel with each other on the both longitudinal sides of the ball running counter-groove **508** is slightly smaller than the diameter of the ball **503**. In such a construction, it is possible to prevent the balls **503** from coming off the ball passage forming portions **521**, **521** even when the ball retainer **512** is not used.

[0326] Guide grooves **509***c*, **510***c* are also formed, as shown in FIGS. **44**(*a*) and **44**(*b*), in the ball returning passage **509**, **509** and the direction changing passage **510**, **510** as non-loaded areas, in order to guide the side edges of the belt portion **512***b*. The guide grooves **509***c*, **510***c* are connected to the above-mentioned guide groove **521***a* in the loaded area so as to form an endless groove on the entire periphery.

[0327] The ball passage forming portions **521**, **521**; **521**, **521** are composed, as shown in **FIG. 42**(*a*), of the first connecting plate portion **525** extending longitudinally along the corner between the horizontal portion **506** and the wing portion **507** of the block body **513** in the longitudinal direction of the block body **513**; the second connecting plate portion **526** extending longitudinally between the ball running counter-grooves **508**, **508** on the inner surface of each of the wing portions **507** of the block body **513**; and a pair of third connecting plate portions **527** extending along the under surface of the wing portion **507** of the block body **513** in the longitudinal direction thereof.

[0328] The upper edge of the first connecting plate portion **525** and the lower edge of the second connecting plate portion **526**, which face to each other, are placed on the opposite longitudinal sides of the upper ball running counter-groove **508** provided in the wing portion **507**, so as to form the ball passage forming portions **521**, **521**. The lower edge of the second connecting plate portion **526** and the upper edge of the third connecting plate portion **527**, which face to each other, are placed on the opposite longitudinal sides of the lower ball running counter-groove **508** provided in the wing portion **507**, so as to form the ball passage forming portions **521, 521**.

[**0329**] As shown in FIGS. **44**(*a*), **44**(*b*) and **44**(*c*), the direction changing passage-inner guide forming portions **522** and the ball passage forming portions **521, 521** are connected by means of the thin sheet portion **529** through integral forming. The resin pipe **523** is inserted in a hole **534** formed on the thin sheet portion **529** so as to make a faucet joint, and fixed to the thin sheet portion **529**.

[**0330**] The thin sheet portion **529** has the direction changing passage-inner guide forming portions **522, 522**, which are formed so as to project corresponding to the two trains of balls **503, 503** on the side surface of the guide rail **502**. The both ends of the first, second and third connecting plate portions **525-527** are connected to the thin sheet portion **529** to be arranged on the end of the block body **513** so as to form the single resin frame **524**.

[**0331**] Each of the direction changing passage-inner guide forming portions **522** has a semi-cylindrical shape. On the outer periphery of the direction changing passage-inner guide forming portion **522**, there is formed an inner guide groove **510***a* having a semi-circular cross section so as to form the inner guide portion for the direction changing passage **510**. The one end of the inner guide groove **510***a* is connected to the end of the ball running counter-groove **508**. Accordingly, the one end of the inner guide groove **510***a* has the same cross-sectional shape as the ball running counter-groove **508** so as to make an alignment of the one end of the inner guide groove **510***a* with the end of the ball running counter-groove **508**. The other end of the inner guide groove **510***a* of the direction changing passage **510** is connected to the end of the ball returning passage **509**. Accordingly, the other end of the inner guide groove **510***a* has the same cross-sectional shape as the ball returning passage **509** so as to make an alignment of the other end of the inner guide groove **510***a* with the end of the ball returning passage **509**.

[**0332**] Cylindrical flange portions **533, 533** are formed on the both ends of the inner guide groove **510***a* . The distance between the respective outer surfaces of the cylindrical flange portions **533, 533** is larger than the width of the belt portion **512***b*. The cylindrical flange portions **533, 533** form a retainer-guide groove **510***c* for the ball retainer **512** in cooperation with a semi-circular recess portion having cutouts, which is formed on the inner periphery of the recess of the side cover plate **5040** described later.

[**0333**] The both ends of the inner guide groove **510***a* for the direction changing passage **510** extend to the contacting surface of the thin sheet portion **529** with the end surface of the block body **513** so as to be connected to the respective ends of the ball running counter-groove **508** and the ball returning passage **509**. Pipe inserting holes **534, 534** having a semi-circular shape, in which the ends of the resin pipes **523** are to be inserted are formed on the thin sheet portion **529**.

[**0334**] As shown in **FIG. 43**, the resin pipe **523** is composed of an outer peripheral side-half pipe member **523***b* located in the outer peripheral side of the ball circulation passage, which is continuously connected to the outer guide groove **510***b* for the direction changing passage **510** of the side cover plate **540**, and an inner peripheral side-half pipe member **523***a* located in the inner peripheral side of the ball circulation passage, which is continuously connected to an inner guide groove **510***a* for the direction changing passage **510** of the side cover plate **540**.

[**0335**] The inner peripheral side-half pipe member **523***a* has a groove portion **509***a* having a semi-circular cross section, and side edge portions **523***c* extending longitudinally along the groove portion **509***a* , as shown in FIGS. **43**(*c*) and **43**(*d*). The outer peripheral side-half pipe member **523***b* is formed into a linear member having the same circular cross section as the outer guide groove **510***b* for the direction changing passage, which is formed on the side cover plate **540**. The outer peripheral side-half pipe. member **523***b* has a groove portion **509***b*, which is continuously connected to the outer guide groove **510***b*, and side edge portions **523***d* extending longitudinally along the groove portion **509***b*. The side edge portions **523***d* is provided on its outer edges with projections **523***e*, which are to be brought into contact with the outer edges of the side edge portions **523***c* of the inner peripheral side-half pipe member **523***a* to form the retainer-guide groove **509***c* for the ball retainer **512**.

[**0336**] The inner peripheral side-half pipe member **523***a* of the resin pipe **523** has the same length of the block body **513**. The inner peripheral side-half pipe member **523***a* is positioned so as to be brought into contact with the back surface of the direction changing passage-inner guide forming portion **522**.

[**0337**] The outer peripheral side-half pipe member **523***b* of the resin pipe **523** has on the other hand a longer length than the block body **513** by a length corresponding to the thickness of the thin sheet portion **529**. The outer peripheral side-half pipe members **523***b* are inserted in the inserting holes **534**. Longitudinal positional determination of the outer peripheral side-half pipe member **523***b* is made by bringing the both ends of the outer peripheral side-half pipe member **523***b* inserted in the inserting holes **534** into contact with the peripheral edge of the end portion of the outer guide grooves **510***b* for the direction changing passage, which are formed on the side cover plate **540**. The projections **523***e* formed on the both side edges of the outer peripheral side-half pipe member **523***b* come into contact with the outer edges of the cylindrical flange portions **533** formed on the direction changing passage-inner guide forming portion **522** to form a part of the guide groove **510***c*, and the outer peripheral side-half pipe member **523***b* and the inner peripheral side-half pipe member **523***a* are restricted to be turned in the inserting hole **514**.

[**0338**] The resin pipes **523** and the direction changing passage-inner guide forming portions **522** are accurately positioned through the inserting holes **534** formed on the thin sheet portion **529** and a proper assembling is carried out in this manner.

[**0339**] As shown in FIGS. **44**(*f*) and **44**(*g*), the side cover plate **540** is provided with an inserting recess portion **540***a*, in which the thin sheet portion **529** is inserted, recess portions **541** having the outer guide grooves **510***b* for the direction changing passage, into which portions the direction changing passage-inner guide forming portions **522** are fitted, and screw fixing portions for securing the side cover plate **540** to the block body **513**. In the screw-fixing portions, the side cover plate **540** is fixed to the block body **513** by inserting bolts (not shown) into holes **543** formed on the side cover plate **540** and engaging the bolts with screwed holes

545 formed on the end surface of the block body **513**. The holes **543** are located at four positions, i.e., the position corresponding to the thin sheet portion **529** between the direction changing passage-inner guide forming portions **522**, **522** of each of the resin-formed bodies **520**, **520**, and the positions in the vicinity of the thin sheet portions **529**, **529** on the horizontal portion **506**.

[0340] As shown in **FIG. 44**(*g*), the outer guide groove **510***b* for the direction changing passage in the recess portion **541** has on its side edges larger diameter arcuate recesses **546**, which form the retainer-guide groove **510***c* in cooperation with the cylindrical flange portions **533** of the direction changing passage-inner guide forming portions **522** as shown in **FIG. 44**(*t*), and a smaller-diameter arcuate recesses **547**, in which the cylindrical flange portions **533** are inserted. The direction changing passage-inner guide forming portion **522** provided with the inner guide groove **510***a* for the direction changing passage is fitted into the recess portion **541** of the side cover plate **540**, and the thin sheet portion **529** is received in the inserting recess portion **540***a* of the side cover plate **540**. The thin sheet portion **529** is held between the side cover plate **540** and the end surface of the block body **513** through a clamping force so as to be firmly fixed therebetween. The direction changing passage-inner guide forming portions **522** and the ball passage forming portion **521** are connected through the thin sheet portion **529**, thus making it possible to maintain an accurate positional relationship of the end of the inner guide groove **510***a* for the direction changing passage formed in the direction changing passage-inner guide forming portion **522** relative to the ball passage forming portions **521**, **521**, as well as an accurate positional relationship of the inner guide groove **510***a* for the direction changing passage relative to the ball returning passage **509**.

[0341] The thin sheet portion **529** located in the vicinity of the direction changing passage-inner guide forming portion **522** is uniformly urged against the flat end surface of the block body **513** through a clamping force applied to the side cover plate **540** (see **FIG. 44**). Even when the direction changing passage-inner guide forming portion **522** is not located in a correct position, the thin sheet portion **529** changes its shape on the end surface of the block body **513**, thus permitting the correct positioning of the direction changing passage-inner guide forming portion **522**. The thin sheet portion **529** is firmly clamped and fixed through a clamping force, which is applied to the side cover plate **540**, and frictional force caused by such a clamping step may prevent an unfavorable movement of the inner guide groove **510***a* for the direction changing passage.

[0342] The side cover plate **540** is secured to the block body **513** so that the direction changing passage-inner guide forming portion **522** assembled to the block body **513** is fitted into the recess portion **541** of the side cover plate **40**. Such a fitting step permits to make an accurate positioning of the side cover plate **540** relative to the block body **513**.

[0343] Now, description will be given of assembling steps for the above-mentioned resin-formed bodies **520** for forming the ball circulation passage.

[0344] First, the inner peripheral side-half pipe member **523***a* of the resin pipe **523** is inserted in the through-hole **514** of the wing portion **507** of the block body **513**.

[0345] Then, the resin frame **524** obtained by integral forming is inserted in the recess of the block body **513**, while causing the thin sheet portions **529** at the both ends of the resin frame **524** to slide on the respective end surfaces of the wing portion **507** of the block body **513**. The first connecting plate portion **525** of the resin frame **524** comes into contact with the corner portion between the horizontal portion **506** and the wing portion **507**, thus making positional determination in the vertical direction of the resin frame **524**. The second connecting plate portion **526** and the third connecting plate portion **527** of the resin frame **524** come into contact with the respective inner surfaces of the wing portions **507** of the block body **513**, thus making positional determination of the ball passage forming portions **521**, **521** and the direction changing passage-inner guide forming portions **522**, **522**. At this time, the inserting holes **534**, **534** of the thin sheet portion **529** are aligned with the through-holes **514**, **514** of the block body **513**.

[0346] Then, the outer peripheral side-half pipe members **523***b*, **523***b* are inserted in the through-holes **514**, **514** from the inserting holes **534**, **534**, thus completing the assembling step of one of the resin-formed bodies **520**, **520** for forming the ball circulation passage.

[0347] The assembling step of the other of the resin-formed bodies **520**, **520** is carried out in the same manner.

[0348] Then, the one side cover plate **540** is secured to the one end surface of the block body **513** by a clamping step, the ball retainer **512** holding the balls is inserted, and the other side cover plate **540** is secured to the other end surface of the block body **513** by the same clamping step, thus completing the assembling step of the movable block **504**.

[0349] According to the present invention, the resin-formed bodies **520**, **520** for forming the ball circulation passage are separately formed from the block body **513**. Even when the movable block **504** has a larger size, there is no restriction of flow of molten resin by the block body **513**, unlike the case where the block body **513** is integrally formed with the resin-formed bodies **520**, **520**. Increase in number of gates formed on a die may ensure proper run of the molten resin, thus improving the formability. Especially, the ball passage forming portions **521**, **521** located at the opposite longitudinal sides of the ball running groove **508** are thin, with the result that molten resin may not reach every part of the space for forming the ball passage forming portions **521**, **521**. It is therefore effective to form the resin-formed bodies **520**, **520** separately from the block body **513** in accordance with the embodiment of the present invention.

[0350] In addition, since there are formed the right and left-hand resin-formed bodies **520**, **520** for forming the ball circulation passage, each of which has two endless circulation passages, a proper run of molten resin is ensured even when the movable block **513** has a larger width.

[0351] The continuous circulation passage is formed by the resin-formed body **520**, and it is therefore possible to make positional determination of the inner guide groove **510***a* for the direction changing passage relative to the ball passage forming portions **521**, **521**, as well as positional determination of the inner guide groove **510***a* for the direction changing passage relative to the ball returning passage **509**, thus ensuring continuity of the circulation passage so as to make smooth circulation of the balls **503**.

[0352] When the proper positional relationship of the inner guide groove **510***a* for the direction changing passage relative to the ball passage forming portions **521**, **521**, is maintained, the ball passage forming portions **521**, **521** are located at the longitudinal both sides of the ball running groove **508** so as to be aligned with the ends of the inner guide groove **510***a* for the direction changing passage.

[**0353**] When the proper positional relationship of the inner guide groove **510***a* for the direction changing passage relative to the ball returning passage **509** is maintained, the inner guide groove **510***a* for the direction changing passage can be aligned with the inner groove **523***a* of the ball returning passage **509**.

[**0354**] The connecting portion of the ball passage forming portions **521**, **521** and the direction changing passage-inner guide forming portion **522** is obtained by integral forming, thus permitting omission of an assembling step of the connecting portion. Although the running direction of the balls **503** is changed in such a connecting portion, the above-mentioned integral structure may ensure continuity of the circulation passage, without being affected by assembling accuracy. It is therefore possible to make smooth run of the balls **503** from the ball running passage between the ball running groove **505** and the ball running counter-groove **508** to the direction changing passage **510**, as well as from the direction changing passage **510** to the ball returning passage **509**.

[**0355**] According to the present invention as described in detail, since the resin-formed body for forming the rolling member circulation passage is separately formed from the block body, even when the movable block has a larger size, increase in number of gates formed on a die may ensure proper run of the molten resin, thus improving the formability. It is therefore effective to form the resin-formed body separately from the block body in accordance with the present invention, taking into consideration the fact that the rolling member passage forming portions located at the opposite longitudinal sides of the rolling member running track are thin, with the result that molten resin may not reach every part of the space for forming the rolling member passage forming portions.

[**0356**] The continuous circulation passage is formed by the resin-formed body, and it is therefore possible to make positional determination of the inner guide groove for the direction changing passage relative to the rolling member passage forming portions, as well as positional determination of the inner guide groove for the direction changing passage relative to the rolling member returning passage, thus ensuring continuity of the circulation passage so as to make smooth circulation of the rolling members.

[**0357**] When the connecting portion of the rolling member passage forming portions and the direction changing passage-inner guide forming portion or the connecting portion of the direction changing passage-inner guide forming portion and the returning passage forming portion, in which portion the running direction of the rolling members is changed is obtained by integral forming, it is possible to omit an assembling step of the connecting portion and to ensure continuity of the circulation passage, without being affected by assembling accuracy.

[**0358**] The integral formation of the connecting portion of the rolling member passage forming portion with the direction changing passage-inner guide forming portion may cause the smooth running of the rolling members between the rolling member running track in the loaded area and the direction changing passage-inner guide forming portion, even when the returning passage forming portion formed of resin is not used.

[**0359**] When the rolling member retainer is used, it is possible to maintain a proper continuity on the entire periphery of the circulation passage in the retainer guide portion for guiding the rolling member retainer.

[**0360**] The thin retainer guide portion is formed without insertion of the body of the movable member in a die, and position of gates in the die can freely be determined without being restricted by the body of the movable member, with the result that molten resin can reach, during formation of the guide portion, the entire space therefor, which is formed in the die.

[**0361**] In addition, the formation of the right and left-hand resin-formed bodies for forming the rolling member circulation passage, each of which has two endless circulation passages may ensure a proper run of molten resin even when the body of the movable member has a larger width.

[**0362**] The connection of the direction changing passage-inner guide forming portion with the rolling member passage forming portion through the thin sheet portion makes it possible to maintain, through deformation of the thin sheet portion, a proper positional relationship between the direction changing passage-inner guide forming portion and the rolling member passage forming portion or a proper positional relationship between the direction changing passage-inner guide forming portion and the rolling member returning passage forming portion, thus making an accurate positional determination of the end of the direction changing passage-inner guide forming portion relative to the rolling member returning passage forming portion as well as an accurate positional determination of the direction changing passage-inner guide forming portion relative to the rolling member returning passage forming portion.

[**0363**] The thin sheet portion is urged against the flat end face of the body of the movable member by a clamping force, which is applied to the side cover plate. It is therefore possible to correct the position of the direction changing passage-inner guide forming portion through deformation of the thin sheet portion, even when the direction changing passage-inner guide forming portion is not correctly positioned relative to the end face of body of the movable member.

[**0364**] In addition, the thin sheet portion can firmly be secured between the side cover plate and the body of the movable member by the clamping force, which is applied to the side cover plate, and it is therefore possible to prevent the direction changing passage-inner guide forming portion from being incorrectly placed.

What is claimed is:

1. A linear motion guiding apparatus comprising:

a guide member provided with a rolling member running track, and

a movable member arranged so as to be movable along the guide member through a large number of rolling members, said movable member being provided with (i) a rolling member running counter-track corresponding to the rolling member running track of said guide member, (ii) a rolling member returning passage arranged away from said rolling member running counter-track by a prescribed distance and in parallel therewith and (iii) a pair of direction changing passages for connecting the rolling member running counter-track and the rolling member returning passage to permit circulation of the rolling members,

characterized in that:

a resin-formed body for forming a rolling member circulation passage comprises a pair of rolling member passage forming portions extending along both longitudinal sides of said rolling member running counter-track, a returning passage forming portion for forming the rolling member returning passage and a pair of direction changing passage-inner guide forming portions for forming inner peripheral guide portions of said direction changing passages, said resin-formed body being separately formed from a body of said movable member; and

at least two portions of (a) said pair of rolling member passage forming portions, (b) said returning passage forming portion, (c) one of said pair of direction changing passage-inner guide forming portions and (d) another of said pair of direction changing passage-inner guide forming portions are connected with each other through integral forming so that said resin-formed body can be built in the body of said movable member.

2. An apparatus as claimed in claim 1, wherein:

said resin-formed body comprises (i) an integral body of said pair of rolling member passage forming portions and said pair of direction changing passage-inner guide forming portions, and (ii) said returning passage forming portion separately formed from said integral body.

3. An apparatus as claimed in claim 1, wherein:

said resin-formed body comprises (i) an integral body of said pair of rolling member passage forming portions, said returning passage forming portion and one of said pair of direction changing passage-inner guide forming portions, and (ii) another of said pair of direction changing passage-inner guide forming portions separately formed from said integral body.

4. An apparatus as claimed in claim 1, wherein:

said resin-formed body is manufactured by preparing an integral body of said pair of rolling member passage forming portions, said returning passage forming portion and said pair of direction changing passage-inner guide forming portions, and then dividing said pair of rolling member passage forming portions and said returning passage forming portion in longitudinal intermediate portions thereof into respective two parts.

5. An apparatus as claimed in claim 1, wherein

a rolling member retainer is provided, said rolling member retainer being able to retain the rolling members in a train with a prescribed distance kept between adjacent two of the rolling members, and said rolling member retainer having side edge portions projecting from both sides of each of the rolling members; and

guide grooves for guiding the side edge portions of the rolling member retainer are formed on an entire periphery of the rolling member circulation passage.

6. An apparatus as claimed in claim 1, wherein:

each of said direction changing passage-inner guide forming portions has a thin sheet portion, which is to be brought into contact with an end face of the body of said movable member, and said each of said direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions or the returning passage forming portion by means of said thin sheet portion.

7. An apparatus as claimed in claim 1, wherein:

said guide member comprises a guide rail;

said movable member comprises a movable block, which is provided with a horizontal portion, which faces an upper surface of said guide rail and a pair of wing portions, between which the guide rail is held at right and left-hand side surfaces thereof; and

two trains of the rolling members are arranged in a gap between the upper surface of the guide rail and a lower surface of the movable block, and a single train of the rolling members is arranged in each of gaps between the right and left-hand side surfaces of the guide rail and both of the wing portions, so as to provide a total number of trains of four.

8. An apparatus as claimed in claim 1, wherein:

said guide member comprises a guide rail;

said movable member comprises a movable block, which is provided with a pair of wing portions, between which the guide rail is held at right and left-hand side surfaces thereof; and

two trains of the rolling members are arranged in each of gaps between the right and left-hand side surfaces of the guide rail and both of the wing portions, so as to provide a total number of trains of four.

9. An apparatus as claimed in claim 8, wherein:

four direction changing passage-inner guide forming portions are formed corresponding to the four trains of the rolling members, respectively, and said four direction changing passage-inner guide forming portions are integrally connected with each other.

10. An apparatus as claimed in claim 8 wherein:

two direction changing passage-inner guide forming portions located at a side of the right-hand side surface of the guide rail are integrally connected with each other, and other two direction changing passage-inner guide forming portions located at a side of the left-hand side surface of the guide rail are integrally connected with each other.

11. An apparatus as claimed in claim 1, wherein:

said guide member comprises a guide rail;

said movable member is provided with a horizontal portion, which faces an upper surface of said guide rail and a single wing portion, which faces one side surface of the guide rail; and

a single train of the rolling members is arranged in a gap between said one side surface of the guide rail and said single wing portion, and another single train of the rolling members is arranged in a gap between the upper surface of the guide rail and a lower surface of said horizontal portion in a vicinity of a corner of the guide rail.

12. An apparatus as claimed in claim 1, wherein:

said guide member comprises a guide rail;

said movable member comprises a movable block, which is provided with a pair of wing portions, between which the guide rail is held at right and left-hand side surfaces thereof; and

a single train of the rolling members is arranged in each of gaps between the right and left-hand side surfaces of the guide rail and both of the wing portions, so as to provide a total number of trains of two.

13. An apparatus as claimed in claim 1, wherein:

said guide member comprises a guide rail;

said movable member comprises a movable block arranged along one side surface of the guide rail; and

two trains of the rolling members are arranged in a gap between said one side surface of the guide rail and the movable block.

14. An apparatus as claimed in claim 1, wherein:

said guide member comprises a spline shaft; and

said movable member comprises an outer tube, said outer tube is movably supported on said spline shaft through a plurality of trains of the rolling members.

There is provided a rolling element spacer used in a rolling guide device having an endless circulation passage for balls, arranged alternately with many balls in the endless circulation passage, and circulating together with the balls in the endless circulation passage. In order to prevent the rolling element spacer from falling sideways and avoid a trouble such as malfunction of the rolling guide device, the rolling element spacer is formed such that its diagonal dimension in a thickness direction becomes larger than an inner diameter of the endless circulation passage.

ROLLING ELEMENT SPACER IN ROLLING GUIDE DEVICE

BACKGROUND OF THE INVENTION

[0001] 1. Field of the Invention

[0002] The present invention relates to a rolling element spacer which, in various rolling guide devices each having an endless circulation passage for balls such as a linear guide device and a ball screw device, is interposed between the mutually adjoining balls in the endless circulation passage and reduces frictions between the balls and a heat generation to thereby smoothen the rolling thereof.

[0003] 2. Description of the Related Art

[0004] Hitherto, as a rolling guide device in which a pair of members continuously performing a relative motion through an endlessly circulating ball row, there have been known devices such as a linear guide device which is used in a linear guide portion in a machine tool, a carrying device and the like and which guides a movable body such as a table on a stationary portion such as a bed or a saddle, and a ball screw which is used together with this linear guide device and which gives a stroke of a linear motion corresponding to a rotation amount of a motor to the movable body.

[0005] The former linear guide device comprises a bearing rail which is disposed on the stationary portion and in which a rolling groove for the balls is formed along a longitudinal direction, and a sliding base which has a load rolling groove facing the rolling groove of the bearing rail through many balls and in which there is formed an endless circulation groove for the balls rolling on the load rolling groove, and it is constituted such that, in accompaniment with the endless circulation of the balls, the sliding base supporting the movable body continuously performs the linear motion along the bearing rail. Further, reversely to this, there is a case where it is constituted such that the bearing rail is moved relative to the fixed sliding base.

[0006] On the other hand, the latter ball screw comprises a screw shaft in which there is formed a spiral ball rolling groove with a predetermined lead, and a nut member which has a load rolling groove facing the ball rolling groove through many balls and in which there is formed an endless circulation passage for the balls rolling on the load rolling groove, and it is constituted such that, in accompaniment with a relative rotation motion between the screw shaft and the nut member, the balls circulate in the endless circulation passage, and the nut member and the screw shaft relatively move in an axial direction.

[0007] On the other hand, in such a rolling guide device, since the individual ball circulating in the endless circulation passage mutually contacts with the balls positioned before and after it, in case that it is used at a high speed, there have been such fears that, besides the fact that the balls are worn in relatively short time by a friction between the balls for instance, there arises a disadvantage such as the fact that the ball or the load rolling groove generates a seizure owing to a friction heat. Therefore, as one for solving such a drawback, in Japanese Patent Laid-Open No. 315835/1999 Gazette, there is disclosed a rolling guide device in which a rolling element spacer is interposed between the balls mutually adjoining in the endless circulation passage.

[0008] In the rolling guide device disclosed in the above Gazette, it is adapted such that a synthetic resin made rolling element spacer referred to as separator is arranged alternately with the ball in the endless circulation passage, thereby preventing the balls from mutually contacting. Such a separator is formed in a disk-like form whose outer diameter is smaller than a diameter of the ball and, in its both front/rear faces contacting with the balls, there are formed spherical face seats whose curvatures are larger than a curvature of a spherical face of the ball. By this, as shown in **FIG. 12**, if the ball **100** and the separator **101** are alternately arranged without a gap in the endless circulation passage **102**, each separator **101** becomes a state of being sandwiched between a pair of balls **100**, **100** adjoining its both front/rear faces, so that it circulates in the endless circulation passage **102** together with the ball **100** while being held in its predetermined attitude.

[0009] However, it is difficult to arrange the balls **100** and the spacers **101** without a gap in the endless circulation passage **102** provided in the rolling guide device. Further, if an accumulated use time of such a rolling guide device is increased, a gap is generated between the ball **100** and the rolling element spacer **101** by a wear. In case that the gap between the rolling element spacer **101** and the ball **100** cannot be removed in this manner and the gap is generated resultantly, the attitude of the rolling element spacer **101** becomes unstable as shown in **FIG. 13**, so that there is a fear that it falls sideways between the balls **100** in the endless circulation passage **102**.

[0010] And, in case that the rolling element spacer has fallen sideways in this manner, since a movement of the rolling element spacer is not restrained by the adjacent balls, the rolling element spacer is separated from the balls to spring out of the endless circulation passage and, in case of the ball screw device for instance, it is discharged outside from between a screw shaft and a nut member. Further, if one of the rolling element spacers drops out in this manner, the gap between the ball and the remaining rolling element spacer in the endless circulation passage widens increasingly, so that the rolling element spacer drops out one after another from the endless circulation passage.

[0011] On the other hand, if the rolling element spacer falls sideways in the endless circulation passage, since the ball attempts to run on this rolling element spacer, the balls are clogged without circulating in the endless circulation passage and, in the ball screw device for instance, there is a fear that the nut member is locked to the screw shaft, so that an operation becomes impossible.

SUMMART OF THE INVENTION

[0012] The invention has been made in view of such a problem, and its object is to prevent the rolling element spacers arranged together with the balls in the endless circulation passage from falling sideways in the endless circulation passage, thereby providing a rolling element spacer capable of avoiding such a trouble that the rolling element spacer drops out of the endless circulation passage and the rolling guide device becomes impossible to operate.

[0013] In order to achieve the above object, the invention provides a rolling element spacer used in a rolling guide device in which a pair of members perform a relative continuous motion through an endlessly circulating ball row, interposed between balls mutually adjoining in its endless circulation passage, and circulating together with the balls, characterized in that a diagonal dimension in a thickness direction is larger than an inner diameter of the endless circulation passage.

[0014] According to such a technical means, since the rolling element spacer arranged in the endless circulation passage is formed such that the diagonal dimension in the thickness direction, i.e., a diagonal dimension between both front/rear faces contacting with a pair of balls, is larger than an inner diameter of the endless circulation passage provided in the rolling guide device, even if a gap is generated between the ball and the rolling element spacer and thus the rolling element spacer slants in the endless circulation passage, the rolling element spacer does not fall sideways completely because its corner portions engage with an inner wall of the endless circulation passage, so that it is restored to an original attitude, i.e., a stable state in which it is sandwiched by the balls from both sides while it circulates together with the balls. By this, it is possible to avoid such troubles that the rolling element spacer drops out of the endless circulation passage and that the balls are clogged in the endless circulation passage.

[0015] According to the rolling element spacer of the invention, by setting the diagonal dimension in the thickness direction of the rolling element spacer larger than the inner diameter of the endless circulation passage provided in the rolling guide device, even if the rolling element spacer slants in the endless circulation passage, such a drawback that this rolling element spacer falls sideways between the balls can be prevented, so that it becomes possible to avoid such a trouble that the rolling guide device itself becomes impossible to operate owing to the fact that the rolling element spacer, which has fallen sideways and thus is not held in a predetermined attitude by the balls, drops out of the endless circulation passage and thus the balls are clogged in the endless circulation passage.

DESCRIPTION OF THE PREFERRED EMBODIMENT

[0029] Hereunder, a rolling element spacer of the invention is detailedly explained on the basis of the attached drawings.

[0030] **FIG. 1** and **FIG. 2** show one embodiment of a ball screw device in which the rolling element spacers of the invention are arranged together with balls in an endless circulation passage. In these drawings, the reference numeral **1** denotes a screw shaft, the reference numeral **2** a ball and the reference numeral **3** a nut member, and the nut member **3** meshes with the screw shaft **1** through many balls **2**.

[0031] A spiral ball rolling groove **10** is formed in an outer periphery face of the screw shaft **1**, while a spiral load rolling groove **30** facing the ball rolling groove **10** of the screw shaft **1** is formed in an inner periphery face of the nut member **3**, and the ball rolling groove **10** and the load rolling groove **30** form a spiral load ball passage between the screw shaft **1** and the nut member **3**. That is, if a relative rotary motion occurs between the screw shaft **1** and the nut member **3**, the ball **2** spirally rolls in the load ball passage while bearing a load. Further, a return pipe **4** mutually communicating both ends of the load ball passage to thereby constitute the endless circulation passage for the balls **2** is attached to the nut member **3**, so that the ball **2** having finished to roll in the load ball passage and having been released from the load becomes a no-load state and rolls in the return pipe **4**, and is returned to an inlet of the load ball passage while jumping the ball rolling groove **10** by several turns. Accordingly, if the screw shaft **1** and the nut member **3** are relatively rotated, it follows that the ball **2** rolls from the load ball passage to the return pipe **4** and from the return pipe **4** to the load ball passage, and is circulated inside the endless circulation passage constituted by the load ball passage and the return pipe **4**.

[0032] In this ball screw device, in order to prevent the balls **2** incorporated in the endless circulation passage from mutually contacting, a rolling element spacer **5** is interposed between the mutually adjoining balls **2**, **2**. As shown in **FIG. 3**, the rolling element spacer **5** is formed by deforming a synthetic resin into an approximately disk form and, in its both front/rear faces, there are respectively formed spherical faces **50** on which the balls **2** slide. The ball **2** and the rolling element spacer **5** are alternately arranged in the endless circulation passage. By this, it is adapted such that the balls **2** rolling in the endless circulation passage are prevented from mutually contacting, a smooth circulation of the ball **2** and, in turn, smoothening of the rotary motion of the nut member **3** relative to the screw shaft **1** are intended, and additionally a generation of noise owing to a collision between the balls during an operation of the ball screw device is reduced.

[0033] As shown in **FIG. 4**, such a rolling element spacer **5** is formed such that—when it is suppose that t is a thickness between both front/rear faces in which the spherical face seats **50** are formed and ϕd an outer diameter—a diagonal dimension A, in a thickness direction, expressed by $\sqrt{(d^2+t^2)}$ becomes larger than an inner diameter ϕD of the endless circulation passage **6** for the ball **2**. That is, the thickness t and the outer diameter ϕd of the rolling element spacer are set such that $\phi D<A=\sqrt{(d^2+t^2)}$ is met. Therefore, it is adapted such that even in case that the gap is generated between the ball **2** and the rolling element spacer **5** in the endless circulation passage **6** and thus the rolling element spacer **5** slants without being supported in a predetermined attitude by the balls **2**, since periphery edges of the rolling element spacer **5** formed in the disk-like form are locked by inner walls of the endless circulation passage as shown in **FIG. 5**, such a trouble is prevented that the rolling element spacer **5** falls sideways in the endless circulation passage **6**.

[0034] Here, since the diagonal dimension A of the rolling element spacer **5** is determined by the thickness t and the outer diameter ϕd of the rolling element spacer **5**, it follows that, in order to make the diagonal dimension A larger than the outer diameter ϕD, the thickness t or the outer diameter ϕd may be set large. However, in case that the thickness of the rolling element spacer **5** is set large, it follows that the number of the balls **2** in the endless circulation passage **6** is reduced correspondingly. Accordingly, in order to avoid a reduction in rated load of the ball screw device and avoid the device concerned from becoming large, it is preferable to set the thickness t small within such a range that the mutually adjoining balls **2** do not contact.

[0035] On the other hand, it is necessary that the outer diameter ϕd of the rolling element spacer **5** is smaller than a ball diameter ϕD_B and, even if the outer diameter ϕd is how large in this range, basically there is no problem. However, as shown in **FIG. 2**, in the ball screw, since the ball **2** and the rolling element spacer **5** spirally circulate around the screw shaft **1**, in case that the outer diameter ϕd of the rolling element spacer **5** is too large, there is a drawback that the outer periphery face **51** of such rolling element spacer **5** interferes with the ball rolling groove **10** of the screw shaft **1**. Further, also in another rolling guide device other than the ball screw, a linear guide device for instance, since a curved portion necessarily exists in the endless circulation passage, in case that the outer diameter ϕd of the rolling element spacer **5** is too large, there is also a drawback that the outer periphery face **51** of such rolling element spacer **5** interferes with an inner diameter side's wall of the endless circulation passage. Accordingly, in order to avoid such an interference between the rolling element spacer **5** and the inner wall of the endless circulation passage to thereby achieve a smooth ball circulation, it is necessary to limit a maximum value of the outer diameter ϕd of the rolling element spacer **5** from a relation with a radius of curvature of the curved portion in the endless circulation passage.

[0036] Here, as shown in **FIG. 6**, if it is supposed that D_B is an outer diameter of the ball **2**, S an inter-center distance between the mutually adjoining balls **2**, **2**, R a radius of curvature in an inner diameter side of the endless circulation passage through which the ball **2** circulates and d an outer diameter of the rolling element spacer **5**, and if it is imagined that an outer periphery face of the rolling element spacer **5** contacts with an inner wall of the endless circulation passage, it is possible to derive a right-angled triangle having such a dimensional relation as shown in **FIG. 7**. Accordingly, from the dimensional relation of this triangle, the following equation is established.

$$(R+D_B/2)^2=(S/2)^2+(R+d/2)^2$$

[0037] And, if d is derived from this equation, it becomes as follows.

$$d\ (d_{max})=\sqrt{\{(2R+D_B)^2-S^2\}}-2R \quad \text{(Equation 1)}$$

[0038] Incidentally, since the outer periphery face **51** of the rolling element spacer **5** is liable to interfere with the inner wall of the endless circulation passage as the radius of curvature in the curved portion of the endless circulation passage becomes small, R used in the Equation 1 is a minimum radius of curvature in the endless circulation passage.

[0039] Since this Equation represents a state that the outer periphery face **51** of the rolling element spacer **5** contacts with the inner wall of the endless circulation passage, i.e., a maximum value d_{max} of the outer diameter of the rolling element spacer **5**, in order to prevent the rolling element spacer **5** from interfering with the endless circulation passage, the outer diameter d of the rolling element spacer **5** must be smaller than this d_{max}. That is, if

$$d<d_{max}=\sqrt{\{(2R+D_B)^2-S^2\}}-2R \quad \text{(Equation 2)}$$

[0040] is met, the rolling element spacer **5** can smoothly circulate in the endless circulation passage with the balls **2** without interfering with the inner wall of the endless circulation passage.

[0041] Accordingly, on setting the diagonal dimension A of the rolling element spacer **5** larger than the inner diameter ϕD of the endless circulation passage, it is preferable to set the outer diameter ϕd of the rolling element spacer **5** as large as possible within a range determined by the Equation 2, and to set the thickness t small. By this, it is possible for the endless circulation passage to arrange the balls **2** in the maximum number while preventing the rolling element spacer **5** from interfering with the endless circulation passage.

[0042] Further, as to the Equation 2, there is imagined a case that the outer periphery face **51** of the rolling element spacer **5** is formed in a cylindrical form. However, as shown in **FIG. 8** and **FIG. 9**, in case that the outer periphery face **51** of the rolling element spacer **5** is formed in a concave face form, since the outer periphery face **51** of the rolling element spacer **5** becomes correspondingly difficult to interfere with the inner wall of the endless circulation passage, it becomes possible to set the outer diameter of the rolling element spacer **5** slightly larger than the aforesaid d_{max}. Accordingly, in this case, it is necessary to add a correction value Δd to the aforesaid d_{max}.

[**0043**] Here, as shown in **FIG. 10**, if it is supposed that W is a width of a recessed portion **52** formed in the outer periphery face **51** of the rolling element/spacer **5**, Δd/2 a height of an inner wall of the endless circulation passage, protruding into the recessed portion **52** and, similarly to the previous time, R the radius of curvature in the inner diameter side of the endless circulation passage, it is possible to derive a right-angled triangle of such a dimensional relation as shown in **FIG. 11**. Accordingly, from the dimensional relation of this triangle, the following equation is established.

$$R^2(W/2)-\surd(4R^2-W^2) \qquad \text{(Equation 3)}$$

[**0044**] And, if Δd is derived from this equation, it becomes as follows.

$$\Delta d=2R-\surd(4R^2W^2) \qquad \text{(Equation 4)}$$

[**0045**] And, in case that the recessed portion **52** exists in the outer periphery face **51** of the rolling element spacer **51** in this manner, if the maximum outer diameter ϕd of the rolling element spacer **5** is smaller than a value obtained by adding the correction value Δd to d_{max} prescribed by the aforesaid Equation 2, i.e., if

$$\phi d<d_{max}+2R-\surd(4R^2-W^2) \qquad \text{(Equation 5)}$$

[**0046**] is met, the outer periphery face **51** of the rolling element spacer **5** is prevented from interfering with the inner wall of the endless circulation passage.

[**0047**] Accordingly, in case that the recessed portion **52** is formed in the outer periphery face **51** of the rolling element spacer **5**, it is possible to set the outer diameter of the rolling element spacer **5** larger by the aforesaid Δd than the case where the outer periphery face **51** is formed merely in the cylindrical form. Therefore, on determining the diagonal dimension A, by correspondingly reducing the thickness t of the rolling element spacer **5**, the number of the balls **2** in the endless circulation passage can be increased, so that it is possible to increase a rated load of the ball screw device by a more compact constitution and prevent the rolling element spacer **5** from falling sideways in the endless circulation passage.

What is claimed is:

1. A rolling element spacer used in a rolling guide device in which a pair of members perform a relative continuous motion through an endlessly circulating ball row, interposed between balls mutually adjoining in its endless circulation passage, and circulating together with the balls,

characterized in that a diagonal dimension in a thickness direction is larger than an inner diameter of the endless circulation passage.

2. A rolling element spacer set forth in claim 1, characterized in that when it is supposed that DB is a ball diameter, S an inter-center distance of the mutually adjoining balls and R a minimum radius of curvature of the endless circulation passage through which the balls circulate, an outer diameter d meets the following equation

$$d<\surd\{(2R+D_B)^2-S^2\}-2R=d_{max}.$$

3. A rolling element spacer set forth in claim 2, characterized in that an outer periphery face is formed in a concave face form, and when it is supposed that W is a width of its concave face portion, the outer diameter meets the following equation

$$d<d_{max}+2R\surd(4R^2-W^2).$$

(57) **ABSTRACT**

A rolling guide device comprises: a track rail formed with a rolling member rolling surface extending along a longitudinal direction thereof; a movable rail formed with a loaded rolling member rolling surface extending along a longitudinal direction thereof so as to oppose to the rolling member rolling surface of the track rail; a track rail side rolling member circulation passage formed to the track rail so as to circulate the rolling members rolling between the track rail and the movable rail; a movable rail side rolling member circulation passage formed to the movable rail so as to circulate the rolling members rolling between the track rail and the movable rail; and a number of rolling members disposed and arranged in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage. A drive system comprises such rolling guide device and linear motors having a primary side mounted to either one of the track rail and the movable rail and a secondary side mounted to another one of the track rail and the movable rail.

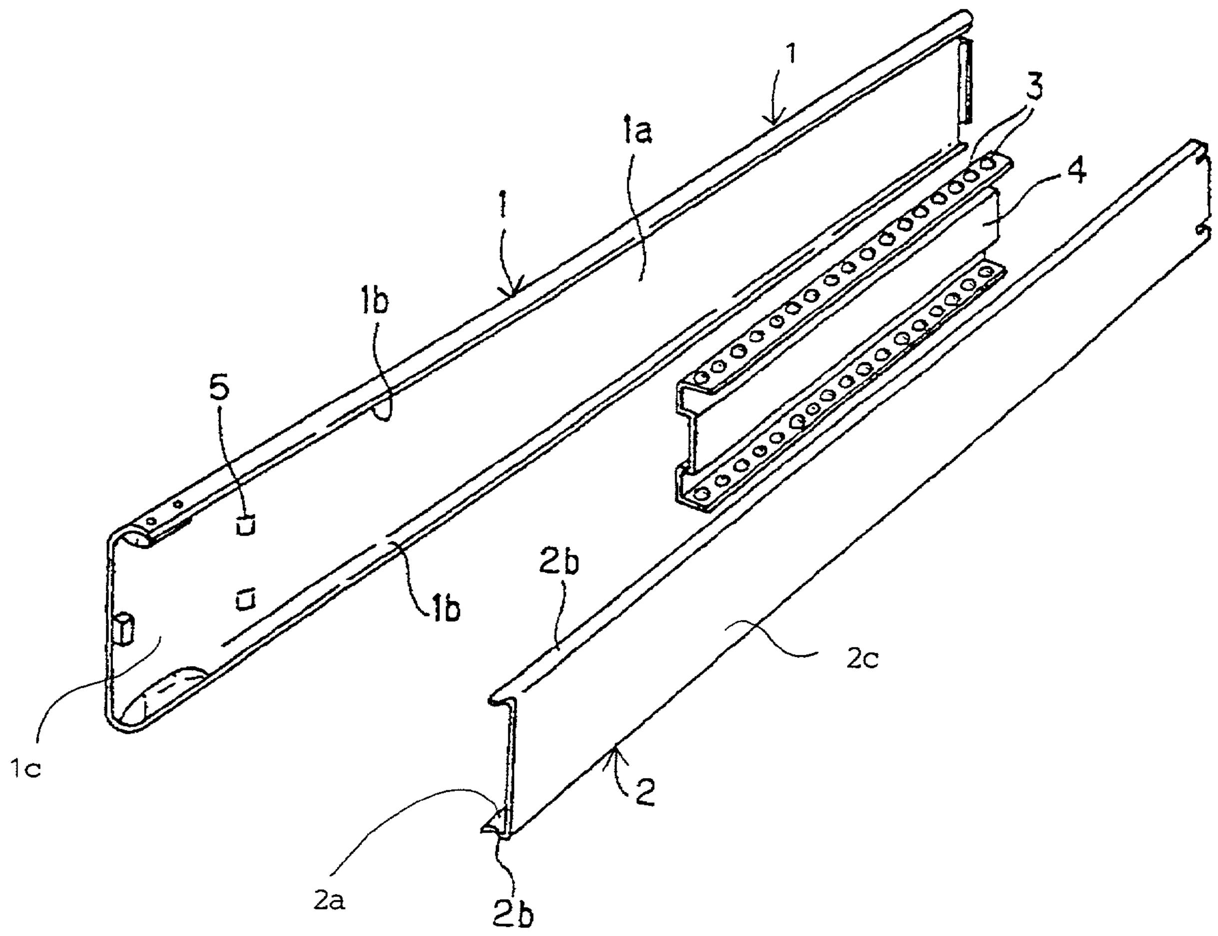
PRIOR ART



ROLLING GUIDE DEVICE AND DRIVE SYSTEM USING ROLLING GUIDE DEVICE

[0001] The present application claims priority under 35 U.S.C §119 to Japanese Patent Application No. 2000-073932 filed Mar. 13, 2000 entitled "ROLLING GUIDE DEVICE", No. 2000-367605 filed Dec. 1, 2000 entitled "ROLLING GUIDE DEVICE AND DRIVE SYSTEM USING ROLLING GUIDE DEVICE", and No. 2001-037486 filed Feb. 14, 2001 entitled "ROLLING GUIDE DEVICE AND DRIVE SYSTEM USING ROLLING GUIDE DEVICE". The contents of that application are incorporated herein by reference in their entirety.

BACKGROUND OF THE INVENTION

[0002] The present invention relates to a rolling guide device in which a movable rail is made slidable with respect to a track rail and also relates to a drive system using such rolling guide device.

[0003] As a rolling guide device in which a movable rail is made slidable with respect to a track rail, there has been known a slide rail such as shown in **FIG. 25** (see Japanese Utility Model Publication No. SHO 62-8765). Such slide rail comprises a track rail member **1** having an opened recess **1***a* (i.e. having substantially ⊐-shaped (box-shaped) cross section) formed by both inner side surfaces **1***b*, **1***b* and a bottom surface **1***c* and a movable rail member **2** which is supported between both the inner side surfaces **1***b*, **1***b* of the track rail member **1** to be movable in the longitudinal direction thereof. The movable rail member **2** also has an opened recess **2***a* (i.e. having substantially ⊐-shaped (box-shaped) cross section).

[0004] The track rail member **1** and the movable rail member **2** have substantially the same longitudinal length. The inner side surfaces **1***b* of the track rail member **1** are formed with ball rolling grooves, respectively, along which balls roll in the longitudinal direction thereof, and outer side surfaces **2***b* of the movable rail member **2** are also formed with loaded ball rolling grooves, respectively, so as to extend in the longitudinal direction thereof and oppose to the ball rolling grooves formed to the track rail member **1**.

[0005] A number of balls **3** are arranged and housed between these ball rolling grooves and loaded ball rolling grooves, and these balls **3** are held by a cage **4** to be rotatable and slidable. When the movable rail member **2** is slid with respect to the track rail member **1** in the longitudinal direction thereof, these balls **3** roll and, hence, the slide rail becomes smoothly expandable or contractive.

[0006] Further, though not shown, there is also known a cam-follower type drawer device of a structure that movable and track rails are both provided with wheels so that the movable rail is drawn with respect to the track rail, as a rolling guide device in which a movable rail is slidable with respect to a track rail.

[0007] However, in the conventional slide rail such as mentioned above, a number of balls **3** disposed and arranged between the track rail member **1** and the movable rail member **2** do not completely perform the rolling motion and will roll with a slight sliding motion. In the conventional slide rail, since the balls **3** do not circulate and only reciprocally move along the loaded rolling passage between the ball rolling grooves and the loaded ball rolling grooves, if the balls **3** are slid, the cage **4** supporting (bearing) the balls **3** would be displaced from the initial position. As a result, in spite of the fact that an effective stroke of the movable rail member **2** is not achieved, the cage **4** collides with a stopper **5** of the track rail member **1** and, hence, such effective stroke could not be obtained. In this case, when it is required to slide the movable rail member **2** with the cage **4** colliding with the stopper **5**, the movable rail member **2** will be slid with the balls **3** being slipped, and accordingly, a large force is required to move the movable rail member **2**.

[0008] Furthermore, in the conventional structure of the slide rail, in order to obtain a large stroke of the movable rail member **2**, it is necessary for the movable rail member **2** to be once come off from a portion at which the balls **3** exist and then to be engaged with that portion at which the balls **3** exist. That is, in the case where the movable rail member **2** is come off from the portion at which the balls **3** exist, for example, the movable rail member **2** which has been loaded with ten (10) balls **3** is loaded with, for example, six (6) balls **3**, and hence, ability for bearing moment load, radial load and thrust load is deteriorated, thus being inconvenient.

[0009] Moreover, with the cam-follower type drawer device, since the wheels generally have backlash or looseness, the movable rail member **2** is not smoothly slid, and furthermore, since the wheel has a cylindrical structure, a direction along which a load is received is determined, and hence, the thrust load cannot be received.

SUMMARY OF THE INVENTION

[0010] An object of the present invention is to substantially eliminate defects or drawbacks encountered in the prior art mentioned above and to provide a rolling guide device capable of taking a large expansion/contraction stroke and sufficiently bearing moment load, radial load and thrust load at any expanded (contracted) attitude and also provide a drive system incorporated with such rolling guide device.

[0011] This and other objects can be achieved according to the present invention by providing, in one aspect, a rolling guide device comprising:

[0012] a track rail formed with a rolling member rolling surface extending along a longitudinal direction thereof;

[0013] a movable rail formed with a loaded rolling member rolling surface extending along a longitudinal direction thereof so as to oppose to the rolling member rolling surface of the track rail;

[0014] a track rail side rolling member circulation passage formed to the track rail so as to circulate the rolling members rolling between the track rail and the movable rail;

[0015] a movable rail side rolling member circulation passage formed to the movable rail so as to circulate the rolling members rolling between the track rail and the movable rail; and

[0016] a number of rolling members disposed and arranged in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage.

[0017] According to the invention of this aspect, when the movable rail is slid with respect to the track rail, the rolling members arranged between the track rail and the movable rail endlessly circulate in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage while rolling therealong. As mentioned, since the rolling members circulate in the endless manner, even if the rolling member slides during the rolling motion, there is no causing of a case that a cage is shifted from the initial position as in the conventional structure, and hence, a large expansion (contraction) stroke is obtainable. Furthermore, in an optional expanded (contracted) attitude, there remains a considerable distance between the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage, so that a rolling guide device, which can bear even the moment load, can be realized.

[0018] Further, when the movable rail is slid and its stroke is made large, the considerable distance corresponding to this stroke is made short and capability of bearing the moment load is reduced. However, according to the present invention, the movable rail is not come off from the balls, so that the capability of bearing the moment load is not extremely reduced. Moreover, since the movable rail is not come off from the balls and the number of the rolling members supported at an optional expansion (contraction) attitude is not changed, different from the conventional slide rail, there can be provided a rolling guide device bearing the constant radial load and thrust load.

[0019] In the above aspect, the following preferred embodiments or examples may be provided with advantageous functions and effects thereof.

[0020] The track rail side rolling member circulation passage is formed to one longitudinal end side of the track rail and the movable rail side rolling member circulation passage is formed to one longitudinal end side, opposing to that one end side of the track rail, of the movable rail.

[0021] Accordingly, the distance between the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage can be made large, so that a rolling guide device bearing the large moment load can be provided.

[0022] Furthermore, the track rail has an opened recess having ⊐-shaped section and has inside surfaces to which the rolling member rolling surfaces are formed, the movable rail is fitted into the recess of the track rail, and the movable rail has outside surfaces to which the loaded rolling member rolling surfaces are formed so as to oppose to the rolling member rolling surfaces formed to the track rail inside surfaces.

[0023] Thus, various kinds of loads including radial load, thrust load and moment load can be supported in a balanced condition.

[0024] The track rail side rolling member circulation passage is provided with a rolling member return passage substantially parallel to the rolling member rolling surface and a rolling direction changing passage communicating the rolling member rolling surface and the rolling member return passage, the movable rail side rolling member circulation passage is provided with a rolling member return passage substantially parallel to the loaded rolling member rolling surface and a rolling direction changing passage communicating the rolling member rolling surface and the rolling member return passage, the rolling direction changing passages of the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage are formed to a deflector which is formed independently from a track rail body and a movable rail body, and the deflector is fitted to holes formed to the track rail body and movable rail body from the side portions thereof.

[0025] According to this embodiment, the rolling direction changing passages can be easily formed to fine long track rail and movable rail.

[0026] The return passages are drilled to the track rail body and the movable rail body from the longitudinal end portions thereof.

[0027] According to this embodiment, the return passages can be easily formed to fine long track rail and movable rail.

[0028] The deflector is composed of a plurality of sections splittable along the rolling direction changing passages.

[0029] Accordingly, the rolling direction changing passages having complicated structure may be easily formed to the deflector.

[0030] The deflector is made of a synthetic resin.

[0031] Accordingly, the rolling direction changing passages having complicated structure may be easily formed to the deflector, and moreover, noise which may be generated when the rolling members roll in the rolling direction changing passages will be suppressed.

[0032] The above mentioned object of the present invention can be also achieved by providing, in another aspect, a drive system comprising:

[0033] a track rail formed with a rolling member rolling surface extending along a longitudinal direction thereof;

[0034] a movable rail formed with a loaded rolling member rolling surface extending along a longitudinal direction thereof so as to oppose to the rolling member rolling surface of the track rail;

[0035] a track rail side rolling member circulation passage formed to the track rail so as to circulate the rolling members rolling between the track rail and the movable rail;

[0036] a movable rail side rolling member circulation passage formed to the movable rail so as to circulate the rolling members rolling between the track rail and the movable rail;

[0037] a number of rolling members disposed and arranged in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage; and

[0038] a linear motor means having a primary side mounted to either one of the track rail and the movable rail and a secondary side mounted to another one of the track rail and the movable rail.

[0039] According to the present invention of this aspect, the expansion (contraction) stroke can be made large and the moment load, the radial load and the thrust load can be sufficiently supported at an optional attitude of the system. Furthermore, since the linear motors are incorporated between the track rail and the movable rail, the use of the ball screw or like can be eliminated, thus moving the movable rail at high speed with less noise. Moreover, since it is not necessary to provide a space for a rotary motor, the drive system can be made thin and compact.

[0040] According to preferred embodiments or examples of this aspect, the following advantageous functions and effects may be attained.

[0041] The track rail side rolling member circulation passage is formed to one longitudinal end side of the track rail and the movable rail side rolling member circulation passage is formed to one longitudinal end side, opposing to that one end side of the track rail, of the movable rail, and the linear motor means comprises first and second linear motors, the first linear motor having a primary side mounted to a portion near the track rail side rolling member circulation passage of the track rail, the second linear motor having a secondary side mounted to the track rail along the longitudinal direction thereof so as to be continuous to the primary side of the first linear motor, and the second linear motor having a primary side mounted to a portion near the movable rail side rolling member circulation passage of the movable rail, the first linear motor having a secondary side mounted to the movable rail along the longitudinal direction thereof so as to be continuous to the primary side of the second linear motor.

[0042] According to this embodiment, since two sets of linear motors are incorporated in the drive system, the thrust force can be made two times (twice), and the excitation is averaged to thereby make smooth the movement of the movable rail. Furthermore, the first linear motor has a primary side mounted to a portion near the track rail side rolling member circulation passage of the track rail and the second linear motor has a primary side mounted to a portion near the movable rail side rolling member circulation passage of the movable rail, so that the thrust force can be generated at substantially the same positions of the movable side rolling member circulation passage and the track rail side rolling member circulation passage, regardless of the stroke of the movable rail. Therefore, even if pitching or yawing moment is applied to the movable rail, the thrust force can be stably applied to the movable rail.

[0043] The first and second linear motors may be composed of linear induction motors or linear pulse motors such that the secondary sides thereof are opposed to each other.

[0044] For example, in a case where linear D.C. motors are used, two sets of linear motors are disposed in back-to-back arrangement and a distance between the secondary side magnets is short, an alternating magnetic field may be generated between the magnets. However, according to this embodiment of the present invention, since the linear induction motors or linear pulse motors are used without using the magnets, there is no fear of causing any alternating magnetic filed. However, a linear D.C. motor may be utilized as far as a relatively large distance between the secondary sides of the linear D.C. motors can be taken so as not to influence from each other.

[0045] The nature and further characteristic features of the present invention may be made clear from the following descriptions made with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

[0046] In the accompanying drawings:

[0047] **FIG. 1** is a perspective view of a rolling guide device according to one embodiment of the present invention;

DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0072] FIGS. **1** to **3** represent a first embodiment of a rolling guide device according to the present invention.

[0073] With reference to FIGS. **1** to **3**, a rolling guide device comprises an outer rail **7** as a track rail, an inner rail **8**, as a movable rail, supported by the outer rail **7** to be slidable in the longitudinal direction thereof and a ball screw **9** driving the inner rail **8**. When a screw shaft **10** of the ball screw **9** is rotated, the inner rail **8** is slid with respect to the outer rail **7**. Such rolling guide device will be utilized for a welding servo-gan, fork-lift or like usable in a stockroom, for example. In a case where the rolling guide device is utilized for the welding servo-gan, a welding rod is attached to the inner rail **8** and, then, the inner rail **8** is slid so as to press the welding rod against an object to be welded. On the other hand, in a case where the rolling guide device is utilized for the fork-lift, an inner rail **8** having a front fork member is slid and the fork-lift is then moved while supporting a cargo by the projected fork member. It is of course to be noted that the illustrated rolling guide device is not limited in its use to the welding servo-gan and the fork-lift and can be applied for various usages as far as expansion/contraction stroke is required and a load is supported.

[0074] The outer rail **7** has a recess **7***a* having an upper opening, in an illustrated state, so as to provide substantially a ⊐-shaped (box-shaped) section having an upper opening. That is, the recess **7***a* is defined by a bottom portion and a lateral pair of ridges **7***b*, **7***b* extending in parallel to each other at both longitudinal side portions of the bottom portion. Each of the ridges **7***b* has an inside surface **7***c* to which one row of ball rolling groove **11** is formed as a rolling member rolling surface extending in the longitudinal direction thereof. An outer rail side ball circulation passage **14** for circulating balls **13**, as rolling members, rolling between the inner rail **8** and the outer rail **7** is formed to one longitudinal side end portion of the outer rail **7**.

[0075] The inner rail **8** is fitted to the recess **7***a* of the outer rail **7** and supported thereby through balls **12, 13** so as to be clamped between the ridges **7***b*, **7***b* of the outer rail **7**. The inner rail **8** has a recess **8***a* having a lower opening, in an installed state, so as to provide substantially a ⊐-shape section having a lower opening, thus easily forming a space into which the screw shaft **10** is moved.

[0076] In the fitted state of the inner and outer rails **8** and **7**, the inside surfaces **7***c*, **7***c* of the outer rail **7** face the outside surfaces **8***c*, **8***c* of the inner rail **8**, respectively, so that the ball rolling grooves **11** formed to the inside surfaces **7***c*, **7***c* of the outer rail **7** oppose to the loaded ball rolling grooves **15** formed to the outside surfaces **8***c*, **8***c* of the inner rail **8**. Inner rail side ball circulation passages **16** are formed to one longitudinal end side of the inner rail **8** opposing to the outer rail side ball circulation passages **14** so as to circulate the balls **12** rolling between the outer and inner rails **7** and **8**. That is, in the structure in which the inner rail **8** projects from (extends over) the outer rail **7**, the outer rail side ball circulation passages **14** on the exit side end of the outer rail **7** and the inner rail side ball circulation passages **16** are formed to the rear side end of the inner rail **8**. This will be explained through a manufacturing processes. The outer rail side ball circulation passages **14** are formed to one end side of the outer rail **7** and the inner rail side ball circulation passages **16** are formed to one end side of the inner rail **8**, and thereafter, the inner and outer rails **8** and **7** are assembled (fitted) from the direction in which both the circulation passages **14** and **16** do not interfere.

[0077] As shown in **FIG. 2**, each of the outer rail side ball circulation passages **14** is composed of a portion of the ball rolling groove **11**, a ball return passage A as a rolling member return passage substantially parallel to the ball rolling groove **11** and a pair of rolling member rolling direction changing passages B communicating with the ball rolling groove **11** and the ball return passage A. On the other hand, each of the inner rail side ball circulation passage **16** is also composed of a portion of the loaded ball rolling groove **15**, a ball return passage A as a rolling member return passage substantially parallel to the ball rolling groove **15** and a pair of rolling member rolling direction changing passages B communicating with the loaded ball rolling groove **15** and the ball return passage A. The ball return passage A is formed through a drilling working effected along the longitudinal direction from the end portions of an outer rail body **7***d* and an inner rail body **8***d*. The rolling direction changing passages B formed to the outer and inner ball circulation passages **14** and **16** are formed to deflectors **19** formed independently from the inner and outer rail bodies **8***d* and **7***d*. The details of such deflector **19** will be described hereinlater.

[0078] The ball screw **9** is engaged with the inner rail **8** so that the ball screw **9** is arranged in the recess **8***a* of the inner rail **8**.

[0079] With reference to **FIG. 4** showing the ball screw **9**, the ball screw **9** comprises the screw shaft **10**, a nut member **22** assembled to the screw shaft **10** to be relatively movable and a number of balls **23** disposed in the ball circulation passage. The screw shaft **10** has an outer peripheral surface on which a spiral rolling member rolling groove **10***a* is formed, the nut member **22** has an inner peripheral surface to which is formed a ball circulation passage including a spiral loaded rolling member rolling groove **22***a* opposing to the ball rolling groove, and the number of balls **23** are arranged in the ball circulation passage so as to circulate therein in association with the relative movement of the nut member **22** with respect to the screw shaft **10**. The nut member **22** has a flanged portion **24** formed at its one end side and is secured to the inner rail **8** by means of screws or like. The nut member **22** is also provided with a deflector **25** (direction changing passage forming member) for taking out the ball **23** rolling along the ball rolling groove **10***a* formed to the screw shaft **10** at one portion thereof and returning the ball **23** to the other portion (one-lead on this side from the ball taken out portion) of the ball rolling groove **10***a* over an outer large diameter portion of the screw shaft **10**. The screw shaft **10** is operatively coupled with an output (drive) shaft of a motor, mentioned hereinlater.

[0080] When the screw shaft **10** is rotated, the ball **23** rolling in the circumferential direction of the screw shaft under load is scooped up by the deflector **25** and the scooped ball **23** is then returned to the position, one-lead on this side of the ball rolling groove **10***a*. When the screw shaft **10** is rotated in the reverse direction, the balls **23** are circulated along the route reverse to that mentioned above. Further, in the described embodiment, although the balls **23** are scooped up by using the direction changing passage forming member (deflector) **25** and returned to the position, one-lead on this side of the ball rolling groove **10***a*, a return pipe may be substituted for such deflector **25**. That is, according to the structure using the return pipe, the ball **23** rolling along the ball rolling groove **10***a* of the screw shaft **10** is scooped up by one end of the return pipe and is then returned through the other one end thereof. Furthermore, so-called a side-cover (lid) type ball screw may be adapted, in which the nut member **22** is composed of a nut body formed with a loaded rolling groove and side lids applied to both ends of this nut body, a ball return passage is formed to the nut body, and both the side lids are formed with communication passages communicated with the loaded rolling groove and the return passage, respectively. An arrangement utilizing rollers in place of balls may be also applicable to the present invention.

[0081] **FIG. 5** shows the details of the deflector **19**, which is utilized commonly for the inner rail side ball circulation passage **16** and the outer rail side ball circulation passage **14**. With reference to the deflector **19** of **FIG. 5**, the deflector **19** is formed with rolling direction changing passage **26** in a semi-circular shape, and the deflector is composed of two bodies **19***a* and **19***b* divided along the rolling direction changing passage **26** for the sake of easy formation of this passage **26**. That is, these two body sections **19***a* and **19***b* are divided vertically, as viewed, through a plane including a central line of the rolling direction changing passage **26**. Both the body sections **19***a* and **19***b* are positioned through the engagement of dowels **27** and holes **28** formed to the body sections **19***a* and **19***b*. The deflector **19** is further formed with a stepped abutment portion **29** for the purpose of positioning it to the inner rail side ball circulation passage **16** and the outer rail side ball circulation passage **14**. The deflector **19** of the structure mentioned above will be formed from synthetic resin, for example, through an injection formation process.

[0082] **FIG. 6** shows another example of the deflector **30**. This deflector **30** is also composed of two divided body sections **30***a* and **30***b* separated along the rolling direction changing passage **26** for the easy formation thereof as mentioned before. In this example, however, the rolling direction changing passage **26** is divided into two sections as inner peripheral side section and outer peripheral side section. This deflector **30** is also formed with a stepped abutment portion **31**.

[0083] With reference to **FIGS. 2 and 3**, the outer rail body **7***d* is drilled from the side thereof to form holes **33** by means of end mill, for example, and the deflectors **19** are fitted to these holes **33**. The fitted deflectors **19** is secured to the outer rail body **7***d* by fastening means **32** such as binder members. The holes **33** are formed so as to penetrate the ball return passages A and extend ball rolling grooves **11** or ball rolling grooves **15** and formed inside with stepped portions **33***a* abutting against the abutment portions **29** of the deflectors **19**. When fitting the deflector **19**, the outer periphery of the deflector **19** is fitted to the hole **33** and the abutment portion **29** of the deflector **19** abuts against the stepped portion **33***a* of the hole **33**, thus positioning the deflector **19** with respect to the outer rail body **7***d* or inner rail body **8***d*.

[0084] Through such positioning of the deflector **19**, the balls **12** and **13** can be surely scooped from the ball rolling groove **11** or loaded ball rolling groove **15** and then returned to the ball return passage A.

[0085] On the other hand, other holes **33** are formed to the inner rail body **8***d* from the side thereof by means of end mill, for example, and the deflectors **19** are fitted to these holes **33**. Furthermore, in the described embodiment, although the holes **33** are formed to the outer rail body **7***d* from the outside thereof and formed to the inner rail body **8***d* from the inside thereof, the holes **33** may be formed to the outer rail body **7***d* from the inside thereof and formed to the inner rail body **8***d* from the outside thereof.

[0086] **FIG. 7** shows one preferred example of a drive system according to the present invention, which uses the rolling guide device mentioned above and is assembled with a rotation motor.

[0087] The screw shaft **10** is screwed with the nut member **22** and has one end rotatably supported by a bearing **35** disposed at one end portion of the outer rail **7** and coupled to a motor, not shown, through a joint member **36**. According to this structure, when the motor is driven, the screw shaft **10** is rotated and the rotational motion thereof is transferred to the inner rail **8** through the ball screw to thereby linearly move the inner rail **8** along the outer rail **7**. According to this linear motion of the inner rail **8** along the outer rail **7**, the rolling guide device is expanded or contracted, and the balls **12** and **13** circulate in an endless manner in the inner rail side ball circulation passage **16** and the outer rail side ball circulation passage **14** while rolling therealong. Since the balls **12** and **13** endlessly circulate, even if the balls **12** and **13** be slid during the rolling motion, there is no fear of being shifted from the original position as in a conventional slide rail, and a rolling guide device having a large expansion stroke can be realized, in which the inner rail **8** can be smoothly moved.

[0088] **FIG. 8** is an illustration showing a state that a load P is applied to the front end of the inner rail **8** of the rolling guide device. In an optional expanded or contracted state, since a considerable distance **1** exists between the outer rail side ball circulation passage **14** and the inner rail side ball circulation passage **16**, there can be provided a rolling guide device bearing the moment load. For example, when the load P is applied to the front end portion of the inner rail **8**, a reaction force Ro acts on the outer rail side ball circulation passage **14** and a reaction force Ri acts on the inner rail side ball circulation passage **16**, thus bearing the moment load of (Ri×1). When the inner rail **8** slides and the stroke of the rolling guide device is made large, the above-mentioned distance **1** is gradually reduced and an ability for loading this moment load is also reduced. However, even if the inner rail

8 is slid, the inner rail 8 never come off as in the conventional slide rail from the balls, so that the moment load bearing ability cannot be largely reduced. Furthermore, the movable rail is not come off from the ball as in the conventional slide rail and the number of balls born in the optional expanded or contracted attitude does not change, so that a rolling guide device capable of bearing constant radial load and thrust load can be realized.

[0089] Furthermore, as mentioned above, the outer rail **7** has a recess **7***a* having an upper opened portion has a box-shaped section and the ball rolling grooves **11** are formed to the inside surfaces **7***c*, respectively. The inner rail **8** is fitted into the recess **7***a* of the outer rail **7** and the loaded ball rolling grooves **15** are formed to the outside surfaces **8***c* of the inner rail **8** so as to oppose to the inside surfaces **7***c* of the outer rail **7**. Accordingly, there is provided the rolling guide device capable of bearing the radial load, the thrust load and the moment load in a balanced condition.

[0090] **FIG. 9** includes perspective views of the rolling guide device according to another embodiment of the present invention. Referring to **FIG. 9**A, the device is provided with inner and outer rails **8** and **7**, constituting a single-stroke structure in which only the inner rail **8** is slid. Further, as shown in **FIG. 9**B, the rolling guide device may be composed of three rail sections comprising the outer rail **7**, a first inner rail **41** fitted to the outer rail **7** and a second inner rail **42** fitted to the first inner rail **41**. In this structure, the first inner rail **41** is slid with respect to the outer rail **8** and the second inner rail **42** is slid with respect to the first inner rail **41**. That is, the first inner rail **41** acts like the inner rail **8** of the aforementioned embodiment with respect to the outer rail **7** and also acts like the outer rail **7** of the aforementioned embodiment with respect to the second inner rail **42**. The second inner rail **42** has a structure identical to that of the inner rail **8**. According to this rolling guide device of the embodiment of **FIG. 9**B, since the first inner rail **41** is slid with double strokes, the expansion stroke can be made further long. As mentioned above, when the rolling guide device is composed of a plurality of members (rail members), the expansion stroke composed of a plurality of expansion stages can be realized, thus providing a rolling guide device having a large stroke.

[0091] In the embodiment described above, although the inner rail side ball circulation passage **16** and the outer rail side ball circulation passage **14** are formed to the inner rail **8** and the outer rail **7**, respectively, these passages may be formed as block members independently from the inner and outer rails **8** and **7**. Furthermore, although the inner rail **8** and the outer rail **7** are formed as linear (straight) rail members, a curved rail member may be utilized therefor. The balls may be also substituted with other rolling members such as rollers. Retainers each having a belt shape having flexibility may be arranged for supporting the balls **12** and **13** to be rotatable, and spacers may be also arranged between the balls **12** and **13** for supporting them to be rotatable and slidable.

[0092] **FIGS. 10 and 11** represent a drive system, using a linear motor as drive source, according to one embodiment of the present invention.

[0093] This drive system comprises an outer rail **7** as a track rail, an inner rail **8** as a movable rail supported by the outer rail **8** to be linearly slidable along the longitudinal direction thereof and first and second linear motors **51** and **52** disposed between the inner and outer rails **8** and **7** to be back-to-back arrangement. The outer rail **7** is provided with a primary side movable piece (called merely movable piece i hereinlater) of the first linear motor **51** and a secondary side stationary piece (called merely stationary piece O**40** hereinlater) of the second linear motor **52**. On the other hand, the inner rail **8** is provided with a secondary side movable piece (called merely movable piece i' hereinlater) of the second linear motor **52** and a primary side stationary piece (called merely stationary piece O hereinlater) of the first linear motor **51**. According to this structure, when energized, suction (attracting) forces are induced between the movable piece i and the stationary piece O and between the movable piece i' and the stationary piece O'.

[0094] As like as the rolling guide device mentioned above, the outer rail **7** is formed with a recess **7***a* having a box-shaped section with an upper opening and also formed with a lateral pair of ridges **7***b*, **7***b* extending on both the sides of the recess **7***a* in parallel to each other along the longitudinal direction of the outer rail **7**. Each of the ridges **7***b*, **7***b* has an inside surfaces **7***c*, to which a single row of ball rolling groove **11** as a rolling member rolling surface is formed so as to extend along the longitudinal direction thereof as shown in **FIG. 11**. An outer rail side ball circulation passage **14** for circulating the balls **13** rolling between the inner and outer rails **8** and **7** is formed to one (front) end side portion of the outer rail **7**.

[0095] The inner rail **8** is fitted to the recess **7***a* of the outer rail **7** and supported thereby so as to be clamped between the ridges **7***b* of the outer rail **7** through the balls **12** and **13**. The inner rail **8** is also formed with a recess **8***a* having an opening opened downward so as to provide a box-shaped section. The inner rail **7** has outside surfaces **8***c* to which loaded ball rolling grooves **15** are formed as loaded rolling member rolling surfaces which face the ball rolling grooves **11** of the outer rail **7**. An inner rail side ball circulation passage **16** for circulating the balls **12** rolling between the inner and outer rails **8** and **7** is formed to one (rear) end side portion of the outer rail **7** in the longitudinal direction thereof.

[0096] As shown in **FIG. 11**, the outer rail side ball circulation passage **14** is composed of a portion of the ball rolling groove **11**, a ball return passage A as a rolling member return passage extending substantially in parallel to the ball rolling groove **11** and a pair of rolling direction changing passages B communicated with the ball rolling groove **11** and the ball return passage A. On the other hand, the inner rail side ball circulation passage **16** is also composed of a portion of the loaded ball rolling groove **15**, a ball return passage A as a rolling member return passage extending substantially in parallel to the loaded ball rolling groove **15** and a pair of rolling direction changing passages B communicated with the loaded ball rolling groove **15** and the ball return passage A. The ball return passages A are formed through drilling working effected from the end portions of the outer rail body **7***d* and the inner rail body **8***d* in their longitudinal directions. The rolling direction changing passages B of the outer rail side ball circulation passage **14** and the inner rail side ball circulation passage **16** are formed to a deflector **19** which is mounted to the inner rail body **8***d* and the outer rail body **7***d* as independent member.

[0097] Holes **33** are formed to the outer rail body **7***d* by means of end mill, for example, from the longitudinal sides thereof, and the deflector **19** is fitted to these holes **33** and then fastened to the outer rail body **7***d*. Holes **33** are also formed to the inner rail body **8***d* by means of end mill, for example, from the longitudinal sides thereof, and the deflector **19** is fitted to these holes **33** and then fastened to the inner rail body **8***d*. Since these deflectors have substantially the same structures as that mentioned herein before with reference to the rolling guide device, the details thereof are omitted herein by adding the same reference numeral of **19**.

[0098] Two linear motors **51** and **52** are interposed between the inner rail **8** and the outer rail **7**, and the linear motors **51** and **52** in this embodiment are linear induction motors and composed of the movable pieces i and i' and the stationary pieces O and O', the induction motors being driven and operated by passing polyphase alternating current to primary windings of the movable pieces i and i'.

[0099] With reference to **FIG. 10**, the movable piece i of the first linear motor **51** is mounted to a portion near one end (front end) in the longitudinal direction of the upper surface of the outer rail **7**, and the stationary piece O' of the second linear motor **52** is also mounted to the upper surface of the outer rail **7** so as to be continuous to the movable piece i of the first linear motor **51** in the longitudinal direction of the outer rail **7**. On the other hand, the movable piece i' of the second linear motor **52** is mounted to a portion near one end (rear end) in the longitudinal direction of the lower surface of the inner rail **8**, and the stationary piece O of the first linear motor **51** is also mounted to the lower surface of the inner rail **8** so as to be continuous to the movable piece i' of the second linear motor **52** in the longitudinal direction of the inner rail **8**. In such arrangement, the movable piece i of the first linear motor **51** and the outer rail side ball circulation passage **14** have substantially the same positions in the longitudinal direction of the outer rail **7**, and on the other hand, the movable piece i' of the second linear motor **52** and the inner rail side ball circulation passage **16** have substantially the same positions in the longitudinal direction of the inner rail **8**. Further, it is to be noted that the terms "upper", "lower" and the like are used herein in the illustrated state in the figures or usable state of the device or system.

[0100] As shown in **FIG. 12**, the movable piece i of the first linear motor **51** is opposed to the stationary piece O of the first linear motor **51**, and as shown in **FIG. 13**, the movable piece i' of the second linear motor **52** is opposed to the stationary piece O' of the second linear motor **52** so that the first and second linear motors **51** and **52** are disposed in the back-to-back arrangement as shown in **FIG. 14**.

[0101] **FIG. 15** shows a linear induction motor **53** constituting one example of the first and second linear motors **51** and **52**. The linear induction motor **53** is provided with the movable piece i and the stationary piece O which is composed of a non-magnetic conductor plate **54** and a magnetic conductor plate **55** by laminating them vertically as viewed. This linear induction motor **53** is driven in a manner basically identical to that of a cage (rotary type) induction motor having an operational function explained by the Lenz's law and the Fleming's left-hand rule.

[0102] When the polyphase alternating current passes the polyphase primary winding **56**, a traveling (progressive) magnetic field moving timely and spacially is generated, and this traveling field induces an eddy current on the non-magnetic conductor plate **54** constituting the secondary side element. The thus generated eddy current constitutes a thrust generation source in cooperation with the traveling field. Further, in the illustrated example of **FIG. 15**, the movable piece i is disposed only to the upper portion of the stationary piece O, but the movable pieces i may be disposed to both the upper and lower portions thereof.

[0103] **FIG. 16** shows a linear pulse motor **57** as another example of the linear motor **51** (**52**).

[0104] With reference to **FIG. 16**, the movable piece i is, for example, composed of a central permanent magnet **58** and two magnetic core members **59** and **60** opposed to each other with the permanent magnet **58** being interposed therebetween. One **59** of the magnetic cores is formed with first and second magnetic poles **61** and **62** magnetized in N-pole by the permanent magnet **58** and, on the contrary, the other one **60** of the magnetic cores is formed with third and fourth magnetic poles **63** and **64** magnetized in S-pole by the permanent magnet **58**.

[0105] On the other hand, the stationary piece O is formed with stationary teeth **65**, each having, a ⊐-shaped section, extending in a direction normal to the longitudinal direction of the stationary piece O equally with the same pitch. The magnetic poles **61** to **64** are formed with magnetic pole teeth **61***a* to **64***a*, respectively, each having the same pitch as that of the stationary piece O.

[0106] A first coil **66** and a second coil **67** are wound up around the first magnetic pole **61** and the second magnetic pole **62** of the N-pole side and connected in series to each other so as to generate magnetic fluxes opposed to each other in directions at a time when current flows. The first coil **66** and the second coil **67** are electrically connected to a pulse generation source, not shown.

[0107] On the other hand, a third coil **68** and a fourth coil **69** are also wound up around the third magnetic pole **63** and the fourth magnetic pole **64** of the S-pole side and connected to a pulse generation source.

[0108] In the described arrangement, the first and second magnetic poles **61** and **62** are arranged so that the magnetic pole teeth **61***a* and **62***a* thereof are shifted from each other by ½ pitch in their phases, and the third and fourth magnetic poles **63** and **64** are also arranged so that the magnetic pole teeth **63***a* and **64***a* thereof are shifted from each other by ½ pitch in their phases. Furthermore, the magnetic pole teeth **63***a* and **64***a* of the third and fourth magnetic poles **63** and **64** of the S-pole side are shifted, by ¼ pitch in phases, from the first and second magnetic pole teeth **61***a* and **62***a* of the first and second magnetic poles **61** and **62** of the N-pole side.

[0109] The linear pulse motor is driven by the following operation theory with reference to **FIGS. 17A** to **17D**.

[0110] Pulses are inputted to the first and second coils **66** and **67** from terminals a, and pulses are also inputted to the third and fourth coils **68** and **69** from terminals b. That is, the pulses are inputted to the terminal a in a direction to energize the first magnetic pole **61** in the state shown in **FIG. 17A**, to the terminal b in a direction to energize the fourth magnetic pole **64** in the state shown in **FIG. 17**B, to the terminal a in a direction to energize the second magnetic pole **62** in the state shown in **FIG. 17**C, and to the terminal b in a direction to energize the third magnetic pole **63** in the state shown in **FIG. 17**D, respectively.

[0111] When the pulse is inputted to the terminal a in a direction to energize the first magnetic pole **61** in the state shown in **FIG. 17**A, the first magnetic pole **61** maintains its stable state under the application of the magnetic fluxes of the permanent magnet **58** and the first coil **66**. Next, in the state shown in **FIG. 17**B, when the pulse is inputted to the terminal b in a direction to energize the fourth magnetic pole **64**, the fourth magnetic pole **64** is moved to a direction so as to maintain its stable state, that is, in the right direction facing the drawing paper by ¼ pitch. As mentioned above, the movable piece is operated continuously as shown in **FIGS. 17C and 17D** by passing alternately the pulse current.

[0112] **FIG. 18** represents a linear D.C. motor **70** as another example of the linear motor.

[0113] With reference to **FIG. 18, a** movable piece of this example is composed of exciting coils **71** and yokes, and a stationary piece O is composed of magnets **72** and yokes. A plurality of exciting coils **71** constituting the movable piece i are arranged along the longitudinal direction thereof, and a plurality of magnets **72** constituting the stationary piece O are arranged along the longitudinal direction so as to provide alternately N- and S-poles.

[0114] The position of the movable piece i is detected by a sensor, and the direction of the current passing the exciting coil **71** at the detected position is changed sequentially reversely. The exciting coil **71** generates a thrust force in accordance with the Fleming's left-hand rule through the relative reaction between the exciting coils **71** and the magnets **72**.

[0115] In the case where such linear D.C. motor is utilized, two sets of linear motors **51** and **52** are disposed in the back-to-back arrangement, and in an arrangement that a distance between the adjacent secondary side magnets **72**, **72** is short, there causes a fear that an alternating magnetic field is caused between the magnets **72** and **72**, which may cause a defective operation. Accordingly, in the case where two sets of the linear motors **51** and **52** are used in the back-to-back arrangement, the linear induction motor **53** and the linear pulse motor **57**, which do not utilize the secondary side magnets **72**, could be effectively utilized. However, in an arrangement in which a relatively large distance could be maintained on the secondary side, no adverse effect is not caused between the magnets **72** and **72**, so that the linear D.C. motor **70** may be utilized.

[0116] The drive system incorporated with the linear motors **51** and **52** of the structures mentioned above will operate in the following manner.

[0117] When the current is applied to the movable pieces i and i' of the first and second linear motors **51** and **52**, suction (attracting) force acts between the movable pieces i and i' and the stationary pieces O and O' to thereby move the inner rail **8** with respect to the outer rail **7** by a predetermined distance in the longitudinal direction thereof. In this case, the movable piece i of the first linear motor **51** moves forward with respect to the stationary piece O. However, with the second linear motor **52**, a current is applied to the movable piece i' in a backward movement direction with respect to the stationary piece O' because of the movement of the stationary piece O', and as a reaction motion thereto, the stationary piece O' is moved forward. Hence, the inner rail **8** is slid with respect to the outer rail **7**, and therefore, the entire structure of the drive system is expanded and contracted.

[0118] In the structure utilizing the linear motors **51** and **52** as driving source, it is not necessary to utilize a ball screw or like, and hence, the inner rail can be moved at high speed with less noise. Furthermore, there is no need for locating a space for a rotary motor or like, thus making the drive system thin and compact in its structure. Still furthermore, since the two sets of linear motors **51** and **52** are arranged between the inner rail **8** and the outer rail **7**, two times of the thrust force is obtainable and the excitation of the linear motors **51** and **52** is averaged, thus making smooth the movement of the inner rail **7**.

[0119] Still furthermore, the movable piece i of the first linear motor **51** is mounted to a portion near the outer rail side rolling member circulation passage **14** and the movable piece i' of the second linear motor **52** is mounted to a portion near the inner rail side rolling member circulation passage **16**, the points on which the thrust force is applied are always positioned at portions near the the outer rail side rolling member circulation passage **14** and the inner rail side rolling member circulation passage **16** irrespective of the stroke of the inner rail **8**. The inner rail **8** is supported by the outer rail **7** at the positions of the inner rail side rolling member circulation passage **16** and the outer rail side rolling member circulation passage **14**. Accordingly, even if a moment causing pitching or yawing acts on the inner rail **8**, the thrust force can be stably generated for the inner rail **8**.

[0120] **FIG. 19** represents a drive system according to a further embodiment of the present invention. The drive system of this embodiment is incorporated with two sets of rod-type linear motors as first and second linear motors **51** and **52**. This drive system is also composed of, like the drive system mentioned hereinbefore, an outer rail **7**, an inner rail **8** supported by the outer rail **7** to be slidable in the longitudinal direction thereof and first and second linear motors **51** and **52** disposed between the outer rail **7** and the inner rail **8** both having box-shaped sections so that the inner rail **8** is fitted into the outer rail **8**. First and second rod-type linear motors are composed of rods O and O' as stationary pieces and cylindrical coils i and i' as movable pieces.

[0121] The cylindrical coil i of the first rod-type linear motor **51** is mounted to the front end portion of the outer rail **7** and, to this front end portion, is also mounted an outer rail side bearer **75** supporting the rod O' of the second rod-type linear motor to be slidable in an axial direction thereof. On the other hand, the cylindrical coil i of the second rod-type linear motor **52** is mounted to the rear end portion of the inner rail **8** and, to this rear end portion, is also mounted an inner rail side bearer **76** supporting the rod O of the first rod-type linear motor to be slidable in an axial direction thereof. The operation theory due to this arrangement is substantially the same as that of the drive system of the embodiment mentioned hereinbefore, and by operating the first and second rod-type linear motors **51** and **52**, the distance between the outer rail side bearer **75** and the inner rail side bearer **76** are expanded or contracted, thus the inner rail **8** being slid with respect to the outer rail **7**. As mentioned above, the rod-type linear motors are also usable as linear motors for the drive system of the present invention.

[0122] Description will be come back to the rolling guide device hereunder.

[0123] **FIG. 20** is a partial sectional view of a drive system using a rolling guide device of a further embodiment of the present invention. The rolling guide device of this embodiment comprises, like the rolling guide device shown in FIGS. **1** to **3**, an outer rail **7** as track rail and an inner rail **8** as movable rail supported to be slidable in the longitudinal direction of the outer rail **7**, and hence, like reference numerals are added to elements or members corresponding to those shown in FIGS. **1** to **3**. The embodiment of **FIG. 20** is provided with a ball screw **9** for driving the inner rail **8**.

[0124] In the rolling guide device of the aforementioned embodiment, although the outer rail **7** and the inner rail **8** are formed with single ball rolling groove to each side portion thereof, in the rolling guide device of this embodiment, the outer rail **7** and the inner rail **8** are formed with two ball rolling grooves **11, 11** (totally four grooves) to each side portion thereof as shown in **FIG. 20** in section. That is, in the rolling guide device of this embodiment, upper and lower two ball rolling grooves **11, 11** are formed respectively to each of the inside surfaces of the opposing ridges **7***b*, **7***b* of the outer rail **7**, i.e. four ball rolling grooves **11, 11** for the outer rail **7**. On the other hand, upper and lower two loaded ball rolling grooves **15, 15** are formed respectively to each of the outside surfaces of the opposing ridges **8***b*, **8***b* of the inner rail **8**, i.e. four loaded ball rolling grooves **15, 15** for the inner rail **8** so as to oppose to the ball rolling grooves **11, 11** of the outer rail **7**, respectively.

[0125] An outer rail side ball circulation passage **14** for circulating the balls rolling between the inner rail **8** and the outer rail **7** is provided to one end side in the longitudinal direction of the outer rail **7** as like as that of the rolling guide device mentioned hereinbefore. This outer rail side ball circulation passage **14** is composed of upper and lower two passages, and more concretely, is composed of portions of the ball rolling grooves **11, 11**, ball return passages A, A as rolling member return passages substantially parallel to the ball rolling grooves **11, 11** and a pair of rolling direction changing passages communicated with the ball rolling grooves **11, 11** and the ball return passages A, A.

[0126] An inner rail side ball circulation passage **16** for circulating the balls rolling between the inner rail **8** and the outer rail **7** is provided to one end side in the longitudinal direction of the outer rail **7** on the side opposing to the outer rail side ball circulation passage **14**. This inner rail side ball circulation passage **16** is composed of upper and lower two passages, and more concretely, is composed of portions of the loaded ball rolling grooves **15, 15**, ball return passages A, A as rolling member return passages substantially parallel to the loaded ball rolling grooves **15, 15** and a pair of rolling direction changing passages communicated with the ball rolling grooves **11, 11** and the ball return passages A, A.

[0127] In the illustration of **FIG. 20**, although it seems that the outer rail side ball circulation passage **14** and the inner rail side ball circulation passage **16** are positioned on the same sectional surface, in an actual arrangement, the outer rail side ball circulation passage **14** and the inner rail side ball circulation passage **16** are shifted in their positions as shown in **FIG. 1**.

[0128] The rolling direction changing passages, each having a semi-circular shape, constituting portions of the outer rail side ball circulation passage **14** and the inner rail side ball circulation passage **16** are formed to deflectors **79** mounted, as independent members, to the inner rail body **8***d* and the outer rail body **7***d*. The deflector **79** is utilized commonly for the outer rail side ball circulation passage **14** and the inner rail side ball circulation passage **16** and is provided with vertical two rolling direction changing passages. The deflector **79** is composed of three sections **79***a*, **79***b* and **78***c* which are splittable vertically along the rolling direction changing passage for easy formation of the vertical two tolling direction changing passages. These three splittable sections **79***a*, **79***b* and **78***c* are divided vertically at planes including central lines of the rolling direction changing passages. These three sections **79***a*, **79***b* and **78***c* are positioned and assembled with each other through fitting of dowels and holes formed to the respective sections. Furthermore, the deflector **79** is formed with a stepped abutment portion **29** to position the deflector **79** at the time when it is mounted to the inner rail side ball circulation passage **16** and the outer rail side ball circulation passage **14**. Holes **33** are formed to the outer rail body **7***d* and the inner rail body **8***d* from the sides thereof, and stepped portions **33***a* are formed to inside surfaces of these holes **33**. Accordingly, the deflector **79** is positioned with respect to the outer rail body **7***d* and the inner rail body **8***d* through the abutment of the stepped abutment portion **29** against the stepped portions **33***a* formed to the holes **33**, i.e. outer rail body **7***d* and the inner rail body **8***d*.

[0129] The ball screw **9** is screw-engaged with the inner rail **8**. This ball screw **9** is composed of a screw shaft **10** having an outer periphery on which a spiral ball rolling groove is formed, a nut (member) **22** having an inner periphery to which a ball circulation passage including a spiral loaded ball rolling groove corresponding to the ball rolling groove formed to the screw shaft **10** and assembled with the screw shaft **10** to be relatively movable thereto, and a number of balls arranged in the ball circulation passage and circulating in accordance with the relative movement of the nut member **22** with respect to the screw shaft **10**.

[0130] **FIG. 21** illustrates a contacting state of the ball rolling groove **11**, the loaded ball rolling groove **15** and the ball **12** or **13**. The ball rolling groove **11** is formed as a single circular groove, so-called, circular arc groove, having a diameter slightly larger than a diameter of the ball so that the ball **12 (13)** contacts the ball rolling groove **11** at one point P1. On the other hand, the loaded ball rolling groove **15** is formed as a single circular groove, so-called, circular arc groove, having a diameter slightly larger than a diameter of the ball so that the ball **12 (13)** contacts the loaded ball rolling groove **15** at one point P2. Further, it is to be noted that a line L connecting the contact point P1 at which the ball **12 (13)** and the ball rolling groove **11** are contacted and the contact point P2 at which the ball **12 (13)** and the loaded ball rolling groove **11** are contacted is defined herein as contact angle line L. In this meaning, the contact angle lines L1, L2, L3 and L4 will be defined as shown in **FIG. 20**.

[0131] That is, with reference to **FIG. 20**, the mutually opposing two ball rolling grooves **11, 11** and the two loaded ball rolling grooves **15, 15** are offset from each other so that the vertical two lines L1 and L2 are inclined towards the horizontal line H passing the center of the screw shaft **10** while reducing a distance therebetween.

[0132] Further, it is desired that a contact angle constituted by the contact angle line L1 (L2) and the horizontal line H is approximately 45°. The center of the screw shaft **10** is positioned on the line passing the intermediate portion between the ball rolling grooves **11, 11** and on the central line of a span of the loaded ball rolling grooves **15, 15**. Furthermore, it is desired that the center of the screw shaft **10** (center of the thrust force of the ball screw **9**) is also positioned on a line connecting a point P3 of the left side contact angle lines L1 and L2 and a point P4 of the right side contact angle lines L1 and L2.

[0133] The moment load as shown in **FIG. 8** will be easily loaded on the rolling guide device of the present invention, and accordingly, the vertical load will be also easily born by the balls **12** and **13**. However, the contact angle lines L1 and L2 between the balls **12, 13** and the ball rolling grooves **11, 11** and between the balls **12, 13** and the loaded ball rolling grooves **15, 15** are inclined with respect to the horizontal line H, thus the vertical load acting on the inner rail **7** being effectively born by the balls **12, 13**. For this reason, the moment load as shown in **FIG. 8** can be surely loaded. Particularly, by setting the inclination angle to 45°, loads acting on the inner rail **7** from vertical and lateral four directions can be effectively supported by the balls **12** or **13**. Furthermore, the ball screw **9** may be smoothly operated by positioning the center of the thrust force of the ball screw **9** on the line connecting the crossing point P3 of the left side contact angle lines L1 and L2 and the crossing point P4 on the right side contact angle lines L1 and L2.

[0134] **FIG. 22** illustrates a contacting state of a ball rolling groove **11***b*, a loaded ball rolling groove **15***b* and the ball **12 (13)** in a rolling guide device in which one ball rolling groove **11***b* and one loaded ball rolling groove **15***b* are formed laterally as like as the rolling guide device shown in **FIGS. 1 and 3**. The ball rolling groove **11***b* and the loaded ball rolling groove **15***b* are each formed as a Gothic arch groove. That is, by forming so-called Gothic arch groove in combination of the ball rolling groove **11***b* and the loaded ball rolling groove **15***b* into two circular arcs, two contact angle lines L3 and L4 inclined from the horizontal line H can be obtained to thereby effectively support the vertical load by the ball **12, 13**.

[0135] **FIG. 23** is an illustration of one embodiment, partially in section, of an essential portion of a drive system utilizing a rolling guide device using rollers **80** as rolling members. In this embodiment, the rollers **80** are utilized in place of the balls **12, 13** in the former embodiments. In this embodiment of **FIG. 23**, the outer rail **7** is provided with ridges **7***b*, **7***b* as mentioned before having opposing inside surfaces **7***c*, **7***c* to which roller rolling grooves **81**, each having a V-shaped section with opening angle of 90°, are formed, respectively. On the other hand, the inner rail **8** has the opposing outside surfaces **8***c*, **8***c* to which loaded roller rolling grooves **82**, each having a V-shaped section with opening angle of 90°, are formed, respectively. Therefore, a roller rolling passage having substantially square cross section is defined between the roller rolling groove **81** and the loaded roller rolling groove **82**. Within this roller rolling passage, a plurality of rollers **80, 80**, - - - are arranged in shape of cross (cross arrangement) so that axes of the adjacent two rollers **80** cross each other.

[0136] The structure of this embodiment other than the above mentioned structure is substantially the same as that of the rolling guide device mentioned with reference to FIGS. **1** to **3**, so that the description thereof is omitted herein by adding the same reference numerals to the corresponding portions or elements.

[0137] According to this embodiment, in which the rollers **80, 80**, - - - are arranged in crossing shape, the rollers **80** can effectively support the vertical load.

[0138] **FIG. 24** is an illustration of another embodiment, partially in section, of an essential portion of a drive system utilizing a rolling guide device using rollers **83, 84** as rolling members. In this embodiment, the outer rail **7** is provided with ridges **7***b*, **7***b* having opposing inside surfaces **7***c*, **7***c* each to which vertical two roller rolling grooves **81, 81** each having a V-shaped section with opening angle of 90°, are formed, respectively. On the other hand, the inner rail **8** has the opposing outside surfaces **8***c*, **8***c* each to which two loaded roller rolling grooves **82, 82** each having a V-shaped section with opening angle of 90°, are formed, respectively. Therefore, vertical two roller rolling passages each having substantially square cross section are defined between the roller rolling grooves **81, 81** and the loaded roller rolling grooves **82, 82**. Within these roller rolling passages, a plurality of rollers **83, 84** are arranged in parallel to each other (parallel arrangement) so that axes of the adjacent two rollers are parallel to each other.

[0139] The rollers **83** disposed in the upper side roller rolling passage are arranged so as to support the load acting in the direction shown by the line L5 (different from the horizontal line H), and on the other hand, the rollers **84** disposed in the lower side roller rolling passage are arranged so as to support the load acting in the direction shown by the line L6 (different from the horizontal line H). Angles constituted by the line L5 and the horizontal line H and by the line L6 and the horizontal line H are defined approximately 45°, respectively. The structure of this embodiment of **FIG. 24** other than the above-mentioned structure is substantially the same as that of the rolling guide device mentioned with reference to **FIG. 20** so that the description thereof is omitted herein by adding the same reference numerals to the corresponding portions or elements.

[0140] According to this embodiment of **FIG. 24**, in which the rollers **83** and **84** are arranged in the vertical two roller rolling passages and the directions along which the rollers **83** and **84** can bear the loads are inclined with respect to the horizontal line H, so that the rollers **83** and **84** can effectively support the vertical loads.

[0141] According to the various preferred embodiments or examples of the present invention mentioned above, the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage, in which the rolling members rolling between the track rail and the movable rail circulate, are formed to the track rail and the movable rail, respectively. Therefore, when the movable rail is slid with respect to the track rail, the rolling members arranged between the track rail and the movable rail endlessly circulate in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage while rolling therealong. As mentioned, since the rolling members circulate in the endless manner, even if the rolling member be slid during the rolling motion, there is no causing of a case that a cage is shifted from the initial position as in the conventional structure, and hence, a large expansion (contraction) stroke can be realized. Furthermore, in an optional expanded (contracted) attitude, there remains a relatively large distance between the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage, so that a rolling guide device, which can bear even the moment load, can be realized.

[0142] Furthermore, according to the present invention, since the linear motor means is incorporated between the track rail and the movable rail, no specific ball screw or like mechanism is needed, so that the movable rail can be moved at high speed with reduced noise.

[0143] It is further to be noted that the present invention is not limited to the described embodiments and many other changes and modifications may be made without departing from the scopes of the appended claims.

What is claimes is:

1. A rolling guide device comprising:

a track rail formed with a rolling member rolling surface extending along a longitudinal direction thereof;

a movable rail formed with a loaded rolling member rolling surface extending along a longitudinal direction thereof so as to oppose to the rolling member rolling surface of the track rail;

a track rail side rolling member circulation passage formed to the track rail so as to circulate the rolling members rolling between the track rail and the movable rail;

a movable rail side rolling member circulation, passage formed to the movable rail so as to circulate the rolling members rolling between the track rail and the movable rail; and

a number of rolling members disposed and arranged in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage.

2. A rolling guide device according to claim 1, wherein said track rail side rolling member circulation passage is formed to one longitudinal end side of the track rail and said movable rail side rolling member circulation passage is formed to one longitudinal end side, opposing to said one end side of the track rail, of the movable rail.

3. A rolling guide device according to claim 1, wherein said track rail has an opened recess having a ⊐-shaped section and has inside surfaces to which said rolling member rolling surfaces are formed, said movable rail is fitted into the recess of the track rail, and said movable rail has outside surfaces to which the loaded rolling member rolling surfaces are formed so as to oppose to the rolling member rolling surfaces formed to the track rail inside surfaces.

4. A rolling guide device according to claim 3, wherein said track rail side rolling member circulation passage is provided with a rolling member return passage substantially parallel to said rolling member rolling surface and a rolling direction changing passage communicating the rolling member rolling surface and the rolling member return passage, said movable rail side rolling member circulation passage is provided with a rolling member return passage substantially parallel to said loaded rolling member rolling surface and a rolling direction changing passage communicating the rolling member rolling surface and the rolling member return passage, said rolling direction changing passages of the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage are formed to a deflector which is formed independently from a track rail body and a movable rail body, and said deflector is fitted to holes formed to the track rail body and movable rail body from side portions thereof.

5. A rolling guide device according to claim 4, wherein said return passages are drilled to the track rail body and the movable rail body from longitudinal end portions thereof.

6. A rolling guide device according to claim 4, wherein said deflector is composed of a plurality of sections splittable along the rolling direction changing passages.

7. A rolling guide device according to claim 4, wherein said deflector is made of a synthetic resin.

8. A drive system comprising:

a track rail formed with a rolling member rolling surface extending along a longitudinal direction thereof;

a movable rail formed with a loaded rolling member rolling surface extending along a longitudinal direction thereof so as to oppose to the rolling member rolling surface of the track rail;

a track rail side rolling member circulation passage formed to the track rail so as to circulate the rolling members rolling between the track rail and the movable rail;

a movable rail side rolling member circulation passage formed to the movable rail so as to circulate the rolling members rolling between the track rail and the movable rail;

a number of rolling members disposed and arranged in the track rail side rolling member circulation passage and the movable rail side rolling member circulation passage; and

a linear motor means having a primary side mounted to either one of the track rail and the movable rail and a secondary side mounted to another one of the track rail and the movable rail.

9. A drive system according to claim 8, wherein said track rail side rolling member circulation passage is formed to one longitudinal end side of the track rail and said movable rail side rolling member circulation passage is formed to one longitudinal end side, opposing to said one end side of the track rail, of the movable rail, and said linear motor means comprises first and second linear motors, said first linear motor having a primary side mounted to a portion near the track rail side rolling member circulation passage of the track rail, said second linear motor having a secondary side mounted to the track rail along the longitudinal direction thereof so as to be continuous to the primary side of the first linear motor, and said second linear motor having a primary side mounted to a portion near the movable rail side rolling member circulation passage of the movable rail, said first linear motor having a secondary side mounted to the movable rail along the longitudinal direction thereof so as to be continuous to the primary side of the second linear motor.

10. A drive system according to claim 9, wherein said first and second linear motors are linear induction motors having secondary sides being opposed to each other.

11. A drive system according to claim 9, wherein said first and second linear motors are linear pulse motors having secondary sides being opposed to each other.

12. A drive system according to claim 8, wherein said track rail has an opened recess having a ⊐-shaped section and has inside surfaces to which said rolling member rolling surfaces are formed, said movable rail is fitted into the recess of the track rail, and said movable rail has outside surfaces to which the loaded rolling member rolling surfaces are formed so as to oppose to the rolling member rolling surfaces formed to the track rail inside surfaces.

(57) **ABSTRACT**

A motion guide device generally comprises a track member having a horizontal surface and two side surfaces continuous to the horizontal surface, a movable member mounted to the track member to be relatively movable with respect to the track member along a longitudinal direction thereof, and a cover member covering the horizontal surface of the track member along an entire width direction thereof. The track member is formed with undercut portions formed to side edge portions of the side surfaces of the track member on the horizontal surface sides, and the undercut portions are recessed towards a central side of the track member in the width direction thereof. The cover member comprises a central flat portion and engaging portions formed at both end portions in the width direction thereof to be engaged with the undercut portions, respectively, so as to clamp the track member therebetween in the width direction. Each of the engaging portions comprises an intermediate section to be engaged with the undercut portion of the track member and a front end section bent outward from the intermediate section so as to be opened outward in the width direction of the track member.

MOTION GUIDE DEVICE

[0001] The present application claims priority under 35 U.S.C § 119 to Japanese Patent Application No.2000-46756, filed Feb. 18, 2000 entitled "MOTION GUIDE DEVICE" The contents of that application are incorporated herein by reference in their entirety.

BACKGROUND OF THE INVENTION

[0002] The present invention relates to a motion guide device for guiding a movable member along a predetermined track member, and more particularly, to a motion guide device capable of covering an opening for attachment formed on an upper surface of the track member by a cover covering an entire area in a width direction of the upper surface thereof.

[0003] As a device for guiding a movable member such as table of a machine tool in a predetermined direction, there is known a motion guide device constituted by mounting a movable member to a track member by means of a number of rolling members. In such device, the track member or movable member is fixed to a stationary portion of a machine, or the movable member or track member is fixed to a movable portion of the machine. The track member is formed with a plurality of bolt mounting holes for fixing the same so as to penetrate vertically the track member. However, according to a use of such guide device, there is a case where foreign bodies invade in the bolt-mounting hole and is bitten by a seal of the movable member, thus causing a trouble.

[0004] In order to solve such trouble or problem, there has been proposed a device in which a track member is entirely covered by a cover to also cover the bolt mounting holes. **FIG. 5 (FIGS. 5A and 5B)** shows a cover mounting structure, as one example of such device, in a motion guide device disclosed in the Japanese Patent Publication No. 2719985. In a device **1** shown in **FIG. 5, a** cover **3** is disposed for covering a track member **2** at an entire area in the width direction (lateral direction as viewed) of an upper surface **2***a* of the track member **2**, undercut portions **4** are formed to both side surface portions **2***a* of the track member **2** at portions continuous to the upper surface **2***a* of the track member **2** through a round corner portions, and engaging portions **3***a* are formed to both the edge portions of the cover **3** to be tightly contacted to contact surfaces **4***a* of the undercut portions **4**.

[0005] Furthermore, in the structure shown in **FIG. 5**, an angle α constituted by a central portion **3***b* of the cover **3** and the engaging portion **3***a* thereof is set to be smaller than an angle β constituted by the contact surface **4***a* of the undercut portion **4** and the upper surface **2***a* of the track member **2**. Accordingly, at a time when the cover **3** is applied to the track member **2**, if the cover **3** is forcibly pushed to the track member **2** such that the central portion **3***b* of the cover **3** is contacted to the upper surface **2***a* of the track member **2** with the engaging portion **3***a* of the cover **3** being engaged with the contact surface **4***a* of the undercut **4**, the engaging portion **3***a* of the cover is elastically deformed so as to be opened outward, and hence, the engaging portion **3***a* is closely contacted to the contact surface **4***a* of the undercut **4** by its elastic restoring force, thus firmly holding the cover **3** on the track member **2**. Further, it is noted that, in **FIG. 5**, although only one end side in the width direction of the track member **2** is shown, the other one end side thereof is also formed symmetrically with the mentioned one end side.

[0006] In the structure mentioned above, the engaging portion **3***a* gets into most inward, at its front (lower) end portion, in the width direction of the track member **2**, and therefore, it is impossible to engage both the lateral pair of engaging portions **3***a* at the same time with the undercut portions **4**.

[0007] Accordingly, the cover **3** is mounted to the track member **2** in the following manner.

[0008] First, as shown in **FIG. 5**B, the cover **3** is inclined (tilted) from the horizontal surface so that one engaging piece **3***a* is engaged with a corresponding one undercut portion **4**. Under this state, the cover **3** is pulled towards the opposite side engaging portion **3***a* as shown with an arrow A and forcibly fitted to the upper surface of the track member **2** to thereby engage the opposite side engaging portion **3***a* with a corresponding undercut portion **4**.

[0009] In such mounting structure, although the come-off of the cover **3** may be surely prevented, it is required to largely elastically deform the one side engaging portion **3***a* at the mounting time, and accordingly, this engaging portion **3***a* may be plastically deformed in a case when this mounting working is not well performed. Furthermore, when the cover **3** is removed, there is a case where the engaging portion **3***a* of the cover **3** tightly contacts the contacting surface **4***a* of the undercut portion **4** and the cover **3** is hence not easily peeled therefrom. In such case, it is obliged to gradually peel off (remove) the engaging portion **3***a* from both the longitudinal end portions of the track member **2**, which requires much working time and labor for a worker, and moreover, at a time of peeling off the engaging portion **3***a,* there may cause an unnatural twisting force which may plastically deform the engaging portion **3***a*.

SUMMARY OF THE INVENTION

[0010] An object of the present invention is to substantially eliminate defects or drawbacks encountered in the prior art mentioned above and to provide a motion guide device capable of easily mounting or dismounting (removing) a cover covering an upper surface of a track member without giving any damage to the cover during the mounting (dismounting) working time.

[0011] This and other objects can be achieved according to the present invention by providing a motion guide device comprising:

[0012] a track member having an upper surface and two side surfaces continuous to the upper surface;

[0013] a movable member mounted to the track member to be relatively movable with respect to the track member along a longitudinal direction thereof; and

[0014] a cover member covering the upper surface of the track member across an entire width direction thereof,

[0015] the track member being formed with undercut portions formed to side edge portions of the side surfaces of the track member on the upper surface side thereof, the undercuts being recessed towards a central side of the track member in the width direction thereof and

[0016] the cover member comprising a central flat portion and engaging portions formed at both end portions in the width direction thereof to be engaged with the undercut portions, respectively, so as to clamp the track member therebetween in the width direction, each of the engaging portions comprising an intermediate section to be engaged with the undercut portion of the track member and a front end section bent outward from the intermediate section so as to be opened outward in the width direction of the track member.

[0017] In the above aspect, it is to be noted that the term "upper" surface of the track member means a surface opposite to a lower surface in a case of providing that a mounting (mount) surface of the track member with respect to an object member is considered to be "lower" surface. Therefore, it is not absolute for this surface to direct the "upper" direction in an actual use, and in claims of the subject application, this term of "upper" surface is referred to as "horizontal" surface with reference to two side surfaces of the track member.

[0018] Furthermore, the movable member is mentioned as a member to be relatively movable with respect to the track member, and the motion guide device of the present invention is not limited to the structure in which the movable member is itself moved in use.

[0019] In a preferred embodiment of the aspect mentioned above, an outline of the intermediate section and the front end section is curved in a circular shape towards the central side of the track member in the width direction thereof. The engaging portion of the cover member has an elasticity so that both the engaging portions are simultaneously engaged with the undercut portions of the track member. That is, the cover member is formed of a plate member having an elasticity so that the central portion of the cover member is engaged with the upper surface of the track member and both the engaging portions of the cover member are simultaneously engaged with the undercut portions of the track member by depressing the flat portion of the cover member to the upper surface of the track member.

[0020] The cover member has a longitudinal dimension substantially equal to that of the track member.

[0021] The upper surface and the side surfaces of the track member are continuous to each other through round portions and each of the engaging portions of the cover member further comprises a base section curved outward from the intermediate section so as to coincide in shape with the round portion of the track member.

[0022] The track member is formed with openings to the upper surface thereof.

[0023] According to the present invention of the structures mentioned above, the front end sections of the engaging portions of the cover member are opened outward from the intermediate portions thereof, so that, by placing the engaging portions to the end edges of the upper surface of the track member and then pushing the cover member towards the upper surface of the track member, the engaging portions are elastically deformed outward and slid over the continuous round portion connecting the upper surface of the track member and the side surfaces thereof and the intermediate sections of the engaging portions are engaged with the recessed undercut portions of the track member. On the other hand, when the cover member is removed from the track member, the outward opened front end sections of the engaging portions are grasped and pulled upward, thus being easily removed. Since such working can be done without applying a large force locally, the cover member cannot be deformed.

[0024] The circularly curved shape of the intermediate section and the front end sections of the engaging portions can allow the engaging portions to be easily elastically deformed at the time of being attached to or removed from the track member and the working efficiency can be improved. The deformation of the cover member can be also prevented.

[0025] The cover member can be easily fitted to the track member by simultaneously fitting the engaging portions to the undercut portions of the track member.

[0026] The nature and further characteristic features of the present invention will be made more clear from the following descriptions made with reference the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

[0027] In the accompanying drawings:

[0028] **FIG. 1** is a developed perspective view showing an entire structure of the motion rolling guide device according to the one embodiment of the present invention;

[0029] **FIG. 2** is a cross sectional view of a track shaft member of a motion rolling guide device according to one embodiment of the present invention;

[0030] **FIG. 3** is a partial enlarged view of a portion III in **FIG. 2**;

[0031] **FIG. 4** includes views of **FIGS. 4A and 4B** showing one example of a cover forming process for the motion rolling guide device; and

[0032] **FIG. 5** includes views for showing mounting processes of the cover of the motion rolling guide device in a prior art in which **FIG. 5A** is a view showing a cover before the mounting to a track shaft (member) of the motion rolling guide device and **FIG. 5B** is a view showing the cover which is mounting to the track shaft.

DESCRIPTION OF THE PREFERRED EMBODIMENT

[0033] FIGS. **1** to **4** represent one preferred embodiment of the present invention.

[0034] First, with reference to **FIG. 1, a** motion rolling guide device **10** of the present invention will be described. The motion rolling guide device comprises a track member **11**, a movable member **12** mounted to the track member **11** to be relatively movable in a longitudinal direction of the track member **11**, a plate cover (cover plate) **14** covering an upper surface of the track member **11** and an inner seal **15** disposed between the movable member **12** and the plate cover **14**. The movable member **12** is mounted to the track member **11** with a number of rollers as rolling members, not shown, being interposed therebetween. In the illustration of **FIG. 1**, although the plate cover **14** has a length shorter than that of the track member **11** in the longitudinal direction thereof, in an actual structure, the plate cover **14** has substantially the same longitudinal length as that of the track member **11**.

[0035] The track member **11** is formed of a material having a high rigidity such as steel, and a number of bolt mounting holes **11***b*, **11***b*, - - - , **11***b* are formed to the upper surface **11***a* of the track member **11** so as to vertically penetrate it for mounting or attaching the track member **11** to a machine part, machine tool or the like. Two rows of roller rolling surfaces, i.e. raceways, along which the rollers travel, are formed to each of side surfaces **11***c*, **11***c* of the track member **11**.

[0036] The movable member **12** comprises a block body **20**, a pair of end plates **23, 23** attached to both longitudinal end portions of the block body **20** and end seals **25, 25** mounted to outer surfaces of the end plates **23, 23** by means of screws **26, 26**, - - - , **26**.

[0037] The block body **20** is formed, as like as the track member **11**, of a material having a high rigidity such as steel and has a lower surface (in an illustrated state) to which a recessed portion **20***a* is formed so as to receive the track member **11**. The recessed portion **20***a* has an inner wall section to which lateral two roller rolling surfaces, not shown, are formed respectively so as to oppose to the rolling surfaces **11***d* of the track member **11**, and loaded rolling passages for the rollers are formed along these rolling surfaces. Inside the block body **20**, a return passage for returning the rollers from one end portion of the loaded rolling passage to the other end portion thereof, and rolling direction changing passages are formed inside the end plates, respectively, so that each connects the return passage and the loaded rolling passage. Accordingly, an endless circulation passage is composed of a pair of loaded rolling passages, the return passage and a pair of rolling direction changing passages connecting the loaded rolling passages and the return passage, and two such endless circulation passages are formed to each of the lateral side portions of the track member **11**, that is, four endless circulation passages are formed in total.

[0038] The inner seal **15** in shape of plate, as shown in **FIG. 1**, is composed of a base member **15***a* formed of a steel plate, for example, lips, not shown, formed to a lower surface thereof and lips **15***b*, **15***b*, - - - , **15***b* for buffer function formed to an upper surface thereof. In an assembling process, both end portions of the inner seal **15** are inserted into recessed portions, not shown, formed to inner surfaces of the end plates **23** and held between both the end plates **23, 23** in the longitudinal direction of the track member **11** so as to prevent the inner seal **15** from coming off in its longitudinal direction. Further, each of the recessed portions formed to the end plates **23, 23** has a vertical thickness (direction normal to the upper surface **11***a* of the track member **11**) larger than a thickness of the end portion of the inner seal plate **15** so that the inner seal plate **15** is idly movable in the vertical direction between the end plates **23, 23**. The lips formed to the lower surface of the inner seal **15** contact the plate cover **14** to thereby prevent foreign bodies from entering into the loaded rolling passage and prevent lubricant such as grease from leaking from the loaded rolling passage.

[0039] The structure and the mounting manner of the cover plate **14** will be explained hereunder with reference to FIGS. **1** to **3**.

[0040] With reference to **FIG. 2** as a sectional view, undercuts **11***e*, **11***e* are formed to side edge portions (upper end portions) of both the side surfaces **11***c*, **11***c* of the track member **11** so as to be recessed in a width direction of the track member **11**. The plate cover **14** has a width approximately the same as the upper surface **11***a* of the track member **11** and has a flat central surface **14***a* in its width direction. The plate cover **14** also has both end portions to which engaging portions **14***b*, **14***b* are engaged with the undercuts **11***e*, **11***e* so as to embrace the track member **11** in the width direction thereof.

[0041] As shown in **FIG. 3**, in an enlarged scale, a connecting portion between the upper surface **11***a* of the track member **11** and the side surface **11***c* thereof is formed as a curved portion **11***f* (i.e. round portion having a radius of curvature R) so as to describe a circular curve bulged outward, and accordingly, the undercut **11***e* is formed so as to be hollowed out like a groove towards the central side in the width direction of the track member **11** from the lower end portion of the curved portion **11***f*. The undercuts **11***e* and the curved portions **11***f* are symmetrically formed at both the end portions in the width direction of the track member **11** so as to extend along the entire longitudinal direction thereof.

[0042] As best shown in **FIG. 3** as a cross sectional view of the track member **11**, the engaging portion **14***b* of the plate cover **14** comprises an intermediate (central) section **14***c* curved inside towards the central portion in the width direction of the track member **11** so as to be coincident with the recessed shape of the undercut **11***e*, a front end section **14***d* curved outward from the intermediate section **14***c* so as to be opened outward and a base section **14***e* curved outward from the intermediate section **14***c* so as to provide a shape coincident with the curved round portion **11***f* of the track member **11**. The flat upper surface **11***a* is continuous to the undercuts **11***e* through round portions **11***f* to which the base sections **14***e* of the engaging portions **14***b* are tightly contacted. And an outline of the intermediate section **14***c* and the front end section **14***d* is curved in a circular shape towards the central side of the track member **11** in the width direction thereof.

[0043] According to the structure mentioned above, the front end section **14***d* of the engaging portion **14***b* of the plate cover **14** is opened outward from the intermediate section **14***c* in the width direction of the track member **11**. Therefore, the plate cover **14** is fitted and secured to the track member **11** by abutting the respective engaging portions **14***b* against the respective curved portions **11***f* and pushing down the plate cover **14** under the mentioned state directly towards the upper surface **11***a* of the track member **11** so that the lateral paired engaging portions **14***b*, **14***b* are elastically deformed and the intermediate sections **14***c*, **14***c* of the engaging portions **14***b*, **14***b* are both simultaneously engaged with the undercuts **11***e*, **11***e* over the curved portions **11***f*, **11***f*, and the plate cover **14** is thereby secured to the track member **11**. On the other hand, when the plate cover **14** is removed from the track member **11**, the plate cover **14** will be moved upward by engaging any means with the projected (outward opened) front end sections **14***d*, **14***d* of the plate cover **14** and forcibly pulling up the plate cover **14** to thereby remove the engaging portions **14***b*, **14***b* at the same time from the undercuts **11***e*, **11***e*, that is, the plate cover **14** can be removed from the track member **11**.

[0044] With reference to **FIG. 3**, the character "X" denotes an amount to be removed from the curved portion **11***f* of the undercut **11***e*, and the value of this amount is set to be within a range in which an internal stress exceeding an elastical limit of the plate cover **14** is never caused at a time when the engaging portions **14***b* are removed over the curved portions **11***f*. For example, in one embodiment in which the track member **11** has a width of 45 mm, the value X will be set to be about 0.25 mm.

[0045] Further, the radius of curvature R of the curved portion **11***f* is set to be more than 1 mm, for example, so that the curved portion **11***f* surely remains even if a working error is caused. Furthermore, although the undercuts **11***e*, **11***e* can be formed by various working methods or processes, a grinding working may be most preferred in viewpoint of working performance.

[0046] With reference to **FIG. 2**, the width Wa between the inside surfaces of the bilateral intermediate sections **14***c*, **14***c* of the engaging portions **14***b*, **14***b* of the plate cover **14** and the width Wb between the undercuts **11***e*, **11***e* of the track member **11** are set such that the intermediate sections **14***c*, **14***c* of the engaging portions **14***b*, **14***b* tighten or clamp the track member **11** in the width direction of the track member with a suitable force at the time when the plate cover **14** is fitted to the track member **11**. Furthermore, it is desired that the width Wc between the base sections **14***e*, **14***e* of the engaging portions **14***b*, **14***b* of the plate cover **14** is set to be larger than the width Wd between the inside surfaces of the curved portions **11***f*, **11***f* of the track member **11** so as not to adversely affect on the clamping force of the plate cover **14** to the track member **11**. However, the difference between these widths Wc and Wd will also have to be set to be slight. The radius of curvature of the base section **14***e* will have to be set to be smaller than that of the curved portion **11***f*.

[0047] **FIGS. 4A and 4B** represent one example for forming the plate cover **14**. According to this example, in the step of **FIG. 4**A, both end portions of a flat steel plate **14M** as a material of the plate cover **14** are subjected to press working as shown by arrows P so as to form intermediate sections **14***c*, **14***c* of the engaging portions **14***b*, **14***b*. Both the end portions of such steel plate **14M** are then bent as shown by arrows B to thereby form the engaging portions **14***b*, **14***b* as shown in **FIG. 4B**. In this process, a mold is placed to portions (shown with arrows C), which form the base sections **14***e*, **14***e* of the engaging portions **14***b*, **14***b*, so as to work these portions to provide the radius of curvature of the base section and the widths Wa, Wc with desired or predetermined performance. The plate cover **14** may be formed by a roll forming method in place of the manufacturing method mentioned above, and other many working methods or processes may be adopted as far as the excellent working precision can be attained.

[0048] Further, it is to be noted that the present invention is not limited to the described embodiment and many other changes and modifications may be made without departing from the scopes of the appended claims.

[0049] For example, the plate cover **14** may be formed from a material other than a metal material as far as the material has an elasticity capable of being repeatedly mounted to and dismounted from the track member **11** and has a friction withstanding property against the inner seal **15**. Balls may be utilized in place of the rollers as rolling members. Moreover, the present invention may be applicable to a slide guide device provided with no rolling member. Furthermore, the openings formed to the upper surface of the track member include various openings such as holes, grooves, recesses, etc. formed for various purposes other than the bolt fastening holes in the described embodiment.

What is claimed is:

1. A motion guide device comprising:

a track member having a horizontal surface and two side surfaces continuous to the horizontal surface;

a movable member mounted to the track member to be relatively movable with respect to the track member across a longitudinal direction thereof; and

a cover member covering the horizontal surface of the track member along an entire width direction thereof,

said track member being formed with undercut portions formed to side edge portions of the side surfaces of the track member, said undercut portions being recessed towards a central side of the track member in the width direction thereof and

said cover member comprising a central flat portion and engaging portions formed at both end portions in the width direction thereof to be engaged with the undercut portions, respectively, so as to clamp the track member therebetween in the width direction, each of said engaging portions comprising an intermediate section to be engaged with the undercut portion of the track member and a front end section bent outward from the intermediate section so as to be opened outward in the width direction of the track member.

2. A motion guide device according to claim 1, wherein an outline of said intermediate section and said front end section is curved in a circular shape towards the central side of the track member in the width direction thereof.

3. A motion guide device according to claim 1, wherein said engaging portions of the cover member has an elasticity so that both the engaging portions are simultaneously engaged with the undercut portions of the track member.

4. A motion guide device according to claim 3, wherein said cover member is formed of a plate member having an elasticity so that the central portion of the cover member is engaged with the horizontal surface of the track member and both the engaging portions of the cover member are simultaneously engaged with the undercut portions of the track member.

5. A motion guide device according to claim 1, wherein said cover member has a longitudinal dimension substantially equal to that of the track member.

6. A motion guide device according to claim 1, wherein the horizontal surface and the side surfaces of said track member are continuous to each other through round portions and each of said engaging portions of the cover member further comprises a base section curved outward from the intermediate section so as to coincide in shape with the round portion of the track member.

7. A motion guide device according to claim 1, wherein said track member is formed with openings to the horizontal surface thereof.

(57) **ABSTRACT**

A first invention of the subject application aims to smoothly circulate the rollers by integrally molding at least one member of the roller returning passage, the roller end surface guide wall and the direction changing portion with the block body.

Namely, at least one member of the roller returning passage forming member **91** for forming the roller returning passage **9,** the roller end surface guide wall **13** and the direction changing passage inner periphery portion forming member **12** for forming the direction changing passage inner periphery portion **10***b* is integrally molded by inserting the block body into a molding die.

A second invention of the subject application aims to realize a smooth circulation and movement of the rollers, and to prevent the running-out of the roller chain during the circulation of the roller.

Namely, the roller returning passage and the direction changing passage inner periphery guide portion are provided with a roller chain guide portion for guiding a track of the roller chain onto a predetermined track, and at least one member of roller returning passage forming member for forming the roller returning passage and direction changing passage inner periphery portion forming member for forming the direction changing passage inner periphery portion is integrally molded by inserting the block body into a molding die.

A linear roller guide device in which the rollers smoothly circulate by integrally molding at least one member of the roller returning passage, the roller end surface guide wall and the direction changing portion with the block body. The roller returning passage and the direction changing passage inner periphery guide portion are provided with a roller chain guide portion for guiding a track of the roller chain onto a predetermined track. At least one of the roller returning passage forming member for forming the roller returning passage and the direction changing passage inner periphery portion forming member for forming the direction changing passage inner periphery portion is integrally molded by inserting the block body into a molding die.

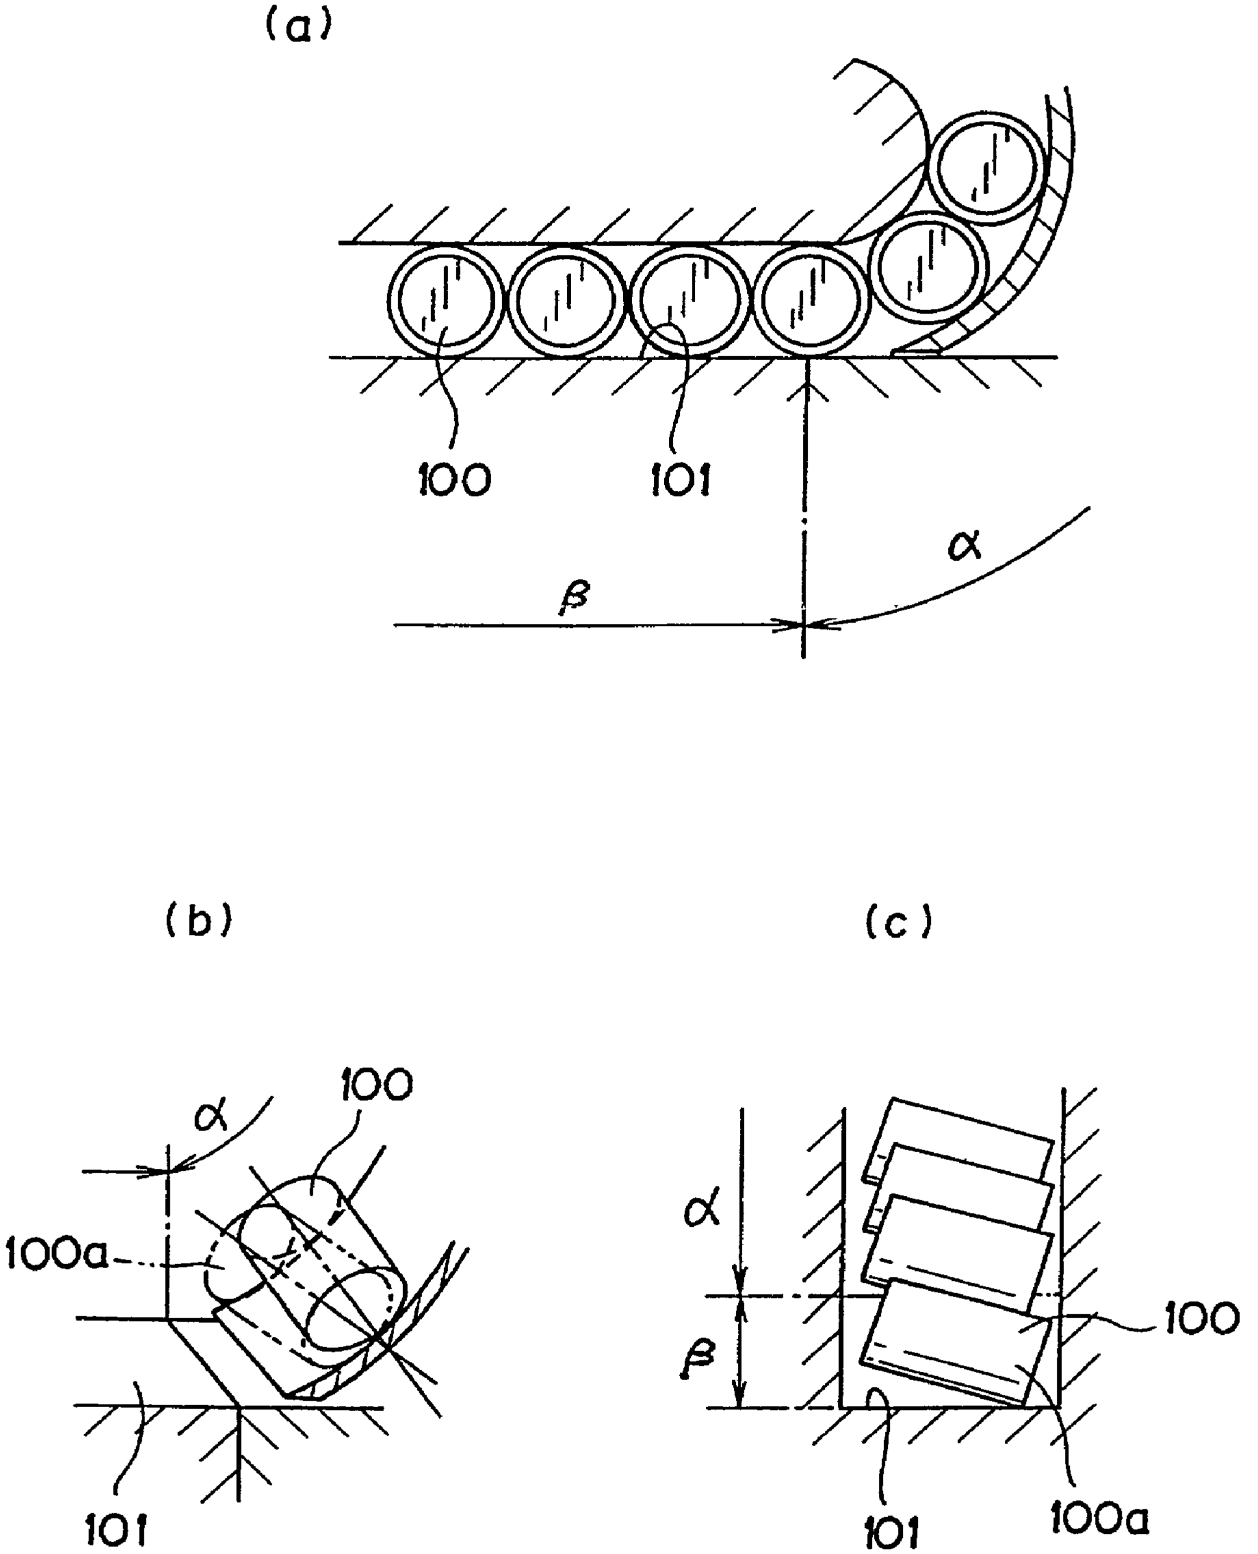
FIG. 15



LINEAR ROLLER GUIDE DEVICE

TECHNICAL FIELD

[0001] The present invention relates to a linear motion guide device, and more particularly, to a linear roller guide device using rollers as rolling elements.

BACKGROUND ART

[0002] The conventional linear roller guide device of this type generally has a structure in which a movable block is movably supported on a track rail through a number of rollers. The guide device using rollers has an advantage of high rigidity and high load bearing ability in comparison with the guide device using balls. The movable block comprises a block body and side covers to be attached to both end portions of the block body. The block body is provided with a roller rolling surface and a roller returning passage for endlessly circulating a roller row, and the side cover is provided with a direction changing passage for connecting the roller rolling surface side to the roller returning passage.

[0003] Both sides of the roller rolling surface of the movable member are provided with a roller end surface guide wall for guiding an end surface of the roller, and each of the roller returning passage and the direction changing passage is also provided with a guide wall which is formed to be continuous to the roller end surface guide wall, whereby the end surfaces of the roller are guided in entire circulating passage so as to orderly circulate the rollers.

[0004] Conventionally, as to structural members such as the roller returning passage, the side cover and the roller end surface guide wall or the like, an attempt to reduce a manufacturing cost has been made by employing resin moldings as the structural members.

[0005] However, the above conventional linear roller guide devices entail drawbacks as described hereunder:

[0006] ①The manufacturing process is complicated.

[0007] That is, each of the resin molded members is a molded member which is formed separately from the block body, so that a process of assembling the respective resin molded members is required after separately forming the respective members.

[0008] ②The circulating defects of the roller at the roller rolling surface are liable to occur.

[0009] Namely, when assembled the resin molded members, irregularities are liable to occur at a connecting portion between the roller returning passage and the direction changing passage, and at a connecting portion between the roller rolling surface and the direction changing passage, so that there may be posed a problem, for example, that a smooth circulation of the rollers is obstructed and a problem of generation of an abnormal noise.

[0010] ③The circulating defects of the roller at the roller end surface are liable to occur.

[0011] In particular, in case of the roller, it is required to prevent skew of the roller (i.e. blurring of a rotational axis of the roller). In order to prevent the skew, it is required to guide the end surface of the roller not only in a range of a loaded area of the roller rolling surface but also in all around of an endlessly circulating passage ranging from the direction changing passage to the non-loaded area of the roller returning passage.

[0012] FIG. 15(*a*) shows a state that the roller **100** changes a rolling direction thereof form an unloaded area α to a loaded area β of the direction changing passage. At the time of direction changing of the roller **100**, for example, as schematically shown in FIGS. **15**(*b*) and **15**(*c*), when the roller **100** moves from the loaded area α, and then enters into the loaded area β in a skewed state, one end portion of the roller **100***a* of the roller **100** will firstly collide against the roller rolling surface **101** in the loaded area, so that the smooth movement of the roller **100** is obstructed. In addition, an edge load may occur at the end portion **100***a* of the roller **100** entering into the loaded area β, so that the roller **100** per se and the roller rolling surface **101** are damaged thereby to deteriorate durability of the guide device. Further, vibration of the roller and changes in rolling resistance during the circulation of the rollers will occur thereby to obstruct the smooth circulation of the rollers.

[0013] In order to prevent such problems, hitherto, the end surface of the roller is formed so as to be guided by the roller end surface guide wall provided at both sides of the roller rolling surface and passage walls provided at the direction changing passage and the roller returning passage. However, since the guide system is formed by connecting the discontinuous roller end surface guide wall, direction changing passage and roller returning passage, a sticking of the roller is liable to occur due to non-uniformity in a width of the respective passages and the irregularities of the connected portions thereby to also obstruct the smooth circulation of the rollers.

[0014] ④A falling-out of the roller is required to be prevented.

[0015] On the other hand, hitherto, in order to prevent the roller from failing out from the movable block when the movable block is detached from the track rail, there is a well known structure in which a chamfered portion is provided at end portion of the roller and an engaging projection with which the chamfered portion is engaged is provided at the roller end surface guide wall formed along the roller rolling surface.

[0016] However, in case of such roller retaining system, when the engaging projection interferes with the roller during the circulation of the roller, the smooth circulation of the roller is obstructed. Therefore, when assembling the guide device, it is required to provide a small gap or clearance between the roller and the engaging projection so as not to interfere the engaging projection with the roller. However, it was difficult to provide the engaging projection to an accurate position.

[0017] In addition, the chamfered portion is required to be provided, so that an effective length for bearing the load is disadvantageously shortened in a length corresponding to the length of the chamfered portion, thereby to lower the load bearing ability.

[0018] On the other hand, there is also another well-known roller retaining system in which a number of rollers are retained in form of a chain by linking the rollers in a roller chain. However, in the case of such rollers retained in the roller chain, a problem of a running-out of the roller chain will arise during the circulation of the rollers. Therefore, it is necessary to guide the roller chain along the predetermined track. However, it was difficult to accurately guide the roller chain.

[0019] The first invention has been achieved for solving the problems described above, and an object of this invention is to provide a linear roller guide device enabling to reduce the assembling processes, to accurately position the structural members to a predetermined positions of the block body, and to secure the smooth circulation of the rollers by integrally forming at least one of the roller returning passage, roller end surface guide wall and direction changing passage with the block body.

[0020] An object of the second invention is, in addition to the object described above, to provide a linear roller guide device enabling to securely prevent the roller chain from running-out during the circulation of the rollers linked by the roller chain.

DISCLOSURE OF THE INVENTION

[0021] In order to achieve the afore-mentioned object, the first invention provides a linear roller guide device comprising a track rail and a movable block assembled to the track rail through a number of rollers,

[0022] the movable block comprising:

[0023] a roller rolling surface on which the rollers roll;

[0024] a block body having a roller returning passage corresponding to the roller rolling surface;

[0025] a direction changing passage inner periphery portion formed to both end surfaces of the block body:

[0026] a pair of roller end surface guide walls formed to both sides of the roller rolling surface of the block body and adapted to guide both the end surfaces of the roller; and

[0027] side covers each having a direction changing passage outer periphery portion for forming a direction changing passage by fitting the side cover into the direction changing passage inner periphery portion formed to both end surfaces of the block body,

[0028] the track rail including a roller rolling surface extending in an axial direction corresponding to the roller rolling surface of the block body, and

[0029] the rollers circulating in an endless circulating passage constituted by a loaded area between the roller rolling surface of the block body and the roller rolling surface corresponding to the track rail, the direction changing passage and the roller returning passage,

[0030] wherein at least one of a roller returning passage forming member for forming the roller returning passage, a roller end surface guide wall forming member for forming at least one of the paired roller end surface guide wall and a direction changing passage inner periphery portion forming member for forming the direction changing passage inner periphery portion is formed as a molded body integrally formed with the block body by inserting the block body into a molding die.

[0031] According to the structure described above, the assembling of the roller end surface guide wall forming member, the roller returning passage forming member and the direction changing passage inner periphery portion forming member is not required, thus eliminating the assembling process for the members.

[0032] In addition, the roller end surface guide wall, the roller returning passage and the direction changing passage inner periphery portion can be formed at accurate positions with respect to the block body.

[0033] After the rollers are rolled from a starting end to a terminal end of the roller rolling surface of the block body, the rollers are rolled and moved to the roller returning passage through the direction changing passage, moved along the roller returning passage, and thereafter, supplied to the starting end side of the roller rolling surface through the direction changing passage formed at the other side of the roller rolling surface.

[0034] When the direction changing passage inner periphery portion forming member is integrally formed with the block body, it becomes possible to eliminate the irregularities to be formed at the connected portion between the roller rolling surface and the direction changing passage inner periphery portion. In addition, as to the roller returning passage forming member, when it is integrally formed with the block body, it also becomes possible to eliminate the irregularities to be formed at the connected portion between the direction changing passage inner periphery portion and the roller returning passage.

[0035] Further, in one aspect of this invention, the device may have a structure in which the roller returning passage and the direction changing passage inner peripheral portion are provided with guide walls for guiding the end surface of the roller, the guide wall being continuous to the roller end surface guide wall, and the roller returning passage, the roller end surface guide wall of at least one of the paired roller end surface guide walls and the direction changing passage inner peripheral portion are integrally formed with the block body.

[0036] According to the structure described above, the roller end surface guide walls of the roller returning passage and the direction changing passage in an unloaded area and the roller end surface guide wall to be formed along the roller rolling surface in loaded area can be continuously molded, so that the irregularities are not formed at the connected portions in all around the endless circulating passage, thus enables the end surface of the roller to smoothly move.

[0037] In addition, the gap or clearance between the guide wall and the roller end surface can be formed with high accuracy in all around the endless circulating passage, so that the generation of the skew of the roller can be securely prevented.

[0038] In another aspect of this invention, the device may have a structure in which a chamfered portion is provided at least one end portion of the roller and an engaging projection with which the chamfered portion of the roller is engaged is provided at the roller end surface guide wall integrally molded with the block body so as to prevent the roller from falling out.

[0039] As described above, when such engaging projection is provided at the roller end surface guide wall to be integrally molded with the block body, the engaging projection can be accurately positioned with respect to the block body, so that the falling-out of the roller can be securely prevented even if the bearing block is detached from the track rail. In addition, there is not the slightest fear of interference of the block body with the roller during the circulation of the roller.

[0040] The guide device has a structure having four rows of rollers in total in which a pair of right and left rows of rollers are disposed to be rollable between the upper surface of the track rail and a lower surface of a horizontal portion of the block body and other two rows of the rollers each is disposed between the right and left side surfaces of the track rail and an inside surfaces of a suspending portion of the block body, respectively.

[0041] In this case, it is preferable that a contact angle line constituted by a line connecting two contact points of the roller disposed between the corresponding roller rolling surfaces formed to the upper surface of the track rail and the horizontal portion of the block body is set to vertically extend with an inclination angle of about 90° with respect to a horizontal line, while a contact angle line of the roller disposed between the corresponding roller rolling surfaces formed to the right and left side surfaces of the track rail and the inside surfaces of the suspending portion of the block body is set to obliquely extend downwards and is formed so as to incline with an inclination angle of 30° with respect to a horizontal line.

[0042] In still another aspect of this invention, the guide device has a structure having four rows of rollers in total in which two rows of rollers are vertically disposed to be rollable between a right side surface of the track rail and a right inside surface of the suspending portion of the block body, and vertically disposed to be rollable between a left side surface of the track rail and a left inside surface of the suspending portion of the block body, respectively.

[0043] Among the two rows of the rollers arranged vertically at upper and lower portions, it is preferable that the upper row of rollers is formed so that a contact angle line of the roller is set to obliquely extend upwards from a side of the track rail to sides of the right and left suspending portions of the block body, and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line, while the lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards, and is formed so as to incline with an inclination angle of almost 45°, or that the upper row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards from a side of the track rail to sides of the right and left suspending portions of the block body, and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line, while the lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards, and is formed so as to incline with an inclination angle of almost 45°.

[0044] In particular, at a time of an insert molding, when a block supporting portion corresponding to the roller rolling surface of the block body is provided to an inner periphery of a molding die and the roller rolling surface is contacted to the block supporting portion, the block body can be effectively positioned in the molding die.

[0045] According to such structure, a pair of right and left roller rolling grooves (surfaces) of the block body will contact to the block supporting portion. As a result, the block body is supported by the paired right and left block supporting portions so that the block body is clamped from every four directions and supported by four points. Therefore, even if an injection pressure of a molding material is applied to the block body from every directions, the block body can be held unmoved, and the burr is not formed at a portion between the roller rolling surface and the block supporting portion.

[0046] In a second invention, there is provided a linear roller guide device comprising a track rail and a movable block assembled to the track rail through a number of rollers,

[0047] the movable block comprising:

[0048] a block body having a roller rolling surface and a roller returning passage corresponding to the roller rolling surface:

[0049] a direction changing passage inner periphery portion formed to both end surfaces of the block body: and side covers each having a direction changing passage outer periphery portion for forming a direction changing passage by fitting the side cover into the direction changing passage inner periphery portion formed at both end surfaces of the block body,

[0050] the track rail including a roller rolling surface extending in an axial direction corresponding to the roller rolling surface of the block body,

[0051] the rollers circulating in an endless circulating passage constituted by a loaded area between the roller rolling surface of the block body and the roller rolling surface corresponding to the track rail, the direction changing passage and the roller returning passage, and the rollers are linked to each other by a roller chain inserted to be movable in the endless circulating passage,

[0052] wherein the roller returning passage and the direction changing passage inner periphery guide portion are provided with a roller chain guide portion for guiding a track of the roller chain onto a predetermined track,

[0053] wherein at least one of the roller returning passage forming member for forming the roller returning passage and the direction changing passage inner periphery portion forming member for forming the direction changing passage inner periphery portion is integrally molded by inserting the block body into a molding die.

[0054] According to the structure described above, the rollers can be smoothly rolled and moved in the endless circulating passage while being kept in a state where center axes of the respective rollers are retained in parallel to each other and intervals of adjacent rollers are retained in a predetermined distance, thus enabling to prevent the skew-generation.

[0055] In addition, the roller chain is guided onto the predetermined track by the roller chain guide portions formed to the roller returning passage and the direction changing passage, and the rollers shall be accurately guided by the roller chain guided by the roller chain guide portion. Further, a run-out of the roller chain can be prevented by the roller chain guide portion.

[0056] In addition, when the roller returning passage forming member for forming the roller returning passage and the direction changing passage inner periphery portion forming member for forming the direction changing passage inner periphery portion to which the roller chain guide portions are formed are integrally molded with the block body, the roller chain guide portions can be formed on accurate positions of the track.

[0057] In addition, when the direction changing passage inner periphery portion forming member is integrally formed with the block body, it becomes possible to eliminate the irregularities to be formed at the connected portion between the roller rolling surface and the direction changing passage inner periphery portion. Further, as to the roller returning passage, when it is integrally formed with the block body, it also becomes possible to eliminate the irregularities to be formed at the connected portion between the direction changing passage inner periphery portion and the roller returning passage. As a result, the rollers can be further smoothly circulated and moved in cooperation with the guiding function of the roller chain.

[0058] Furthermore, when the roller chain is formed so as to have an endless structure and is provided with a falling-out preventing portion for the rollers, the falling-out of the rollers can be prevented by the roller chain even if the movable block is detached from the track rail.

[0059] Further, the roller chain is preferably provided with a guide projecting portion so as to project from the end surface of the roller in an axial direction of the roller, while the roller returning passage and the direction changing passage inner peripheral portion are preferably provided with guide grooves with which the guide projecting portion is engaged. In addition, at least one side of the roller rolling surfaces formed to the block body is preferably provided with a guide wall having the guide groove extending in parallel to the roller rolling surface for guiding the guide projecting portion in parallel to the roller rolling surface. As to this guide wall, it is also preferable to integrally mold the guide wall with the block body by using an insert molding method and to continuously form the guide groove to the roller returning passage, the direction changing passage inner periphery portion and the guide wall so that the guide groove ranges to all around the endless circulating passage.

[0060] According to the structure described above, when the roller chain is circulated and moved, the guide projecting portion is engaged with the guide groove formed to the roller returning passage and the direction changing passage inner peripheral portion, so that the run-out of the roller chain is suppressed. As a result, the rollers can be rolled and moved in orderly arranged state in all around the endless circulating passage.

[0061] In addition, in a case where the roller chain is formed in a striped-shape having no connected portion at both ends thereof, when the movable block is detached from the track rail, the guide projecting portion is engaged with the guide groove, thus enabling to prevent a sagging or slack of an end portion of the roller chain. Further, also in a case of the roller chain having an endless structure, the sagging or slack of an intermediate portion of the roller chain can be prevented.

[0062] In still another aspect of this invention, the roller chain comprises spacer portions disposed between the adjacent rollers and connecting portions for connecting the respective spacer portions, and the guide projecting portion is provided to the connecting portion.

[0063] Accordingly, each of the rollers is arranged and circulated in a state where the rollers are retained by the spacer portions form back and forth in the arranging direction thereof.

[0064] Further, when a falling-out preventing portion for the roller is provided to the spacer portion so as to prevent the falling-out of the roller from back and forth of the roller, it becomes unnecessary to chamfer the end portion of the roller, so that an effective length of the roller for bearing the load can be increased.

[0065] Furthermore, since only the spacer portion is disposed between the adjacent rollers, a pitch of the rollers can be formed as small as possible, so that a number of the rollers to be disposed per unit length for bearing the load can be increased as many as possible, thus improving the load bearing ability of the roller.

[0066] In still another aspect of this invention, the connecting member and the spacer portion disposed between the adjacent rollers are formed as resin moldings, the roller is formed to have a hollow portion, and the roller is retained by inserting a resin portion into the hollow portion of the roller.

[0067] According to the structure described above, the falling-out of the roller can be surely prevented and a degree of parallelization between the adjacent rollers can be accurately maintained.

[0068] In addition, the roller may be retained in such a manner that a recessed portion is formed to both end portions of the roller and the resin portion is inserted into the recessed portion or in a manner that a grooved portion is formed to a center peripheral portion of the roller and the resin portion is fitted into the grooved portion.

[0069] When the roller chain moves at portion between the roller rolling surfaces and the unloaded roller rolling passage, the roller chain takes a linear shape. In contrast, when the roller chain moves in the direction changing passage, the roller chain is deformed from linear-shape to a curved-shape. As a result, the roller chain is repeatedly deformed in accordance with the movement of the movable block.

[0070] In view of this point, it is preferable to reinforce the roller chain by inserting a wire or thin plate into the connecting member.

[0071] In the guide device of the present invention, the number of rollers and arrangement thereof are optional. However, the following arrangements are more effective.

[0072] That is, the guide device may have a structure having four rows of rollers in total in which a pair of right and left rows of rollers are disposed to be rollable between the upper surface of the track rail and a lower surface of a horizontal portion of the block body, and one row of the roller is disposed between the right and left side surfaces of the track rail and inside surfaces of a suspending portion of the block body, respectively.

[0073] In this case, it is preferable that a contact angle line constituted by a line connecting two contact points of the roller disposed between the corresponding to the roller rolling surfaces formed to the upper surface of the track rail and the horizontal portion of the block body is set to vertically extend with an inclination angle of about 90° with respect to a horizontal line, while a contact angle line of the roller disposed between the corresponding roller rolling surfaces formed to the right and left side surfaces of the track rail and the inside surfaces of the suspending portion of the block body is set to obliquely extend downwards and is formed so as to incline with an inclination angle of 30° with respect to a horizontal line.

[0074] In addition, the guide device may have a structure having four rows of rollers in total in which two rows of rollers are vertically disposed at upper and lower portions to be rollable between a right side surface of the track rail and a right inside surface of the suspending portion of the block body, and vertically disposed to be rollable between a left side surface of the track rail and a left inside surface of the suspending portion of the block body, respectively.

[0075] Among the two rows of the rollers arranged vertically, it is preferable that the upper row of rollers is formed so that a contact angle line of the roller is set to obliquely extend upwards from a side of the track rail to sides of the right and left suspending portions of the block body and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line, while the lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards, and is formed so as to incline with an inclination angle of almost 45°; or that the upper row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards from a side of the track rail to sides of the right and left suspending portions of the block body and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line, while the lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards and is formed so as to incline with an inclination angle of almost 45°.

[0076] In particular, at a time of an insert molding, when a block supporting portion corresponding to the roller rolling surface of the block body is provided to an inner periphery of a molding die and the roller rolling surface is contacted to the block supporting portion, the block body can be effectively positioned in the molding die.

[0077] According to such structure, a pair of right and left roller rolling grooves (surfaces) of the block body will contact to the block supporting portion. As a result, the block body is supported by the paired right and left block supporting portions so that the block body is clamped from every four directions and supported by four points. Therefore, even if an injection pressure of a molding material is applied to the block body from every directions, the block body can be held unmoved, and the burr is not formed at a portion between the roller rolling surface and the block supporting portion.

BEST MODE FOR EMBODYING THE INVENTION

The First Invention

[0093] Hereunder, the first invention will be explained with reference to the accompanying drawings.

[0094] **FIGS. 1 and 2** are views showing an embodiment of a linear roller guide device according to the first invention. The linear roller guide device **1** comprises a track rail **2**, four rows of rollers **3** in total of which two rows of rollers are disposed to an upper side surface of the track rail **2** and one row of rollers is disposed to both right and left side surfaces of the track rail **2** respectively, and a movable block **4** assembled to be movable through the four rows of rollers **3**.

[**0095**] The track rail **2** is an elongated member formed to have a rectangular shape in section, an upper portion of both the side surfaces of the track rail being formed to have tapered surfaces which gradually expand outwardly in upward direction, and each of the right and left tapered surfaces is provided with one row of roller rolling surface **5**, respectively. In addition, the upper surface of the track rail **2** is formed to be a plain surface of which both right and left end portions are provided with one row of roller rolling surface **6**, respectively, i.e., two rows of the roller rolling surfaces **6** in total.

[**0096**] The movable block **4** comprises a block body **40** formed of metal, and side covers **11** to be attached to both end surfaces of the block body **40**.

[**0097**] The block body **40** has a U-shaped cross section and high rigidity, and comprises a horizontal portion **41** opposing to the upper surface of the track rail **2**, a pair of suspending portions **42** and **42** suspending from the right and left end portions of the horizontal portion **41** so as to clamp both the right and left side surfaces of the track rail **2**. A lower surface of the horizontal portion **41** is provided with a pair of roller rolling surfaces **7**, **7** corresponding to the paired roller rolling surfaces **6**, **6** formed to the upper surface of the track rail **2**, while each of inner side surfaces of the right and left suspending portions **42**, **42** is provided with a roller rolling surface **8** corresponding to the respective roller rolling surfaces **5**, **5** formed to the right and left side surfaces of the track rail **2**.

[**0098**] A number of rollers **3** are disposed between four pairs of roller rolling surfaces **5**, **8**; **6**, **7**, corresponding to each other, that are formed to opposing surfaces between the track rail **2** and the movable block **4**, whereby roller rows for bearing a load to be applied to portions between the track rail **2** and the movable block **4** are assembled. A predetermined pre-load is applied to respective rollers **3**. The roller **3** is formed as a cylindrical roller. However, as shown in **FIG. 3**(*d*), a barrel-shaped roller having a circular-arc shaped cross section in axial direction can be also available as the roller **3**.

[**0099**] Each of the rollers **3** linearly contacts to the roller rolling surfaces **5**, **8**; **6**, **7**. A contact angle line L1 constituted by a line connecting two contact portions of the roller disposed between the corresponding to the roller rolling surfaces **5**, **8**; **6**, **7** formed to the upper surface of the track rail **2** and the horizontal portion **41** of the block body **40** is set to vertically extend with an inclination angle of about 90° with respect to a horizontal line passing through a center of the roller **3**, while a contact angle line of the roller **3** disposed between the corresponding to the roller rolling surfaces formed to the right and left side surfaces of the track rail **2** and the inside surfaces of the right and left suspending portions **42**, **42** of the block body **40** is set to obliquely extend toward a center of the track rail **2** and is formed so as to upwardly incline with a predetermined angle of α with respect to a horizontal line H passing through a center of the roller **3**, thereby to form a structure in which both the right and left corner portions **22**, **22** of an upper portion of the track rail **2** are clamped by the two rows of rollers **3**, **3** disposed to the right and left sides of the track rail **2** and by the two rows of rollers **3**, **3** disposed to the upper surface side of the track rail **2**. In the embodiment shown in Figure, the angle of α is set to about 30°.

[**0100**] The block body **40** is provided with four rows of the roller returning passages **9** for circulating and guiding the four rows of rollers **3**. The roller returning passage **9** linearly extend in parallel to the respective roller rolling surfaces **5**, **6** formed to the block body **40**. Two rows of the roller returning passages **9** are provided to the horizontal portion **41**, while two rows of the roller returning passages **9** are respectively provided to the right and left suspending portions of the block body **40**. The roller returning passage **9** is formed from a roller returning passage forming member **91** composed of resin.

[**0101**] The roller returning passage forming member **91** is integrally bonded to an inner peripheral portion of a penetration bore **43** penetrating through the horizontal portion **41** and the suspending portion **42** of the block body **40**. An outer peripheral shape of the roller returning passage forming member **91** is formed to have a cylindrical shape which conforms to an inner peripheral shape of the penetration bore **43**. The inner periphery of the roller returning passage forming member **91** is provided with a roller returning passage **9** having a rectangular cross section for guiding the roller **3**.

[**0102**] The roller returning passage **9** comprises a pair of unloaded roller guide surfaces **9***a*, **9***b* extending in parallel to each other for guiding a cylindrical outer periphery surface of the roller **3**, and a pair of unloaded roller end surface guide surfaces **9***c*, **9***c* extending in parallel to each other for guiding end surfaces of the roller **3**.

[**0103**] A gap or clearance between the paired unloaded roller guide surfaces **9***a*, **9***b* is set to slightly larger than a diameter of the roller **3** so as to form a small gap therebetween, while a gap or clearance between the paired unloaded roller end surface guide surfaces **9***c*, **9***c* is set to slightly larger than a length of the roller **3** so as to form a small gap therebetween, thus resulting in a structure enabling to smoothly move the rollers **3** (see **FIG. 3**(*e*)).

[**0104**] **FIG. 5** shows another embodiment of a roller returning passage forming member **92** to be formed to the suspending portion **42** of the block body **40**. Namely, the roller returning passage forming member **92** is integrally bonded to a recessed portion **44** formed to a lower end portion of the right and left suspending portions **42** of the block body **40**. The roller returning passage forming member **91** is integrally connected to a third loaded roller end surface guide wall forming member **143** provided to the inner peripheral side of the suspending portion **42**.

[**0105**] According to the structure described above, the block body **40** is required to be provided with only two penetration bores **43** to be formed to the horizontal portion **41**, thus enabling to simplify the manufacturing of the device.

[**0106**] In addition, as shown in FIGS. **1**(*b*), (*c*) and **2**, both end portions of the block body **40** are provided with side covers **11** constituting a direction changing passage **10** for changing the rolling direction of the roller **3** to the roller returning passage **9**, the roller **3** being disposed between the loaded roller rolling surfaces **5**, **8**; **6**, **7** formed to the track rail **2** and the block body **40**.

[0107] The direction changing passage **10** is formed to be a pipe having a U-shape. The side cover **11** is formed with only a direction changing passage inner periphery portion **10***a* of the direction changing passage **10**, while a direction changing passage inner periphery portion forming member **12** is integrally bonded to both end portions of the block body **40**.

[0108] This direction changing passage **10** has a rectangular shaped cross section, and both side portions of the direction changing passage outer periphery portion **10***a* and the inner periphery portion **10***b* for guiding the outer periphery surface of the roller **3** are provided with direction changing roller end surface guide walls **10***c*, **10***c* for guiding the end surfaces of the roller **3**. This direction changing roller end surface guide walls **10***c* together with the direction changing passage inner periphery portion **10***b* are formed to the direction changing passage inner periphery portion forming member **12**. Then, when the side cover **11** formed with the direction changing passage outer periphery portion **10***a* is fitted into the end surface of the block body **40** formed with the direction changing passage inner periphery portion **10***b* and the direction changing roller end surface guide walls **10***c*, the direction changing passage **10** having a U pipe shape is formed.

[0109] In this regard, the direction changing roller end surface guide walls **10***c*, **10***c* together with the direction changing passage outer periphery portion **10***a* may be provided to the side cover **11**. In another way, one direction changing roller end surface guide wall **10***c* together with the direction changing passage inner periphery portion **10***b* may be provided to a side of the direction changing passage inner periphery portion forming member **12**, while the other direction changing roller end surface guide walls **10***c* together with the direction changing passage outer periphery portion **10***a* may be provided to the side cover **11**.

[0110] In still another way, the direction changing roller end surface guide wall **10***c* is divided into two portions i.e., an inner periphery side portion and an outer periphery side portion, and then, the outer periphery side portion may be formed to the side cover **11**, while the inner periphery side portion may be provided to the direction changing passage inner periphery portion forming member **12**.

[0111] Further, as shown in **FIG. 1**(*a*) , along the respective four rows of roller rolling surfaces **7**, **8** of the block body **40**, there is provided with a loaded roller end surface guide wall **13** for guiding the end surfaces of the roller in the loaded area. In order to form the loaded roller end surface guide wall **13**, the block body **40** comprises a first end surface guide wall forming member **141** to be integrally bonded to a lower surface of the horizontal portion **40**, right and left second end surface guide wall forming members **142** to be integrally bonded to recessed corner portions between the horizontal portion **41** and the right and left suspending portions **42**, and right and left third end surface guide wall forming members **143** to be integrally bonded to a lower portion of inner side surface of the right and left suspending portions **42**.

[0112] The both end portions of the first end surface guide wall forming member **141** and an upper end portion of the second end surface guide wall forming members **142** are provided with loaded roller end surface guide walls **13**, **13**; **13**, **13** for guiding the end surfaces of the roller **3** rolling on the roller rolling surfaces **7**, **7** formed to the lower surface of the horizontal portion **41** of the block body **40**.

[0113] In addition, the lower end portions of the right and left second end surface guide wall forming member **142** and an upper end portion of the third end surface guide wall forming members **143** are provided with loaded roller end surface guide walls **13**, **13**; **13**, **13** for guiding the end surfaces of the roller **3** rolling on the roller rolling surfaces **8**, **8** formed to the suspending portion **42** of the block body **40**.

[0114] A gap or clearance between the paired loaded roller end surface guide walls **13**, **13** is set to slightly larger than a length of the roller **3** so as to form a small gap between the end surface of the roller **3** and the guide wall **13**.

[0115] Further, a first seal member **15** for sealing the gap formed between the horizontal portion **41** of the block body **40** and the upper surface of the track rail **2** is attached to the first end surface guide wall forming member **141**, while a second seal member **16** for sealing the gap formed between the suspending portion **42** of the block body **40** and the right and left side surfaces of the track rail **2** is attached to the third end surface guide wall forming member **143**.

[0116] In this embodiment, the loaded roller end surface guide walls **13** for guiding both end surfaces of the roller **3** is formed by the first to third end surface guide wall forming members **141**-**143** that are all composed of resin.

[0117] However, as shown in **FIG. 3**(*a*), the loaded roller end surface guide walls **13** for guiding one end surface of the roller **3** may be formed by the block body **40** per se, while the loaded roller end surface guide wall **13** for guiding the other end surface of the roller **3** may be formed by the loaded roller end surface guide wall forming member **14**. In another way, as shown in **FIG. 3**(*f*), both side of the loaded roller end surface guide walls **13** can be also formed by the block body **40**.

[0118] In this first embodiment, all of the roller returning passage forming member **91**, the roller end surface guide wall forming members **141**-**143** and the direction changing passage inner periphery portion forming member **12** are formed by integrally molding with the movable block.

[0119] Accordingly, the unloaded roller guide surfaces **9***a*, **9***b* of the roller returning passage **9** and both the inner and outer periphery portions **10***a*, **10***b* of the direction changing passage can be continuously and integrally molded. Further, the direction changing passage inner periphery portion **10***b* and the roller rolling surfaces **7**, **8** in the loaded area can be also integrally molded.

[0120] In addition, the roller end surface guide wall **9***c* of the roller returning passage **9**, the direction changing roller end surface guide wall **10***c* of the direction changing passage **10** and the loaded area roller end surface guide wall **13** are continuously formed by being integrally molded, so that the roller end surface guide wall can be continuously formed in all around the endless circulating passage.

[0121] According to the linear roller guide device of this invention, the assembling of the loaded roller end surface guide wall forming member **14**, the roller returning passage forming member **91** and the direction changing passage inner periphery portion forming member **12** is not required, thus enabling to omit the assembling process for the members.

[0122] In addition, the roller end surface guide wall **13**, the roller returning passage **9** and the direction changing passage inner periphery portion **10***b* can be provided at accurate positions with respect to the block body **40**.

[0123] As a result, after the rollers **3** are rolled from a starting end to a terminal end of the roller rolling surfaces **7**, **8** in the loaded area of the block body **40**, the rollers **3** are moved to the roller returning passage **9** through the direction changing passage **10**, then moved along the roller returning passage **9**, and thereafter, supplied to the starting end side of the roller rolling surfaces **7**, **8** through the direction changing passage **10** formed at the other end of the roller rolling surfaces **7**, **8**.

[0124] When the direction changing passage inner periphery portion forming member **12** is integrally formed with the block body **40**, it becomes possible to eliminate the irregularities to be formed at the connected portion between the roller rolling surfaces **7**, **8** and the direction changing passage inner periphery portion **10***b*. In addition, as to also the roller returning passage forming member **91**, when the member **91** is integrally formed with the block body **40**, it also becomes possible to eliminate the irregularities to be formed at the connected portion between the direction changing passage inner periphery portion **10***b* and the roller returning passage **9**.

[0125] Further, when the roller returning passage forming member **91** and the direction changing passage inner peripheral portion forming member **12** are provided with unloaded roller end surface guide wall **9***c* and the direction changing roller end surface guide wall **10***c* for guiding the end surface of the roller, the guide walls being continuous to the loaded roller end surface guide wall **13** and these roller end surface guide walls are integrally formed with the block body **40**, the loaded roller end surface guide wall **13**, the direction changing roller end surface guide wall **10***c* and the unloaded roller end surface guide wall **9***c* can be continuously molded in all around the endless circulating passage without forming the irregularities at the connected portions of the guide walls, thus enabling the end surface of the roller to smoothly move.

[0126] In addition, the gaps or clearances between the the loaded roller end surface guide wall **13**, the direction changing roller end surface guide wall **10***c*, the unloaded roller end surface guide wall **9***c* and the roller end surfaces can be accurately maintained to constant values, so that the gaps or clearances can be limited to a small value, and the skew of the roller **3** can be securely prevented.

[0127] In addition, as shown in FIGS. **3**(*b*) and **3**(*c*), the device may have a structure in which a chamfered portion **3***a* is provided at least one end portion of the roller **3** while an engaging projection **13***a*, with which the chamfered portion **3***a* of the roller **3** is engaged, is provided at the loaded roller end surface guide wall **13** integrally molded with the block body **40** so as to prevent the roller **3** from falling out when the movable block **4** is detached from the track rail **2**. A small gap is formed between the engaging projection **13***a* and the roller **3** so that the engaging projection **13***a* would not interfere with the roller **3** when the rollers **3** roll and move between the roller rolling surfaces **6**, **7**; **5**, **8**.

[0128] As described above, when the engaging projection **13***a* is provided at the roller end surface guide wall **13** to be integrally molded with the block body **40**, the engaging projection **13***a* can be accurately positioned with respect to the block body **40**, and the gap between the engaging projection **13***a* and the chamfered portion **3***a* of the roller **3** can be accurately maintained to a constant value, whereby there is no fear of interference of the engaging projection **13***a* with the roller during the circulation of the roller **3**.

[0129] The integrally molding of the roller returning passage forming member **91**, the direction changing passage inner peripheral portion forming member **12** and the loaded roller end surface guide wall **13** with the block body **40** is performed in accordance with an insert molding method comprising the steps of disposing the block body **40** into a molding die **15** on the basis of the roller rolling surfaces **7**, **8** formed to the block body **40**, forming cavities corresponding to the respective resin molded portions to be formed between an inner wall of the molding die **15** and the block body **40**, and injecting a molding material into the respective cavities to form the resin molded portions.

[0130] **FIG. 4** is a schematic view showing the block body **40** and states where the molding dies **15** are clamped or opened at the time of the insert molding. Namely, a fixed molding die **15***a* is provided with block supporting portions **15***b* to which the roller rolling surfaces **7**, **7**; **8**, **8** are fitted for positioning, while a movable molding die **15***c* is provided with pins **15***d* for forming the roller returning passage.

[0131] The block supporting portions **15***b* have plain shapes corresponding to the roller rolling surfaces **7**, **7**; **8**, **8** and linearly extend in parallel to each other. In this regard, FIGS. **4**(*b*) and **4**(*c*) show only a circumference of the roller returning passage **9** of a side of the suspending portion **42**.

[0132] Cavities **15***e* for forming the roller returning passage forming member **91** are provided to inside the penetration bores **43** formed in the horizontal portion **41** and the suspending portion **42** of the block body **40**, respectively. Further, cavities **15***f*-**15***h* for forming the first to third loaded roller end surface guide wall forming members **141**-**143** are provided to inner periphery portions of the horizontal portion **41** and the suspending portion **42**, respectively. Furthermore, cavities **15***i* for forming the direction changing passage inner periphery portion forming members **12** are provided to both front and back end portions of the block body **40**, respectively.

[0133] In this embodiment, the paired right and left roller rolling surfaces **7**, **7**: **8**, **8** of the block body **40** are supported at four points by the block supporting portions **15***b* of the molding die **15**. As a result, the block body **40** can be supported unmoved by the block supporting portions **15***b*, even if an injection pressure of a molding material is applied to the block body **40** from every directions, whereby the roller returning passage **9**, the direction changing inner periphery portion **10***b* and the first to third loaded roller end surface guide walls **131**-**133** can be accurately formed at predetermined positions.

[0134] In addition, since the block body **40** is stably positioned in the molding die **15**, the burr is not formed at portions between the roller rolling surfaces **7**, **7**: **8**, **8**.

[0135] It is preferable that the block supporting portions **15***b* closely contact to the roller rolling surfaces **7**, **8**. However, even the block supporting portions **15***b* and the roller rolling surfaces **7**, **8** are moved in a small distance due to a small gap formed therebetween, the small gap can be allowed as far as a dimension accuracy is within an allowable range and the resin material would not penetrate through the gap.

Modifications of Roller Contact Angles

[0136] Though the explanation described above has been made by taking an example of a case in which total four rows of rollers are disposed between corresponding portions i.e., the right and left two rows of rollers being disposed between the upper surface of the track rail **2** and the lower surface of the horizontal portion **41** of the block body **40** while one row of rollers being disposed between the right and left side surfaces of the track rail **2** and the inner side surfaces of the right and left suspending portions **42** respectively, a number and an arrangement of the roller rows are optional.

[0137] For example, as shown in **FIGS. 6 and 7**, the device may have a structure having four rows of rollers in total of which right and left two rows of rollers are disposed between the right and left side surfaces of the track rail **2** and the inner side surfaces of the right and left suspending portions **42** of the block body **40**, respectively.

[0138] **FIG. 6** shows an example having a structure in which the upper row of rollers **3** among the two rows of the rollers **3** arranged vertically is formed so that a contact angle line L1 of the roller **3** is set to obliquely extend upwards from a side of the track rail **2** to the right and left suspending portions **42** of the block body **40** and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line H, while the lower row of rollers **3** is formed so that a contact angle line L2 of the roller **3** is set to obliquely extend downwards, and is formed so as to incline with an inclination angle of almost 45°.

[0139] **FIG. 7** shows an example having a structure in which the upper row of rollers **3** among the two rows of the rollers **3** arranged vertically is formed so that a contact angle line L1 of the roller **3** is set to obliquely extend downwards from a side of the track rail to sides of the right and left suspending portions **42, 42** of the block body **40** and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line, while the lower row of rollers **3** is formed so that a contact angle line L2 of the roller **3** is set to obliquely extend upwards, and is formed so as to incline with an inclination angle of almost 45°.

[0140] In the case of this embodiment, the direction changing passages **10**A, **10**B of vertically arranged two rows of rollers **3** disposed to both end portions of the block body **40** are arranged alternately with a predetermined interval in an axial direction so as to intersect to each other. In this case, the direction changing passage inner peripheral portion forming member **12** formed to the end surface of the block body **40** is provided with the direction changing passage inner periphery portion **10***b* of the direction changing passage **10**A of a side close to the block body **40** and the direction changing roller end surface guide wall **10***c*, the inner periphery portion **10***b* and the guide wall **10***c* being integrally molded with the block body **40**.

[0141] As to the direction changing passage **10**B far from the block body **40**, at least one portion of the loaded roller rolling surfaces **7, 8** of an end surface side of the block body **40**, the direction changing passage inner periphery portion **10***b* of a part which is connected to an end portion of the roller returning passage **9** and the direction changing roller end surface guide wall **10***c* are integrally molded with the block body **40**. While, a round piece **10**C formed with the direction changing passage inner periphery portion **10***b* is attached to a part far from the direction changing passage **10**A. An inner periphery of this round piece **10**C is formed with a part of an outer periphery guide portion of the inside direction changing passage **10**A. The side cover **11** is formed with the direction changing passage outer peripheral portions **10***a*, **10***a* for both the direction changing passages **10**A, **10**B arranged vertically.

[0142] According to the first invention described above, the assembling of the roller end surface guide wall, the roller returning passage and the direction changing passage inner periphery portion is not required, thus eliminating the assembling process for the members.

[0143] In addition, the roller end surface guide wall, the roller returning passage and the direction changing passage inner periphery portion can be formed at accurate positions with respect to the block body.

[0144] When the direction changing passage inner periphery portion is integrally formed with the block body, it becomes possible to eliminate the irregularities to be formed at the connected portion between the roller rolling surface and the direction changing passage inner periphery portion. In addition, as to the roller returning passage, when it is integrally formed with the block body, it also becomes possible to eliminate the irregularities to be formed at the connected portion between the direction changing passage inner periphery portion and the roller returning passage.

[0145] Further, when the roller returning passage and the direction changing passage inner peripheral portion are provided with guide walls for guiding the end surface of the roller, the guide wall being continuous to the roller end surface guide wall, and the roller returning passage, the roller end surface guide wall of at least one the paired roller end surface guide walls and the direction changing passage inner peripheral portion are integrally formed with the block body, so that the roller returning passage, the guide walls of the direction changing passage inner periphery portions and the roller end surface guide walls can be continuously molded, whereby irregularities are not formed at the connected portions, thus enabling the end surface of the roller to smoothly move.

[0146] In addition, the guide walls for the roller end surfaces can be integrally formed in continuous in all around the endless circulating passage and a gap between the guide wall and the end surface of the roller can be formed with a high accuracy, so that the skew of the roller can be securely prevented.

[0147] In addition, when the engaging projection for preventing the roller from falling out by engaging with the chamfered portion of the roller is provided at the roller end surface guide wall to be integrally molded with the block body, the engaging projection can be accurately positioned with respect to the block body, so that the falling-out of the roller can be surely prevented even if the bearing blocks is detached from the track rail. In addition, there is no fear of interference of the block body with the roller during the circulation of the roller.

[0148] In addition, at a time of an insert molding, when a block supporting portion having a shape obtained by cutting an outer peripheral portion of the roller with a cross section passing through a center axis of the roller is provided to an inner periphery of a molding die so as to correspond to the roller rolling surface of the block body and the block body is positioned in the molding die by contacting the roller rolling surface to the block supporting portion, the burr would not occur at the roller rolling surfaces.

[0149] In particular, when the paired right and left roller rolling surfaces of the block body are supported by the block supporting portions of the molding die, the block body is clamped from every four directions and supported by the paired right and left block supporting portions at four points. Therefore, even if an injection pressure of a molding material is applied to the block body from every directions, the block body can be held unmoved, and the block body can be accurately positioned.

Second Invention

[0150] Next, an embodiment of a second invention will be explained hereunder with reference to the accompanying drawings.

[0151] **FIGS. 8 and 9** disclose embodiments of linear roller guide devices according to the second invention, respectively.

[0152] The linear roller guide device **201** comprises a track rail **202** and a movable block **204** assembled to be movable on an upper surface of the track rail **202** through four rows of rollers **203** in total of which two rows of rollers are disposed on an upper surface side of the track rail **202** and one row of rollers is disposed on the right and left side surface sides of the track rail **202**, respectively.

[0153] Each of the four rows of the rollers **203** circulates in an endless circulating passage constituted by the loaded area between the roller rolling surfaces **206**, **207**; **205**, **208** of the block body **2040** and corresponding to the track rail **202**, the direction changing passage **210** and the roller returning passage **209**. In this regard, the embodiment of this second invention is different form that of the first invention in a point where the rollers **203** are linked to each other by a roller chain **218** inserted to be movable in the endless circulating passage.

[0154] The roller chain **218** is a resin molded product, as shown in **FIG. 9**(*c*)-(*e*), and comprises spacer portions **218***a* disposed between the adjacent rollers **203** and connecting bands (plates) **218***b* as connecting members for connecting the respective spacer portions **218***a*, the connecting bands **218***b* being flexible and having a thin plate-shape.

[0155] Both side surfaces of the spacer portion **218** is provided with a retaining recessed portion **218***c* for constituting the falling-out preventing portion having a circular-arc shape corresponding to a cylindrical surface of the roller **203**. The connecting plates **218***b* are positioned on a virtual surface connecting the center axes of the respective rollers **203**.

[0156] The spacer portion **218***a* is a member having a rectangular parallelepiped shape and a predetermined thickness so as to be disposed between the rollers **203** and has almost the same length in axial direction as that of the roller **203** and a width shorter than a diameter of the roller **203**. In addition, side surfaces in a thickness direction of the spacer portion **218***a* to which the roller **203** contacts are formed with retaining recessed portions **218***c* having a circular-arc shape corresponding to the shape of the roller **203**.

[0157] Both side end portions in axial direction of the roller of the connecting band **218***b* of the roller chain **218** project from the end surfaces of the roller in axial direction of the roller thereby to form guide projecting portions **2181**.

[0158] Each of the rollers **203** is retained from back and forth in an arranging direction by the respective spacer portions **218***a* of the roller chain **218**, so that it becomes unnecessary to form the chamfered portion to the end portion of the roller. As a result, a load can be supported by an entire length of the roller **203**, and an effective length of the roller **203** for bearing the load can be increased.

[0159] Furthermore, since only the spacer portion **218***a* is disposed between the adjacent rollers **203**, a pitch of the rollers **203** can be formed as small as possible, so that a number of the rollers **203** to be disposed per unit length for bearing the load can be increased as many as possible, thus improving the load bearing ability of the roller **203**.

[0160] **FIG. 10**(*a*) shows an example of the roller chain **218** of a case where the roller **2031** has a hollow structure having a penetration bore **2032**. In the case of the roller **203** having the hollow structure, a pre-load can be easily applied in comparison with a case of a solid roller **203**, thus resulting in advantage.

[0161] A shaft portion **218***d* to be inserted into the penetration bore **2032** is formed to the roller chain **218**, whereby the roller chain **218** is integrated with the roller **203**. According to the structure described above, the falling-out of the roller **203** can be securely prevented, and the degree of parallelization between the respective rollers **203** can be accurately maintained.

[0162] **FIG. 10**(*b*) shows an example of the roller chain **218** of a case where the roller **2034** has a structure having recessed portions **2033** at its both ends.

[0163] The roller chain **218** is provided with convex portions **218***e* to be rotatively inserted into the recessed portions **2033** formed to both the end portions of the roller **203**. According to this structure, the falling-out of the roller **2034** can be surely prevented, and the degree of parallelization between the respective rollers **2034** can be accurately maintained.

[0164] **FIG. 10**(*c*) shows an example of the roller chain **218** of a case where the roller **2036** has a structure having a circular groove **2035** at a center of outer periphery of the roller **2036**.

[0165] The roller **203** is retained by fitting a ring member **218***f* formed to the roller chain **218** into the circular groove **2035** of the roller chain **218**.

[0166] On the other hand, **FIG. 10**(*d*) shows an example of the roller chain **218** of a case where the connecting plate **218***b* of the roller chain **218** is reinforced. Namely, the roller **218** is moved in the endless circulating passage having a track shape in accordance with the movement of the movable block **204**, and the roller chain **218** is repeatedly subjected to deformations from a linear-shape to a curved-shape, so that it is required to increase a fatigue strength of the roller chain **218**.

[0167] In view of this point, it is preferable to reinforce the connecting plate **218***b* for linking the roller **203** by inserting reinforcing members **218***g* such as wire, thin plate or the like into the connecting plate **218***b*.

[0168] The track rail **202** is an elongated member formed to have a rectangular shape in section, an upper portion of both the side surfaces of the track rail being formed to have tapered surfaces which gradually expand outwardly in upward direction, and each of the right and left tapered surfaces is provided with one row of roller rolling surface **205**, respectively. In addition, the upper surface of the track rail **202** is formed to be a plain surface of which both right and left end portions are provided with one row of roller rolling surface **206**, respectively, i.e., two rows of the roller rolling surfaces **206** in total.

[0169] The movable block **204** comprises a block body **2040** formed of metal, and side covers **211** to be attached to both end surfaces of the block body **2040**.

[0170] The block body **2040** has a U-shaped cross section and high rigidity and comprises a horizontal portion **2041** opposing to the upper surface of the track rail **202**, a pair of suspending portions **2042, 2042** suspending from the right and left end portions of the horizontal portion **2041** so as to clamp both the right and left side surfaces of the track rail **202**. A lower surface of the horizontal portion **2041** is provided with a pair of roller rolling surfaces **207, 207** corresponding to the paired roller rolling surfaces **206, 206** formed to the upper surface of the track rail **202**, while each of inner side surfaces of the right and left suspending portions **2042, 2042** is provided with roller rolling surface **208, 208** corresponding to the respective roller rolling surfaces **205, 205** formed to the right and left side surfaces of the track rail **202**.

[0171] A number of rollers **203** are disposed between four pairs of roller rolling surfaces **205, 208**; **206, 207** corresponding to each other, that are formed to opposing surfaces between the track rail **202** and the movable block **204**, whereby roller rows for bearing a load to be applied to portions between the track rail **202** and the movable block **204** are assembled. A predetermined pre-load is applied to respective rollers **203**.

[0172] Each of the rollers **203** linearly contacts to the roller rolling surfaces **205, 208**; **206, 207**. A contact angle line L1 constituted by a line connecting two contact portions of the roller disposed between the corresponding roller rolling surfaces **205, 208**; **206, 207** formed to the upper surface of the track rail **202** and the horizontal portion **2041** of the block body **2040** is set to vertically extend with an inclination angle of about 90° with respect to a horizontal line passing through a center of the roller **203**, while a contact angle line of the roller **203** disposed between the corresponding to the roller rolling surfaces formed to the right and left side surfaces of the track rail **202** and the inside surfaces of the right and left suspending portions **2042, 2042** of the block body **2040** is set to obliquely extend toward a center of the track rail **202** and is formed so as to upwardly incline with a predetermined angle of α with respect to a horizontal line H passing through a center of the roller **203**, thereby to form a structure in which both the right and left corner portions **2022, 2022** of an upper portion of the track rail **202** are clamped by the two rows of rollers **203, 203** disposed to the right and left sides of the track rail **202** and by the two rows of rollers **203, 203** disposed to the upper surface side of the track rail **202**. In the embodiment shown in Figure, the inclination angle of α is set to about 30°.

[0173] The block body **2040** is provided with four rows of the roller returning passages **209** for circulating and guiding the four rows of rollers **203**. The roller returning passage **209** linearly extend in parallel to the respective roller rolling surfaces **205, 206** formed to the block body **2040**. Two rows of the roller returning passages **209** are provided to the horizontal portion **2041**, while two rows of the roller returning passages **209** are respectively provided to the right and left suspending portions **2042** of the block body **2040**. The roller returning passage **209** is formed of a roller returning passage forming member **2091** composed of resin.

[0174] The roller returning passage forming member **2091** is integrally bonded to an inner peripheral portion of a penetration bore **2043** penetrating through the horizontal portion **2041** and the suspending portion **2042** of the block body **2040**. An outer peripheral shape of the roller returning passage forming member **2091** is formed to have a cylindrical shape which conforms to an inner peripheral shape of the penetration bore **2041**. The inner periphery of the roller returning passage forming member **2091** is provided with a roller returning passage **209** having a rectangular cross section for guiding the roller **203**.

[0175] The roller returning passage **209** comprises a pair of unloaded roller guide surfaces **209***a*, **209***b* extending in parallel to each other for guiding a cylindrical outer periphery surface of the roller **203**, and a pair of unloaded roller end surface guide surfaces **209***c*, **209***c* extending in parallel to each other for guiding end surfaces of the roller **203**.

[0176] A gap or clearance between the paired unloaded roller guide surfaces **209***a*, **209***b* is set to slightly larger than a diameter of the roller **203** so as to form a small gap therebetween, while a gap or clearance between the paired roller end surface guide walls **209***c*, **209***c* is set to slightly larger than a length of the roller **203** so as to form a small gap therebetween, thus resulting in a structure enabling to smoothly move the rollers **3**.

[0177] The unloaded roller end surface guide walls **209***c*, **209***c* are formed with guide grooves **209***d* with which the guide projecting portions **2181** of the roller chain **218** are engaged.

[0178] **FIG. 11** shows another embodiment of a roller returning passage forming member **2092** to be formed to the suspending portion **2042** of the block body **2040**. Namely, the roller returning passage forming member **2092** is integrally bonded to a recessed portion **2044** formed to a lower end portion of the right and left suspending portions **2042** of the block body **2040**. The roller returning passage forming member **2091** is integrally connected to a third loaded roller end surface guide wall forming member **2143** provided to the inner peripheral side of the suspending portion **2042**.

[0179] According to the structure described above, the block body **2040** is required to be provided with only two penetration bores **2043** to be formed to the horizontal portion **2041**, thus making simple the manufacturing of the device.

[0180] In addition, as shown in FIGS. **8**, **9**(*a*) and **9**(*b*), both end portions of the block body **2040** are provided with side covers **211** constituting a direction changing passage **210** for changing the rolling direction of the roller **203** to the roller returning passage **209**, the roller **203** being disposed between the loaded roller rolling surfaces **205**, **208**; **206**, **207** formed to the track rail **202** and the block body **2040**.

[0181] The direction changing passage **210** is formed to be a pipe having a U-shape. The side cover **211** is formed with only a direction changing passage inner periphery portion **210***a* of the direction changing passage **210**, while a direction changing passage inner periphery portion forming member **212** is integrally bonded to both end portions of the block body **2040**.

[0182] This direction changing passage **210** has a rectangular shaped cross section, and both side portions of the direction changing passage outer periphery portion **210***a* and the inner periphery portion **210***b* for guiding the outer periphery surface of the roller **203** are provided with direction changing roller end surface guide walls **210***c*, **210***c* for guiding the end surfaces of the roller **203**. This direction changing roller end surface guide walls **210***c* together with the direction changing passage inner periphery portion **210***b* are formed to the direction changing passage inner periphery portion forming member **212**. Then, when the side cover **211** formed with the direction changing passage outer periphery portion **210***a* is fitted into the end surface of the block body **2040** formed with the direction changing passage inner periphery portion **210***b* and the direction changing roller end surface guide walls **210***c*, the direction changing passage **210** having a U pipe shape is formed.

[0183] The direction changing roller end surface guide walls **210***c*, **210***c* are formed with guide grooves **210***d* with which the guide projecting portions **2181** of the roller chain **218** are engaged.

[0184] In this regard, the direction changing roller end surface guide walls **210***c*, **210***c* together with the direction changing passage outer periphery portion **210***a* may be provided to the side cover **211**. In another way, one direction changing roller end surface guide wall **210***c* together with the direction changing passage inner periphery portion **210***b* may be provided to a side of the direction changing passage inner periphery portion forming member **212**, while the other direction changing roller end surface guide walls **210***c* together with the direction changing passage outer periphery portion **210***a* may be provided to the side cover **211**.

[0185] In still another way, the direction changing roller end surface guide wall **210***c* is divided into two portions i.e., an inner periphery side portion and an outer periphery side portion, and then, the outer periphery side portion may be formed to the side cover **211**, while the inner periphery side portion may be provided to the direction changing passage inner periphery portion forming member **212**.

[0186] Further, as shown in **FIG. 8**(*a*) along the respective four rows of roller rolling surfaces **207**, **208** of the block body **240**, there is provided with a loaded roller end surface guide wall **213** for guiding the end surfaces of the roller in the loaded area.

[0187] The loaded roller end surface guide walls **213** are formed with guide grooves **213***a* with which the guide projecting portions **2181** of the roller chain **218** are engaged. In order to form the loaded roller end surface guide wall **213**, the block body **240** comprises a first end surface guide wall forming member **2141** to be integrally bonded to a lower surface of the horizontal portion **2040**, the right and left second end surface guide wall forming members **2142** to be integrally bonded to recessed corner portions between the horizontal portion **2041** and the right and left suspending portions **2042**, and right and left third end surface guide wall forming members **2143** to be integrally bonded to a lower portion of inner side surface of the right and left suspending portions **2042**.

[0188] Both the end portions of the first end surface guide wall forming member **2141** and an upper end portion of the second end surface guide wall forming members **2142** are provided with loaded roller end surface guide walls **213**, **213**; **213**, **213** for guiding the end surfaces of the roller **203** rolling on the roller rolling surfaces **207**, **207** formed to the lower surface of the horizontal portion **2041** of the block body **2040**.

[0189] In addition, the lower end portions of the right and left second end surface guide wall forming members **2142** and an upper end portion of the third end surface guide wall forming members **2143** are provided with loaded roller end surface guide walls **213**, **213**; **213**, **213** for guiding the end surfaces of the roller **203** rolling on the roller rolling surfaces **208**, **208** formed to the suspending portion **2042** of the block body **2040**.

[0190] A gap or clearance between the paired loaded roller end surface guide walls **213**, **213** is set to slightly larger than a length of the roller **203** so as to form a small gap between the end surface of the roller **203** and the guide wall **213**.

[0191] Further, a first seal member **216** for sealing the gap formed between the horizontal portion **2041** of the block body **2040** and the upper surface of the track rail **202** is attached to the first end surface guide wall forming member **2141**, while a second seal member **217** for sealing the gap formed between the suspending portion **2042** of the block body **2040** and the right and left side surfaces of the track rail **202** is attached to the third end surface guide wall forming member **2143**.

[0192] In this embodiment, the loaded roller end surface guide walls **213** for guiding both end surfaces of the roller **203** is formed by the first to third end surface guide wall forming members **2141**-**2143** that are all composed of resin.

[0193] However, as shown in **FIG. 11**(*a*), the loaded roller end surface guide walls **213** for guiding one end surface of the roller **203** may be formed by the block body **2040** per se, while the loaded roller end surface guide wall **213** for guiding the other end surface of the roller **203** may be formed by the loaded roller end surface guide wall forming member **214**. In this case, the loaded roller end surface guide walls **213** may be formed with guide grooves with which the guide projecting portions **2181** of the roller chain **218** are engaged. In another way, as shown in **FIG. 11**(*b*), a cutout **213***b* can be also formed in place of the guide groove.

[0194] In this second embodiment, all of the roller returning passage forming member **2091**, the roller end surface guide wall forming members **2141**-**2143** and the direction changing passage inner periphery portion forming member **212** is formed by integrally molding with the movable block **2040**.

[0195] Accordingly, the unloaded roller guide surfaces **209***a*, **209***b* of the roller returning passage **209** and both the inner and outer periphery portions **210**_a_, **210**_b_ of the direction changing passage can be continuously and integrally molded. Further, the direction changing passage inner periphery portion **210**_b_ and the roller rolling surfaces **207**, **208** in the loaded area can be also integrally molded.

[**0196**] In addition, the roller end surface guide wall **209**_c_ of the roller returning passage **209**, the direction changing roller end surface guide wall **210**_c_ of the direction changing passage **210** and the loaded area roller end surface guide wall **213** are continuously formed by being integrally molded, so that the roller end surface guide wall can be continuously formed in all around the endless circulating passage. In addition, the guide groove for engaging with the guide projecting portion **2181** of the roller chain **218** can be continuously formed in all around the endless circulating passage.

[**0197**] According to the linear roller guide device of this invention, the roller returning passage forming member **2091** and the direction changing passage inner periphery portion forming member **212** are not required, thus enabling to omit the assembling process for the members. In addition, the roller returning passage **209** and the direction changing passage inner periphery portion **210**_a_ can be provided at accurate positions with respect to the block body **2040**.

[**0198**] When the direction changing passage inner periphery portion forming member **212** is integrally formed with the block body **2040**, it becomes possible to eliminate the irregularities to be formed at the connected portion between the roller rolling surfaces **207**, **208** and the direction changing passage inner periphery portion **210**_b_. In addition, as to the roller returning passage **209**, when the member **91** is integrally formed with the block body **2040**, it becomes also possible to eliminate the irregularities to be formed at the connected portion between the direction changing passage inner periphery portion **210**_b_ and the unloaded roller guide surface **209**_b_ of the roller returning passage **209**.

[**0199**] On the other hand, the rollers **203** can be smoothly rolled and moved from the roller returning passage **209** in the unloaded area and the direction changing passage **210** to the loaded area between the roller rolling surfaces **206**, **207**; **205**, **208** while being held in a state where the center axes of the respective rollers **203** are retained in parallel to each other and intervals of adjacent rollers **203** are retained in a predetermined distance by the roller chain **218**.

[**0200**] In particular, when the roller chain **218** is circulated and moved, the guide projecting portions **218**_a_ formed to the roller chain **218** are guided in all around the circulating passage by the guide grooves **209**_d_, **210**_d_ and **213**_a_ formed to the guide walls **213** provided to both sides of the roller returning passage **209**, the direction changing inner periphery portion **210**_b_ and the roller rolling surfaces **207**, **208**, so that the run-out of the roller chain **218** during the circulation can be suppressed in all around the circulating passage. Accordingly, the roller chain **218** can circulate and move on a predetermined track in all around the endless circulating passage. As a result, the rollers **203** can accurately roll and move, thus preventing the skew-generation of the rollers **203**.

[**0201**] Furthermore, in this embodiment, the gaps between the guide walls **213**, the direction changing roller end surface guide wall **210**_c_ in the loaded area and the unloaded roller end surface guide wall **209**_c_ and the roller end surfaces can be accurately maintained to a predetermined value, so that the gap can be reduced to a sufficiently small value. As a result, the skew of the rollers **203** can be securely prevented in cooperation with the retaining function of the roller chain **218**.

[**0202**] Furthermore, when the movable block **204** is detached from the track rail **202**, the rollers **203** are retained by the roller chain **218**.

[**0203**] The integrally molding of the roller returning passage forming member **2091**, the direction changing passage inner peripheral portion forming member **212** and the loaded roller end surface guide wall **213** with the block body **2040** is performed in accordance with an insert molding method comprising the steps of disposing the block body **2040** into a molding die **215** on the basis of the roller rolling surfaces **207**, **208** formed to the block body **2040**, forming cavities corresponding to the respective resin molded portions to be formed between an inner wall of the molding die **215** and the block body **2040**, and injecting a molding material into the cavities to form the resin molded portions.

[**0204**] **FIG. 12** is a schematic view showing the block body **2040** and states where the molding dies **215** are clamped or opened at the time of the insert molding. Namely, a fixed molding die **215**_a_ is provided with block supporting portions **215**_b_ to which the roller rolling surfaces **207**, **207**; **208**, **208** are fitted for positioning, while a movable molding die **215**_c_ is provided with pins **215**_d_ for forming the roller returning passage. The block supporting portions **215**_b_ and the pins **215**_d_ are formed with projecting portions **215**_b_**1**, **215**_d_**1** corresponding to the guide projecting portion **2181** of the roller chain **218**.

[**0205**] The block supporting portions **215**_b_ have plain shapes corresponding to the roller rolling surfaces **207**, **207**; **208**, **208** and linearly extend in parallel to each other. In this regard, FIGS. 12(_b_) and 12(_c_) shows only a circumference of the roller returning passage **209** of a side of the suspending portion **2042**.

[**0206**] Cavities **215**_d_ for forming the roller returning passage forming member **2091** are provided inside the penetration bores **2043** formed in the horizontal portion **2041** and the suspending portion **2042** of the block body **2040**, respectively. Further, cavities **215**_e_ for forming the first to third loaded roller end surface guide wall forming members **213** are provided to inner periphery portions of the horizontal portion **2041** and the suspending portion **2042**, respectively. Furthermore, cavities **215**_f_ for forming the direction changing passage inner periphery portion forming members **212** are provided to both front and back end portions of the block body **2040**, respectively.

[**0207**] In this embodiment, the paired right and left roller rolling surfaces **207**, **207**; **208**, **208** of the block body **2040** are supported at four points by the block supporting portions **215**_b_ of the molding die **215**. As a result, the block body **2040** can be supported unmoved by the block supporting portions **215**_b_, even if an injection pressure of a molding material is applied to the block body **2040** from every directions, whereby the roller returning passage **209**, the direction changing inner periphery portion **210**_b_ and the first to third loaded roller end surface guide walls **2131-2133** can be accurately formed at predetermined positions.

[0208] In addition, since the block body **2040** is stably positioned in the molding die **215**, the burr is not formed at portions between the roller rolling surfaces **207**, **207**; **208**, **208**.

[0209] It is preferable that the block supporting portions **215***b* closely contact to the roller rolling surfaces **207**, **208**. However, even the block supporting portions **215***b* and the roller rolling surfaces **207**, **208** are moved in a small distance due to a small gap formed therebetween, the small gap shall be allowed as far as a dimension accuracy is within an allowable range and the resin material would not penetrate through the gap.

Modifications of Roller Contact Angles

[0210] Though the explanation described above has been made by taking into consideration an example of a case in which total four rows of rollers are disposed between corresponding portions i.e., the right and left two rows of rollers being disposed between the upper surface of the track rail **202** and the lower surface of the horizontal portion **2041** of the block body **2040** while one row of rollers being disposed between the right and left side surfaces of the track rail **202** and the inner side surfaces of the right and left suspending portions **2042** respectively, a number and an arrangement of the roller rows are optional.

[0211] For example, as shown in **FIGS. 13 and 14**, the device may have a structure having four rows of rollers in total in which right and left two rows of rollers are disposed between the right and left side surfaces of the track rail **202** and the inner side surfaces of the right and left suspending portions **2042** of the block body **2040**, respectively.

[0212] **FIG. 13** shows an example having a structure in which the upper row of rollers **203** among the two rows of the rollers **203** arranged vertically is formed so that a contact angle line of the roller **203** is set to obliquely extend upwards from a side of the track rail **202** to the right and left suspending portions **2042** of the block body **2040** and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line, while the lower row of rollers **203** is formed so that a contact angle line of the roller **203** is set to obliquely extend downwards and is formed so as to incline with an inclination angle of almost 45°.

[0213] **FIG. 14** shows an example having a structure in which the upper row of rollers **203** among the two rows of the rollers **203** arranged vertically is formed so that a contact angle line **L1** of the roller **203** is set to obliquely extend downwards from a side of the track rail to sides of the right and left suspending portions **2042**, **2042** of the block body **2040** and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line H, while the lower row of rollers **203** is formed so that a contact angle line **L2** of the roller **203** is set to obliquely extend upwards and is formed so as to incline with an inclination angle of almost 45°.

[0214] In the case of this embodiment, the direction changing passages **210**A, **210**B of vertically arranged two rows of rollers **3** disposed to both end portions of the block body **2040** are arranged alternately with a predetermined interval in an axial direction so as to intersect to each other. In this case, the direction changing passage inner peripheral portion forming member **212** formed to the end surface of the block body **2040** is provided with the direction changing passage inner periphery portion **210***b* of the direction changing passage **210**A of a side close to the block body **2040** and the direction changing roller end surface guide wall **210***c*, the inner periphery portion **210***b* and the guide wall **210***c* being integrally molded with the block body **2040**.

[0215] As to the direction changing passage **210**B far from the block body **2040**, at least one portion of the loaded roller rolling surfaces **207**, **208** of an end surface side of the block body **2040**, the direction changing passage inner periphery portion **210***b* of a part which is connected to an end portion of the roller returning passage **209** and the direction changing roller end surface guide wall **210***c* are integrally molded with the block body **2040**. While, a round piece **210**C formed with the direction changing passage inner periphery portion **210***b* is attached to a part far from the direction changing passage **210**A. An inner periphery of this round piece **210**C is formed with a part of an outer periphery guide portion of the inside direction changing passage **210**A. The side cover **211** is formed with the direction changing passage outer peripheral portions **210***a*, **210***a* for both the direction changing passages **210**A, **210**B arranged vertically.

[0216] According to the second invention described above, since the rollers are circulated in a state of being retained by the roller chain, the rollers are rolled and moved in a state where center axes of the respective rollers are retained in parallel to each other by the roller chain. Therefore, the generation of skew can be prevented and the rollers can be smoothly rolled and moved.

[0217] In addition, since the roller chain is guided on a predetermined track through the roller chain guide portions formed to the roller returning passage and the direction changing passage, the rollers retained by the roller chain can be also accurately guided.

[0218] In addition, the running-out of the roller chain can be prevented by the roller chain guide portions.

[0219] In particular, when the roller returning passage to be formed with the roller chain guide portions, the roller returning passage forming member to be formed with the direction changing inner periphery portion and the direction changing passage inner periphery portion forming member are integrally molded with the block body, the roller chain guide portions can be accurately formed on the track.

[0220] In addition, when the direction changing passage inner periphery portion forming member is integrally formed with the block body, it becomes possible to eliminate the irregularities to be formed at the connected portion between the roller rolling surface and the direction changing passage inner periphery portion. In addition, as to the roller returning passage, when it is integrally formed with the block body, it also becomes possible to eliminate the irregularities to be formed at the connected portion between the direction changing passage inner periphery portion and the roller returning passage, whereby the rollers can be further smoothly circulated and moved in cooperation with the guiding function of the roller chain.

[0221] Furthermore, when the roller chain is formed so as to have an endless structure and is provided with a falling-out preventing portion for the rollers, the falling-out of the rollers can be prevented by the roller chain even if the movable block is detached from the track rail.

[0222] In addition, the roller chain is provided with a guide projecting portion, while the roller returning passage and the direction changing passage inner peripheral portion are provided with guide grooves. In addition, a side of the roller rolling surface in the loaded area is provided with a guide wall having the guide groove, and the guide wall is integrally molded with the block body by using an insert molding method, so that the roller chain can be accurately guided in all around the endless circulating passage, thus enabling the rollers to further smoothly circulate and move.

[0223] According to the structure described above, when the roller chain is circulated and moved, the guide projecting portion is engaged with the guide groove formed to the roller returning passage and the direction changing passage inner peripheral portion, so that the run-out of the roller chain during the circulation is suppressed. As a result, the rollers can be rolled and moved in orderly arranged state in all around the endless circulating passage.

[0224] In addition, in a case where the roller chain is formed in a striped-shape having no connected portion at both ends thereof, when the movable block is detached from the track rail, the guide projecting portion is engaged with the guide groove, thus enabling to prevent a sagging or slack of an end portion of the roller chain. Further, also in the case of the roller chain having an endless structure, the sagging or slack of an intermediate portion of the roller chain can be prevented.

[0225] When the roller chain comprises spacer portions disposed between the adjacent rollers and connecting members for connecting the respective spacer portions, each of the rollers is arranged and circulated in a state where the rollers are retained by the spacer portions from back and forth in the arranging direction thereof.

[0226] Further, when a falling-out preventing portion for the roller is Provided to the spacer portion so as to prevent the roller falling-out from back and forth of the roller, it becomes unnecessary to chamfer the end portion of the roller, so that an effective length of the roller for bearing the load can be increased, thus enabling to improve the load bearing ability.

[0227] Furthermore, since only the spacer portion is disposed between the adjacent rollers, a pitch of the rollers can be formed as small as possible, so that a number of the rollers required to be disposed per unit length for bearing the load can be increased as many as possible, thus further improving the load bearing ability of the roller.

[0228] In addition, when the roller is formed to have a hollow structure and the roller is retained by inserting a resin portion into the hollow portion of the roller, the falling-out of the roller can be securely prevented and a degree of parallelization between the adjacent rollers can be accurately maintained.

[0229] In addition, as an example of a case where the hollow portion does not penetrate, the roller may be retained in such a manner that a recessed portion is formed to both end portions of the roller and the resin portion is inserted into the recessed portion or in a manner that a grooved portion is formed to a center peripheral portion of the roller and the resin portion is fitted into the grooved portion.

[0230] In addition, when the roller chain is reinforced by inserting a wire or thin plate into the connecting member for linking the rollers, a fatigue strength and life duration of the roller chain can be increased.

[0231] In addition, at a time of the insert molding, when a block supporting portion having a shape obtained by cutting an outer peripheral portion of the roller with a cross section passing through a center axis of the roller is provided to an inner periphery of a molding die so as to correspond to the roller rolling surface of the block body, and the block body is positioned in the molding die by contacting the roller rolling surface to the block supporting portion, the burr would not occur at the roller rolling surfaces.

[0232] In particular, when the paired right and left roller rolling surfaces of the block body are supported by the block supporting portions of the molding die, the block body is clamped from every four directions and supported by the paired right and left block supporting portions at four points. Therefore, even if an injection pressure of a molding material is applied to the block body from every directions, the block body can be held unmoved, thus the block body can be accurately positioned.

INDUSTRIAL APPLICABILITY

[0233] As described above, the linear roller guide device according to the present invention is widely applicable to linear guide mechanisms for various industrial equipments such as machine tool, robot operating system, measuring apparatus or the like.

1. A linear roller guide device comprising a track rail and a movable block assembled to the track rail through a number of rollers,

said movable block comprising:

a roller rolling surface on which said rollers roll;

a block body having a roller returning passage corresponding to the roller rolling surface;

a direction changing passage inner periphery portion formed to both end surfaces of the block body;

a pair of roller end surface guide walls formed to both sides of the roller rolling surface of the block body and adapted to guide both the end surfaces of the roller; and

side covers each having a direction changing passage outer periphery portion for forming a direction changing passage by fitting the side cover into the direction changing passage inner periphery portion formed to both end surfaces of the block body,

said track rail including a roller rolling surface extending in an axial direction corresponding to the roller rolling surface of the block body, and

said rollers circulating in an endless circulating passage constituted by a loaded area between the roller rolling surface of the block body and the roller rolling surface corresponding to the track rail, the direction changing passage and the roller returning passage,

wherein at least one of a roller returning passage forming member for forming the roller returning passage, a roller end surface guide wall forming member for forming at least one of the paired roller end surface guide wall and a direction changing passage inner periphery portion forming member for forming the direction changing passage inner periphery portion is formed as a molded body integrally formed with the block body by inserting the block body into a molding die.

2. A linear roller guide device according to claim 1, wherein said roller returning passage forming member and said direction changing passage inner peripheral portion forming member are provided with guide walls for guiding the end surfaces of the rollers, the guide walls being continuous to the roller end surface guide wall, and said roller returning passage forming member, said roller end surface guide wall forming member of at least one of the paired roller end surface guide wall forming members and said direction changing passage inner peripheral portion forming member are integrally molded with the block body.

3. A linear roller guide device according to claim **1**, wherein said roller is provided with a chamfered portion formed to at least one end portion of the roller, and an engaging projection with which said chamfered portion of the roller is engaged is provided at the roller end surface guide wall integrally molded with the block body so as to prevent the roller from falling-out.

4. A linear roller guide device according to any one of claims **1**, **2** and **3**, wherein said device has a structure having four rows of rollers in total in which a paired right and left rows of rollers are disposed to be rollable between the upper surface of the track rail and a lower surface of a horizontal portion of the block body and two rows of the rollers each is disposed between the right and left side surfaces of the track rail and inside surfaces of a suspending portion of the block body, respectively.

5. A linear roller guide device according to claim 4, wherein a contact angle line constituted by a line connecting two contact points of said roller disposed between the roller rolling surfaces formed to the upper surface of the track rail and the horizontal portion of the block body is set to vertically extend with an inclination angle of approximately 90° with respect to a horizontal line, while a contact angle line of the roller disposed between the roller rolling surfaces formed to the right and left side surfaces of the track rail and the inside surfaces of the suspending portion of the block body is set to obliquely extend downwards and is formed so as to incline with an inclination angle of approximately 30° with respect to a horizontal line.

6. A linear roller guide device according to any one of claims **1**, **2** and **3**, wherein said guide device has a structure having four rows of rollers in total in which two rows of rollers are vertically disposed to be rollable at upper and lower portions between a right side surface of the track rail and a right inside surface of the suspending portion of the block body, respectively, while the remaining two rows of rollers are vertically disposed to be rollable at upper and lower portions between a left side surface of the track rail and a left inside surface of the suspending portion of the block body, respectively.

7. A linear roller guide device according to claim 6, wherein said upper row of rollers is formed so that a contact angle line of the roller is set to obliquely extend upwards from a side of the track rail to sides of the right and left suspending portions of the block body and is formed so as to incline with an inclination angle of approximately 45° with respect to a horizontal line, while said lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards and is formed so as to incline with an inclination angle of approximately 45° with respect to a horizontal line.

8. A linear roller guide device according to claim 6, wherein said upper row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards from a side of the track rail to sides of the right and left suspending portions of the block body, and is formed so as to incline with an inclination angle of approximately 45° with respect to a horizontal line, while the lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards and is formed so as to incline with an inclination angle of almost 45° with respect to a horizontal line.

9. A linear roller guide device according to any one of claims 1 to 7, wherein a block supporting portion having a shape obtained by cutting an outer peripheral portion of the roller with a cross section passing through a center axis of the roller is formed to an inner periphery of a molding die so as to correspond to the roller rolling surface of the block body at a time of an insert molding, and the block body is positioned in the molding die by contacting the roller rolling surface to the block supporting portion.

10. A linear roller guide device comprising a track rail and a movable block assembled to the track rail through a number of rollers,

said movable block comprising:

a block body having a roller rolling surface and a roller returning passage corresponding to the roller rolling surface;

a direction changing passage inner periphery portion formed to both end surfaces of the block body: and

side covers each having a direction changing passage outer periphery portion for forming a direction changing passage by fitting the side cover into the direction changing passage inner periphery portion formed at both end surfaces of the block body,

said track rail including a roller rolling surface extending in an axial direction corresponding to the roller rolling surface of the block body,

said rollers circulating in an endless circulating passage constituted by a loaded area between the roller rolling surface of the block body and the roller rolling surface corresponding to the track rail, the direction changing passage and the roller returning passage, and the rollers are linked to each other by a roller chain inserted to be movable in the endless circulating passage,

wherein said roller returning passage and said direction changing passage inner periphery guide portion are provided with a roller chain guide portion for guiding a track of the roller chain onto a predetermined track,

wherein at least one of the roller returning passage forming member for forming the roller returning passage and the direction changing passage inner periphery portion forming member for forming the direction changing passage inner periphery portion is integrally molded by inserting the block body into a molding die.

11. A linear roller guide device according to claim 10, wherein said roller chain is provided with a guide projecting portion so as to project from the end surface of the roller in an axial direction of the roller, while said roller returning passage and the direction changing passage are provided with guide grooves with which said guide projecting portion is engaged, at least one side of the roller rolling surfaces formed to the block body is provided with a guide wall having the guide groove with which said guide projecting portion is engaged, and said guide wall is integrally molded with the block body by inserting the block body into a molding die to thereby continuously form the guide groove to the roller returning passage forming member, the direction changing passage inner periphery portion forming member and the guide wall so that the guide groove ranges to all around the endless circulating passage.

12. A linear roller guide device according to claim 11, wherein said roller chain comprises spacer portions disposed between the adjacent rollers and connecting members for connecting the respective spacer portions, and said guide projecting portion is provided to the connecting member.

13. A linear roller guide device according to claim 11 or 12, wherein said connecting member and said spacer portion disposed between the adjacent rollers are formed as resin moldings, said roller is formed to have a hollowed portion, and the roller is retained by inserting a resin portion into said hollowed portion of the roller.

14. A linear roller guide device according to claim 11 or 12, wherein said roller is retained in such a manner that a recessed portion is formed to both end portions of said roller and the resin portion is inserted into the recessed portion.

15. A linear roller guide device according to claim 11 or 12, wherein said roller is retained in such a manner that a grooved portion is formed to a center peripheral portion of the roller and the resin portion is fitted into the grooved portion.

16. A linear roller guide device according to any one of claims **11**, **12**, **13**, **14** and **15** wherein said connecting member for linking the rollers is reinforced by inserting a wire or thin plate into the connecting member.

17. A linear roller guide device according to any one of claims 10 to 16, wherein said device has a structure having four rows of rollers in total in which a paired right and left rows of rollers are disposed to be rollable between the upper surface of the track rail and a lower surface of a horizontal portion of the block body and two rows of the rollers each is disposed between the right and left side surfaces of the track rail and inside surfaces of a suspending portion of the block body, respectively.

18. A linear roller guide device according to claim 17, wherein a contact angle line constituted by a line connecting two contact points of said roller disposed between the roller rolling surfaces formed to the upper surface of the track rail and the horizontal portion of the block body is set to vertically extend with an inclination angle of approximately 90° with respect to a horizontal line, while a contact angle line of the roller disposed between the roller rolling surfaces formed to the right and left side surfaces of the track rail and the inside surfaces of the suspending portion of the block body is set to obliquely extend downwards and is formed so as to incline with an inclination angle of approximately 30° with respect to a horizontal line.

19. A linear roller guide device according to any one of claims 10 to 16, wherein said device has a structure having four rows of rollers in total in which two rows of rollers are vertically disposed to be rollable at upper and lower portions between a right side surface of the track rail and a right inside surface of the suspending portion of the block body, while the remaining two rows of rollers are vertically disposed to be rollable at upper and lower portions between a left side surface of the track rail and a left inside surface of the suspending portion of the block body, respectively.

20. A linear roller guide device according to claim 19, wherein said upper row of rollers of the two rows of rollers is formed so that a contact angle line of the roller is set to obliquely extend upwards from a side of the track rail to sides of the right and left suspending portions of the block body and is formed so as to incline with an inclination angle of approximately 45° with respect to a horizontal line, while said lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards and is formed so as to incline with an inclination angle of approximately 45° with respect to a horizontal line.

21. A linear roller guide device according to claim 19, wherein said upper row of rollers of the two rows of rollers is formed so that a contact angle line of the roller is set to obliquely extend downwards from a side of the track rail to sides of the right and left suspending portions of the block body and is formed so as to incline with an inclination angle of approximately 45° with respect to a horizontal line, while the lower row of rollers is formed so that a contact angle line of the roller is set to obliquely extend upwards and is formed so as to incline with an inclination angle of approximately 45° with respect to a horizontal line.

22. A linear roller guide device according to any one of claims 10 to 21, wherein a block supporting portion having a shape obtained by cutting an outer peripheral portion of the roller with a cross section passing through a center axis of the roller is provided to an inner periphery of a molding die so as to correspond to the roller rolling surface of the block body at a time of an insert molding, and the block body is positioned in the molding die by contacting the roller rolling surface to the block supporting portion.

TWO-DIMENSIONAL MOVING SYSTEM

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a two-dimensional moving system for moving a table two dimensionally in a plane, such as X-Y table, in which a table is movable in an X (lateral) direction and a Y (longitudinal) direction, or a X-Z table in which a table is movable in the X direction and a Z (vertical) direction.

2. Related Art

FIG. **11** shows a known plane-type X-Y table, having a conventional structure, a two-dimensional moving system for moving a table in a plane (for example, as disclosed in Japanese Patent Publication No. SHO 63-9477). Such X-Y table comprises a table **1**, a guide mechanism **2** for guiding the table to be movable in a plane, an X-axis driving mechanism **3** and a Y-axis driving mechanism **4**.

Further, it is to be noted that the terms "X-axis "Y-axis " and "Z-axis " used herein may be substituted with terms "X-directional", "Y-directional " and "Z-directional", in which X, Y and Z mean the axial directions (axes) normal to each other.

The guide mechanism **2** includes a base plate **5**, columns (posts) **6**, - - - , **6** disposed at four corner portions of the base plate **5**, two X-axis slider shafts **7**, **7** arranged in parallel between opposed two columns **6**, **6**, two Y-axis slider shafts **8**, **8** arranged in parallel between other opposed two columns **6**, **6**, X-axis sliders **9**, **9** mounted to the X-axis slider shafts **7**, **7** to be slidable, Y-axis sliders **10**, **10** mounted to the Y-axis sliders **8**, **8** to be slidable, a Y-axis guide shaft **11** arranged between the X-axis sliders **9**, **9**, and an X-axis guide shaft **12** arranged between the Y-axis sliders **10**, **10**. Both the X-axis guide shaft **11** and Y-axis guide shaft **12** penetrate the table **1** so as to intersect to each other at right angles.

The X-axis driving mechanism **3** includes a Y-axis motor **13**, a Y-axis driving shaft **14** connected to the Y-axis motor **13** and a pair of X-axis belt transmission devices **15**, **15** fixed to the Y-axis driving shaft **14**. Each of the X-axis belt transmission devices **15**, **15** includes an X-axis belt **16**, which is coupled to the X-axis slider **9** by means of bracket **17**.

The Y-axis driving mechanism **4** includes an X-axis motor **19**, an X-axis driving shaft **20** connected to the X-axis motor **19** and a pair of Y-axis belt transmission devices **21**, **21** fixed to the X-axis driving shaft **14**. Each of the Y-axis belt transmission devices **21**, **21** includes an Y-axis belt **22**, which is coupled to the Y-axis slider **10** by means of bracket **23**.

Then, when the Y-axis motor **13** is driven to be rotated, the Y-axis driving shaft **14** is rotated, the X-axis belts **16**, **16** are moved in the longitudinal direction thereof, and the X-axis sliders **9**, **9** and the Y-axis guide shaft **11** are moved in the X-axis direction. According to such movement, the table **1** is moved in the X-axis direction. On the other hand, when the X-axis motor **19** is driven to be rotated, the X-axis driving shaft **20** is rotated, the Y-axis belts **22**, **22** are moved in the longitudinal direction thereof, and the Y-axis sliders **10**, **10** and the X-axis guide shaft **12** are moved in the Y-axis direction. According to such movement, the table **1** is moved in the Y-axis direction.

In the X-Y table of the structure mentioned above, the Y-axis guide shaft **11** is disposed between the X-axis belts **16**, **16** extending in the X-axis direction, and when the Y-axis driving shaft **14** is driven to be rotated, the Y-axis guide shaft **11** is moved in the X-axis direction, and thereby, the table **1** is moved in the X-axis direction. On the other hand, the X-axis guide shaft **12** is disposed between the Y-axis belts **22**, **22** extending in the Y-axis direction, and when the X-axis driving shaft **20** is driven to be rotated, the X-axis guide shaft **12** is moved in the Y-axis direction, and thereby, the table **1** is moved in the Y-axis direction.

However, in the conventional X-Y table of the structures mentioned above and shown, for example, in FIG. **11**, there is a possibility that rotational angles of tandem pulleys **25**, **25** of the belt transmission devices **15**, **15** are changed at the driving time due to twisting (torsion) force of the Y-axis driving shaft **14**, and the motion of one of the X-axis belts **16** disposed apart from the Y-axis motor **13** always delays from the motion of the other one of the X-axis belts **16** disposed near the Y-axis motor **13**. Such delay of the motion also occurs on the Y-axis belts **22**, **22**. When the table **1** is moved at a highly accelerated speed, the twisting of the Y-axis driving shaft **14** and the X-axis driving shaft **20** is made large. Therefore, in the conventional X-Y table, it is impossible to move the table **1** at a highly accelerated speed.

In order to solve such problem, the Japanese Patent Publication mentioned hereinbefore provides an X-Y table having structure, as shown in FIG. **12**, that the Y-axis driving shaft **14** or X-axis driving shaft **20** is driven at a central portion between the tandem pulleys **25**, **25** so as to make equal the twisting amounts thereof and, hence, to substantially eliminate variation or change of the rotational angles of the tandem pulleys **25**, **25**. In such X-Y table, central driving devices **26**, **26** are arranged at a central portion between the parallel paired X-axis belt transmission devices **15**, **15** and a central portion between the parallel paired Y-axis belt transmission devices **21**, **21**, respectively.

However, in the X-Y table in which the rotational angle variation between the tandem pulleys **25**, **25** are eliminated, the central driving devices **26**, **26** merely serve to distribute a driving force to or between the tandem belt transmission assemblies (including a pair of X-axis belt transmission devices **15**, **15** and a pair of Y-axis belt transmission devices **21**, **21**), and in an actual arrangement, the driving force is applied to the central position between the tandem belt transmission assemblies. That is, the driving force is focused and concentrated on the central portion in the longitudinal direction between the X- and Y-axis guide shafts **12** and **11**. For this reason, when the table **1** is shifted from the central portion between the tandem belt transmission assemblies, it is impossible to position the driving force on the central portion of the table **1**. Therefore, in the case where the table **1** is not accurately positioned on the central portion of the tandem belt transmission assemblies, there will cause a yawing (YAW) moment to the peripheral support bearings, which will be described hereunder in detail.

FIG. **13** shows a schematic arrangement of the X-Y table in which the rotational angle variation between the tandem pulleys **25**, **25** is eliminated. With reference to FIG. **13**, when the central driving device **26** drives the X-axis driving shaft **20**, the tandem belt transmission assemblies **21**, **21**, and the X-axis guide shaft **12** is moved in the Y-axis direction. As shown in FIG. **13**, the equally divided X-axis driving shaft **20** distributes a torque (T) equally to ½ torque (T/2) which equally balances a force of F/2 at both sides of the X-Y table. Finally, a composed force F is positioned on the central portion of the tandem belt transmission assemblies at both the sides of the X-Y table. When the table **1** is shifted from the central position by a distance D, since no means for controlling the supply of the torque exists on the closer side, the force F for acceleration is always applied to the central portion of the X-axis guide shaft **12**. As a result, the yawing moment equal to F×D is caused. In the case where such yawing moment is caused, it becomes difficult to move the table **1** at the highly accelerated speed.

SUMMARY OF THE INVENTION

An object of the present invention is to substantially eliminate defects or drawbacks encountered in the prior art mentioned above and to provide a two-dimensional moving system capable of moving a table or like at a highly accelerated speed without causing any moment such as yawing moment and achieving a high moving (motion) performance, that is, capable of effectively concentrating the accelerated speed on the table regardless of the position of the table when moved.

This and other objects can be achieved according to the present invention by providing a two-dimensional moving system for moving a table in a plane comprising:

a table;

a guide mechanism for guiding the table to be movable in the plane;

first and second belt members which are connected to the table so as to intersect to each other at substantially right angles;

a first driving mechanism for driving the first belt members so as to move the table in a longitudinal direction of the first belt members and to allow the first belt members to be movable in a longitudinal direction of the second belt members; and

a second driving mechanism for driving the second belt members so as to move the table in the longitudinal direction of the second belt members and to allow the second belt members to be movable in the longitudinal direction of the first belt members.

In the present invention, the first and second belt members each preferably comprises an annular endless member including, for example, timing belt, V-belt, chain or rope.

According to the present invention of the structure mentioned above, since the table is moved by driving the first and second belt members, the accelerated force can be effectively concentrated to the table regardless of the position of the table. Further, the moving load including the weight of the table and the load applied thereto is larger than a moving load preliminarily applied to a movable portion of the guide mechanism. However, according to the structure of the present invention, since any yawing moment is not caused, the table can be moved at a high acceleration speed, thus achieving the improved moving performance.

In a preferred embodiment of the present invention, the first driving mechanism comprises a pair of first pulleys provided for both end portions of the first belt members, a first spline shaft extending in parallel to the longitudinal direction of the second belt members so as to penetrate one of the first pulleys and a first driving source for driving the first spline shaft to be rotated, this one of the first pulleys being movable in an axial direction of the first spline shaft and being rotated thereby, and the second driving mechanism comprises a pair of second pulleys provided for both end portions of the second belt members, a second spline shaft extending in parallel to the longitudinal direction of the first belt members so as to penetrate one of the second pulleys and a second driving source for driving the second spline shaft to be rotated, this one of the second pulleys being movable in an axial direction of the second spline shaft and being rotated thereby.

According to this embodiment, the first belt member is rotated and the first belt member can be moved in the longitudinal direction of the second belt member. Furthermore, the second belt member is rotated and the second belt member can be moved in the longitudinal direction of the first belt member. The use of the spline shaft makes simple the structures of the first and second driving mechanisms, improving the reliability. Moreover, even if the driving sources are disposed at corner portions of the X-Y table for the sake of easy usage, the acceleration force can be concentrated to substantially the central portion of the table without using, for example, wrapping transmission member.

The pulleys may be timing pulleys and the belt members may be timing belts.

According to the use of the timing belt having less slip or noise, the table can be smoothly moved at a high acceleration speed and backlash is eliminated, thus improving the positioning performance.

In a further embodiment, the guide mechanism comprises a pair of first guide shafts extending in parallel to the longitudinal direction of the first belt members so as to guide the table to be movable, a pair of second guide shafts extending in parallel to the longitudinal direction of the second belt members so as to guide the table to be movable, a pair of first linear motion guides provided for both end portions of the first guide shafts and adapted to guide the linear motion of the first guide shafts in the longitudinal direction of the second belt members, and a pair of second linear motion guides provided for both end portions of the second guide shafts and adapted to guide the linear motion of the second guide shafts in the longitudinal direction of the first belt members, a pair of the first guide shafts being arranged on both sides of the first belt members and a pair of the second guide shafts being arranged on both sides of the second belt members.

According to this embodiment, since the paired first guide shafts are arranged on both sides of the first belt members and the paired second guide shafts are arranged on both sides of the second belt member, the table can be smoothly guided in a balanced state even if the table is moved at the highly accelerated speed.

In a further embodiment, each of the first pulleys is guided by each of the first linear motion guides so as to be linearly moved in the longitudinal direction of the second belt member and each of the second pulleys is guided by each of the second linear motion guides so as to be linearly moved in the longitudinal direction of the first belt members.

According to this embodiment, the motion of the table can accord with the motions of the first and second belt members, and hence, the table can be moved at the highly accelerated speed.

In a further embodiment, the first and second spline shafts are formed with ball rolling grooves extending in axial directions thereof, the above-mentioned one of the first pulleys and the above-mentioned one of the second pulleys are formed with ball circulation passages including ball rolling grooves corresponding respectively to the ball rolling grooves formed to the first and second spline shafts, and an outer sleeve is assembled to each of the first and second spline shafts to be linearly movable thereto and a number of balls housed and arranged in the ball circulation passage of the outer sleeve so as to circulate in accordance with the linear motion of the outer sleeve with respect to each of the first and second spline shafts.

According to this embodiment, the pulleys can be smoothly moved in the axial direction of the spline shafts through the rolling motion guide, and as a result, the table can be moved at the highly accelerated speed.

In a further embodiment, the linear motion guides each comprises a track shaft having a rolling member rolling surface, a slider member formed with a rolling member circulation passage including a loaded rolling member rolling surface corresponding to the rolling member rolling surface of the track shaft and assembled with the track shaft to be relatively movable, and a number of rolling members arranged in the rolling member circulation passage so as to circulate therein in accordance with the relative motion of the slider member with respect to the track shaft.

According to this embodiment, the motion of the linear motion guide device can be made smooth through the rolling motion of the rolling members, and hence, the guide shafts and the table can be moved at the highly accelerated speed.

In a further embodiment, the first and second belt members are coupled to substantially a central portion of the table in the plane.

According to such structure, the accelerated force can be more effectively concentrated to the central portion of the table, so that the table can be moved at the more highly accelerated speed.

In a further embodiment, the table comprises an upper table section and a lower table section which are shifted from each other in positions in a direction normal to the plane, and one of the first and second belt members is coupled to the upper table section and the other one thereof is coupled to the lower table section.

According to this embodiment, the belt attaching positions are shifted in the vertical direction, so that the interference between the first and second belt members can be prevented even if they intersect to each other.

The nature and further characteristic features of the present invention will be made more clear from the following descriptions made with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

In the accompanying drawings:

FIG. **1** is a plan view of a two-dimensional moving system according to one embodiment of the present invention;

FIG. **2** is a side view of the two-dimensional moving system of FIG. **1**;

FIG. **3** is a view, in an enlarged scale, of an encircled portion III shown in FIG. **1**;

FIG. **4** is a side view of FIG. **3**;

FIG. **5** is a perspective view, partially including a sectional portion, of a linear guide;

FIG. **6** is a side view of the linear guide including a longitudinal sectional view of a guide rail;

FIG. **7** is a perspective view, partially including a sectional portion, of X-axis or Y-axis spline shaft and an outer sleeve thereof;

FIG. **8** is a side view of the X-axis or Y-axis spline shaft, partially including an axial sectional view of the spline shaft;

FIG. **9** is a perspective view, partially including a sectional portion, of X-axis or Y-axis guide shaft and a ball bush;

FIG. **10** is a side view, partially including an axial sectional portion, of the ball bush;

FIG. **11** is a perspective view of one example of an X-Y table having a conventional structure;

FIG. **12** is a perspective view of another example of an X-Y table having a conventional structure; and

FIG. **13** a schematic view of an X-Y table of a further example of a conventional structure.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention will be described hereunder with reference to the accompanying drawings.

FIGS. **1** to **4** represents a two-dimensional moving system according to one embodiment of the present invention. This two-dimensional moving system is used as X-Y table which moves a table in an X-direction (lateral direction in FIG. **1**, for example,) and a Y-direction (vertical direction therein). As shown in FIG. **1**, the two-dimensional moving system includes a table **31**, a guide mechanism **33** for guiding the table **31** to be movable in a plane, an X-axis (directional) driving mechanism **33** for driving, i.e., moving, the table in the X direction and a Y-axis (directional) driving mechanism **34**. At substantially the central portion in the plane of the table **1**, an X-axis belt as first belt **35** and a Y-axis belt as second belt **36**, which intersect at right angles to each other, are coupled together. In the two-dimensional moving system of this embodiment, the table **31** is directly driven and moved by such X-axis belt **35** and the Y-axis belt **36** so that an acceleration force can be effectively concentrated to substantially the central portion of the table **31** even if the table **31** is positioned at any portion. It is preferred that such X-axis belt **35** and the Y-axis belt **36** are formed from annular timing belts.

The guide mechanism **32** for guiding the table **31** to be movable in a plane comprises a frame **37** formed so as to provide a rectangular frame shape, Y-axis linear guides **38**, **38** as first linear motion guide means fixed to two side portions in the Y-direction of the upper surface of the frame **37**, X-axis linear guides **39**, **39** as second linear motion guide means fixed to two side portions in the X-direction of the upper surface of the frame **37**, a pair of X-axis guide shafts **40**, **40** as first guide shafts disposed between the Y-axis linear guides **38**, **38** so as to be parallel to the longitudinal direction of the X-axis belt **35**, and a pair of Y-axis guide shafts **41**, **41** as first guide shafts disposed between the X-axis linear guides **39**, **39** so as to be parallel to the longitudinal direction of the Y-axis belt **36**. The table **31** is guided to be movable in the X-direction by the paired X-axis guide shafts **40**, **40** and in the Y-direction by the paired Y-axis guide shafts **41**, **41**.

The frame **37** is fabricated by arranging frame pieces, which are formed as aluminum product through extrusion molding, into substantially a square shape and connecting four corner portions of the square frame pieces by means of gussets **42**, - - - , **42**, for example. As shown in FIG. **2**, the frame **37** is fixed on a frame mounting bracket **43**.

With reference to FIGS. **1** and **2**, the X-axis linear guides **39**, **39** and the Y-axis linear guides **38**, **38** are each provided with a track rail **44** as a track shaft having a long scale and two slider members **45**, **45** sliding along the track rail **44**. Further, as shown in FIG. **3**, two slider members **45**, **45** are coupled together by means of connection (coupling) plate **46**. The details of the structures of such track rail **44** and slider members **45**, **45** will be mentioned hereinlater. A pulley **50** is mounted to the outside portion of the connection plate **46** through a pulley mounting plate **48** also mentioned hereinlater, and a shock absorber cushion **49** for absorbing an impact energy of the table **31** is also mounted to the inside portion of the connection plate **46**.

Referring to FIG. **1**, a pair of X-axis guide shafts **40**, **40** extending in parallel to the longitudinal direction of the

X-axis belt **35** have both end portions to which a pair of Y-axis linear guides **38, 38** are mounted so as to guide the linear motion in the Y-direction of the X-axis guide shafts **40, 40**. Furthermore, a pair of Y-axis guide shafts **41, 41** extending in parallel to the longitudinal direction of the Y-axis belt **36** have both end portions to which a pair of Y-axis linear guides **39, 39** are mounted so as to guide the linear motion in the X-axis direction of the Y-axis guide shafts **41, 41**.

The paired X-axis guide shafts **40, 40** are on both the side portions of the X-axis belt **35** with equal distance in the Y-axis direction, and the paired Y-axis guide shafts **41, 41** are on both the side portions of the Y-axis belt **36** with equal distance in the X-direction. These X-axis guide shafts **40, 40** and Y-axis guide shafts **41, 41** are composed of hollow shafts having inner hollow structures and attached to the connection plates **46, 46** so as to adjust a tension. That is, as shown in FIGS. **3** and **4**, each of both the end portions of these X-axis guide shafts **40, 40** and Y-axis guide shafts **41, 41** is attached to the connection plate **46** through tension adjusting bolts **51, 51**, a split bush **52** and a tension adjusting bracket **53**. According to this structure, the tensions of the X-axis guide shafts **40, 40** and the Y-axis guide shafts **41, 41** can be adjusted by the tension adjusting bolts **51, 51**, respectively.

With reference to FIG. **1**, the X-axis driving mechanism **33** as the first driving mechanism comprises a pair of X-axis pulleys **50***a*, **50***b* mounted to both end portions of the X-axis belt **35**, a Y-axis spline shaft **55** as a first spline shaft extending in the Y-axis direction and a Y-axis motor **56** such as stepping motor or like as a first driving source for rotating the Y-axis spline shaft **55**, which penetrates one **50***b* of the X-axis pulleys **50***a*, **50***b*. This one X-axis pulley **50***b* is made movable in the axial direction of the Y-axis spline shaft **55** to be rotatable thereby.

The Y-axis driving mechanism **34** as the second driving mechanism comprises a pair of Y-axis pulleys **57***a*, **57***b* mounted to both end portions of the Y-axis belt **36**, a X-axis spline shaft **58** as a second spline shaft extending in the X-axis direction and an X-axis motor **59** such as stepping motor or like as a second driving source for rotating the X-axis spline shaft **58**, which penetrates one **57***b* of the Y-axis pulleys **57***a*, **57***b*. This one Y-axis pulley **57***b* is made movable in the axial direction of the X-axis spline shaft **58** to be rotatable thereby.

The X-axis driving mechanism **33** drives the X-axis belt **35** to be rotated to allow the table **31** to move in the longitudinal direction (X-axis direction) of the X-axis belt **35** and also allow the X-axis belt **35** to move in the longitudinal direction (Y-axis direction) of the Y-axis belt **36**. Further, the Y-axis driving mechanism **34** drives the Y-axis belt **36** to be rotated to allow the table **31** to move in the longitudinal direction of the Y-axis belt **36** and also allow the Y-axis belt **36** to move in the longitudinal direction of the X-axis belt **35**.

The X-axis spline shaft **58** and the Y-axis spline shaft **55** are supported to be rotatable at both ends thereof by support brackets **60, 60** through radial bearings. The support brackets **60, 60** are mounted to the corner portions of the frame **37**.

As shown in FIGS. **1** and **3**, a pair of X-axis pulleys **50***a*, **50***b* and a pair of Y-axis pulleys **57***a*, **57***b* comprises timing pulleys, which are mounted to pulley mounting plates **48**, - - - , **48** mounted and supported to the side surfaces of the connection plates **46, 46** so as to be rotatable through radial bearings, respectively.

The respective X-axis pulleys **50***a*, **50***b* are guided by the Y-axis linear guides **38, 38** to be linearly movable in the Y-axis direction, and the respective Y-axis pulleys **57***a*, **57***b* are guided by the X-axis linear guides **39, 39** to be linearly movable in the X-axis direction. The X-axis pulley **50***b* and the Y-axis pulley **57***b* are formed in combination of outer sleeves **61, 61** and gears **62, 62**, respectively.

As shown in FIGS. **1, 2** and **4**, the table **31** is provided with an upper side table section **31***a* and a lower side table section **31***b* which are shifted from each other in positions in a direction (Z-axis direction) normal to the X-Y plane. The upper side table section **31***a* and the lower side table section **31***b* are coupled together through bush housings **63**, - - - , **63** arranged to four corners of the table **31**. The paired X-axis guide shafts **40, 40** and the paired Y-axis guide shafts **41, 41** penetrate the bush housings **63**, - - - , **63**. Furthermore, ball bushes **64**, - - - , **64** are provided for the X-axis guide shafts **40, 40** and the Y-axis guide shafts **41, 41** at portions penetrating the bush housings **63**, - - - , **63** so as to enable the table to be smoothly movable with respect to the X-axis guide shafts **40, 40** and the Y-axis guide shafts **41, 41**, respectively.

As shown in FIG. **4**, the Y-axis belt **36** is fastened at its upper end side to the lower surface of the upper table section **31***a* by the belt mounting plates **65, 65**, and further, the X-axis belt **35** is also fastened at its lower end side to the upper surface of the lower table section **31***b* by the belt mounting plates, not shown. Further, the upper side of the annular X-axis belt **35** passes through the annular Y-axis belt **36**.

FIGS. **5** and **6** show the track rail **44** and the slider member **45** constituting the linear guides **38, 39**. The linear guides **38** and **39** are disposed on the frame **37** and each comprises the track rail **44** (track shaft) formed with a ball rolling groove **44***a* as a rolling member rolling surface so as to extend in the longitudinal direction thereof, the slider member **45** assembled to the track rail **44** to be relatively movable and a number of balls **69**, - - - , **69** as rolling members. The slider member **45** is formed with a ball circulation passage **68** (rolling member circulation passage) including a loaded ball rolling groove **45***a* as a loaded rolling surface corresponding to the ball rolling groove **44***a* formed to the track rail **44**, and the balls **69** endlessly circulate in the ball circulation passage **68** in association with the relative motion of the slider member **45** with respect to the track rail **44**. According to the endless circulation of the balls **69**, the slider member **45** supporting the table **31** moves linearly along the track rail **44**. The respective balls **69** are held to be rotatable and slidable by retainer means **70**. The balls may be substituted with rollers as rolling members.

The track rail **44** is composed of a linear long member and has substantially a rectangular sectional shape. The ball rolling grooves **44***a* are formed on the upper surface and to both side surfaces of the track rail **44** so as to extend in its longitudinal direction along which the balls **69** are rolled. Two ball rolling grooves **44***a*, totally, four grooves, are formed on left and right side portions of the track rail **44**, respectively. That is, for example, on the left side, one ball rolling groove **44***a* is formed on the left side upper surface of the track rail **44** and one ball rolling groove is formed on the left side side surface thereof.

The slider member **45** comprises a block body **71** and a pair of end covers **72, 72** disposed to both end sides of the block body **71** and fastened thereto by means of bolts. The block body **71** is formed with four loaded rolling member rolling grooves **45***a* opposing to the ball rolling grooves **44***a*, respectively, and the opposing ball rolling grooves **44***a* and **45***a* constitute, when they are assembled, a loaded ball rolling passage α, that is, four loaded ball rolling passages are formed between the track rail **44** and the slider member **45**. Furthermore, four ball return passages β are formed to the movable member so as to extend in parallel to the corresponding loaded ball rolling passages α, and rolling direction changing passages γ connecting the loaded ball rolling passages α and the ball return passages β, respectively, are also formed to the movable member, and one ball circulation passage **68** is constituted by one loaded ball rolling passage α, one return passage β and two rolling direction changing passages γ.

FIGS. **7** and **8** show an example of the X-axis spline shaft **58** and the outer sleeve **61** mounted thereto. Although only the X-axis spline shaft **58** is explained herein, the Y-axis spline shaft **55** has substantially the same structure.

The X-axis spline shaft **58** is formed with, for example, six ball rolling grooves **55***a* extending in the axial direction thereof. The outer sleeve **61** is assembled to the X-axis spline shaft **58** to be linearly movable and comprises a sleeve body **61***a* formed with ball circulation passages **75** including ball rolling grooves **61***a* opposing to the ball rolling grooves **55***a* formed to the spline shaft **58**, a number of balls **76**, - - - , **76** which are housed and arranged in the ball circulation passage **75** and circulate therein in accordance with the relative linear motion of the outer sleeve **61** with respect to the X-axis spline shaft **58**, and retainers **77** assembled to the sleeve body **61***a* so as to align and hold the balls **76** in the ball circulation passages **75**.

Further, a ball rolling groove **61***b* is formed to the inner peripheral surface of the sleeve body **61***a*, as the track for the balls **76**, so as to extend in the axial direction thereof, and the loaded ball rolling groove α is formed by the combination of the ball rolling groove **55***a*formed to the X-axis spline shaft **55** and the ball rolling groove **61***b* formed to the sleeve body **61***a*. A non-loaded ball return passage β, in which the balls **76** released from the load are circulated, is formed adjacent to the loaded ball rolling passage α.

According to the structure mentioned above, when the outer sleeve **61** is moved relatively to the X-axis spline shaft **55**, the balls **76** roll in the loaded rolling passage a under the loaded state and, then, return to the non-loaded return passage β disposed adjacent to the loaded rolling passage α thus endlessly circulating in the circulation passage in shape of circuit.

FIGS. **9** and **10** show the X-axis guide shaft **40** (Y-axis guide shaft **41**) and the ball bush **64** in an assembled state. The ball bush **64** is assembled with the X-axis guide shaft **40** or Y-axis guide shaft **41** to be relatively linearly movable thereto. The ball bush **64** comprises an outer sleeve **80** formed with a ball circulation passage, a number of balls **81**, - - - , **81**, as rolling members which are housed and arranged in the ball circulation passage **75** and circulate therein in accordance with the relative linear motion of the outer sleeve **80** with respect to the X-axis guide shaft **40** or Y-axis guide shaft **41**, and retainers **82** assembled to the outer sleeve **80** so as to align and hold the balls **81** in the ball circulation passages. When the ball bush **64** is relatively linearly moved with respect to the X-axis guide shaft **40** or Y-axis guide shaft **41**, the balls **81** circulate in the ball circulation passage, including the loaded ball rolling passage, between the surface of the X-axis guide shaft **40** (Y-axis guide shaft **41**) and the outer sleeve **80**.

As shown in FIG. **1**, when the Y-axis motor **56** is driven, the X-axis spline shaft **55** is rotated, then, the X-axis belt **35** is driven to be rotated and the table **31** fixed to the X-axis belt **35** is moved in the X-axis direction. In this operation, the Y-axis belt **36** connected to the table **31** is also moved in the X-axis direction under the guidance of the X-axis linear guide. On the other hand, when the X-axis motor **59** is driven, the Y-axis spline shaft **58** is rotated, then, the Y-axis belt **36** is driven to be rotated and the table **31** fixed to the Y-axis belt **36** is moved in the Y-axis direction. In this operation, the X-axis belt **35** connected to the table **31** is also moved in the Y-axis direction under the guidance of the Y-axis linear guide. According to such structure and operation of the present invention, the table is moved in the X and/or Y directions.

Furthermore, according to the present invention, since the table **31** is driven through the driving of the X-axis belt **35** and the Y-axis belt **36**, which are directly connected to the table **31**, the acceleration force can be effectively concentrated to the central portion of the table **31** regardless of the position of the table **31**.

Therefore, according to such structure, no yawing moment is caused, and hence, the table can be moved at a highly accelerated speed with high performance.

It is to be noted that the present invention is not limited to the described embodiments and many other changes and modifications may be made without departing from the scopes of the appended claims.

What is claimed is:

1. A two-dimensional moving system for moving a table in a plane comprising:

a table;

a guide mechanism for guiding the table to be movable in the plane;

a first and second belt means which are connected to the table so as to intersect to each other at substantially right angles;

a first driving mechanism for driving the first belt means so as to move the table in a longitudinal direction of the first belt means and to allow the first belt means to be movable in a longitudinal direction of the second belt means; and

a second driving mechanism for driving the second belt means so as to move the table in a longitudinal direction of the second belt means and to allow the second belt means to be movable in a longitudinal direction of the first belt means,

wherein mechanical force for driving the first and second belt means is provided by motors, and wherein movement of the table does not require translational movement of the motors.

2. A two-dimensional moving system according to claim **1**, wherein said first driving mechanism comprises a pair of first pulleys provided for both end portions of the first belt means, a first spline shaft extending in parallel to the longitudinal direction of the second belt means so as to penetrate one of the first pulleys and a first driving source for driving the first spline shaft to be rotated, said one of the first pulleys being movable in an axial direction of the first spline shaft and being rotated thereby, and wherein said second driving mechanism comprises a pair of second pulleys provided for both end portions of the second belt means, a second spline shaft extending in parallel to the longitudinal direction of the first belt means so as to penetrate one of the second pulleys and a second driving source for driving the second spline shaft to be rotated, said one of the second pulleys being movable in an axial direction of the second spline shaft and being rotated thereby.

3. A two-dimensional moving system according to claim **2**, wherein said pulleys are timing pulleys and said belt means are timing belts.

4. A two-dimensional moving system according to claim **2**, wherein said guide mechanism comprises a pair of first guide shafts extending in parallel to the longitudinal direction of the first belt means so as to guide the table to be movable, a pair of second guide shafts extending in parallel to the longitudinal direction of the second belt means so as to guide the table to be movable, a pair of first linear motion guide means provided for both end portions of the first guide shafts and adapted to guide the linear motion of the first guide shafts in the longitudinal direction of the second belt means, and a pair of second linear motion guide means provided for both end portions of the second guide shafts and adapted to guide the linear motion of the second guide shafts in the longitudinal direction of the first belt means, a pair of said first guide shafts being arranged on both sides of the first belt means and a pair of said second guide shafts being arranged on both sides of the second belt means.

5. A two-dimensional moving system according to claim **4**, wherein each of said first pulleys is guided by each of said first linear motion guide means so as to be linearly moved in the longitudinal direction of the second belt means and each of said second pulleys is guided by each of said second linear motion guide means so as to be linearly moved in the longitudinal direction of the first belt means.

6. A two-dimensional moving system according to claim **4**, wherein said first and second spline shafts are formed with ball rolling grooves extending in axial directions thereof, said one of the first pulleys and said one of the second pulleys are formed with ball circulation passages including ball rolling grooves corresponding respectively to the ball rolling grooves formed to the first and second spline shafts, and wherein an outer sleeve is assembled to each of the first and second spline shafts to be linearly movable thereto and a number of balls housed and arranged in the ball circulation passage of the outer sleeve so as to circulate in accordance with the linear motion of the outer sleeve with respect to each of the first and second spline shafts.

7. A two-dimensional moving system according to claim **4**, wherein said linear motion guide means each comprises a track shaft having a rolling member rolling surface, a slider member formed with a rolling member circulation passage including a loaded rolling member rolling surface corresponding to the rolling member rolling surface of the track shaft and assembled with the track shaft to be relatively movable, and a number of rolling members arranged in the rolling member circulation passage so as to circulate therein in accordance with the relative motion of the slider member with respect to the track shaft.

8. A two-dimensional moving system according to claim **1**, wherein said first and second belt means are coupled to substantially a central portion of the table in the plane.

9. A two-dimensional moving system according to claim **1**, wherein said table comprises an upper table section and a lower table section which are shifted from each other in positions in a direction normal to the plane, and one of said first and second belt means is coupled to the upper table section and the other one thereof is coupled to the lower table section.

(57) **ABSTRACT**

A linear motor drive unit which is connected to a movable body supported movably on a stationary portion such as a head, like a work table and the like of a machine table for instance, and which drives such a movable body in reciprocation while giving a predetermined movement amount to it. The linear motor drive unit comprises a base plate, a magnet plate provided on the base plate, a top plate having a face for attaching the movable body, a movable element fixed to the top plate and facing the magnet plate, one pair of track rails provided on the base plate along both sides of the magnet plate, and slide members fixed to the top plate along both sides of the movable element and moving on the track rails, and the track rails and the slide members are constituted so as to be able to freely divide in a direction along which the movable element is separated from the magnet plate.

LINEAR MOTOR DRIVE UNIT

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a linear motor drive unit which is connected to a movable body supported movably on a stationary portion such as a head, like a work table and the like of a machine tool for instance, and which drives such a movable body in reciprocation while giving a predetermined movement amount to it.

2. Description of the Related Art

In various tables of the machine tool, a travelling portion of an industrial robot, various carrier apparatuses and the like, it is required to linearly guide the movable body on the stationary portion such as head and column, and position it to a predetermined position. Hitherto, as such a guide structure of the movable body, one shown in FIG. **6** is generally well known. Concretely, it is constituted such that a movable body **102** is supported by arranging one pair of linear guide units **101**, **101** on a stationary portion **100**, a ball screw **103** is disposed below the movable body **102**, and the ball screw **103** is driven by a rotary motor **104**. The linear guide unit **101** is composed of a track rail **105** incorporated through balls, and slide blocks **106**. Accordingly, by fixing the track rails **105** to the stationary portion **100** and the slide blocks **106** to the movable body **102**, it becomes possible to freely guide the movable body **102** on the stationary portion **100** along the track rails **105**. Further, the ball screw **103** is one in which a screw shaft **107** meshes with a nut member (not shown in the drawing) through balls and the nut member is fixed to the movable body **102**, while the screw shaft **107** is provided rotatively and parallel to the track rails **105** of the linear guide units **101**. Therefore, it is adapted such that if the screw shaft **107** is rotated by the rotary motor **104**, the nut member is moved on the screw shaft **107** in compliance with rotations of the rotary motor **104** to thereby give a thrust in a direction along the track rails **105** to the movable body **102** and, further, the movable body **102** can be stopped at a predetermined position.

In order to accurately position the movable body on the stationary portion by using the ball screw in this manner, it is required to suitably control a rotational speed and a rotational amount of the rotary motor. However, a precision rotary motor unitized with an encoder being stored and a feedback control function being provided is supplied in a market in various kinds. Accordingly, a person who intends to construct the aforesaid guide structure can very easily construct it merely by purchasing that precision rotary motor, installing it to the stationary portion, and connecting it to the screw shaft through a coupling.

On the other hand, in recent years, also a guide structure in which the movable body is directly driven by using a linear motor without using the ball screw becomes increased. However, different from the rotary motor in which a stator and a rotor are integrated within a casing, magnet plates and coils are under a separated state in the linear motor, so that there arises a necessity to individually fix the magnet plates to the stationary portion and the coils to the movable body. That is, the linear motor is not traded under a state that the magnet plates and the coils are integrated, so that a handling after the purchase is very troublesome. Especially, since it is required that the magnet plate and the coil are faced each other with a very small predetermined gap, in case where these magnet plate and coil are individually handled, a work for attaching them requires much labor, and such a trouble that the magnet plate is brought into contact with the coil to thereby damage them and such an accident that a hand is nipped between the magnet plate and the coil are liable to occur.

Further, also a linear encoder for detecting a movement amount of the coil with respect to the magnet plate is completely separately traded and, in order to realize the feedback control function, it is necessary to purchase the linear encoder separately from the linear motor and incorporate it to the stationary portion and the movable body. And, when completely individually incorporating the magnet plate, the coil and the linear encoder in this manner, a constant accuracy is required for every attaching work, so that the work becomes very troublesome.

Also a linear motor in which these magnet plate, coil and linear encoder are completely unitized exists in the market, but such a linear motor is directed to a specified use, so that a room for improving it in compliance with required conditions scarcely exists.

SUMMARY OF THE INVENTION

The invention has been made in view of such problems, and its object is to provide a linear motor drive unit capable of being easily and safely attached as a drive source of various guide structures, and capable of being flexibly applied to required uses.

In order to achieve the above object, the invention provides a linear motor drive unit attached to a movable body linearly movable with respect to a stationary portion and used for the purpose of giving a thrust to the movable body, comprising: a long base plate; a magnet plate which is provided on the base plate, and in which plural magnetic poles are arranged at a predetermined pitch along a longitudinal direction of the base plate; a top plate having a face for attaching the movable body; a movable element fixed to the top plate and facing the magnet plate; one pair of track rails provided on the base plate along both sides of the magnet plate; and slide members fixed to the top plate along both sides of the movable element and moving on the track rails while keeping an un-contact state between the movable element and the magnet plate; characterized in that the track rails and the slide members are constituted so as to be able to freely divide in a direction along which the movable element is separated from the magnet plate.

According to such a technical means, since the magnet plate is fixed to the base plate, while the movable element is fixed to the top plate and, moreover, since the top plate is incorporated to the base plate through the slide members and the track rails, it becomes possible to handle the magnet plate and the movable element as an integrated one in which they are unitized. Therefore, a work for attaching the magnet plate and the movable element to the stationary portion and the movable body can be easily performed, so that it become possible to avoid such troubles that, during such a work, the magnet plate is damaged and a hand is nipped between the magnet plate and the movable element. That is, since the track rails and the slide members are constituted so as to be able to divide in a direction along which the movable element is separated from the magnet plate, by inserting the linear motor drive unit of the invention to a lower side of the movable body supported movably by linear guide units, and fixing respectively the base plate to the stationary portion and the top plate to the movable body, the magnet plate and the movable element can be easily faced with a predetermined gap.

Further, it is also possible to incorporate a linear encoder between the base plate and the top plate and, in case of being constituted in such a manner, since the linear motor and the linear encoder can be handled as an integrated one in which they are unitized, it becomes also possible to construct easily and within a short time a guide structure having a feedback control function.

Accordingly, the linear motor drive unit of the invention can be easily applied to a wide use, and it becomes possible to intend to reduce a cost by mass production.

Further, in regard to a limited use, it is also possible to use the top plate as a table as it is. In this case, since it results in the fact that a magnetic force applied between the magnet plate and the movable element gives a pre-load between the track rail and the slide member, it becomes possible, in a range not impairing such a pre-load, to use the top plate as the table.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a front sectional view showing an embodiment of a linear motor drive unit of the invention;

FIG. **2** is a perspective view showing one example of a linear guide used in the linear motor drive unit according to the embodiment;

FIG. **3** is a sectional view showing one example of the linear guide used in the linear motor drive unit according to the embodiment;

FIG. **4** is a front view of the linear motor drive unit according to the embodiment;

FIG. **5** is a front view showing a guide structure in which the linear motor drive unit according to the embodiment is used as drive means of a movable body;

FIG. **6** is a perspective view showing one example of a conventional guide structure in which a rotary motor is used as drive means; and

FIG. **7** is a perspective view showing another example of the linear guide.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

Hereunder, a linear motor drive unit of the invention is explained in detail on the basis of the attached drawings.

FIG. **1** is a front sectional view showing a linear motor drive unit **1** to which the invention is applied. The linear drive unit **1** is constituted such that a top plate **4** is movably supported on a long base plate **2** through one pair of linear guides **3** and a linear servomotor **5** is provided between the base plate **2** and the top plate **4** to thereby give a thrust to the top plate **4**.

FIG. **2** and FIG. **3** are a perspective view and a front sectional view, respectively showing details of a constitution of the linear guide **3**. The linear guide **3** is composed of a track rail **30** arranged along a longitudinal direction of the base plate **2**, and a slide member **31** moving along the track rail **30** and fixed to the top plate **4**. The track rail **30** is formed in an approximately rectangular shape in its section perpendicular to a longitudinal direction and, in its one side face along the longitudinal direction, two ball rolling faces **32** are formed toward a direction mutually diverging at 90°. On the other hand, in a side face of the slide member **31**, two load rolling faces **33** facing the ball rolling faces **32** of the track rail **30** are formed, and it is adapted such that many balls **34** roll between the ball rolling faces **32** of the track rail **30** and the load rolling faces **33** of the slide member **31** while bearing a load. Further, it is constituted such that a ball endless track **35** for circulating the balls **34** having finished rolling on the load rolling face **33** is formed in the slide member **31**, so that the slide member **31** can be continuously moved by the fact that the balls **34** are endlessly circulated. Incidentally, in FIG. **2** and FIG. **3**, a reference numeral **36** denotes a retainer, and it prevents the balls **34** from rolling down from the load rolling faces **33** of the slide member **31** when the slide member **31** is separated from the track rail **30**.

As shown in FIG. **1**, one pair of standoffs **20**, **20** are provided in both side edge portions of the base plate **2** along the longitudinal direction, and the track rails **30** are respectively fixed to each standoff **20** by bolts. On the other hand, the slide members **31** are fixed to both side edge portions of the top plate **4** while corresponding to each track rail **30**, and the top plate **4** is provided so as to span between the one pair of standoffs **20**, **20**. Here, each track rail **30** is fixed to the standoff **20** with its face formed with the ball rolling faces **32** being directed upward, while each slide member **31** is fixed to the top plate **4** with its side face formed with the load rolling faces **33** being directed downward, and the slide member **31** is incorporated to the track rail **30** from above (upper side of a paper of FIG. **1**). Accordingly, the ball rolling faces **32** of the track rail **30** contact with the balls **34** at 45° upwardly with respect to a horizontal direction (left and right direction of the paper of FIG. **1**), while the load rolling faces **33** of the slide member **31** contact with the balls **34** at 45° downwardly with respect to the horizontal direction, and it is adapted such that the linear guide **3** constituted by the track rail **30** and the slide member **31** bears only a vertically downward load F1 applied to the top plate **4** and a load F2 applied in the horizontal direction. That is, the top plate **4** is supported on the base plate **2** by the linear guides **3** and freely movable while bearing the loads F1 and F2, whereas it is adapted so as to be able to separate from the base plate **2** when a vertically upward load is applied thereto.

Further, the linear servomotor motor **5** is provided between the top plate **4** and the base plate **2**, and it is constituted such that the top plate **4** is moved on the base plate **2** by the thrust and a holding force, which are generated by the linear servomotor **5**, and can be stopped at a predetermined position on the base plate **2**. The linear servomotor **5** is composed of a magnet plate **50** fixed to the base plate **2** side, and a movable element **51** fixed to the top plate **4** side. A bolster **52** is fixed onto the base plate **2** so as to be put between the standoffs **20**, and the magnet plate **50** is disposed on the bolster **52**. Further, in the magnet plate **50**, plural magnetic poles are magnetized at a predetermined pitch along the longitudinal direction of the base plate **2**, and these magnetic poles are arranged such that an N pole and an S pole exist alternately. On the other hand, the movable element **51** is constituted by repeatedly arranging plural coil assemblies along a moving direction of the top plate **4**, and each coil assembly is constituted by winding a coil **54** around an exciting core **53**. And, each coil assembly is fixed to a lower face of the top plate **4** through a yoke **55**, and an arrangement pitch between the mutually adjoining coil assemblies is the same as that between the magnetic poles in the magnet plate **50**.

Further, as shown in FIG. **4**, in the linear motor drive unit **1**, a Hall sensor **6** is fixed to the top plate **4** through a bracket **60**, and it faces the magnet plate **50** fixed to the base plate **2** with a predetermined interval being kept between them. Since the Hall sensor **6** generates a signal complying with a change in magnetic flux density, if the top plate **4** moves on the base plate **2** along the track rails **30**, it generates a signal in compliance with the intensity of a magnetic field generated by the magnetic pole of the magnet plate **50**. Accordingly, by controlling, on the basis of this signal of the Hall element **6**, a timing of power supply for each coil assembly, a magnetic attraction force is generated between a tip of the exciting core **53** and the magnetic pole of the magnet plate **50**, so that it becomes possible to continuously give a thrust along the longitudinal direction of the base plate **2** to the top plate **4**, while it becomes possible to give a holding force for binding the top plate **4** to one place on the base plate **2**.

Additionally, a reading section **61** of optical type linear encoder is fixed to the bracket **60**, and the reading section **61** faces an encoder tape **62** adhered on a side face of the standoff **20** along the longitudinal of the track rail **30**. Accordingly, it is adapted such that, if the top plate **4** moves on the base plate **2** along the track rails **30**, the reading section **61** counts light and dark stripes formed in the encoder tape **62** at predetermined pitches and, on the basis of such a counted value, a movement amount of the top plate **4** with respect to the base plate **2** can be grasped. Incidentally, a reference numeral **63** in FIG. **4** denotes a cable for transmitting signals from the Hall sensor **6** and the reading section **61** to a control section outside the drawing and supplying an electric power to the movable element **51**. Further, the linear encoder composed of the reading section **61** and the encoder tape **62** is not limited to the optical type one, and may be a magnetic type one for reading the magnetism of a magnet scale.

And, the linear motor drive unit **1** of this embodiment constituted as mentioned above is arranged, for example as shown in FIG. **5**, in the lower face side of a movable body **9** guided on a stationary portion **8** by another linear guides **7**, **7**, and is used as drive means of the movable body **9**. That is, the linear motor drive unit **1** is used with its base plate **2** being fixed to the stationary portion **8** and its top plate **4** to the movable body **9**. Further, the longitudinal direction of the base plate **2** is set parallel to a moving direction of the movable body **9** by the guide units **7**. And, under this state by supplying the electric power to each coil assembly constituting the movable element **51**, a thrust given to the top plate **4** is transmitted to the movable body **9**, so that it is possible to move the movable body **9** on the stationary portion **8** by an optional amount and, further, hold it to a predetermined position.

In such a using method, if a height H from the stationary portion **8** to the movable body **9** is set slightly larger (for example, by about 0.1 mm) than a height h (refer to FIG. **1**) of the linear motor drive unit **1** of this embodiment, a state in which the slide member **31** slightly floats from the track rail **30** is obtained by the fact that the top plate **4** is fixed to the movable body **9**, so that it follows that the movable body **9** is guided on the stationary portion **8** only by the linear guides **7** supporting the movable body **9**. Therefore, even if a guide direction of the top plate **4** by the linear motor drive unit **1** does not strictly agree with that of the movable body **9** on the stationary portion **8**, it is possible to lightly drive the movable body **9** without applying a large resistance to the movement of the movable body **9**. In other words, if the height H of the movable body **9** is set slightly larger than the height h of the linear motor drive unit **1**, an incorporation of the linear motor drive unit **1** to the stationary portion **8** and the movable body **9** can be performed roughly in some extent, so that it is possible to reduce a labor required for the incorporation.

Further, before the linear motor drive unit **1** is incorporated to the movable body **9**, since the top plate **4** fixed with the movable element **51** is mounted on the base plate **2** by the linear guides **3**, **3**, such a trouble that the movable element **51** is brought into contact with the magnet plate **50** can be prevented and, besides, such an accident that a hand is nipped between the movable element **51** and the magnet plate **50** can be prevented as well.

Additionally, according to the linear motor drive unit **1** of this embodiment, since also the top plate **4** itself fixed with the movable element **51** is supported on the base plate **2** by the linear guides **3**, a vertically upward load (load in a direction reverse to F1) is not applied to the top plate **4** and, further if F1 is a very light load, it is also possible to construct a table guide structure by utilizing the top plate **4** itself as a movable body, even if the movable body **9** supported by the linear guides **7** as shown in FIG. **5** is not provided separately. Since an attraction force of the linear servomotor **5**, i.e., a magnetic attraction force between the movable element **51** and the magnet plate **50**, is applied between the top plate **4** and the base plate **2**, this magnetic attraction force acts as a pre-load for pushing the slide member **31** to the track rail **30** and thus, so long as the vertically upward load applied to the top plate **4** does not exceed this pre-load, the top plate **4** is not separated from the base plate **2**.

Further additionally, in the linear motor drive unit of this embodiment, since the magnet plate and the movable element constituting the linear servomotor is unitized through the linear bearings, and since the hall sensor and the linear encoder necessary for controlling the linear servomotor are integrated with the linear servomotor, if this linear motor drive unit is used when constructing a guide structure of the movable body, it becomes possible to construct easily and within a short time the guide structure having a feedback control function.

Incidentally, the linear guide **3** is not limited to one shown in FIG. **2** and FIG. **3** and, so long as it is one capable of bearing the vertically downward load F1 applied to the top plate **4**, its constitution can be suitably changed. However, in case where the fact that it is used with the top plate **4** being fixed to the movable body **9** is taken into consideration, it is necessary that the linear guide **3** has no bearing ability as to a direction reverse to an action direction of the load F1 in order that an interval between the magnet plate **50** fixed to the base plate **2** and the movable element **51** fixed to the top plate **4** can be freely adjusted. For example, as another example of the linear guide **3**, as shown in FIG. **7** there is considered one in which a guide shaft **70** extending along a moving direction of the movable body **9** is arranged on the standoff **20**, while the movable body **9** is provided with rollers **71** travelling on the guide shaft **70**.

Further, the linear motor provided between the top plate **4** and the base plate **2** is not limited to the linear servomotor **5**, and it is also possible to use a linear motor of another type such as a linear pulse motor for instance.

What is claimed is:

1. A linear motor drive unit attached to a movable body linearly movable with respect to a stationary portion and used for the purpose of giving a thrust to the movable body, comprising:

a long base plate;

a magnet plate which is provided on the base plate, and in which plural magnetic poles are arranged at a predetermined pitch along a longitudinal direction of the base plate;

a top plate having a face for attaching the movable body;

a movable element fixed to the top plate and facing the magnet plate;

one pair of track rails provided on the base plate along both sides of the magnet plate; and

slide members fixed to the top plate along both sides of the movable element and moving on the track rails while keeping an un-contact state between the movable element and the magnet plate;

characterized in that the track rails and the slide members are constituted so as to be able to freely divide in a direction along which the movable element is separated from the magnet plate.

2. A linear motor drive unit set forth in claim **1**, characterized in that a linear encoder for detecting a movement distance of the top plate with respect to the base plate is provided.

3. A linear motor drive unit set forth in claim **1**, characterized by having a Hall element for detecting a magnetic flux density between the magnet plate and the movable element.

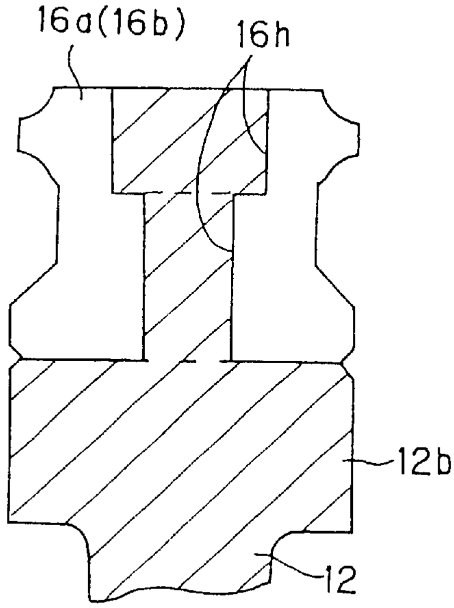

FIG. 15
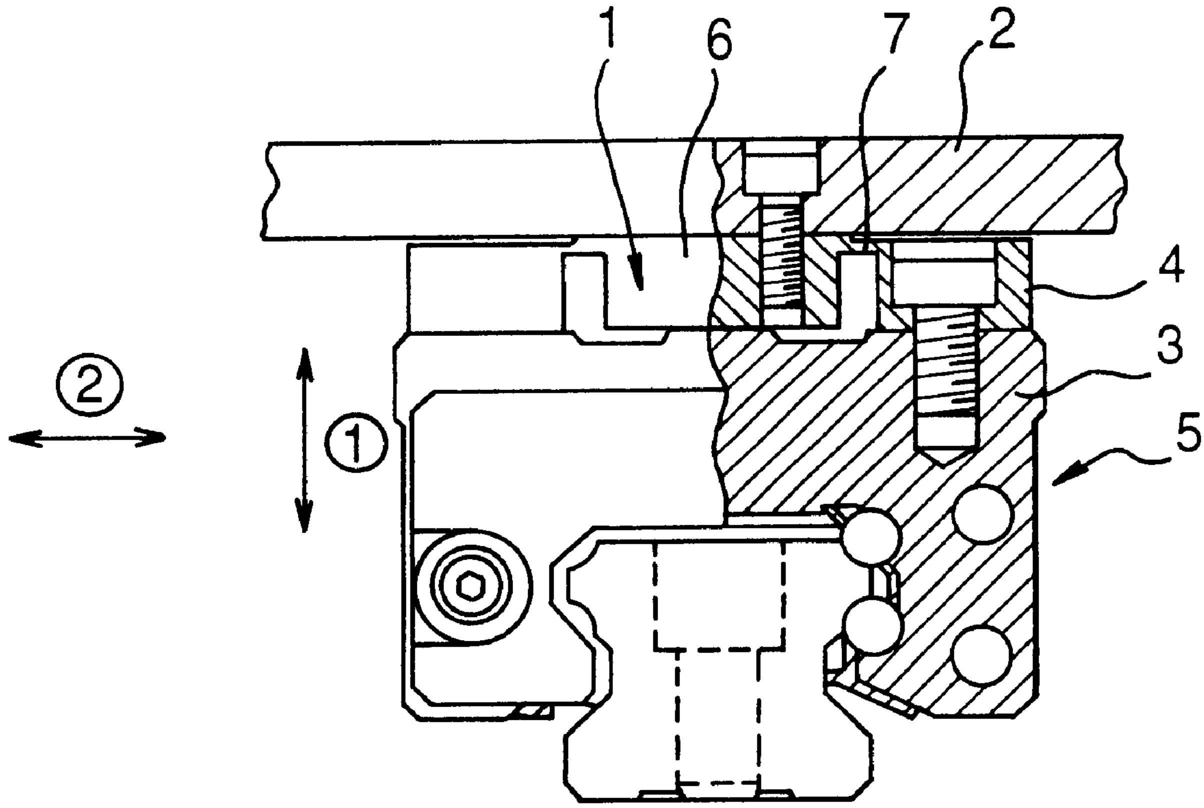
PRIOR ART



RELATIVE LINEAR MOTION APPARATUS

BACKGROUND OF THE INVENTION

The present invention relates to a relative linear motion apparatus in which a second structure is movable in linear motion relative to a first structure, for example in which the second structure formed like a plate is put in the first structure formed like a frame, plurality of rectilinear guides are arranged between the first structure and the second structure so that the second structure is movable relative to the first structure.

In a known art, the Japanese Patent Laid-open Publication No. HEI 7-190053 discloses a mounting plate for a rectilinear guide in order to allow misalignment such as an installation error caused when rectilinear guide is installed. FIG. **15** shows this mounting plate. The mounting plate **1** is put between the rectilinear guide **5** and a fixed member **2**, and allows the rectilinear guide **5** to move in a perpendicular direction 1 against the fixed member **2**. The mounting plate **1** consists of fixed portion **6** mounted to the fixed member **2**, attached portion **4** mounted to a movable block **3** of the rectilinear guide **5**, and thin board portion **7** which connect the fixed portion **6** with the attached portion **4**.

Since the misalignment such as the installation error deforms the thin board portion **7**, the attached portion **4** moves relative to the fixed portion **6** in the perpendicular direction 1 and the mounting plate **1** absorbs the misalignment.

SUMMARY OF THE INVENTION

In some cases, a relative linear motion apparatus comprises a fixed member (first structure) having at least a pair of inner wall surfaces opposing to each other, a movable member (second structure) arranged between the pair of inner wall surfaces, two rectilinear guides arranged between the fixed member and the movable member. The movable member guided by the rectilinear guides slides relative to the fixed member in linear motion to a direction parallel to the inner wall surfaces of the fixed member.

In such a relative linear motion apparatus, when the parallelism of one rectilinear guide to the other rectilinear guide is spoiled by an installation error, or when installing position for the rectilinear guide is under slight error, the movable member can not slide smoothly. Therefore it is necessary to install the rectilinear guides with high accuracy. Also, even if the rectilinear guides are installed with high accuracy, since the rectilinear guides are applied a load caused by thermal expansion and contraction difference between the fixed member and the movable member in a perpendicular direction to the wall, the movable member sometimes can not slide smoothly

In case the conventional mounting plate **1** is used for the relative linear motion apparatus described above, deformation of the thin board portion **7** is small and the mounting plate **1** can not absorb a large error. Therefore, though the mounting plate **1** can absorb small misalignment, the mounting plate **1** can not sufficiently absorb thermal expansion and contraction difference between the fixed member and the movable member.

Also the conventional mounting plate **1** allows the movable member to move slightly not only in the perpendicular direction 1 but also in a horizontal direction 2 (which is parallel to the inner wall surface and perpendicular to a sliding direction of the movable member). So the movable member can not be guided with good rigidity. Further, it is difficult to process the thin board portion **7** on the mounting plate **1**.

An object of the present invention is to provide a relative linear motion apparatus which can sufficiently absorb the installing error of rectilinear guides or thermal expansion and contraction difference between the fixed member and the movable member, and guide the movable member with good rigidity.

In order to achieve the above-mentioned object, the relative linear motion apparatus according to the present invention is constructed so as to comprise: a first structure having at least a pair of inner wall surfaces opposing to each other; a second structure arranged between the pair of inner wall surfaces, the second structure being movable in linear motion relative to the first structure; at least two rectilinear guides arranged between the first structure and the second structure; and a displacement absorbing device arranged on at least one of the first structure and the second structure so as to allow at least one of the two rectilinear guides to move in a intersecting direction against the wall surfaces. The two rectilinear guides make the second structure to be movable in linear motion relative to the first structure.

When the second structure is arranged between the pair of inner wall surfaces of the first structure through the rectilinear guides, and a processing error including an installation error or thermal expansion and contraction difference between the first structure and the second structure occurs, the second structure could not smoothly slide relative to the first structure.

According to the invention described above, even if the processing error including the installation error occurs, or even if the thermal expansion and contraction difference occurs, the displacement absorbing device can absorb the displacement of the rectilinear guide in the intersecting direction against the wall surfaces. Therefore the rectilinear guides are not applied an excessive load and work smoothly, and the second structure smoothly slide relative to the first structure. If the displacement absorbing device allows at least one of the two rectilinear guides to move only in the intersecting direction against the wall surfaces (for example only in the perpendicular direction to the wall surfaces), and restricts the rectilinear guide to move in a horizontal direction (which is parallel to the inner wall surface and perpendicular to a sliding direction of the second structure), it is possible to guide the second structure with good rigidity.

In the relative linear motion apparatus to which the present invention is applied, at least one of the two rectilinear guides moves in the intersecting direction against the wall surfaces due to a processing error including an installation error caused when said at least one of the two rectilinear guides is installed or thermal expansion or thermal contraction difference between the first structure and the second structure.

The relative linear motion apparatus of the invention is effective in absorbing such large displacement.

In a preferred embodiment of the present invention, the displacement absorbing device is arranged between (i) one of said first structure and said second structure and (ii) one of said two rectilinear guides, said displacement absorbing device having an elastic beam which can deflect toward the intersecting direction against the wall surfaces.

According to this embodiment, an elastic beam can deflect and absorb the processing error or the thermal expansion and contraction difference between the first structure and the second structure.

In a further embodiment, said elastic beam has span which is capable of deflection, and the span is longer than width of said one of the two rectilinear guides.

According to this embodiment, the span of the elastic beam become longer, and the deflection of the elastic beam become larger. Therefore the elastic beam can absorb the large processing error or the large thermal expansion and contraction difference.

In a further embodiment, a spacer is arranged between said elastic beam and said one of the two rectilinear guides so that said elastic beam deflects larger, the spacer having width less than the width of said one of the two rectilinear guides.

According to this embodiment, since the load placed on the elastic beam approaches to concentrated load from distributed load, the elastic beam deflects larger.

In a further embodiment, said elastic beam has both longitudinal end portions fixed to said first structure or said second structure, and said one of the two rectilinear guides is arranged in the middle of said elastic beam in a longitudinal direction thereof.

According to this embodiment, the elastic beam deflects with easy construction.

In a further embodiment, said first structure or said second structure has guide surfaces which guide said one of the two rectilinear guides to move in the intersecting direction against the wall surfaces.

According to this embodiment, since the rectilinear guide is guided to move in the intersecting direction against the wall surfaces, the rectilinear guide is prevented from moving in another direction except the intersecting direction. For example it is possible for the rectilinear guide to move only in the perpendicular direction to the wall surfaces so as to absorb the error and not to move in the horizontal direction. Therefore the second structure can be guided with good rigidity.

In a further embodiment, said guide surfaces allows said one of the two rectilinear guides to move only in a perpendicular direction to the wall surfaces without occurrence of change in posture thereof.

According to this embodiment, the rectilinear guide is allowed to move only in the perpendicular direction to the wall surfaces, and is restricted to move in the horizontal direction.

In a further embodiment, each of said rectilinear guides comprises:

- a track member formed with a rolling member rolling surface along a longitudinal direction;
- a movable block mounted to be relatively movable to the track member formed with a rolling member circulation passage including a loaded rolling member rolling surface opposing to the rolling member rolling surface of the track member when mounted;
- and a number of rolling members arranged in the rolling member circulation passage so as to circulate therein in conformity with the relative motion of the movable block with respect to the track rail.

In a further embodiment, each of movable blocks is fixed to said each of said inner wall surfaces of said first structure, and each of track members is fixed to each of edges of said second structure.

In a further embodiment, said track member is integrally formed with said second structure by an inserting mold.

In case the second structure is arranged between the pair of the inner wall surfaces of the first structure through the rectilinear guides, it is necessary to reduce the processing error including the installation error so that the second structure smoothly slides relative to the first structure.

According to this embodiment, since the track rail is inserted in second structure and is integrally molded with the second structure, the processing error is reduced as small as possible. Also, since component parts are reduced too, a relative linear motion apparatus of the invention can be fitted for mass production. On the contrary, if the track rail and the second structure are separately made and the track rail and the second structure are joined together with bolts and so on, the occurrence of the installing error caused by the operator's degree of aging can not be avoided.

BRIEF DESCRIPTION OF THE DRAWINGS

In the accompanying drawings:

FIG. **1** is a perspective view showing a relative linear motion apparatus according to a first embodiment of the present invention.

FIG. **2** is a cross sectional view of the apparatus shown in FIG. **1**, the cross section being taken in a direction parallel to a movable member of the device.

FIG. **3** is a side view of the apparatus of FIG. **2** taken along the line III—III therein.

FIG. **4** is a plan view of the apparatus of FIG. **2** taken along the line IV—IV therein, partially in section.

FIG. **5** is a cross sectional view showing the deflection of the elastic beam.

FIG. **6** is perspective view showing a rectilinear guide put in the apparatus.

FIG. **7** is a cross sectional view showing the rectilinear guide, the cross section being taken in a direction normal to a track rail of the guide.

FIG. **8** is a cross sectional view showing a movable block of the rectilinear guide, the cross section being taken in a direction parallel to a track rail of the guide.

FIG. **9** is a cross sectional view showing a relative linear motion apparatus according to a second embodiment of the present invention, the cross section being taken in a direction normal to a movable member.

FIG. **10** is a cross sectional view showing another crossing portion of the apparatus in FIG. **9**.

FIG. **11** is a perspective view showing a relative linear motion apparatus according to a third embodiment of the present invention.

FIG. **12** is a plan view of the apparatus in FIG. **11**, partially in section.

FIG. **13** is a cross sectional view showing a combination of a movable member and a track rail of the apparatus in FIG. **11**.

FIG. **14** is a cross sectional view showing another variations of the point of apparatus in FIG. **11**, and includes FIG. **14**A showing a first variation, FIG. **14**B showing a second variation, FIG. **14**(C) showing a third variation.

FIG. **15** is a plan view, partially in section, of a mounting plate having a conventional structure.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIGS. **1** to **4** respectively show a relative linear motion apparatus according to a first embodiment of the present invention.

As shown in FIG. **1**, This relative linear motion apparatus comprises a fixed member **11** formed like a quadrilateral frame as first structure, movable member **12** (a second structure) arranged between a pair of inner wall surfaces

11*a*, 11*b* in short sides of the quadrilateral frame, movable member 12 being formed like a plate, and a pair of rectilinear guides 13*a*, 13*b* arranged between each of the inner wall surfaces 11*a*, 11*b* and each of both edges of the movable member 12. The inner wall surfaces 11*a*, 11*b* are parallel to each other. The movable member 12 arranged between the pair of inner wall surfaces 11*a*, 11*b* is perpendicular to the pair of inner wall surfaces 11*a*, 11*b*. Also the movable member 12 slides relative to the inner wall surfaces 11*a* 11*b* in a direction parallel to the inner wall surfaces 11*a* 11*b*.

This relative linear motion apparatus is used for a linear motor for example. In this case, as shown in FIG. 4 a permanent magnet 14 as a magnetic material is disposed in a frame of the movable member 12. And a pair of coils 8, 8 are disposed on a pair of inner wall surfaces 11*c* 11*d* in long sides of the fixed member 11. And the movable member 12 is put between the pair of coils 8, 8. Producing a magnetic field of the coils 8, 8 slides the movable member 12.

The movable member 12 is composed of a frame 12*a*, the permanent magnet 14 disposed in the frame 12*a*, and rail holding portions 12*b*, 12*b* which are fixed to both edges of the frame 12*a*. Track rails 16*a*, 16*b* are attached to the rail holding portions 12*b*, 12*b*. This movable member 12 slides in a direction parallel to the inner wall surfaces 11*a* 11*b* (in FIG. 1 vertical direction) with the track rails 16*a*, 16*b*.

Each of the rectilinear guides 13*a*, 13*b* comprises the track rail 16*a* (16*b*) as a track member, and the movable block 17*a* (17*b*) as slide member. In this embodiment, two movable blocks 17*a*, 17*a* (17*b*, 17*b*) are put side by side on the track rail 16*a* (16*b*). Each of the track rails 16*a*, 16*b* is arranged on each of both edges of the movable member 12. And the movable blocks 17*a*, 17*a*, 17*b*, 17*b* are arranged on the inner wall surfaces 11*a*, 11*b* of fixed member 11. The track rails 16*a*, 16*b* slide along the movable blocks 17*a*, 17*a*, 17*b*, 17*b* without changing the position of the movable blocks 17*a*, 17*a*, 17*b*, 17*b*.

In this embodiment, although the backs of the movable blocks 17*a*, 17*a*, 17*b*, 17*b* are attached to the inner wall surfaces 11*a*, 11*b* and the movable member 12 is arranged between the track rails 16*a*, 16*b* opposing to each other, the arrangement of the rectilinear guides 13*a*, 13*b* is not restricted to these. For example, it may be possible to turn the rectilinear guides 13*a*, 13*b* over so that the backs of the movable blocks 17*a*, 17*b* are attached to the both edges of the movable member 12 and the track rails 16*a*, 16*b* are attached to the inner wall surfaces 11*a*, 11*b*. Also it may be possible to turn only one of the rectilinear guides 13*a*, 13*b* over. In this case, the track rail 16*b* is attached to the inner wall surface 11*b* in one rectilinear guide 13*b* and the back of movable block 17*a* is attached to the inner wall surface 11*a* in other rectilinear guide 13*a*.

As shown in FIGS. 2 to 4, the fixed member 11 is formed like a quadrilateral frame. And the movable blocks 17*a*, 17*a*, 17*b*, 17*b* are attached to the inner wall surfaces 11*a*, 11*b* in short sides of the quadrilateral frame. The movable blocks 17*a*, 17*a* attached to the inner wall surface 11*a* does not change the position. And the movable blocks 17*b*, 17*b* attached to the inner wall surface 11*b* are allowed to be movable in a perpendicular direction to the inner wall surface 11*b* so as to absorb an installation error caused when said the pair of rectilinear guides 13*a*, 13*b* are installed, or thermal expansion and contraction difference between the fixed member 11 and the movable member 12.

In the inner wall surface 11*a*, a fitting groove 21*a* which has a width equal to the width of the movable blocks 17*a*, 17*a* are formed so as to locate the movable blocks 17*a*, 17*a*. The movable blocks 17*a*, 17*b* are fitted in the fitting groove 21*a* and fixed to the inner wall surface 11*a*. In the inner wall surface 11*b*, fitting groove 21*b* is formed by which the rectilinear guide 13*b* is guided to move in the direction perpendicular to the inner wall surface 11*b*. The width of the fitting groove 21*b* is equal to the width of the movable blocks 17*b*, 17*b* of the rectilinear guide 13*b*. The fitting groove 21*b* has a pair of wall guide surfaces opposing to each other. Being guided by a pair of wall guide surfaces of the fitting groove 21*b*, movable blocks 17*b*, 17*b* move in the perpendicular direction.

The movable blocks 17*b*, 17*b* are attached to the inner wall surface 11*b* of the fixed member 11 through elastic beams 19, 19 as a displacement absorbing device.

As shown in FIG. 4, the elastic beam 19 has both longitudinal end portions fixed to the fixed member 11, the movable block 17*b* is substantially arranged in the middle of the elastic beam 19 in the longitudinal direction thereof. A hollow 23 which has the same area as the elastic beam 19 is formed on an outer wall surface 22, and the elastic beam 19 is fitted in the hollow 23. The hollow 23 is extended to the fitting groove 21*b*. A wall is penetrated by the hollow 23 and the fitting groove 21*b*. The elastic beam 19 has span which is capable of deflection, and the span is longer than the width W of the movable block 17*b*. And a spacer 20 is arranged between the elastic beam 19 and the movable block 17*b* so that the elastic beam 19 deflects larger. The spacer 20 has width less than the width of the movable block 17*b*.

As shown FIG. 5, when a processing error including an installation error caused by the installation of the two rectilinear guides 13*a*, 13*b* occurs, or when thermal expansion and contraction difference between the fixed member 11 and the movable member 12 occurs, or when a deformation of the relative linear motion apparatus caused by a load from the inside or the outside of the apparatus occurs, the elastic beam 19 is deflected by a load applied from the spacer 20 to the elastic beam 19. The elastic beam 19 is deflected by the load, as if a fixed beam is deflected by a concentrated load applied to the middle of the fixed beam. Deflecting the elastic beam 19 to the perpendicular direction allows the movable block 17*b* to move in the perpendicular direction ① and absorbs the installing error or the thermal expansion and contraction difference or the deformation of the relative linear motion apparatus caused by the load. Since the movable block 17*b* is allowed to move only in the direction ① perpendicular to the inner wall surface 11*b* and restricted to move in the horizontal direction ②, it is possible to guide the movable member 12 in good rigidity. Further, In this embodiment, since elastic beam 19 is disposed only on the movable block 17*b* and is not disposed on the movable block 17*a*, the movable member 12 is stably supported by the rectilinear guides 13*a*, 13*b* in the perpendicular direction ①.

In order to absorb the expansion and contraction difference, it is expected that the elastic beam 19 deflect largely. Disposing the spacer between the movable member 17*b* and the elastic beam 19 the load placed on the elastic beam 19 approaches to the concentrated load from the distributed load, and deflects the elastic beam 19 larger. Furthermore, since the span of the elastic beam 19 is longer than the width W of the movable block 17*b*, the deflection of the elastic beam 19 becomes all the more larger.

FIG. 6. Shows the rectilinear guide 13*a* (13*b*). The rectilinear guides 13*a* (13*b*) comprises, a track rail 16*a* (16*b*) as a track member formed with rolling member rolling grooves 31,31 as rolling member rolling surfaces along a

longitudinal direction thereof, a movable block **17**a (**17**b) mounted to be relatively movable to the track rail **16**a (**16**b), the movable block **17**a (**17**b) being formed with rolling member circulation passages including loaded rolling member rolling grooves as loaded rolling member rolling surfaces opposing to the rolling member rolling grooves **31**,**31** of the track rail **16**a (**16**b) when mounted, and a number of balls **33**, - - - , **33** as rolling members arranged in the rolling member circulation passages so as to circulate therein in conformity with the relative motion of the movable block **17**a (**17**b) with respect to the track rail **16**a (**16**b). This rectilinear guides **13**a (**13**b) is constructed so as to bear a load not only in the perpendicular direction but also in the horizontal direction.

The track rail **16**a (**16**b) has a rectangular shape in section. Each of the right and left side surfaces of the track rail **16**a (**16**b) is formed with two lines of loaded ball rolling grooves **31**,**31**. And the total of ball rolling grooves **31**,**31** is four.

The movable block **17**a (**17**b) comprises a body portion **34** and end covers (plates) **35**, **35** disposed on both longitudinal end sides of the body portion **34**, the body portion **34** and the end covers **35**, **35** being secured together by means of bolts. The movable block **17**a (**17**b) straddles the track rail **16**a (**16**b). The movable block **17**a (**17**b) is formed with the loaded ball rolling grooves **32**,**32** and the ball escape bores, while each of the end plates **35**,**35** is formed with the direction changing passages. Each of the ball escape bores linearly passes through the movable block **17**a (**17**b). A fixing surface **36** attached to the inner wall surface **11**a (**11**b) or the spacer **20** is formed on the upper surface of the body portion **34**. Four screw holes **37**a, - - - , **37**a for fixing the inner wall surface **11** a (**11** b) are formed around the fixing surface **36**, and two screw holes **37**b, **37**b for fixing the spacer **20** are formed inside the screw holes **37**a, - - - , **37**a.

The loaded rolling member rolling grooves **32**, **32** are opposing to the rolling member rolling grooves **31**, **31** of the track rail **16**a (**16**b), and the loaded rolling member rolling grooves **32**, **32** and the rolling member rolling grooves **31**, **31** compose loaded ball rolling passages. A number of balls (rolling members) **33**, - - - , **33** are arranged in the ball circulation passages and are put between the loaded rolling member rolling grooves **32**, **32** and the rolling member rolling grooves **31**,**31**. According to the movement of the movable blocks **17**a (**17**b) along the track rail **16**a (**16**b), the balls **33**, - - - , **33** are moved (rolled) from one end to the other end of the loaded ball rolling passages and scooped by the direction changing passages of the end plates **35**, **35** and guided by the ball escape bores, and then returned to the one end of the loaded ball rolling passages through the other one of the direction changing passages. The balls circulate in conformity with the relative motion of the movable block **17**a (**17**b) with respect to the guide rail **16**a (**16**b).

As shown in FIGS. **7** to **8**, a chain of balls are held capable of rotation and slide by retainer **44**. This retainer **44** is composed of a plurality of spacers **40**, - - - , **40** interposed alternately between a plurality of balls **33**, - - - , **33**, and a thin belt **41** connecting the each of the spacers **40**, - - - , **40**.

A seal member **42** is disposed between the movable block **17**a (**17**b) and a upper surface of track rail **16**a (**16**b). Seal members **43**, **43** are disposed between the movable block **17**a (**17**b) and side surfaces of the track rail **16**a (**16**b). This seal members **42**, **43**, **43** seal lubricating oil filled between the ball rolling grooves **31**, **31** and the loaded ball rolling grooves **32**, **32**.

FIG. **9** shows a relative linear motion apparatus according to a second embodiment of the present invention. In this embodiment, a fixed member **51** has a octagonal frame in section, a movable member **52** is cross-shaped in section. Four rectilinear guides **53**a, **53**a, **53**b, **53**b are disposed between tips of a cross and inner wall surfaces opposing to the tips. Four permanent magnets **54**, - - - , **54** are fitted in four plate members **52**a, **52**b, **52**c, **52**d composing the cross. And four coils **55**, - - - , **55** are attached to the fixed member so that the each of permanent magnets **54**, - - - , **54** are put between each of the coils **55**, - - - , **55**. The movable member **52** is moved by producing a magnetic field of the coils **55**, - - - , **55**.

In one direction and in other direction crossing to one direction, rectilinear guides **53**a, **53**a and rectilinear guides **53**b, **53**b are arranged between the fixed member **51** and the plate members **52**a, **52**b, **52**c, **52**d of the movable member **52**. As the relative linear motion apparatus according to the first embodiment, movable blocks **56**b, **56**b are attached to the fixed member **51** through elastic beams **57**, **57**, and are capable of moving in a direction perpendicular to the inner wall surfaces. Also, these movable blocks **56**b, **56**b are guided to move only in the direction perpendicular to the inner wall surfaces and restricted to move in a horizontal direction by guide surfaces.

At the crossing part of the movable member **52**, notches **58**, - - - , **58** are made to reduce a rigidity of the movable member **52** slightly. Since there is a reduction in the rigidity of the crossing part, the crossing part absorbs the displacement caused by the thermal expansion and contraction of the plate members **52**a, **52**c in one direction or the plate members **52**b, **52**d in other direction. And a load which is caused by the thermal expansion and contraction of the plate members **52**a, **52**c is not transmitted to the plate members **52**b, **52**d. Also, a load which is caused by the thermal expansion and contraction of the plate members **52**b, **52**d is not transmitted to the plate members **52**a, **52**c in the same way.

FIG. **10** shows another variation of the crossing part. In this variation, four plate members **52**a, **52**b, **52**c, **52**d which compose the cross are connected with gussets **59**, - - - , **59**. The rigidity of gussets **59**, - - -, **59** are reduced. In this case, the gussets **59**, - - - , **59** absorb the displacement caused by the thermal expansion and contraction of the plate members **52**a, **52**c in one direction or the plate members **52**b, **52**d in other direction. And a load which is caused by the thermal expansion and contraction of the plate members **52**a, **52**c is not transmitted to the plate members **52**b, **52**d. Also, a load which is caused by the thermal expansion and contraction of the plate members **52**b, **52**d is not transmitted to the plate members **52**a, **52**c in the same way.

In this embodiment, making the movable member in the shape of the cross give good rigidity to the movable member **52** itself. Also, since an area of the coils **55**, - - - , **55** and the permanent magnets **54**, - - - , **54** become larger, an output of the primary drive become larger.

Further, in the described embodiment of the relative linear motion apparatus, the elastic beam **57** is arranged on only one side of the rectilinear guides **53**a, **53**b opposing to each other so that only one side of the rectilinear guides **53**a, **53**b moves in the perpendicular direction. However, in an alternation, it may be adopted that the elastic beams **57**, **57** are arranged on both rectilinear guides **53**a, **53**b so that both sides of the rectilinear guides **53**a, **53**b move in the perpendicular direction.

Further, in the described embodiment of the relative linear motion apparatus, the elastic beams (plate) **57** are attached to the fixed member **51**. However, in an alternation, it may be adopted that the elastic beam **57**, **57** are attached to the movable member **52**.

Still furthermore, the shape of the fixed member **51** in cross section is not restricted to a quadrilateral or an octagon, and alternations and many other changes such as a polygon or a circle or a substantially ⊐-shaped cross section of which one side is opened may be adopted. As to the movable member **52**, the shape of the movable member **52** in cross section is not restricted to a plate or an crossing which miniaturize the relative linear motion apparatus, and alternations and many other changes such as a cylinder may be adopted.

FIGS. **11** to **13** show a relative linear motion apparatus according to a third embodiment of the present invention. In this embodiment, the relative linear motion apparatus comprises a fixed member **11** formed like a quadrilateral frame as first structure, movable member **12** arranged between a pair of inner wall surfaces **11***a* **11***b* in short sides of the quadrilateral frame as second structure, the movable member **12** being formed like a plate as a second structure, and a pair of rectilinear guides **13***a*, **13***b* arranged between each of the inner wall surfaces **11***a*, **11***b* and each of both edges of the movable member **12**. The movable member **12** slides relative to the inner wall surfaces **11***a*, **11***b* in a direction parallel to the inner wall surfaces **11***a*, **11***b*.

Each of the rectilinear guides **13***a*, **13***b* comprises the track rail **16***a* (**16***b*) as a track member, and the movable block **17***a* (**17***b*) as slide member. Each of the track rails **16***a*, **16***b* is arranged on each of both edges of the movable member **12**. And the movable blocks **17***a*, **17***a*, **17***b*, **17***b* are arranged on the inner wall surfaces **11***a*, **11***b* of fixed member **11**. The movable blocks **17***a*, **17***a* are attached to the inner wall surface **11***a*, and the movable blocks **17***b*, **17***b* are attached to the inner wall surface **11***b*. And the movable blocks **17***b*, **17***b* are set to be movable only in the direction perpendicular to the inner wall surface **11***b* so as to absorb the installing error of the rectilinear guides **13***a*, **13***b* or the thermal expansion and construction difference between fixed member **11** and movable member **12**.

The arrangements and functions of elements or parts of the relative linear motion apparatus the same as the relative linear motion apparatus shown in FIGS. **1** to **6** are not described herein by adding the same reference numerals to the corresponding elements or parts.

The frame **12***a* and rail holding portions **12***b*, **12***b* fixed to the both edges of the frame **12***a* are integrally formed by a die casting using metal such as aluminum. Further, the track rails **16***a*, **16***b* are inserted in rail holding portions **12***b*, **12***b* of the movable member **12**, and are integrally molded with movable member **12**. In different words, the movable member **12** is integrally formed with the track rails **16***a*, **16***b* by injecting metal such as aluminum into a metal mold in which the track rails **16***a*, **16***b* are placed, i.e. through a so-called insert molding method. Since the track rails **16***a*, **16***b* are affected by heat when the track rails **16***a*, **16***b* are molded, the ball rolling grooves **31**,**31** are formed by machining or grinder after molding the track rails **16***a*, **16***b*. Also, it may be possible to arrange a means for preventing the track rails **16***a*, **16***b* from slipping out of the rail holding portions **12***b*, **12***b* to the axial direction of the track rails **16***a* **16***b*. And forming a difference in level on the track rails **16***a* **16***b* prevents the track rails **16***a*, **16***b* from slipping out of the rail holding portions **12***b*, **12***b*.

When movable member **12** are arranged between the pair of inner wall surfaces **11***a*, **11***b* opposing to each other of the fixed member **11** through the rectilinear guides **13***a*, **13***b*, it is necessary to reduce the processing error including the installing error of the rectilinear guides **13***a*, **13***b*. According to this embodiment, since the track rails **16***a*, **16***b* are inserted in the movable member **12** and are integrally molded with the movable member **12**, it is possible to reduce the processing error as much as possible. Also it is possible to reduce the number of articles.

FIG. **14** shows a variation of the point in the third embodiment. As shown in FIG. **14**(*a*), the rail holding portion **12***b* of the movable member **12** is extended from a base of the track rail **16***a* (**16***b*) to hollows **16***f*, **16***f* formed on side surfaces of the track rail **16***a* (**16***b*). A lower part of the track rail **16***a* (**16***b*) is wrapped by the rail holding portion **12***b*. According to this construction, since combination of the track rail **16***a* (**16***b*) and the rail holding portion **12***b* becomes firmer, both are not separated by added vibration or shock.

In a second variation shown in FIG. **14**(*b*), a dovetail groove **16***g* is formed on the base of the track rail **16***a* (**16***b*), a part **12***e* of the rail holding portion **12***b* is injected into the dovetail groove **16***g*. According to this structure, combination of the track rail **16***a* (**16***b*) and the rail holding portion **12***b* becomes firmer as much as the variation shown in FIG. **14**(*a*). Also, it is possible to narrow down the width of the rail holding portion **12***b* to the width of the track rail **16***a* (**16***b*) and to miniaturize the relative linear motion apparatus.

In a third variation shown in FIG. **14**(*c*), a part **12***f* of the rail holding portion **12***b* is injected into bore **16** for inserting bolt. According to this structure, combination of the track rail **16***a* (**16***b*) and the rail holding portion **12***b* becomes firmer as much as the variations shown in FIG. **14**(*a*) and FIG. **14**(*b*). And it is possible to narrow down the width of the rail holding portion to the width of the track rail **16***a* (**16***b*). Furthermore since the existing bore **16***h* for inserting bolt is used for casting, it is not necessary to form the dovetail groove **16***g* shown in FIG. **14**(*b*) on the track rail **16***a* (**16***b*), and as a result costs fall.

It is further to be noted that the present invention is not limited to the described embodiments and alternations and many other changes and modifications may be made without departing from the scopes of the appended claims.

What is claimed is:

1. A relative linear motion apparatus comprising:

a first structure having at least a pair of inner wall surfaces opposing to each other;

a second structure arranged between the a pair of inner wall surfaces, the second structure being movable in linear motion relative to the first structure;

at least two rectilinear guides arranged between the pair of inner wall surfaces of the first structure and the second structure; and

a displacement absorbing device arranged on at least one of the first structure and the second structure so as to allow at least one of the two rectilinear guides to move in an intersecting direction against the wall surfaces.

2. A relative linear motion apparatus according to claim **1**, wherein said at least one of the two rectilinear guides moves in the intersecting direction against the wall surfaces due to a processing error including an installation error caused when said at least one of the two rectilinear guides is installed or thermal expansion and contraction difference between the first structure and the second structure.

3. A relative linear motion apparatus according to claim **1** or **2**, wherein said displacement absorbing device is arranged between (i) one of said first structure and said second structure (ii) and one of said two rectilinear guides, and said displacement absorbing device having an elastic beam which can deflect toward the intersecting direction against the wall surfaces.

4. A relative linear motion apparatus according to claim **3**, wherein said elastic beam has span that is capable of deflection, and the span is longer than the width of said one of the two rectilinear guides.

5. A relative linear motion apparatus according to claim **4**, wherein a spacer is arranged between said elastic beam and one of said rectilinear guides so that said elastic beam deflects larger, and the spacer having width less than the width of said one of the two rectilinear guides.

6.A relative linear motion apparatus according to claim **4**, wherein said elastic beam has both longitudinal end portions fixed to said first structure or said second structure, and said one of the two rectilinear guides is substantially arranged in the middle of said elastic beam in a longitudinal direction thereof.

7. A relative linear motion apparatus according to claim **1**, wherein said first structure or said second structure has guide surfaces which guide said one of the two rectilinear guides to move in the intersecting direction against the wall surfaces.

8. A relative linear motion apparatus according to claim **7**, wherein said guide surfaces, being formed on fitting groove of which the width is equal to the width of said one of the two rectilinear guides, allow said one of the two rectilinear guides to move only in a perpendicular direction to the wall surfaces without occurrence of change in posture of said one of the two rectilinear guides.

9. A relative linear motion apparatus according to claim **1**, wherein each of said rectilinear guides comprises:

a track member formed with a rolling member rolling surface along a longitudinal direction;

a movable block mounted to be relatively movable to the track member formed with a rolling member circulation passage including a loaded rolling member rolling surface opposing to the rolling member rolling surface of the track member when mounted; and

a number of rolling members arranged in the rolling member circulation passage so as to circulate therein in conformity with the relative motion of the movable block with respect to the track rail.

10. A relative linear motion apparatus according to claim **9**, wherein each of movable blocks is fixed to said each of said inner wall surfaces of said first structure, and each of track members is fixed to each of edges of said second structure.

11. A relative linear motion apparatus comprising:

a first structure having at least a pair of inner wall surfaces opposing to each other;

a second structure arranged between the pair of inner wall surfaces, the second structure being movable in linear motion relative to the first structure;

at least two rectilinear guides arranged between the first structure and the second structure; and

a displacement absorbing device arranged on at least one of the first structure and the second structure so as to allow at least one of the two rectilinear guides to move in an intersecting direction against the wall surfaces;

wherein said displacement absorbing device is arranged between (i) one of said first structure and said second structure (ii) and one of said two rectilinear guides, said displacement absorbing device having an elastic beam which can deflect toward the intersecting direction against the wall surfaces,

and wherein said elastic beam has a span which is capable of deflection, and the span is longer than the width of said one of the two rectilinear guides.

12. A relative linear motion apparatus according to claim **11**, wherein a spacer is arranged between said elastic beam and said one of the two rectilinear guides so that said elastic beam deflects larger, and the spacer having width less than the width of said one of the two rectilinear guides.

13. A relative linear motion apparatus according to claim **11**, wherein said elastic beam has both longitudinal end portions fixed to said first structure or said second structure, and said one of the two rectilinear guides is substantially arranged in the middle of said elastic beam in a longitudinal direction thereof.

14. A relative linear motion apparatus comprising:

a first structure having at least a pair of inner wall surfaces opposing to each other;

a second structure arranged between the pair of inner wall surfaces, the second structure being movable in linear motion relative to the first structure;

at least two rectilinear guides arranged between the first structure and the second structure; and

a displacement absorbing device arranged on at least one of the first structure and the second structure so as to allow at least one of the two rectilinear guides to move in an intersecting direction against the wall surfaces;

wherein each of said rectilinear guides comprises:

a track member formed with a rolling member rolling surface along a longitudinal direction;

a movable block mounted to be relatively movable to the track member formed with a rolling member circulation passage including a loaded rolling member rolling surface opposing to the rolling member rolling surface of the track member when mounted; and

a number of rolling members arranged in the rolling member circulation passage so as to circulate therein in conformity with the relative motion of the movable block with respect to the track rail;

wherein each of said movable blocks is fixed to each of said inner wall surfaces of said first structure, and each track member is fixed to each of edges of said second structure, and wherein said track member is integrally formed with said second structure by an inserting mold.

15. A relative linear motion apparatus comprising:

a first structure having at least a pair of inner wall surfaces opposing to each other;

a second structure arranged between the pair of inner wall surfaces, the second structure being movable in linear motion relative to the first structure;

at least two rectilinear guides arranged between the pair of inner wall surfaces of the first structure and the second structure; and

a displacement absorbing device arranged on at least one of the first structure and the second structure, said displacement absorbing device comprising a span that is capable of deflection supported by at least two supports connected to one of said first structure and said second structure, and further wherein said span bends in response to contact from an opposing force from the other of said first structure and said second structure so as to allow at least one of the two rectilinear guides to move in an intersecting direction against the wall surface.

ROLLER CONNECTED BODY AND LINEAR GUIDE DEVICE USING IT

FIELD OF THE INVENTION

The present invention relates to a roller connector which rotatably retains a plurality of rollers in a line and which is incorporated into an endless roller-circulation path of an endless sliding type linear guide unit and also to an improvement in the linear guide unit of the above-type using such roller connector.

DESCRIPTION OF THE RELATED ART

Conventionally, there has been known a linear guide unit in which a slider is movably held in engagement with a track rail through a line of endlessly circulating rollers. More concretely, this linear guide unit comprises a plurality of rollers, a track rail which is arranged on a stationary portion such as a bed and which is provided with roller rolling surfaces and a slider provided with load rolling surfaces on which the rollers roll with respect to the roller rolling surfaces of the track rail while bearing a load thereon and an endless roller-circulation path with the inclusion of the load rolling surfaces whereby the slider having a table or a mechanical apparatus mounted thereon can move freely on the track rail following the endless circulation of the rollers.

The above-described linear guide unit having the track rail and the slider held in engagement with the track rail through the rollers has the advantage of improving the load bearing capacity of the slider as compared to such type of linear guide unit that makes use of rollers while on the other hand, it has the problem that the so called skewing of the rollers (oscillatory rotation of each roller about its axis) tends to take place. Therefore, it has been an important theme in securing the smooth rotation of the rollers and hence the smooth movement of the slider within the endless roller-circulation path how to prevent the above-described skewing of the rollers.

Therefore, as a means for solving the above-described problems, there have already been provided a roller connector comprising a plurality of rollers connected together in a predetermined posture like a string of beads and a linear guide unit having an endless roller-circulation path of the slider into which the roller connector is incorporated (Japanese Patent Laid-Open No. 52217/1993). As shown in FIGS. **18** and **19**, such roller connector comprises a plurality of rollers **100** arranged in a line with the axes of rotation thereof being held parallel to one another, a plurality of spacers **102** interposed among the rollers **100** and provided with concave seats **101** with which the rollers **100** come into sliding contact, respectively, and elongate flexible connecting portions **103** connecting the spacers **102** together and adapted to rotatably retain each of the rollers **100** by causing the spacers to sandwich the roller **100** therebetween from the front and rear sides thereof.

Accordingly, when such roller connector is incorporated into the endless roller-circulation path of the slider of the linear guide unit, each of the rollers **100** rolls within the endless roller-circulation path while it is retained in its predetermined posture by means of the spacers **102** from on both front and rear sides so that it is possible to cause the rollers **100** to smoothly circulate through the endless roller-circulation path while preventing the skewing of the rollers **100** and hence it is possible to make smooth the movement of the sliders with respect to the track rail.

However, in the case of the conventional roller connector of the above-described structure, there has hitherto been the

possibility that the connecting portions become fatigued at an early stage of operation since the connecting portions are formed along both axial end surfaces of each of the rollers as shown in FIGS. **18** and **19**, and therefore, when a force urging each of the rollers rolling through the endless roller-circulation path to skew, that is, a force oscillating the axis of rotation of each of the rollers acts on the roller, the connecting portions expand and contract in a repetitive fashion by such force.

Further, where the above-described roller connector is incorporated into the endless roller-circulation path of the slider, the sectional area of the endless roller-circulation path must be enlarged by a width corresponding to each of the connecting portions connecting the spacers together. Accordingly, if the connecting portions are present on both axial ends of each of the rollers as described above, where, for example, an endless roller-circulation path is formed by opening a roller return path in a slider, the diameter of the roller return path has to be made large so that the rigidity of the slider lowers to that degree which results in hindering the miniaturization of the slider.

SUMMARY OF THE INVENTION

The present invention has been made in view of the above-described problems.

Accordingly, an object of the invention is to provide a roller connector which can rotatably and stably retain a plurality of rollers in a predetermined posture for a prolonged period of time within an endless roller-circulation path formed in a slider of a linear guide unit.

Another object of the invention is to provide a roller connector which can improve the rigidity of the slider and contribute to the miniaturization of the slider.

A further object of the invention is to provide a linear guide unit using such roller connector.

In order to achieve the above-described objects, the roller connector of the present invention comprises a plurality of rollers arranged in a line with the axes of rotation of the rollers being held parallel to one another, a plurality of spacers interposed among the rollers and each provided with a pair of concave seats with which each of the rollers comes into sliding contact and an elongate flexible connecting portion connecting the spacers together and characterized in that the connecting portion is connected to the spacers at a position at which the connecting portion divides the outer peripheral surface of each of the rollers into two substantially equal parts in the axial direction and that the connecting portion is arranged only on one side of the line of rollers.

Further, the linear guide unit of the present invention using the above-described roller connector is required to have a structure comprising a number of rollers, a track rail having roller-rolling surfaces and a slider provided with an endless roller-circulation path having load rolling surfaces on which the rollers roll with respect to the roller-rolling surface of the track rail while bearing a load and it is characterized in that the above-described roller connector is incorporated into the endless roller-circulation path with the connecting portion of the roller connector lying inside the inner peripheral surface of the endless roller-circulation path of the slider, and that the endless roller-circulation path is provided with clearance grooves by which the connecting portion of the roller connector is received and guided.

According to such technical means, as in the case of the above-described conventional roller connector, each of the rollers is embraced in front and in rear by the adjoining spacers and rolls through the endless roller-circulation path of the slider of the linear guide unit in a state in which it is retained in a predetermined posture by the spacers. Consequently, it becomes possible to effectively prevent each of the rollers from skewing within the endless roller-circulation path.

However, in the case of the conventional roller connector, the connecting portions connecting the spacers are arranged along both end surfaces of each of the rollers in the axial direction thereof so that the connecting portions tend to become fatigued due to the application thereon of a force urging the rollers to skew during rolling while, on the contrary, the connecting portion of the roller connector according to the present invention is connected to each of the spacers at a position at which the connecting portion divides the outer peripheral surface of each of the rollers into two substantially equal parts in the axial direction so that the connecting portion does not expand and contract repeatedly due to the above kind of force thereby preventing the breakage of the connecting portion resulting from the fatigue thereof.

Further, since the connecting portion is provided only on one side of the line of rollers, where the roller connector of the present invention is incorporated into the endless roller-circulation path of the slider of the liner guide unit, the sectional area of the endless roller-circulation path can be made smaller than in the case of the conventional roller connector and also where roller return paths are formed in the slider, the lowering of the rigidity of the slider can be avoided and the miniaturization of the slider can be made with ease.

At the same time, when both axial end surfaces of each of the rollers come into contact with the inner wall of the endless roller-circulation path of the slider during the rolling operation of the roller, the posture of the roller becomes unstable due to a frictional force generating between the two so that the skewing of the roller tends to take place. Accordingly, it is preferable from the above point of view that the spacers be so provided as to prevent the movement of each of the rollers in the axial direction. For example, an annular groove may be provided in the central portion of the outer peripheral surface of each of the rollers in the axial direction so that each of the spacers fits in such annular groove so as to come into sliding contact with the roller.

With the above structure, since the axial position of each of the rollers is determined by the connecting portion of the roller connector and each of the spacers, if clearance grooves for guiding the connecting portion of the roller connector are formed in the endless roller-circulation path of the slider to be incorporated with the roller connector, it will be possible to completely prevent the displacement of each of the rollers in the axial direction during the rotation thereof and to minimize the possibility of skewing of the roller.

Further, where the roller connector circulates through the endless roller-circulation path as it expands and contracts, it is preferable to form a slit in each of the spacers from the side opposite to the connecting portion so as to separate the pair of concave seats formed on both sides thereof from the point of view of allowing each of the rollers to keep its suitable posture by the spacers. Thus, by the formation of such slit in each of the spacers, even when the roller connector bends to a great degree within the endless roller-circulation path, each of the spacers can be kept in sliding contact with the outer peripheral surface of each of the rollers by widening the slit so that the roller can always keep its suitable posture. Further, the formation of the slit has the advantage that each of the rollers can be removably mounted between the adjoining spacers with ease.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a front view (partly in section) of a linear guide unit using a roller connector according to the present invention;

FIG. **2** is a side view (partly in section) of the linear guide unit shown in FIG. **1**;

FIG. **3** is an exploded sectional view of an endless roller-circulation path of a slider of the linear guide unit shown in FIG. **1** with the view showing how the endless roller-circulation path of the slider is assembled;

FIG. **4** is a perspective view of one end surface portion of a movable block according to the present invention;

FIG. **5** is a perspective view of a roller connector to be incorporated into a liner guide unit according to a first embodiment of the present invention;

FIG. **6** is a front view of a roller connector according to the first embodiment of the present invention:

FIG. **7** is a side view of the roller connector shown in FIG. **6**;

FIG. **8** is a plan view of the roller connector shown in FIG. **6**;

FIG. **9** is an enlarged sectional view of the roller connector shown in FIG. **6** especially when the roller connector is incorporated into the endless roller-circulation path of the slider of the linear guide unit according to the first embodiment of the present invention;

FIG. **10** is a perspective view of a roller connector to be incorporated into the linear guide unit according to a second embodiment of the present invention;

FIG. **11** is a front view of the roller connector shown in FIG. **10**;

FIG. **12** is a plan view of the roller connector shown in FIG. **10**;

FIG. **13** is a sectional view taken along the XIII—XIII line of FIG. **11**;

FIG. **14** is a sectional view taken along the XIV—XIV line of FIG. **13**;

FIG. **15** is a sectional view of the roller connector shown in FIG. **10** especially when the roller connector is in its curved state within an endless roller-circulation path of a slider;

FIG. **16** is an enlarged sectional view of the roller connector shown in FIG. **10** especially when the roller connector is incorporated into the endless roller-circulation path of the slider;

FIG. **17** is an enlarged sectional view illustrating how the connecting portion of the roller connector is affected by the skewing of each of the rollers;

FIG. **18** is a side view of a conventional roller connector; and

FIG. **19** is a plan view of a conventional roller connector.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

A roller connector according to the present invention and a linear guide unit using the roller connector will now be described with reference to the accompanying drawings.

FIGS. **1** and **2** show a linear guide unit using a roller connector according to the present invention.

In these figures, reference numeral **1** designates a track rail arranged on a stationary portion such as a bed of a machine tool, reference numeral **2** designates a slider for guiding a movable body such as a table along the track rail **1** and reference numeral **3** designates rollers capable of rolling between the track rail **1** and the slider **2** while bearing a load and circulating endlessly within the slider **2**.

First, the track rail **1** is substantially rectangular in shape and is provided with a total of four roller rolling surfaces **11***a* and **11***b* extending along the longitudinal direction (vertically in FIG. **1**) of the slider. These roller rolling surfaces **11***a* and **11***b* are formed on both side surfaces and on both edges of the upper surface of the track rail **1**, respectively, in such a manner that the roller rolling surfaces **11***a* on both side surfaces formed inwardly and downwardly at an angle of 30° with respect to the horizontal while the roller rolling surfaces **11***b* on the upper surface are formed vertically and upwardly. Further, the track rail **1** is provided with a plurality of bolt fitting holes **12** arranged in the longitudinal direction of the track rail **1** in spaced-apart relationships with one another and is fixed to the stationary portion by means of fixing bolts (not shown) to be inserted into the bolt fitting holes **12**, respectively.

On the other hand, the slider **2** is formed of a movable block **4** having a fixing surface **41** to which a movable body such as a table is fixed and a plurality of tapped holes **42** into which fixing bolts for the movable body are respectively screw-fitted and a pair of covers **5** to be respectively fixed to the front and rear end surfaces of the movable block **4** whereby an endless roller-circulation path for the rollers **3** is formed within the slider by fixing the covers **5** to the movable block **4**. Further, to the covers **5** there are respectively fixed sealing members **6** which come into sliding contact with the track rail **1** whereby the entry of dust adhered to the track rail **1** into the slider **2** due to the movement of the slider **2** is prevented. Note that in the drawings, reference numeral **7** designates a grease nipple for supplying grease into the slider **2**.

The movable block **4** is substantially saddle-shaped in section with the inclusion of a horizontal portion **4***a* on which the mounting surface **41** is formed and a pair of skirts **4***b* and **4***b* extending downward from the horizontal portion **4***a*. Further, on the lower surface of the horizontal portion **4***a* and on the inner surface of each of the skirt portions **4***b* there are formed four load rolling surfaces **43***a* and **43***b* in opposite relationships with the roller rolling surfaces **11***a* and **11***b* of the track rail **1**, respectively. In addition, on the horizontal portions **4***a* and the skirt portions **4***b* there are formed roller return ports **44***a* and **44***b* so as to correspond to the load rolling surfaces **43***a* and **43***b*, respectively.

This movable block **4** is manufactured by injection-molding a synthetic resin material. That is, it comprises a metallic block **40** and a synthetic resin portion padded to the former by injection-molding and the above-described movable body mounting surface **41** and the load rolling surfaces **43***a* and **43***b* of the rollers **3** of which a sufficient mechanical strength is required are formed on the movable block **40** while the roller return ports **44***a* and **44***b* of which not so high mechanical strength is required are formed on the synthetic resin portion thereby reducing the weight of the movable block **4** as small as possible.

As shown in FIG. **3**, the endless circulation path for the rollers becomes complete by fixing the covers **5** to the end surfaces of the movable block **4**, respectively. That is, on the inner surface of each of the covers **5** is provided with a U-shaped groove **51** for guiding the rollers **3** which have rolled on the load rolling surfaces **43***a* and **43***b* while projecting semicircular roller guide portions **46** are formed on the both end surfaces of the movable block **4** as shown in FIG. **4** so that when the covers **5** are respectively fixed to the end surfaces of the movable block **4**, the roller guide portion **46** of the movable block **4** fits in the U-shaped groove **51** of each of the covers **5** to thereby complete a U-shaped change direction path **52** as shown in FIG.**2**. Thus, by this change direction path **52** the load rolling surfaces **43***a* and **43***b* of the movable block **4** and the roller return ports **44***a* and **44***b* are connected.

With the above arrangement, when the rollers **3** which are bearing a load between the roller rolling surfaces **11***a* and **11***b* of the track rail **1** and the load rolling surfaces **43***a* and **43***b* of the movable block **4** have rolled on the load rolling surfaces **43***a* and **43***b* with the movement of the slider **2**, the rollers **3** are released from the load to enter into the change direction path **52** of one of the covers **5**. Then the rollers **3** roll through the roller return ports **44***a* and **44***b* of the movable block **4** in a direction reverse to their rolling direction through the load rolling surfaces **43***a* and **43***b* in a no-load state. Further, the rollers **3** which have finished rolling through the roller return ports **44***a* and **44***b* again enter between the track rail **1** and the movable block **4** through the change direction path **52** of the other cover **5** and roll on the load rolling surfaces **43***a* and **43***b* while bearing the load.

Further, on both sides of each of the load rolling surfaces **43***a* and **43***b* there are formed synthetic resin roller guide portions **45** for guiding both end surfaces of the rollers **3** rolling on the load rolling surfaces **43***a* and **43***b* so that the rolling direction of the rollers **3** is regulated by these roller guide portions **45** from on both sides thereof and the skewing of the rollers **3** during their rolling operation is prevented.

FIGS. **5** through **8** show first embodiment of the roller connector of the present invention to be used in the linear guide unit. The roller connector **30** comprises a flexible synthetic resin roller connecting member **31** and a plurality of rollers **3** arranged on the roller connecting member **31** in spaced apart relationships with one another with the axes of rotation of the rollers **3** being held parallel to one another. The roller connecting member **31** comprises a plurality of spacers **32** interposed among the adjoining rollers **3**, respectively, and a band-shaped connecting portion **33** for connecting the spacers **32** and each of the spacers **32** is provided with a pair of concave seats which come into sliding contact with the adjoining rollers **3**. Accordingly, each of the rollers **3** is held by the spacers **32** from on both front and rear sides of its rolling direction so that the rollers **3** are rotatably retained by the connecting member **31**. Further, the spacer **32** and the connecting portion **33** at the front or rear end of the roller connector **30** have convex curved guide surfaces **34**, respectively, so that the movement of the roller connector **30** at the time of rolling of the rollers **3** is made smooth.

Further, the connecting portion **33** connecting the spacers **32** is connected to the spacers **32** at a position at which the outer peripheral surface of the roller **3** is divided into substantially two equal parts in the axial direction and the end surfaces of each of the rollers **3** are left open without being covered by the connecting portion **33**. Accordingly, the movement of each of the rollers **3** in the axial direction at the time of its rolling is regulated by the above-described roller guide portions **45**.

Still further, the connecting portion **33** is provided only on one side of the rollers **3** arranged in a line and with respect to the direction opposite to the other side of the rollers **3**, the roller connector **1** is made to bend freely. Consequently, where the roller connector **30** is incorporated into the endless circulation path of the slider **2**, the connecting portion **33** is made to lie inside the endless circulation path as shown in FIGS. **1** and **2**.

Such roller connector **30** is formed by injection-molding a synthetic resin material in such a manner that the rollers **3** are inserted, as cores, into a mold and by such injection molding, the connecting member **31** comprising each of the spacers **32** and the connecting member **31** which are integral with each other is formed and the roller connector **30** with the rollers **3** arranged along the connecting portion **33** can be taken out of the mold.

FIG. **9** is an enlarged sectional view showing how the rollers **3** roll within the endless roller-circulation path. In the instant embodiment, the rollers **3** are incorporated into the endless roller-circulation path of the slider in a state in which they are arranged along the synthetic resin connecting member **31** as described above and the connecting portion **33** of the member **31** which connects the spacers **32** projects outwardly of the outer periphery of each of the rollers **3** so that the load rolling surfaces **43***a* and **43***b* of the slider **2** are respectively provided with clearance grooves **47** for receiving the connecting portion **33** while at the same time, similar clearance grooves **48** are respectively formed in the roller return ports **44***a* and **44***b* along the longitudinal direction. Accordingly, when the rollers **3** circulate through the endless roller-circulation path of the slider **2** following the movement of the slider **2** relative to the track rail **1**, the roller connector **30** circulates through the endless roller circulation path together with the rollers **3** in a state in which the connecting portion **33** of the roller connector **30** is kept received within the clearance grooves **47** and **48**.

According to the linear guide unit of the instant embodiment having the above-described structure, when the slider **2** moves on the track rail **1**, the rollers **3** roll between the slider **2** and the track rail **1** and the roller connector **30** circulates through the endless track formed within the slider **2**. In this case, even if a force urging each of the rolling rollers **3** to skew, that is, a force causing the axis of rotation of each of the rollers **3** to oscillate acts on the roller, since the connecting portion **33** of the roller connector **30** of the instant embodiment is connected to the spacers **32** at the position at which the connecting portion **33** connecting the spacers **32** together divides the outer peripheral surface of each of the rollers **3** into two substantially equal parts in the axial direction as shown in FIG. **17**, the oscillatory force acts on each of the rollers **3** in the manner shown by the dashed lines about the central portion of the connecting portion **33** so that the connecting portion **33** does not expand and contract due to such oscillatory force. Consequently, the trouble that the roller connector **30** breaks within the endless roller-circulation path due to the fatigue of the connecting portion **33** at the early stage of operation can be avoided and it is possible to maintain the smooth circulation of the rollers **3** within the endless roller-circulation path for a prolonged period of time and to secure the smooth movement of the slider with respect to the track rail **1**.

Further, in the case of the roller connector of the instant embodiment, the connecting portion for connecting the spacers is provided only on one side of the line of rollers and therefore, when compared to the conventional roller connector having roller connecting portions on both end surfaces of each of the rollers in the axial direction, the size of the roller return port formed in the slider can be reduced and it is possible to improve the mechanical rigidity of the slider to that degree of size-reduction.

FIGS. **10** through **14** show a roller connector according to a second embodiment of the present invention. As in the case of the first embodiment, the roller connector **70** comprises a connecting member **71** made of a flexible synthetic resin material and a plurality of rollers **8** arranged along the connecting member **71** in spaced apart relationships with one another with the axes of rotation of the rollers **8** being held parallel to one another. The connecting member **71** comprises a plurality of spacers **72** interposed among the adjoining rollers **8** and a band-shaped connecting portion **73** for connecting the spacers **72** together wherein each of the spacers **72** is provided with a pair of concave seats **74** which come into sliding contact with the adjoining roller **8**. Further, each of the rollers **8** is provided on the peripheral surface thereof with an annular groove **81** so as to bisect the peripheral surface of the roller in the axial direction so that each of the spacers **72** fits in this annular groove **81** and the pair of concave seats **74** are in sliding contact with the roller **8** within the annular groove **81**. Accordingly, each of the rollers **8** is embraced by the spacers **72** on both front and rear sides in the rolling direction thereof and is rotatably retained by the connecting member **71** while the movement of the roller **8** in the axial direction is held stopped by the spacers **72** fitted into the annular groove **81**.

Further, as in the case of the roller connector **30** according to the first embodiment of the present invention, the connecting portion **73** is provided only on one side of the line of rollers **8** in such a manner that the roller connector **70** can be bent freely on that side. In addition, in the case of the roller connector **70** of this second embodiment, each of the spacers **72** is provided with a slit **75** which is so formed as to separate the pair of concave seats **74** formed on both sides thereof, respectively, as shown in FIGS. **13** and **14**. More concretely, this slit **75** is formed in each of the spacers **72** from on the side opposite to the connecting portion **73**.

Accordingly, when the roller connector **70** is incorporated into the endless roller-circulation path of the slider **2**, if it is incorporated in such a manner that the connecting portion **73** comes to lie at the inner side of the endless circulation path, each of the slits **75** opens wide when the roller connector **70** bends in the shape of the letter-U within the change direction path **52** as shown in FIG. **15** so that the spacer **72** bisected by the slit **75** can maintain a state in which the concave seats **74** are in sliding contact with each of the rollers **8**. Consequently, the spacers **72** lying on both sides of each of the rollers **8** within the change direction path **52** securely retain the roller **8** thereby constantly stabilizing the posture of each of the rollers **8** rolling within the endless roller-circulation path of the slider.

The connecting member **71** provided with the spacers **72** and the connecting portion **73** is formed by injection-molding of a synthetic resin material but unlike the roller connector **30** of the first embodiment, each of the rollers **8** is mounted on the connecting member **71** after the connecting member **71** has been formed by molding. Thus, in the case of the roller connector **70** of the second embodiment, the slit **75** is formed in each of the spacers **72**, so that in contrast to the connecting member of the first embodiment which is not provided with slits, the space between the pair of concave seats **74** retaining the rollers **8** can be opened wide with ease whereby each of the rollers **8** can be mounted between the spacers **72** with ease. Further, for the same reason, the replacement of the rollers **8** mounted on the connecting member **71** can be performed with ease so that the amount of pre-load on the linear guide unit can be adjusted with ease.

FIG. **16** is an enlarged sectional view showing a state in which the roller connector **70** of the second embodiment of the present invention is incorporated into the endless circulation path of the linear guide unit shown in FIGS. **1** and **2**. As in the case of the roller connector **30** of the first embodiment, also in the roller connector **70** of the second embodiment, the connecting portion **73** which connects the spacers **72** together projects outwardly of the outer peripheral surfaces of the rollers **8** so that it is received within the clearance grooves **47** formed in the load rolling surfaces **43***a* and **43***b* of the slider **2** and also in the clearance grooves **48** formed in the roller return ports **44***a* and **44***b*. Consequently, where the roller connector **70** circulates through the endless roller-circulation path of the slider **2**, the connecting portion **73** of the roller connector **70** of the second embodiment can be always guided by the clearance grooves **47** and **48** on the side of the slider **2**.

As in the case of the roller connector **30** of the first embodiment, the roller connector **70** of this second embodiment is constructed such that the connecting portion **33** which connects the spacers **32** together is connected to each of the spacers **32** at a position at which the connecting portion **33** divides the outer peripheral surface of each of the rollers **3** into two substantially equal parts in the axial direction and further, it is provided only on one side of the line of rollers so that the second embodiment of the invention produces the same operation and effect as in the case of the first embodiment.

Further, in addition to the above, since the spacers **72** formed integral with the connecting-portion **73** stop the axial movement of each of the rollers **8**, when the connecting portion **73** is guided by the clearance grooves **47** and **48**, the rollers **8** are also guided by these clearance grooves **47** and **48** whereby the axial movement of each of the rollers through the endless roller-circulation path can be prevented by the clearance grooves **47** and **48**. Therefore, where the roller connector **70** of the second embodiment is incorporated into the endless roller-circulation path of the linear guide unit for use, the endless circulation of the rollers can be guided smoothly without the necessity of providing roller guides **45** on both sides of the load rolling surfaces **43***a* and **43***b* so as to guide both end surfaces of each of the rollers **8** thereby simplifying the structure of the linear guide unit.

It should be noted in this connection that the roller connector **70** of the second embodiment can be bent smoothly within the change direction path **52** of the slider due to the provision of the slit **75** in each of the spacers **72** but the roller connector **30** of the first embodiment will be able to be done so if the same slit is formed in each of the spacers **32** of the roller connector **30**.

Further, the connecting member **31** of the first embodiment and the connecting member **71** of the second embodiment are made of a synthetic resin material but the spacers **32** and the connecting portion **33** forming the connecting member **31** or the spacers **72** and the connecting portion **73** forming the connecting member **71** may be formed integral with each other by using the same material or by using different materials. When the different materials are used, it is preferable that the material for forming the connecting portion **33** (**73**) have an anti-abrasion property higher than that for the spacer **32** (**72**).

As described above, according to the roller connector of the present invention and the linear guide unit using the same, the connecting portion which connects the spacers interposed among the adjoining rollers is connected to each of the spacers at a position at which it divides the outer peripheral surface of each of the rollers into two substantially equal parts in the axial direction so that the connecting portion does not get fatigued at the early stage of operation due to a force urging the rolling rollers to skew with the advantages that there is no fear of breakage of the roller connector within the endless roller-circulation path of the linear guide unit and it is possible to secure the smooth movement of the slider with respect to the track rail for a prolonged period of time.

Further, where the roller connector of the present invention is incorporated into the endless roller-circulation path of the slider of the liner guide unit, it is possible to make the sectional area of the endless roller-circulation path for the passage of the rollers therethrough smaller than that of the conventional roller connector. Consequently, it becomes possible to prevent the lowering of the rigidity of the slider thereby improving the moving accuracy and the load bearing capacity of the slider and also to make the slider compact with ease.

What is claimed is:

1. A roller connector assembly comprising a plurality of rollers arranged in a line while keeping the axes of rotation thereof parallel to one another, a plurality of spacers interposed among the rollers and provided with concave seats with which the rollers come into sliding contact and an elongate flexible connecting portion adapted to connect said spacers with one another, wherein said connecting portion is connected to said spacers at a position at which the outer peripheral surface of each of said rollers is divided into two substantially equal parts in the axial direction and is arranged only at one side of said line of rollers.

2. The roller connector assembly as claimed in claim **1**, wherein an annular groove is formed on the outer peripheral surface of each of the rollers at a position along which the outer peripheral surface is bisected in the axial direction and each of said spacers fits in the annular groove so as to come into sliding contact with each of said rollers.

3. The roller connector assembly as claimed in claim **1**, wherein each of said spacers is provided with a pair of concave seats on both sides thereof, respectively, and a slit formed on the side opposite said connecting portion so as to separate said pair of concave seats.

4. A linear guide unit comprising a roller connector assembly retaining a plurality of rollers, a track rail having rolling surfaces for the rollers; and a slider having an endless roller-circulation path which includes load rolling surfaces along which the rollers roll with respect to the rolling surfaces of the track rail while bearing a load thereon, wherein said roller connector assembly which is claimed in any one of claims **1** through **3** is incorporated into said endless roller-circulation path of the slider in such a manner that the connecting portion of said roller connector assembly comes to lie on the inner peripheral surface portion of said endless roller-circulation path and said endless roller-circulation path is provided with clearance grooves by which the connecting portion of said roller connector assembly is received and guided.

(57) **ABSTRACT**

A linear motion guiding apparatus comprises a guide rail provided with a ball running groove, and a movable block movably arranged along the guide rail through balls. The movable block is provided with a ball running counter-groove, a ball returning passage arranged away from the ball running counter-groove and direction changing passages for connecting these members. A resin-formed body for forming a ball circulation passage comprises a pair of ball passage forming portions, a returning passage forming portion and a pair of direction changing passage-inner guide forming portions. The resin-formed body is separately formed from a body of the movable block. At least two portions of (a) the ball passage forming portions, (b) the returning passage forming portion, (c) one of the direction changing passage-inner guide forming portions and (d) another of the of direction changing passage-inner guide forming portions are connected with each other through integral forming so that the resin-formed body can be built in the body of the movable block.

LINEAR MOTION GUIDING APPARATUS

CROSS-REFERENCE TO RELATED APPLICATIONS

This application is a division of application Ser. No. 09/088,491, filed Jun. 2, 1998 now U.S. Pat. No. 6,132,093.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a linear motion guiding apparatus in which a passage forming member formed of resin is built into a body of movable member.

2. Description of the Related Art

The applicant has already proposed a technical idea that, in a movable block of a linear motion guiding apparatus, a pair of ball passage forming portions extending along the opposite longitudinal sides of a loaded-ball running groove, a ball returning passage forming portion and a pair of direction changing passage-inner guide forming portions were integrally formed of resin with a body of the movable block (refer to Japanese Patent Provisional Publication No. H7-317,762).

More specifically, when a resin forming is carried out, the body of the movable block is inserted in a die, and the ball passage forming portions, the direction changing passage-inner guide forming portions or the ball returning passage forming portion is integrally formed with the block body.

In the conventional movable block obtained by the integral forming, the block body is inserted in the die, as mentioned above. When the block body has a large size, a large-scaled die is required to be used. It is not easy to prepare such a large-scaled die, and there is actual restriction in size. The ball passage forming portions located at the opposite longitudinal sides of the ball running groove extending along the longitudinal direction of the block body are thin and long, with the result that molten resin may not reach every part of the space for forming the ball passage forming portions during the resin forming treatment.

Increase in number of gates formed on the die may solve the above-mentioned problem of misrun of the molten resin. However, when the block body is inserted in the die, the block body may deteriorate the run of the molten resin.

When the movable block has a pair of wing portions, which face right and left-hand side portions of the guide rail so that the guide rail is held between the wing portions, and there are four trains of balls between the right and left-hand side portions of the guide rail and the right and left-hand wing portions of the moving block, and more specifically, the upper and lower trains of balls are arranged at each of a gap between the right-hand side portion of the guide rail and the corresponding right-hand wing portion of the moving block and another gap between the left-hand side portion of the guide rail and the corresponding left-hand wing portion of the moving block, the block body inserted in the die may deteriorate the run of the molten resin in the width direction of the moving block.

SUMMARY OF THE INVENTION

An object of the present invention is therefore to provide a linear motion guiding apparatus in which a resin-formed body for forming a rolling member circulation passage is formed separately from a body of a movable member so as to permit easy formation of the resin-formed body, and such a resin-formed body is able to be built in the body of the

movable member, ensuring integral formability of the maximum number of unit parts for defining the rolling member circulation passage.

In order to attain the aforementioned object, a linear motion guiding apparatus comprises:

a guide member provided with a rolling member running track, and

a movable member arranged so as to be movable along the guide member through a large number of rolling members, said movable member being provided with (i) a rolling member running counter-track corresponding to the rolling member running track of said guide member, (ii) a rolling member returning passage arranged away from said rolling member running counter-track by a prescribed distance and in parallel therewith and (iii) a pair of direction changing passages for connecting the rolling member running counter-track and the rolling member returning passage to permit circulation of the rolling members,

characterized in that:

a resin-formed body for forming a rolling member circulation passage comprises a pair of rolling member passage forming portions extending along both longitudinal sides of said rolling member running counter-track, a returning passage forming portion for forming the rolling member returning passage and a pair of direction changing passage-inner guide forming portions for forming inner peripheral guide portions of said direction changing passages, said resin-formed body being separately formed from a body of said movable member; and

at least two portions of (a) said pair of rolling member passage forming portions, (b) said returning passage forming portion, (c) one of said pair of direction changing passage-inner guide forming portions and (d) another of said pair of direction changing passage-inner guide forming portions are connected with each other through integral forming so that said resin-formed body can be built in the body of said movable member.

Embodiments of the combination of these portions (a) to (d) for the resin-formed body for forming the rolling member circulation passage may include the following three examples:

the first example in which the resin-formed body comprises (i) an integral body of the pair of rolling member passage forming portions and the pair of direction changing passage-inner guide forming portions, and (ii) the returning passage forming portion separately formed from the integral body the second example in which the resin-formed body comprises (i) an integral body of the pair of rolling member passage forming portions, the returning passage forming portion and one of the pair of direction changing passage-inner guide forming portions, and (ii) another of the pair of direction changing passage-inner guide forming portions separately formed from the integral body; and

the third example in which the resin-formed body is manufactured by preparing an integral body of the pair of rolling member passage forming portions, the returning passage forming portion and the pair of direction changing passage-inner guide forming portions, and then dividing the pair of rolling member passage forming portions and the returning passage forming portion in longitudinal intermediate portions thereof into respective two parts.

According to the present invention, the resin-formed body for forming the rolling member circulation passage is separately formed from the body of the movable member. Even if the movable member has a large size, the flow of molten resin is not therefore restricted by the body of the movable member unlike the conventional prior art in which the body of the movable member and the resin-formed body are integrally formed with each other, and it is possible to ensure proper run of molten resin through increase in a number of gates in the die, thus leading to an excellent formability. In general, it is hard to achieve proper run of molten resin especially at the rolling member passage forming portions extending along the longitudinal sides of the rolling member running counter-track, and it is therefore effective to separately form the resin-formed body from the body of the movable member in the same manner as the present invention.

The rolling member circulation passage is formed by the resin-formed body. Therefore, the direct positioning can be achieved in the relative positional relationship between the direction changing passage-inner guide forming portions and the rolling member passage forming portion, as well as the relative positional relationship between the direction changing passage-inner guide forming portions and the returning passage forming portion, and the continuity of the rolling member circulation passage is properly ensured, thus leading to smooth run of the rolling members.

Since the rolling member passage forming portions are located along the both longitudinal sides of the rolling member running counter-track, the direction changing passage-inner guide forming portions having a proper relative positional relationship with the rolling member passage forming portions are accurately set on the both ends of the rolling member running counter-track.

Maintenance of a proper relative positional relationship of the direction changing passage-inner guide forming portions with the rolling member returning passage causes the direction changing passage-inner guide forming portions to be accurately connected to the inner surface of the rolling member returning passage.

Especially, change in a running direction of the rolling members takes place in the connection area of the rolling member passage forming portions with the direction changing passage-inner guide forming portions as well as in the connection area of the direction changing passage-inner guide forming portions with returning passage forming portion. When two portions in such a connection area are connected with each other by integral forming, a step for assembling these two portions is not required, thus making it possible to ensure a smooth continuity of these two portions without being affected by accuracy of assembly.

The rolling member returning passage may be a through-hole formed in the body of the movable member, the resin formed-body may comprise the pair of direction changing passage-inner guide forming portions and the rolling member passage forming portions extending along the both longitudinal sides of the rolling member running counter-track, and the rolling member passage forming portions and at least one of the pair of direction changing passage-inner guide forming portions may be connected with each other through integral forming.

When the rolling member passage forming portions and the direction changing passage-inner guide forming portions are integrally formed with each other so as to provide the smooth connection area in this manner, it is possible to achieve the smooth run of the rolling members in the connection area of these portions, thus improving circulation property of the rolling member without providing any returning passage forming portion made of resin. Such a construction causes easy manufacture of the apparatus due to no existence of the returning passage forming portion.

The present invention may have additional features that a rolling member retainer is provided, the rolling member retainer being able to retain the rolling members in a train with a prescribed distance kept between adjacent two of the rolling members, and the rolling member retainer having side edge portions projecting from both sides of each of the rolling members; and guide grooves for guiding the side edge portions of the rolling member retainer are formed on an entire periphery of the rolling member circulation passage.

The present invention may have additional features that a retaining portion is provided on the rolling member passage forming portion, for preventing the rolling member retainer being out of place, when the movable member is removed from the guide member, and a guide portion is continuously formed on the entire periphery of the rolling member circulation passage, for guiding the side edge portions of the rolling member retainer.

Such provision of the rolling member retainer permits the smooth run of the rolling members by means of the rolling member retainer, due to proper maintenance of continuity of the guide portion for the rolling member retainer.

Since the guide portion for the rolling member retainer having a small thickness is not formed by inserting the body of the movable member in a die and then injecting molten resin into the die, but is separately formed from the body of the movable member, position of gates can freely be determined without being restricted by the body of the movable member, with the result that molten resin can reach, during formation of the guide portion, the entire space therefor, which is formed in the die.

The present invention may have additional features that each of the direction changing passage-inner guide forming portions has a thin sheet portion, which is to be brought into contact with the end face of the body of the movable member, and each of the direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions or the returning passage forming portion by means of the thin sheet portion.

When each of the direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions by means of the thin sheet portion, deformation of the thin sheet portion can absorb distortion, which occurs between the direction changing passage-inner guide forming portion and the rolling member passage forming portion, or between the direction changing passage-inner guide forming portion and the returning passage forming portion. Accordingly, it is possible to maintain an accurate positional relationship between the end of the direction changing passage-inner guide forming portion and the rolling member passage forming portion or between the direction changing passage-inner guide forming portion and the returning passage forming portion.

The thin sheet portion is urged against the flat end face of the body of the movable member by a clamping force, which is applied to the side cover plate. The position of the direction changing passage-inner guide forming portion can therefore be corrected through deformation of the thin sheet portion, even when the direction changing passage-inner guide forming portion is not correctly positioned relative to the end face of the body of the movable member. In addition, the thin sheet portion can firmly be secured between the side cover plate and the body of the movable member by the clamping force, which is applied to the side cover plate, thus preventing the direction changing passage-inner guide forming portion from being incorrectly placed.

The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member comprises a movable block, which is provided with a horizontal portion, which faces an upper surface of the guide rail and a pair of wing portions, between which the guide rail is held at right and left-hand side surfaces thereof; two trains of the rolling members are arranged in a gap between the upper surface of the guide rail and a lower surface of the movable block, and a single train of the rolling members is arranged in each of gaps between the right and left-hand side surfaces of the guide rail and both of the wing portions, so as to provide a total number of trains of four.

The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member comprises a movable block, which is provided with a pair of wing portions, between which the guide rail is held at right and left-hand side surfaces thereof; and two trains of the rolling members are arranged in each of gaps between the right and left-hand side surfaces of the guide rail and both of the wing portions, so as to provide a total number of trains of four.

In these cases, the respective four direction changing passage-inner guide forming portions may be formed into an integral body, or the respective two direction changing passage-inner guide forming portions at each of the right and left-hand sides of the movable block may be formed into an integral body.

The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member is provided with a horizontal portion, which faces an upper surface of the guide rail and a single wing portion, which faces one side surface of the guide rail; a single train of the rolling members is arranged in a gap between the one side surface of the guide rail and the single wing portion, and another single train of the rolling members is arranged in a gap between the upper surface of the guide rail and a lower surface of the horizontal portion in a vicinity of a corner of the guide rail.

The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member comprises a movable block, which is provided with a pair of wing portions, between which the guide rail is held at right and left-hand side surfaces thereof; and a single train of the rolling members is arranged in each of gaps between the right and left-hand side surfaces of the guide rail and both of the wing portions, so as to provide a total number of trains of two.

The apparatus of the present invention may have the construction that the guide member comprises a guide rail; the movable member comprises a movable block arranged along one side surface of the guide rail; and two trains of the rolling members are arranged in a gap between the one side surface of the guide rail and the movable block.

The apparatus of the present invention may have the construction that the guide member comprises a spline shaft; and the movable member comprises an outer tube, which is movably supported on the spline shaft through a plurality of trains of the rolling members.

In addition, according to the present invention, there is also provided a linear motion guiding apparatus comprising:

a guide rail provided with two rolling member running tracks on each of right and left-hand side surfaces of the guide rail, so as to provide a total number of the rolling member running tracks of four; and

a movable block provided with a pair of wing portions, between which the guide rail is held at the right and left-hand side surfaces thereof, each of said wing portions having on an inner surface thereof two rolling member running counter-tracks corresponding to said two rolling member running tracks of the guide rail, so as to provide a total number of the rolling member running counter-tracks of four, said movable block having four endless circulation passages, which are formed by four rolling member returning passages arranged in parallel with said four rolling member running counter-tracks, respectively, and rolling member returning, passages for connecting. both ends of each of said four rolling member running counter-tracks with both ends of each of said four rolling member returning passages, respectively

characterized in that:

a resin-formed body comprises, for each of said endless circulation passages, a pair of rolling member passage forming portions extending along both longitudinal sides of said rolling member running counter-track, a returning passage forming portion for forming the rolling member returning passage and a pair of direction changing passage-inner guide forming portions for forming inner peripheral guide portions of said direction changing passages, said resin-formed body being separately formed from a body of said movable block;

said resin-formed body is divided into two body-parts, which are arranged on the wing portions of the movable block, respectively, so as to form the two endless circulation passages at an inner side of each of the wing portions; and

in each of the two body-parts, the rolling member running counter-track and the pair of direction changing passage-inner guide forming portions are formed into an integral body, and the returning passage forming portion is separately formed from said integral body.

According to the present invention, the resin-formed body for forming the rolling member circulation passage is separately formed from the body of the movable block. Even if the movable block has a large size, the flow of molten resin is not therefore restricted by the body of the movable block unlike the conventional prior art in which the body of the movable block and the resin-formed body are integrally formed with each other, and it is possible to ensure proper run of molten resin through increase in a number of gates in the die, thus leading to an excellent formability. In general, it is hard to achieve proper run of molten resin especially at the rolling member passage forming portions extending along the longitudinal sides of the rolling member running counter-track, and it is therefore effective to separately form the resin-formed body from the body of the movable block in the same manner as the present invention.

Especially, since the resin-formed body is divided into the two body-parts, each of which forms two endless circulation passages, a proper run of molten resin can be ensured, even when the block of the movable block has a larger width.

The rolling member circulation passage is formed by the resin-formed body. Therefore, the direct positioning can be achieved in the relative positional relationship between the direction changing passage-inner guide forming portions and the rolling member passage forming portion, as well as the relative positional relationship between the direction changing passage-inner guide forming portions and the returning passage forming portion, and the continuity of the rolling member circulation passage is properly ensured, thus leading to smooth run of the rolling members.

Since the rolling member passage forming portions are located along the both longitudinal sides of the rolling member running counter-track, the direction changing passage-inner guide forming portions having a proper relative positional relationship with the rolling member passage forming portions are accurately set on the both ends of the rolling member running counter-track.

Maintenance of a proper relative positional relationship of the direction changing passage-inner guide forming portions with the rolling member returning passage causes the direction changing passage-inner guide forming portions to be accurately connected to the inner surface of the rolling member returning passage.

Especially, change in a running direction of the rolling members takes place in the connection area of the rolling member passage forming portions with the direction changing passage-inner guide forming portions. When these two portions in such a connection area are connected with each other by integral forming, a step for assembling these two portions is not required, thus making it possible to ensure a smooth continuity of these two portions without being affected by accuracy of assembly.

The present invention may have additional features that a rolling member retainer is provided, the rolling member retainer being able to retain the rolling members in a train with a prescribed distance kept between adjacent two of the rolling members, and the rolling member retainer having side edge portions projecting from both sides of each of the rolling members; and guide grooves for guiding the side edge portions of the rolling member retainer are formed on an entire periphery of the rolling member circulation passage.

Such provision of the rolling member retainer permits the smooth run of the rolling members by means of the rolling member retainer, due to proper maintenance of continuity of the guide portion for the rolling member retainer.

Since the guide portion for the rolling member retainer having a small thickness is not formed by inserting the body of the movable block in a die and then injecting molten resin into the die, but is separately formed from the body of the movable block, position of gates can freely be determined without being restricted by the body of the movable block, with the result that molten resin can reach, during formation of the guide portion, the entire space therefor, which is formed in the die.

The present invention may have additional features that each of the direction changing passage-inner guide forming portions has a thin sheet portion, which is to be brought into contact with the end face of the body of the movable block, and each of the direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions or the returning passage forming portion by means of the thin sheet portion.

When each of the direction changing passage-inner guide forming portions is connected to the rolling member passage forming portions by means of the thin sheet portion, deformation of the thin sheet portion can absorb distortion, which occurs between the direction changing passage-inner guide forming portion and the rolling member passage forming portion, or between the direction changing passage-inner guide forming portion and the returning passage forming portion. Accordingly, it is possible to maintain an accurate positional relationship between the end of the direction changing passage-inner guide forming portion and the rolling member passage forming portion or between the direction changing passage-inner guide forming portion and the returning passage forming portion.

The thin sheet portion is urged against the flat end face of the body of the movable member by a clamping force, which is applied to the side cover plate. The position of the direction changing passage-inner guide forming portion can therefore be corrected through deformation of the thin sheet portion, even when the direction changing passage-inner guide forming portion is not correctly positioned relative to the end face of the body of the movable block. In addition, the thin sheet portion can firmly be secured between the side cover plate and the body of the movable block by the clamping force, which is applied to the side cover plate, thus preventing the direction changing passage-inner guide forming portion from being incorrectly placed.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic disassembling perspective view illustrating a movable block of a linear motion guiding apparatus of the first embodiment of the present invention;

FIG. **2** shows a resin frame member as shown in FIG. **1**, as one of resin-formed bodies for forming a ball circulation passage, and more specifically, FIG. **2**(*a*) is a front view of the resin frame member, FIG. **2**(*b*) is a side view thereof, FIG. **2**(*c*) is a cross-sectional view cut along the line C—C as indicated in FIG. **2**(*a*), FIG. **2**(*d*) is a cross-sectional view cut along the line D—D as indicated in FIG. **2**(*b*), FIG. **2**(*e*) is an enlarged cross-sectional view cut along the line E—E as indicated in FIG. **2**(*a*) and FIG. **2**(*f*) is an enlarged cross-sectional view cut along the line F—F as indicated in FIG. **2**(*a*);

FIG. **3**(*a*) is a front view having a cross-section, illustrating the linear motion guiding apparatus of the first embodiment of the present invention as shown in FIG. **1**, FIG. **3**(*b*) is a front view of the apparatus as shown in FIG. **3**(*a*), in which a half portion of a side cover plate is omitted, and FIGS. **3**(*c*) to (*f*) are partially cross-sectional views illustrating embodiments of the structure of a ball passage forming portion and the vicinity thereof, as shown in FIG. **3**(*a*);

FIG. **4**(*a*) is a side view having a partial cross section, of the linear motion guiding apparatus of the first embodiment of the present invention, FIG. **4**(*b*) is a cross-sectional view of a ball circulation passage of the movable block as shown in FIG. 4(A), from which a ball retainer is removed, FIG. **4**(*c*) is a partial side view of the ball retainer, FIG. **4**(*d*) is a plan view of the ball retainer as shown in FIG. **4**(*c*) and FIG. **4**(*e*) is a view of the ball retainer, with sight being placed in a direction of an arrow of "a" as indicated in FIG. **4**(*d*);

FIG. **5** shows a side cover plate of the movable block, and more specifically, FIG. **5**(*a*) is a front view of the side cover plate, FIG. **5**(*b*) is a back view thereof and FIG. **5**(*c*) is a transverse sectional view thereof at its central portion;

FIGS. **6**(*a*) to **6**(*i*) are descriptive views illustrating steps for assembling the movable block as shown in FIG. **1**;

FIG. **7**(*a*) is an enlarged partial view of the direction changing passage as shown in FIG. **4***b*), FIG. **7**(*b*) is a partial side view of the direction changing passage as shown in FIG. **4**(*b*), in which the side cover plate is removed, FIG. **7**(*c*) is a partial side view illustrating a recess portion, which forms the direction changing passage in the side cover plate as shown in FIG. **7**(*a*), FIG. **7**(*d*) is a partial cross-sectional view of an outer peripheral side-half pipe member for forming a part of a resin pipe as shown in FIG. **7**(*a*), FIG. **7**(*e*) is a side view of the outer peripheral side-half pipe member as shown in FIG. **7**(*d*), FIG. **7**(*f*) is a partial cross-sectional view of an inner peripheral side-half pipe member for forming another part of the resin pipe as shown in FIG. 7(*a*), FIG. 7(*g*) is a side view of the inner peripheral side-half pipe member as shown in FIG. 7(*f*);

FIG. **8** is a schematic disassembling perspective view illustrating the first modification of the resin-formed body for forming the ball circulation passage in the first embodiment of the present invention;

FIG. **9**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in

FIG. **8**, FIG. **9**(*b*) is a view illustrating the first resin frame of the resin-formed body, FIG. **9**(*c*) is a view illustrating the second resin frame thereof, FIG. **9**(*d*) is a back view of the first resin frame and FIG. **9**(*e*) is a back view of the second resin frame;

FIG. **10** is a schematic disassembling perspective view illustrating the second modification of the resin-formed body for forming the ball circulation passage in the first embodiment of the present invention;

FIG. **11**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in FIG. **10**, FIG. **11**(*b*) is a side view illustrating the connecting end of one of divided resin frames, as shown in FIG. **11**(*a*) and FIG. **11**(*c*) is an enlarged cross-sectional view illustrating the connecting portion of the resin frames;

FIG. **12** is a schematic disassembling perspective view illustrating the third modification of the resin-formed body for forming the ball circulation passage in the first embodiment of the present invention;

FIG. **13**(*a*) is a side view having a partial cross section, illustrating the linear motion guiding apparatus, in which the movable block as shown in FIG. **12** is used, and FIG. **13**(*b*) is a cross-sectional view of the resin-formed body for forming the ball circulation passage as shown in FIG. **13**(*a*);

FIG. **14**(*a*) is an enlarged partial cross-sectional view of the direction changing passage as shown in FIG. **13**(*b*), which is formed in the side cover plate removed from the ball passage forming portion, FIG. **14**(*b*) is a partial cross-sectional view illustrating the side cover as shown in FIG. **14**(*a*), which is secured to the ball passage forming portion, FIG. **14**(*c*) is a partial side view illustrating the ball passage forming portion, in which the side cover plate as shown in FIG. **14**(*a*) is removed, and FIG. **14**(*d*) is a partial side view illustrating a recess portion, which forms the direction changing passage in the side cover plate as shown in FIG. **14**(*a*);

FIG. **15** is a schematic disassembling perspective view illustrating the fourth modification of the resin-formed body for forming the ball circulation passage in the first embodiment of the present invention;

FIGS. **16**(*a*) to **16**(*h*) are descriptive views illustrating the other embodiments of arrangement of the trains of balls in the linear motion guiding apparatus of the first embodiment of the present invention;

FIG. **17** is a perspective view illustrating the constructional elements other than the resin-formed body for forming the ball circulation passage of the linear motion guiding apparatus as shown in FIG. **16**(*a*), which is provided with two trains of balls at each of the both sides;

FIG. **18** is a schematic disassembling perspective view illustrating a movable block of a linear motion guiding apparatus of the second embodiment of the present invention;

FIG. **19**(*a*) is a front view illustrating the linear motion guiding apparatus of the second embodiment of the present invention as shown in FIG. **18**, FIG. **19**(*b*) is a partial cross-sectional view illustrating one ball circulation passage of the apparatus as shown in FIG. **19**(*a*), FIG. **19**(*c*) is a partial plan view of a roller retainer as shown in FIG. **19**(*b*) and FIG. **19**(*d*) is a view of the roller retainer, with sight being placed in a direction of an arrow of "d" as indicated in FIG. **19**(*c*);

FIG. **20** shows the resin-formed body for forming the ball circulation passage as shown in FIG. **18**, and more specifically, FIG. **20**(*a*) is a cross-sectional view cut along the line a—a as indicated in FIG. **20**(*b*), FIG. **20**(*b*) is a front view of the resin-formed body for forming the ball circulation passage as shown in FIG. **20**(*a*), FIG. **20**(*c*) is a partial side view of the resin-formed body for forming the ball circulation passage, in which the resin pipe as shown in FIG. **20**(*a*) is removed, FIG. **20**(*d*) is a cross-sectional view of an outer peripheral side-half pipe member for forming a part of a resin pipe as shown in FIG. **20**(*a*), FIG. **20**(*e*) is a side view of the outer peripheral side-half pipe member as shown in FIG. **20**(*d*), FIG. **20**(*f*) is a cross-sectional view of an inner peripheral side-half pipe member for forming another part of the resin pipe as shown in FIG. **20**(*a*), FIG. **20**(*g*) is a side view of the inner peripheral side-half pipe member as shown in FIG. **20**(*g*) and FIG. **20**(*h*) is a partial cross-sectional view illustrating the constructional example of the roller passage forming portion, in which the roller retainer is not used;

FIG. **21** is a schematic disassembling perspective view illustrating the first modification of the resin-formed body for forming the ball circulation passage in the second embodiment of the present invention;

FIG. **22**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in

FIG. **21**, FIG. **22**(*b*) is a view illustrating the first resin frame as shown in FIG. **22**(*a*), with sight being placed on the divided end side thereof and FIG. **22**(*c*) is a view illustrating the second resin frame as shown in FIG. **22**(*a*), with sight being placed on the divided end side thereof;

FIG. **23** is a schematic disassembling perspective view illustrating the second modification of the resin-formed body for forming the ball circulation passage in the second embodiment of the present invention;

FIG. **24**(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in FIG. **23**, FIG. **24**(*b*) is a view illustrating one resin frame as shown in FIG. **24**(*a*), with sight being placed on the divided end side thereof and FIG. **24**(*c*) is a view illustrating the other resin frame as shown in FIG. **24**(*a*), with sight being placed on the divided end side thereof;

FIG. **25** is a schematic disassembling perspective view illustrating the third modification of the resin-formed body for forming the ball circulation passage in the second embodiment of the present invention;

FIG. **26** is a schematic disassembling perspective view illustrating the fourth modification of the resin-formed body for forming the ball circulation passage in the second embodiment of the present invention;

FIG. **27** is a front view having a cross-sectional half portion, illustrating the other embodiment of arrangement of the trains of balls in the linear motion guiding apparatus of the second embodiment of the present invention;

FIG. **28** is a schematic disassembling perspective view of an outer tube of a ball-spline as a linear motion guiding apparatus of the third embodiment of the present invention;

FIG. 29(*a*) is a front view having a cross-section, illustrating the ball spline of the third embodiment of the present invention, in which the outer tube as shown in FIG. 28 is used, FIG. 29(*b*) is a partial cross-sectional view illustrating one ball circulation passage of the apparatus as shown in FIG. 29(*a*) and FIG. 29(*c*) is a disassembling cross-sectional view illustrating the construction of the ball circulation passage, in which the roller retainer as shown in FIG. 29(*b*) is removed;

FIG. 30 shows the resin-formed body for forming the ball circulation passage as shown in FIG. 29, and more specifically, FIG. 30(*a*) is a cross-sectional view cut along the line a—a as indicated in FIG. 30(*b*), FIG. 30(*b*) is a front view of the resin-formed body for forming the ball circulation passage as shown in FIG. 30(*a*), FIG. 30(*c*) is a partial side view of the resin-formed body for forming the ball circulation passage, in which the resin pipe as shown in FIG. 30(*a*) is removed, FIG. 30(*d*) is a cross-sectional view of an outer peripheral side-half pipe member for forming a part of a resin pipe as shown in FIG. 30(*a*), FIG. 30(*e*) is a side view of the outer peripheral side-half pipe member as shown in FIG. 30(*d*), FIG. 30(*f*) is a cross-sectional view of an inner peripheral side-half pipe member for forming another part of the resin pipe as shown in FIG. 30(*a*) and FIG. 30(*g*) is a side view of the inner peripheral side-half pipe member as shown in FIG. 30(*f*);

FIG. 31 is a schematic disassembling perspective view illustrating the first modification of the resin-formed body for forming the ball circulation passage in the third embodiment of the present invention;

FIG. 32(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in FIG. 31, FIG. 32(*b*) is a view illustrating the first resin frame as shown in FIG. 32(*a*), with sight being placed on the divided end side thereof and FIG. 32(*c*) is a view illustrating the second resin frame as shown in FIG. 32(*a*), with sight being placed on the divided end side thereof;

FIG. 33 is a schematic disassembling perspective view illustrating the second modification of the resin-formed body for forming the ball circulation passage in the third embodiment of the present invention;

FIG. 34(*a*) is a disassembling side view having a partial cross-section, illustrating the resin-formed body for the ball circulation passage as shown in FIG. 33, FIG. 34(*b*) is a view illustrating one resin frame as shown in FIG. 34(*a*), with sight being placed on the divided end side thereof and FIG. 34(*c*) is a view illustrating the other resin frame as shown in FIG. 34(*a*), with sight being placed on the divided end side thereof;

FIG. 35 is a schematic disassembling perspective view illustrating the third modification of the resin-formed body for forming the ball circulation passage in the third embodiment of the present invention;

FIG. 36 is a schematic disassembling perspective view illustrating the fourth modification of the resin-formed body for forming the ball circulation passage in the third embodiment of the present invention;

FIG. 37 is a front view having a partial cross-section, illustrating the another embodiment of arrangement of the trains of balls in the ball spline as the linear motion guiding apparatus of the third embodiment of the present invention;

FIG. 38(*a*) is a front view having a partial cross-section, illustrating a roller-spline as the linear motion guiding apparatus of the fourth embodiment of the present invention, in which a side cover plate is removed, and FIG. 38(*b*) is a longitudinal partial cross-sectional view of one roller circulation passage as shown in FIG. 38(*b*);

FIG. 39(*a*) is a partial cross-sectional view illustrating the constructional example of the resin-formed body for forming the roller circulation passage of the roller spline as shown in FIG. 38, and FIGS. 39(*b*) to 39(*e*) are views illustrating the first to fourth modifications of the resin-formed body for forming the roller circulation passage;

FIG. 40(*a*) is a front view of the movable block of the linear motion guiding apparatus of the fourth embodiment of the present invention, in which the side cover plate is removed, and FIG. 40(*b*) is a perspective view of the movable block as shown in FIG. 40(*a*);

FIG. 41 is a schematic disassembling perspective view of the resinformed bodies for forming the ball circulation passage as shown in FIG. 40;

FIG. 42 is a front view of the resin frame composing the resin-formed body for forming the ball circulation passage, as shown in FIG. 41, FIG. 42(*b*) is a left-hand side view of the resin-formed body as shown in FIG. 42(*a*) and FIG. 42(*c*) is a right-hand side view of the resin-formed body as shown in FIG. 42(*a*);

FIG. 43 shows a resin pipe for forming a part of the resin-formed body for forming the ball circulation passage, as shown in FIG. 41, and more specifically, FIG. 43(*a*) is a front view of an outer peripheral side-half pipe member, FIG. 43(*b*) is a side view of the outer peripheral side-half pipe member as shown in FIG. 43(*a*), FIG. 43(*c*) is a front view of an inner peripheral side-half pipe member, FIG. 43(*d*) is a side view of the inner peripheral side-half pipe member as shown in FIG. 43(*c*); and

FIG. 44(*a*) is a cross-sectional view of one ball circulation passage, in which the ball retainer is removed from the movable block as shown in FIG. 40(*a*), FIG. 44(*b*) is an enlarged partial view of the direction changing passage as shown in FIG. 44(*a*), FIG. 44(*c*) is a partial side view of the ball retainer, FIG. 44(*d*) is a plan view of the ball retainer as shown in FIG. 44(*c*), FIG. 44(*e*) is a view of the ball retainer, with sight being placed in a direction of an arrow of "a" as indicated in FIG. 44(*d*), FIG. 44(*f*) is a partial side view of the direction changing passage as shown in FIG. 44(*b*), in which the side cover plate is removed, and FIG. 44(*g*) is a partial side view illustrating a recess portion, which forms the direction changing passage in the side cover plate as shown in FIG. 44(*b*).

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Now, embodiments of a linear motion guiding apparatus the present invention will be described in detail below with reference to the accompanying drawings.

[FIRST EMBODIMENT]

FIGS. 1 to 7 show a linear motion guiding apparatus of the first embodiment of the present invention.

The linear motion guiding apparatus **1** is provided with a guide rail **2** as a guide member, which extends linearly, and a movable block **4** as a movable member, which is arranged so as to be movable along the guide rail **2** through a large number of balls **3** as rolling members.

The guide rail **2** is formed into a long bar shape having a rectangular cross-section. Two ball running grooves **5, 5** as a rolling member running track are formed on the horizontal upper surface of the guide rail **2**, and a single ball running groove **5** as the rolling member running track is formed on each of the right and left-hand vertical surfaces of the guide rail **2**, so as to provide a total number of grooves **5** of four.

The movable block **4** is formed as a block body having an inverse U-shaped cross-section, with its opening end being directed downwardly. The block body is provided with a horizontal portion **6**, which faces the upper surface of the guide rail **2** and with a pair of wing portions **7, 7**, which extend downwardly from the right and left ends of the horizontal portion **6** and face the right and left-hand side surfaces of the guide rail **2**, respectively. The horizontal portion **6** has on its lower surface two ball running counter-grooves **8, 8** as a rolling member running counter-track, which correspond to the ball running grooves **5, 5** formed on the upper surface of the guide rail **2**. Each of the wing portions **7, 7** has on its inner surface a single ball running counter-groove **8** as the rolling member running counter-track, which corresponds to the respective ball running grooves **5, 5** formed on the right and left-hand side surfaces of the guide rail **2**.

In addition, in the movable block **4**, there are formed four ball returning passages **9, 9, 9, 9** as a rolling member returning passage, which are provided in parallel with the four ball running counter-grooves **8, 8, 8, 8**, respectively, as well as four pairs of direction changing passages **10, 10, 10, 10** each having a U-shape, for connecting the respective both ends of the ball running counter-grooves **8, 8, 8, 8** with the respective both ends of the ball returning passages **9, 9, 9, 9**, so as to form four endless circulation passages. The ball returning passages **9, 9** respectively corresponding to the ball running grooves **5, 5** formed on the upper side of the guide rail **2** are formed in the horizontal portion **6**. The other ball returning passages **9, 9** respectively corresponding to the ball running grooves **5, 5** formed on the right and lefthand vertical surfaces of the guide rail **2** are formed in the wing portions **7, 7** of the movable block **4**, respectively.

In each of the four endless circulation passages in this embodiment, the balls **3** are retained in the form of train by means a ball retainer **12** as a rolling member retainer, as shown in FIG. **4** so that the balls **3** can be circulated while being guided by the ball retainer **12**.

The ball retainer **12** comprises a flexible belt portion **12*b***, which is provided with ball holes **12*a*** for respectively receiving the balls **3**, and spacing portions **12*c*** provided between the adjacent two balls **3, 3**. The belt portion **12*b*** has a width longer than the diameter of the ball **3** so that the both side edges of the belt portion **12*b*** extend outwardly from the ball **3**.

The spacing portion **12*c*** is provided with a ball supporting spherical recess **12*d*** corresponding to the spherical surface of the ball **3**. The ball **3** is supported on its both sides by a pair of supporting spherical recesses **12*d*** so as to prevent the ball **3** from coming off the belt portion **12*b***. In this embodiment, the one end of the belt portion **12*b*** is not connected to the other end thereof, thus forming a strip-shaped belt having the both ends. The one end of the belt portion **12*b*** may be connected to the other end thereof so as to form an endless belt.

The movable block **4** is composed of a block body **13** having ball running counter-grooves **8, 8, 8, 8**, a resin-formed body **20** for forming ball circulation passages, which is inserted in the block body **13**, and a pair of side cover plates **40, 40** secured to the both end surfaces of the block body **13**, in which the resin-formed body **20** is inserted.

Each of the ball circulation passages of the resin-formed body **20** comprises a pair of ball passage forming portions **21, 21** extending along both longitudinal sides of the ball running counter-groove **8**, a pair of direction changing passage inner guide forming portion **22, 22** provided on the both side surfaces of the block body **13**, and a resin pipe **23** as a returning passage forming portion, which is inserted into a through-hole formed in the block body **13**. In this embodiment, the ball passage forming portions **21, 21** and the pair of direction changing passage-inner guide forming portions **22, 22** are integrally formed with each other into an integral body, and the resin pipe **23** is separately formed from the above-mentioned integral body. More specifically, there is used a construction that the ball passage forming portions **21, 21** and the pair of direction changing passage-inner guide forming portions **22, 22** are integrally connected with each other through integral forming to form an integral resin frame **24**, and the four resin pipes **23** can respectively be inserted into the block body **13**.

The ball passage forming portions **21, 21** are provided with guide grooves for guiding the both side edges of the belt portion **12*b*** of the ball retainer **12** in a loaded area. The guide grooves can prevent the ball retainer **12** not only from being swung during run of the ball, but also from being sagged by engaging the side edges of the belt portion **12*b*** with the guide groove **21*a***, when the movable block **4** is removed from the guide rail **2**. The balls **3** are supported by the ball retainer **12**. More specifically, the ball retainer **12** is supported by a jaw portion of the guide groove **21*a***, with the result that the balls **3** are kept in its proper position so as not to come off the movable block **4**.

In this embodiment, a distance between the pair of ball passage forming portions **21, 21** arranged in parallel with each other on the both longitudinal sides of the ball running counter-groove **8** is slightly larger than the diameter of the ball **3**. The balls **3** come off the ball running counter-groove **8**, if the ball retainer **12** is not used. When an amount of projection of the jaw portion **21*b*** is predetermined so that a distance between the pair of ball passage forming portions **21, 21** is slightly smaller than the diameter of the ball **3** as shown in FIG. **3(*d*)**, it is however possible to prevent the balls **3** from coming off the ball running counter-groove **8** even without the ball retainer **12**. Such a construction can apply not only to the case where the balls **3** are inserted into the ball circulation passage with the use of the ball retainer **12**, but also to the case where the balls are inserted therein without the ball retainer **12**. The distance between the pair of ball passage forming portions **21, 21** may be slightly smaller than the diameter of the ball **3** so that the ball passage forming portions **21, 21** directly hold the ball **3** without the use of the ball retainer **12** as shown in FIG. **3(*e*)**.

Guide grooves **9*c*, 10*c*** are also formed in the ball returning passage **9** and the direction changing passage **10** as non-loaded areas, in order to guide the side edges of the belt portion **12*b***. The guide grooves **9*c*, 10*c*** are connected to the above-mentioned guide groove **21*a*** in the loaded area so as to form an endless groove on the entire periphery.

When the ball retainer **12** is not used as shown in FIG. **3(*f*)**, the distance between the pair of ball passage forming portions **21, 21** arranged on the both longitudinal sides of the ball running counter-groove **8**, which portions do not have any jaw portions **21**, may be slightly smaller than the diameter of the ball **3**, thus preventing the balls **3** from coming off the ball running counter-groove **8**.

The four sets of ball passage forming portions **21, 21** are composed of the first thin connecting plate portion **25** extending longitudinally along the under surface of the horizontal portion **6** of the block body **13**, a pair of second connecting plate portions **26, 26**, which have an L-shaped cross section and extend in the longitudinal direction of the block body **13** along the corner portions between the horizontal portion **6** and the wing portions **7, 7** of the block body **13**, and a pair of third connecting plate portions **27, 27**, which extend in the longitudinal direction of the block body **13** along the lower surfaces of the wing portions **7**, **7** of the block body **13**.

More specifically, the right and left-hand side edges of the first connecting plate portion **25** and the upper edges of the pair of right and left-hand second connecting plate portions **26**, **26** are located at the both sides of the respective ball running counter-grooves **8**, **8** provided on the under surface of the horizontal portion **6**, so as to form the ball passage forming portions **21**, **21**; **21**, **21**. The lower edges of the second connecting plate portions **26**, **26** and the inner edges of the third connecting plate portions **27**, **27** are located at the both sides of the respective ball running counter-grooves **8**, **8** provided on the respective inner surface of the wing portions **7**, **7**, so as to form the other ball passage forming portions **21**, **21**; **21**, **21**.

The direction changing passage-inner guide forming portion **22** has a thin sheet portion **29**, which is to be connected to the end surface of the block body **13**. The ball passage forming portions **21**, **21** and the resin pipe **23** are connected through the above-mentioned thin sheet portion **29**. In this embodiment, the direction changing passage-inner guide forming portions **22**, **22** and the ball passage forming portions **21**, **21** are connected by means of the thin sheet portion **29** through integral forming. The resin pipe **23** is inserted in a hole **34** formed on the thin sheet portion **29** so as to make a faucet joint, and fixed to the thin sheet portion **29**.

The thin sheet portion **29** has the first end plate portion **30** corresponding to the end surface of the horizontal portion **6** of the block body **13**, a pair of third end plate portions **32**, **32** corresponding to the end surfaces of the wing portions **7**, **7** and the second end plate portions **31**, **31** for connecting the first end plate portion **30** and the respective third end plate portions **32**, **32**. The first end plate portion **30** has the direction changing passage-inner guide forming portions **22**, **22**, which are formed so as to project corresponding to the two trains of balls **3**, **3** on the upper surface side of the guide rail **2**. Each of the third end plate portions **32**, **32** has the direction changing passage-inner guide forming portion **22**, which is formed so as to project corresponding to the single train of balls **3** on the side surface of the guide rail **2**

The first end plate portions **30**, **30**, which are to be placed respectively on the both ends of the block body **13** are connected at its lower portion with the both ends of the first connecting plate portion **25** extending longitudinally between the first end plate portions **30**, **30**. The second end plate portions **31**, **31**, which are to be placed respectively on the both ends of the block body **13** are connected at its inner edge portion with the both ends of the second connecting plate portion **26** extending longitudinally between the second end plate portions **31**, **31**. The other second end plate portions **31**, **31** have the same connecting structure. The third end plate portions **32**, **32**, which are to be placed respectively on the both ends of the block body **13** are connected at its inner edge portion with the both ends of the third connecting plate portion **27** extending longitudinally between the third end plate portions **32**, **32**. The other third end plate portions **32**, **32** have the same connecting structure. A single resin frame **24** is formed in this way.

Each of the direction changing passage-inner guide forming portions **22** has a semi-cylindrical shape. On the outer periphery of the direction changing passage-inner guide forming portion **22**, there is formed an inner guide-groove **10***a* -having a semi-circular cross-section so as to form the inner guide portion for the direction changing passage **10**. The one end of the inner guide groove **10***a* is connected to the end of the ball running counter-groove **8**. Accordingly, the one end of the inner guide groove **10***a* has the same cross-sectional shape as the ball running counter-groove **8** so as to make an alignment of the one end of the inner guide groove **10***a* with the end of the ball running counter-groove **8**. The other end of the inner guide groove **10***a* of the direction changing passage **10** is connected to the end of the ball returning passage **9**. Accordingly, the other end of the inner guide groove **10***a* has the same cross-sectional shape as the ball returning passage **9** so as to make an alignment of the other end of the inner guide groove **10***a* with the end of the ball returning passage **9**.

Cylindrical flange portions **33**, **33** are formed on the both ends of the inner guide groove **10***a*. The distance between the respective outer surfaces of the cylindrical flange portions **33**, **33** is larger than the width of the belt portion **12***b*. The cylindrical flange portions **33**, **33** form a retainer-guide groove **10***c* for the ball retainer **12** in cooperation with a semi-circular recess portion having cutouts, which is formed on the inner periphery of the recess of the side cover plate **40**, described later.

The both ends of the inner guide groove **10***a* for the direction changing passage **10** extend to the contacting surface of the first and third end plate portions **30**, **32** with the end surface of the block body **13** so as to be connected to the respective ends of the ball running counter-groove **8** and the ball returning passage **9**. Pipe inserting holes **34**, **34**, **34**, **34** having a semi-circular shape, in which the ends of the resin pipes **23** are to be inserted are formed on the first and third end plate portions **30**, **32**.

As shown in FIG. **7**, the resin pipe **23** is composed of an inner peripheral side-half pipe member **23***a* located in the inner peripheral side of the ball circulation passage, which is continuously connected to the inner guide groove **10***a* for the direction changing passage, and an outer peripheral side-half pipe member **23***b* located in the outer peripheral side of the ball circulation passage, which is continuously connected to an outer guide groove **10***b* for the direction changing passage **10**, which is formed on the side cover plate **40**. The inner peripheral side-half pipe member **23***a* has a groove portion **9***a* having a semi-circular cross section, and side edge portions **23***c* extending longitudinally along the groove portion **9***a*.

The outer peripheral side-half pipe member **23***b* is formed into a linear member having the same circular cross section as the outer guide groove **10***b* for the direction changing passage, which is formed on the side cover plate **40**. The outer peripheral side-half pipe member **23***b* has a groove portion **9***b*, which is continuously connected to the outer guide groove **10***b*, and side edge portions **23***d* extending longitudinally along the groove portion **9***b*. The side edge portions **23***d* is provided on its outer edges with projections **23***e*, which are to be brought into contact with the outer edges of the side edge portions **23***c* of the inner peripheral side-half pipe member **23***a* to form the retainer-guide groove **9***c* for the ball retainer **12**.

The inner peripheral side-half pipe member **23***a* of the resin pipe **23** has the same length of the block body **13**. The inner peripheral side-half pipe member **23***a* is positioned so as to be brought into contact with the back surface of the direction changing passage-inner guide forming portion **22**.

The outer peripheral side-half pipe member **23***b* of the resin pipe **23** has on the other hand a longer length than the block body **13** by a length corresponding to the thickness of the thin sheet portion **29**. The outer peripheral side-half pipe members **23***b* are inserted in the inserting holes **34** of the first and third end plate portions **30**, **32**. Longitudinal positional determination of the outer peripheral side-half pipe member **23***b* is made by bringing the both ends of the outer peripheral side-half pipe member **23***b* inserted in the inserting holes **34** into contact with the peripheral edge of the end portion of the outer guide grooves **10***b* for the direction changing passage, which are formed on the side cover plate **40**. The projections **23***e* formed on the both side edges of the outer peripheral side-half pipe member **23***b* come into contact with the outer edges of the cylindrical flange portions **33** formed on the direction changing passage-inner guide forming portion **22** to form a part of the guide groove **10***c*, and the outer peripheral side-half pipe member **23***b* and the inner peripheral side-half pipe member **23***a* are restricted to be turned in the inserting hole **14**.

The resin pipes **23** and the direction changing passage-inner guide forming portions **22** are accurately positioned through the inserting holes **34** formed on the first and third end plate portions **30**, **32** of the thin sheet portion **29** and a proper assembling is carried out in this manner.

As shown in FIG. **5**, the side cover plate **40** is provided with an inserting recess portion **40***a*, in which the thin sheet portion **29** is inserted, four recess portions **41** having the outer guide grooves **10***b* for the direction changing passage, into which portions the direction changing passage-inner guide forming portions **22** are fitted, and screw-fixing portions for securing the side cover plate **40** to the block body **13**. In the screw-fixing portions, the side cover plate **40** is fixed to the block body **13** by inserting bolts **44** into holes **43** formed on the side cover plate **40** and engaging the bolts with screwed holes **45** formed on the end surface of the block body **13**. The holes **43** are located between the first and third end plate portions **30**, **32** of the thin sheet portion

As shown in FIG. **7**, the outer guide groove **10***b* for the direction changing passage in the recess portion **41** has on its side edges larger-diameter arcuate recesses **46**, which form the retainer-guide groove **10***c* in cooperation with the cylindrical flange portions **33** of the direction changing passage-inner guide forming portions **22**, and a smaller-diameter arcuate recesses **47**, in which the cylindrical flange portions **33** are inserted. The direction changing passage-inner guide forming portion **22** provided with the inner guide groove **10***a* for the direction changing passage is fitted into the recess portion **41** of the side cover plate **40**, and the thin sheet portion **29** is received in the inserting recess portion **40***a* of the side cover plate **40**. The thin sheet portion **29** is held between the side cover plate **40** and the end surface of the block body **13** through a clamping force so as to be firmly fixed therebetween.

The direction changing passage-inner guide forming portions **22** and the ball passage forming portion **21** are connected through the thin sheet portion **29**, thus making it possible to maintain an accurate positional relationship of the end of the inner guide groove **10***a* for the direction changing passage formed in the direction changing passage-inner guide forming portion **22** relative to the ball passage forming portions **21**, **21**, as well as an accurate positional relationship of the inner guide groove **10***a* for the direction changing passage relative to the ball returning passage **9**.

The thin sheet portion **29** located in the vicinity of the direction changing passage-inner guide forming portion **22** is uniformly urged against the flat end surface of the block body **13** through a clamping force applied to the side cover plate **40** (see FIG. **7**). Even when the direction changing passage-inner guide forming portion **22** is not located in a correct position, the thin sheet portion **29** changes its shape on the end surface of the block body **13**, thus permitting the correct positioning of the direction changing passage-inner guide forming portion **22**. The thin sheet portion **29** is firmly clamped and fixed through a clamping force, which is applied to the side cover plate **40**, and frictional force caused by such a clamping step may prevent an unfavorable movement of the inner guide groove **10***a* for the direction changing passage.

The side cover plate **40** is secured to the block body **13** so that the direction changing passage-inner guide forming portion **22** assembled to the block body **13** is fitted into the recess portion **41** of the side cover plate **40**. Such a fitting step permits to make an accurate positioning of the side cover plate **40** relative to the block body **13**.

FIG. **6** shows assembling steps for the above-described resin-formed body for forming the ball circulation passage.

First, the inner peripheral side-half pipe member **23***a* of the resin pipe **23** is inserted in the through-hole **14** of the block body **13** (see FIGS. **6**(*a*) and **6**(*b*)).

Then, the resin frame **24** obtained by integral forming is inserted in the recess of the block body **13**, while causing the thin sheet portions **29** at the both ends of the resin frame **24** to slide on the respective end surfaces of the block body **13** (see FIGS. **6**(*c*) and **6**(*d*)). The first connecting plate portion **25** of the resin frame **24** comes into contact with the under surface of the horizontal portion **6**, thus making positional determination in the vertical direction of the resin frame **24**. The second connecting plate portion **26** and the third connecting plate portion **27** of the resin frame **24** come into contact with the respective inner surfaces of the wing portions **7**, **7** of the block body **13**, thus making positional determination of the ball passage forming portions **21**, **21** and the direction changing passage-inner guide forming portion **22** (see FIGS. **6**(*e*) and **6**(*f*). At this time, the inserting hole **34** of the thin sheet portion **29** is aligned with the through-hole **14** of the block body **13**.

Then, the outer peripheral side-half pipe member **23***b* is inserted in the through-hole **14** from the inserting hole **34**, thus completing the assembling step of the resin-formed body **20** for forming the ball circulation passage (see FIGS. **6**(*g*) and **6**(*h*)).

Then, the one side cover plate **40** is secured to the one end surface of the block body **13** by a clamping step, the ball retainer **12** holding the balls is inserted, and the other side cover plate **40** is secured to the other end surface of the block body **13** by the same clamping step, thus completing the assembling step of the movable block **4**.

According to the present invention, the resin-formed body **20** for forming the ball circulation passage is separately formed from the block body **13**. Even when the movable block **4** has a larger size, there is no restriction of flow of molten resin by the block body **13**, unlike the case where the block body **13** is integrally formed with the resin-formed body **20**. Increase in number of gates formed on a die may ensure proper run of the molten resin, thus improving the formability. Especially, the ball passage forming portions **21**, **21** located at the opposite longitudinal sides of the ball running groove **8** are thin, with the result that molten resin may not reach every part of the space for forming the ball passage forming portions **21**, **21**. It is therefore effective to form the resin-formed body **20** separately from the block body **13** in accordance with the embodiment of the present invention.

The continuous circulation passage is formed by the resin-formed body **20**, and it is therefore possible to make positional determination of the inner guide groove **10***a* for the direction changing passage relative to the ball passage forming portions **21**, **21**, as well as positional determination of the inner guide groove **10***a* for the direction changing passage relative to the ball returning passage **9**, thus ensuring continuity of the circulation passage so as to make smooth circulation of the balls **3**.

When the proper positional relationship of the inner guide groove **10***a* for the direction changing passage relative to the ball passage forming portions **21, 21**, is maintained, the ball passage forming portions **21, 21** are located at the longitudinal both sides of the ball running groove **8** so as to be aligned with the ends of the inner guide groove **10***a* for the direction changing passage.

When the proper positional relationship of the inner guide groove **10***a* for the direction changing passage relative to the ball returning passage **9** is maintained, the inner guide groove **10***a* for the direction changing passage can be aligned with the inner groove **23***a* of the ball returning passage **9**.

The connecting portion of the ball passage forming portions **21, 21** and the direction changing passage-inner guide forming portion **22** is obtained by integral forming, thus permitting omission of an assembling step of the connecting portion. Although the running direction of the balls **3** is changed in such a connecting portion, the above-mentioned integral structure may ensure continuity of the circulation passage, without being affected by assembling accuracy. It is therefore possible to make smooth run of the balls **3** from the ball running passage between the ball running groove **5** and the ball running counter-groove **8** to the direction changing passage **10**, as well as from the direction changing passage **10** to the ball returning passage **9**.

Description will be given of modifications of the resin-formed body **20** for forming the ball circulation passage, which is divided into parts In the description of the modifications, modified features will only be explained in comparison with the first embodiment of the present invention. The same reference numerals will be given to the same components as those in the first embodiment of the present invention, and description thereof will be omitted.

[First Modification]

FIGS. **8** and **9** show the first modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the first embodiment.

In the first modification, the resin-formed body **20** for forming the ball circulation passage is composed of the first resin-formed frame **20**A, which is obtained by integrally connecting both of the ball passage forming portions **21, 21** and the resin pipes **23** at their ends with the direction changing passage-inner guide forming portions **22**A for one side, and the second resin-formed frame **20**B, which is provided with the direction changing passage-inner guide forming portions **22**B for the other side and separately formed from the first resin-formed frame **20**A.

In this case, the ball passage forming portions **21, 21** are integrally connected with the direction changing passage-inner guide forming portions **22**A through the thin sheet portion **29**A as in the first embodiment.

The direction changing passage-inner guide forming portions **22**A are also integrally connected with the resin pipes **23** through the thin sheet portion **29**A. In this case, the resin pipe **23** is formed into a tubular integral body, although the half pipe members are used in the first embodiment. Accordingly, there exists no inserting hole **34** in the thin sheet portion **29**A, and the ball returning passage **9** is exposed on the thin sheet portion **29**A.

The first resin-formed frame **20**A and the second resin-formed frame **20**B are connected, as shown in FIG. **9**, by means of a joint method using the combination of a recess and a projection to be inserted therein, such as a faucet joint method. In the illustrated example, a recess portion **36** of a dove-tail groove is formed in the second resin-formed frame **20**B, and an engaging projection **35** to be engaged with the recess portion **36** is formed, on the other hand, in the ball passage forming portions **21, 21**.

In this case, the resin pipe **23** of the first resin-formed frame **20**A is inserted in the through-hole **14** of the block body **13**, and the first, second and third connecting plate portions **25, 26, 27** are inserted along the under surface of the horizontal portion **6** of the block body **13** and the inner surfaces of the wing portions **7, 7**.

Then, the engaging projections **35** formed at the respective free end portions of the first, second and third connecting plate portions **25, 26, 27** are engaged with the recess portions **36** formed on the thin sheet portion **29**B of the second resin-formed frame **24**B, which is arranged on the other end surface of the block body **13**.

The recess portions **36** may be formed on the first resin-formed frame **20**A and the engaging projections **35** may be formed on the second resin-formed frame **20**B. The connecting method is not limited to the method described above, and there may be used any conventional connecting method, in which the ends of the divided parts can be maintained in a proper connecting position and connected.

[Second Modification]

FIGS. **10** and **11** show the second modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the first embodiment.

In the second modification, the resin-formed body **20** for forming the ball circulation passage, which has been obtained by integrally forming both of the ball passage forming portions **21, 21** and the resin pipes **23** as a returning passage forming portion with a pair of direction changing passage-inner guide forming portions **22, 22**, is divided at the middle portion of each of the ball passage forming portions **21, 21** and the resin pipes **23** into two parts. More specifically, the ball passage forming portions **21, 21** and the resin pipes **23** are divided at their middle portion into the respective two half parts, and each of the thus divided two half parts is integrally formed with the direction changing passage-inner guide forming portions **22, 22**, thus forming two resin-formed frames **20**C, **20**D having substantially the same shape.

Four sets of the ball passage forming portions **21, 21** are formed on the first, second and third connecting plate portions **25, 26, 27**. Recess portions **38** and engaging projections **37** to be inserted therein are formed on the divided ends of the first, second and third connecting plate portions **25, 26, 27** and the divided ends of the resin pipes **23**.

[Third Modification]

FIGS. **12** to **14** show the third modification of the resin-formed body for forming the ball circulation passage, which is described in the first embodiment.

In the third modification, there is not used the resin pipe **23** as a returning passage forming portion described in the first embodiment, and a resin-formed frame **20**E is obtained by integrally forming the first, second and third connecting plate portions **25, 26, 27** having the ball passage forming portions **21, 21** with the thin sheet portions **29, 29** each having the pair of direction changing passage-inner guide forming portions **22, 22**. The ball returning passage **9** is composed as a through-hole formed in the block body **13**.

In this case, an engaging projection **39***a*, which is engageable with a tapered portion **15** formed in the opening end of the ball returning passage **9** may be formed in the opening end of the ball hole **39** of the thin sheet portion **29**. Such a construction permits to make a proper connection of the end of the ball returning passage **9** and the direction changing passage-inner guide forming portion **22**.

In the illustrated example, an arcuate engaging projection **48** is additionally formed on the connection portion of the outer guide groove **10***b* for the direction changing passage with the ball returning passage **9**. The engaging projection **48** can be fitted into the ball hole **39** of the thin sheet portion **29** and engaged with the tapered portion **15** of the opening end of the ball returning passage **9**.

[Fourth Modification]

FIG. **15** shows the fourth modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the first embodiment.

In the fourth modification, there is not used the resin pipe **23** described in the third modification, a resin-formed frame **24**B is obtained by integrally forming, the ball passage forming portions **21** with the direction changing passage-inner guide forming portions **22** for the one side, the other resin-formed frame **24**C provided with the direction changing passage-inner guide forming portions **22** for the other side is separately formed from the above-mentioned resin-formed frame **24**B, and the resin-formed frames **24**B, **24**C are connected with each other by engagement of the engaging projection **35** with the recess **36**. The structure other than the above-mentioned construction is the same as that of the third modification.

[Modifications of the ball train]

In the first embodiment and the first to fourth modifications, there is described that two trains of the balls are provided on the upper surface of the guide rail **2** and the single train of the balls is provided on each of the side surfaces of the guide rail **2**, so as to provide the total number of trains of four. In the present invention, the other type of ball trains can however be applied as shown in FIG. **16**. With respect to the division of the resin-formed body **20** for forming the ball circulation passage, all the modifications as shown in FIG. **16** are based on the divisional pattern of the first embodiment. All the divisional patterns of the first to fourth modifications may however be applied to the modifications of the ball train as shown in FIG. **16**.

In the example as shown in FIGS. **16**(*a*) and **16**(*b*), two lower and upper trains of the balls as rolling members are provided on each of the gaps between the right and left-hand side surfaces of the guide rail **2** and the inner surfaces of the right and left-hand wing portions **7**, **7** of the movable block **13**, so as to provide the total number of trains of four.

FIG. **16**(*b*) shows the resin-formed body **20** in which all the ball passage forming portions for the four trains of the balls are integrally formed with each other. The resin-formed body **20** may however be divided into two resin-formed bodies **20**, **20**, which correspond to two trains of the balls for each of the right and left-hand sides of the guide rail **2**, as shown in FIG. **18**.

In the example as shown in FIGS. **16**(*c*) and **16**(*d*), the movable block **4** is provided with the horizontal portion **6** facing the upper surface of the guide rail **2** and a single wing portion **7** facing the one side surface of the guide rail **2**. The single train of the balls **3** as rolling members is provided between the one side surface of the guide rail **2** and the single wing portion **7** of the movable block **4**, and the other single train of the balls **3** is provided between the upper surface of the guide rail **2** and the lower surface of the horizontal portion in the vicinity of the corner of the guide rail **2**, so as to provide the total number of trains of two.

In the example as shown in FIGS. **16**(*e*) and **16**(*f*), the movable block **4** is provided with a pair of wing portions **7**, **7** between which the guide rail **2** is held at its right and left-hand surfaces. The single train of the balls **3** is provided in each of the gaps between the right and left-hand surfaces of the guide rail **2** and the inner surfaces of the right and left-hand wing portions **7**, **7** of the movable block **4**, so as to provide the total number of trains of two.

In the example as shown in FIGS. **16**(*g*) and **16**(*h*), the movable block **4** is arranged along the one side surface of the guide rail **2**. Two upper and lower trains of the balls **3** are provided between the one side surface of the guide rail **2** and the movable block **4**.

[SECOND EMBODIMENT]

FIGS. **18** to **20** show a linear motion guiding apparatus of the second embodiment of the present invention.

In the second embodiment, rollers are used as rolling members. More specifically, the linear motion guiding apparatus comprises a guide rail **202** as a guide member, extending linearly, and a movable block **204** arranged so as to be movable along the guide rail **202** through a large number of rollers **203** as rolling members.

The guide rail **202** is formed into a long bar shape having a rectangular cross-section. Two roller running surfaces **205**, **205** as a rolling member running track are formed on the horizontal upper surface of the guide rail **2**, and a single roller running surface **205** as the rolling member running track is formed on each of the right and left-hand vertical surfaces of the guide rail **2**, so as to provide a total number of surfaces **5** of four.

The movable block **204** is formed as a block body having an inverse U-shaped cross-section, with its opening end being directed downwardly. The block body is provided with a horizontal portion **206**, which faces the upper surface of the guide rail **202** and with a pair of wing portions **207**, **207**, which extend downwardly from the right and left ends of the horizontal portion **206** and face the right and left-hand side surfaces of the guide rail **202**, respectively. The horizontal portion **206** has on its lower surface two roller running counter-surfaces **208**, **208** as a rolling member running counter-track, which correspond to the roller running surfaces **205**, **205** formed on the upper surface of the guide rail **202**. Each of the wing portions **207**, **207** has on its inner surface a single roller running counter-surface **208** as the rolling member running counter-track, which corresponds to the respective roller running surfaces **205**, **205** formed on the right and left-hand side surfaces of the guide rail **202**.

In addition, in the movable block **204**, there are formed four roller returning passages **209**, **209**, **209**, **209** as a rolling member returning passage, which are provided in parallel with the four roller running counter-surfaces **208**, **208**, **208**, **208**, respectively, as well as four pairs of direction changing passages **210**, **210**, **210**, **210** each having a U-shape, for connecting the respective both ends of the roller running counter-surfaces **208**, **208**, **208**, **208** with the respective both ends of the roller returning passages **209**, **209**, **209**, **209**, so as to form four endless circulation passages.

The roller returning passages **209**, **209** respectively corresponding to the roller running surfaces **205**, **205** formed on the upper side of the guide rail **202** are formed in the horizontal portion **206**. The other roller returning passages **209**, **209** respectively corresponding to the roller running surfaces **205**, **205** formed on the right and left-hand vertical surfaces of the guide rail **202** are formed in the wing portions **207**, **207** of the movable block **204**, respectively.

In each of the endless circulation passages in this embodiment, the rollers **3** are retained in the form of train by means a roller retainer **212** as a rolling member retainer so that the rollers **203** can be circulated while being guided by the roller retainer **212**.

As shown in FIGS. **19**(*b*) to **19**(*d*), the roller retainer **212** comprises a flexible belt portion **212***b*, which is provided with roller holes **212***a* for respectively receiving the rollers **203**, and spacing portions **212***c* provided between the adjacent two rollers **203, 203**. The belt portion **212***b* has a width longer than the diameter of the roller **203** so that the both side edges of the belt portion **212***b* extend outwardly from the roller **203**.

The spacing portion **212***c* is provided with a roller supporting recess **212***d* corresponding to the cylindrical surface of the roller **203**. The roller **203** is supported on its both sides by a pair of supporting recesses **212***d* so as to prevent the roller **203** from coming off the belt portion **212***b*. In this embodiment, the one end of the belt portion **212***b* is not connected to the other end thereof, thus forming a strip-shaped belt having the both ends. The one end of the belt portion **212***b* may be connected to the other end thereof so as to form an endless belt.

As shown in FIGS. **18** and **20**, the movable block **204** is composed of a metallic block body **213** having roller running counter-surfaces **208, 208, 208, 208**, a resin-formed body **220** for forming roller circulation passages, which is inserted in the block body **213**, and a pair of side cover plates **214, 214** secured to the both end surfaces of the block body **213**, in which the resin-formed body **220** is inserted.

In the second embodiment, four circulation passages are formed by two resin-formed bodies **220, 220** for forming the roller circulation passage, which are arranged at the right and left-hand sides.

Each of the roller circulation passages of the resin-formed bodies **220** comprises a pair of roller passage forming portions **221, 221** extending along both longitudinal sides of the roller running counter-surface **208**, a pair of direction changing passage-inner guide forming portions **222, 222** provided on the both side surfaces of the block body **213**, and a resin pipe **223** as a returning passage forming portion, which is inserted into a through-hole formed in the block body **213**.

The roller passage forming portions **221, 221** are provided with guide surfaces for guiding the both side edges of the belt portion **212***b* of the roller retainer **212** in a loaded area as illustrated in detain in FIG. **20**. The guide grooves can prevent the roller retainer **212** not only from being swung during run of the roller, but also from being sagged by engaging the side edges of the belt portion **212***b* with the guide groove **221***a*. The rollers **203** are supported by the roller retainer **212**. More specifically, the roller retainer **212** is supported by a jaw portion of the guide groove **221***a*, with the result that the rollers **203** are kept-in its proper position so as not to come off the movable block **204**.

In this embodiment, the one end of the belt portion **212***b* is not connected to the other end thereof, thus forming a strip-shaped belt having the both ends. The one end of the belt portion **212***b* may be connected to the other end thereof so as to form an endless belt.

Guide grooves **209***c*, **210***c* are also formed in the roller returning passage **209** and the direction changing passage **210** as non-loaded areas, in order to guide the side edges of the belt portion **212***b*. The guide grooves **209***c*, **210***c* are connected to the above-mentioned guide groove **221***a* in the loaded area so as to form an endless groove on the entire periphery.

In each of the resin-formed bodies **220, 220** for forming the roller circulation passage, the roller passage forming portions **221, 221** and the pair of the direction changing passage-inner guide forming portions **222, 222** are integrally formed with each other. The resin pipe **223** for forming the roller returning passage **209** is separately formed from the resin-formed bodies **220, 220**. More specifically, the one ends of the two pairs of the roller passage forming portions **221, 221** are integrally connected with the ends of the pair of direction changing passage-inner guide forming portions **222, 222** to form a single resin frame **220**A so that the thus formed resin frame **220**A can be inserted into the block body **213**. The other resin frame **220**A has the same construction.

The roller passage forming portions **221, 221** to be arranged on the upper surface of the guide rail **202** are integrally connected with the other roller passage forming portions **221, 221** to be arranged on the side surface of the guide rail **202** by means of a thin connecting plate portion **226**.

The direction changing passage-inner guide forming portion **222** is integrally formed with a thin sheet portion **229**, which is to be brought into contact with the end surface of the block body **213**.

The thin sheet portion **229** has the first end plate portion **230**, which is to be brought into contact with the end surface of the horizontal portion **206** of the block body **213**, the third end plate portion **232**, which is to be brought into contact with the end surface of the wing portion **207**, and the second end plate portion **231**, which is arranged at the corner between the horizontal portion **206** and the wing portion **207** on the end surface of the block body **213**, and connects the first end plate portion **230** with the third end plate portion **232**.

The pair of roller passage forming portions **221, 221**, which are arranged on the both longitudinal sides of the roller running surface **208** are integrally formed on the inside edge of the first end plate portion **230** and the inside edge of the third end plate portion **232**, respectively. The both ends of the connecting plate portion **226** are integrally connected with the inside edges of the second plate portions **231, 231**.

Each of the direction changing passage-inner guide forming portions **222** has a semi-cylindrical shape. On the outer periphery of the direction changing passage-inner guide forming portion **222**, there is formed an inner guide groove **210***a* having a rectangular cross section so as to form the inner guide portion for the direction changing passage **210**. The one end of the bottom of the inner guide groove **210***a* is connected to the end of the roller running counter-surface **208**. Accordingly, the one end of the inner guide groove **210***a* has the same cross-sectional shape as the roller running counter-surface **208** so as to make an alignment of the one end of the inner guide groove **210***a* with the end of the roller running counter-surface **208**. The other end of the inner guide groove **210***a* of the direction changing passage **210** is connected to the end of the roller returning passage **229**. Accordingly, the other end of the inner guide groove **210***a* has the same cross-sectional shape as the roller returning passage **209** so as to make an alignment of the other end of the inner guide groove **210***a* with the end of the roller returning passage **209**.

Cylindrical flange portions **233, 233** are formed on the both ends of the inner guide groove **210***a*. The distance between the respective outer surfaces of the cylindrical flange portions **233, 233** is larger than the width of the belt portion **212***b*. The cylindrical flange portions **233, 233** form a guide groove **210***c* for the roller retainer **212** in cooperation with the side cover plate **240** described later.

The one end of the inner guide groove **210***a* for the direction changing passage **210** extends to the contacting surface of the first and third end plate portions **230, 232** with the end surface of the block body **213** so as to be connected to the end of the roller running counter-surface **208**. The other end of the inner guide groove **210***a* for the direction changing passage **210** extends to the end surface of the thin sheet portion **229**, which is apart from the block body **213**. A step portion **222***a* having a depth identical to the thickness of the thin sheet portion **229** is formed at the other end of the inner guide groove **210***a*. The inner peripheral side-half pipe member for the resin pipe **223** projects from the end surface of the block body **13** by a length identical to the thickness of the thin sheet portion **229**. The projected end of the half pipe member **223***a* is fitted into the step portion **222***a* of the thin sheet portion **229**.

Pipe inserting holes **234**, **234** having a semi-circular shape, in which the ends of for the outer peripheral side-half pipe member **223***a* for the resin pipes **223** for forming the roller returning passage **209** are to be inserted are formed on the first and third end plate portions **230**, **232** of the thin sheet portion **229**. The resin pipe **223** is inserted into the circular through-hole **214** formed in the block body **213** so that the inner peripheral surface of the resin pipe **223** form the roller returning passage **209**.

As shown in FIG. **20**, the resin pipe **223** is composed of the inner peripheral side-half pipe member **223***a*, which is continuously connected to the inner guide groove **210***a* for the direction changing passage, and the outer peripheral side-half pipe member **223***b*, which is continuously connected to the outer guide groove **210***b* for the direction changing passage **210**, which is formed on the side cover plate **240**. The inner peripheral side-half pipe member **223***a* has an inner groove portion **209***a* having a rectangular cross section, and side edge portions **223***b* extending longitudinally along the inner groove portion **209***a*. The longitudinal edge portions **223***c* of the inner peripheral side-half pipe member **223***a* has the same width as the flange portion **233** of the portion **228**.

The outer peripheral side-half pipe member **223***b* is formed into a linear member having the same rectangular cross section as the outer guide groove **210***b* for the direction changing passage, which is formed on the side cover plate **240**. The outer peripheral side-half pipe member **223***b* has a outer groove portion **209***b*, which is continuously connected to the outer guide groove **210***b*, and side edge portions **223***d* extending longitudinally along the outer groove portion **209***b*. The side edge portions **223***d* is provided on its outer edges with projections **223***e*, which are to be brought into contact with the side edge portions **223***c* of the inner peripheral side-half pipe member **223***a* to form the guide groove for the belt portion **212** of the roller retainer **212**.

The inner peripheral side-half pipe member **223***a* of the resin pipe **223** has the same length of the block body **213**. The inner peripheral side-half pipe member **223***a* is positioned so as to be brought into contact with the end surface of the direction changing passage-inner guide forming portion **222**, which is arranged on the side of the block body **213**.

The outer peripheral side-half pipe member **223***b* of the resin pipe **223** has on the other hand a longer length than the block body **213** by a length corresponding to the thickness of the first and third end plate portions of the thin sheet portion **229**, which are arranged on the both ends of the block body **213**. The outer peripheral side-half pipe members **223***b* are inserted in the inserting holes **234** of the first and third end plate portions **230**, **232**. Longitudinal positional determination of the outer peripheral side-half pipe member **223***b* is made by bringing the both ends of the outer peripheral side-half pipe member **223***b* inserted in the inserting holes **234** into contact with the peripheral edge of the end portion of the outer guide grooves **210***b* for the direction changing passage, which are formed on the side cover plate **240**. The projections **223***e* formed on the both longitudinal side edges **223** of the outer peripheral side-half pipe member **223***b* come into contact with the cylindrical flange portions **233** at the side edges of the inner guide groove **210***a* of the direction changing passage-inner guide forming portion **222**, and the outer peripheral side-half pipe member **223***b* and the inner peripheral side-half pipe member **223***a* are restricted to be turned in the inserting hole **214**.

The resin pipes **223** and the direction changing passage-inner guide forming portions **222** are accurately positioned through the inserting holes **234** formed on the first and third end plate portions **230**, **232** of the thin sheet portion **229** and a proper assembling is carried out in this manner.

The side cover plate **240** is provided with four recess portions **241** having the outer guide grooves **210***b* for the direction changing passage, into which the portions **228** of the direction changing passage-inner guide forming portions **222** are fitted, and screw-fixing portions for securing the side cover plate **240** to the block body **213**. In the screw-fixing portions, the side cover plate **240** is fixed to the block body **213** by inserting bolts **244** into holes **243** formed on the side cover plate **240** and engaging the bolts **244** with screwed holes **245** formed on the end surface of the block body **213**. The holes **243** are located between the first and third end plate portions **230**, **232** of the thin sheet portion **229**.

The direction changing passage-inner guide forming portion **222** provided with the inner guide groove **210***a* for the direction changing passage is fitted into the recess portion **241** of the side cover plate **240**. The thin sheet portion **229** is held between the side cover plate **240** and the end surface of the block body **213** through a clamping force so as to be firmly fixed therebetween.

The direction changing passage-inner guide forming portions **222** and the roller passage forming portion **221** are connected through the thin sheet portion **229**, thus making it possible to maintain an accurate positional relationship of the end of the inner guide groove **210***a* for the direction changing passage relative to the roller passage forming portions **221**, as well as an accurate positional relationship of the inner guide groove **210***a* for the direction changing passage relative to the roller returning passage **209**.

The thin sheet portion **229** is uniformly urged against the flat end surface of the block body **213** through a clamping force applied to the side cover plate **240**. Even when the direction changing passage-inner guide forming portion **222** is not located in a correct position, the thin sheet portion **229** changes its shape, thus permitting the correct positioning of the direction changing passage-inner guide forming portion **222**. The thin sheet portion **229** is firmly clamped and fixed through a clamping force, which is applied to the side cover plate **240**, and frictional force caused by such a clamping step may prevent an unfavorable movement of the inner guide groove **210***a* for the direction changing passage;

Description will be given of modifications of the resin-formed body **220** for forming the roller circulation passage, which is divided into parts In the description of the modifications, modified features will only be explained in comparison with the second embodiment of the present invention. The same reference numerals will be given to the same components as those in the second embodiment of the present invention, and description thereof will be omitted.

[First Modification]

FIGS. **21** and **22** show the first modification of the resin-formed body **20** for forming the ball circulation passage, which is described in the second embodiment.

In the first modification, the resin-formed body **220** for forming the ball circulation passage is composed of the first resin-formed frame **220**A, which is obtained by integrally connecting both of the roller passage forming portions **221**, **221** and the resin pipes **223** at their ends with the direction changing passage-inner guide forming portions **222**A for one side, and the second resin-formed frame **220**B, which is provided with the direction changing passage-inner guide forming portions **222**B for the other side and separately formed from the first resin-formed frame **220**A.

In this case, the roller passage forming portions **221**, **221** are integrally connected with the direction changing passage-inner guide forming portions **222**A through the thin sheet portion **229**A as in the second embodiment.

The direction changing passage-inner guide forming portions **222** are also integrally connected with the resin pipes **223** through the thin sheet portion **229**A. In this case, the resin pipe **223** is formed into a tubular integral body, although the half pipe members are used in the second embodiment. Accordingly, there exists no inserting hole **234** in the thin sheet portion **229**A, and the roller returning passage **209** is exposed on the thin sheet portion **229**A.

The first resin-formed frame **220**A and the second resin-formed frame **220**B are connected, as shown in FIG. **22**, by means of a joint method using the combination of a recess and a projection to be inserted therein, such as a faucet joint method. In the illustrated example, a recess portion **236** of a dove-tail groove is formed in the second resin-formed frame **220**B, and an engaging projection **235** to be engaged with the recess portion **236** is formed, on the other hand, in the roller passage forming portions **221**, **221**.

In this case, the resin pipe **223** of the first resin-formed frame **220**A is inserted in the through-hole **214** of the block body **213**, and the roller passage forming portions **221**, **221** and the connecting plate portion **226** are inserted along the under surface of the horizontal portion **206** of the block body **213** and the inner surfaces of the wing portions **207**, **207**.

Then, the engaging projections **235** formed at the roller passage forming portions **221**, **221** and the connecting plate portion **226** are engaged with the recess portions **236** formed on the thin sheet portion **229**B of the second resin-formed frame **224**B, which is arranged on the other end surface of the block body **213**.

The recess portions **236** may be formed on the first resin-formed frame **220**A and the engaging projections **235** may be formed on the second resin-formed frame **220**B. The connecting method is not limited to the method described above, and there may be used any conventional connecting method in which the ends of the divided parts can be maintained in a proper connecting position and connected.

[Second Modification]

FIGS. **23** and **24** show the second modification of the resin-formed body **220** for forming the ball circulation passage, which is described in the second embodiment.

In the second modification, the resin-formed body **220** for forming the roller circulation passage, which has been obtained by integrally forming both of the roller passage forming portions **221**, **221** and the resin pipes **223** as a returning passage forming portion with a pair of direction changing passage-inner guide forming portions **222**, **222**, is divided at the middle portion of each of the roller passage forming portions **221**, **221** and the resin pipes **223** into two parts. More specifically, the roller passage forming portions **221**, **221** and the resin pipes **223** are divided at their middle portion into the respective two half parts, and each of the thus divided two half parts is integrally formed with the direction changing passage-inner guide forming portions **222**, **222**, thus forming two resin-formed frames **220**C, **220**D having substantially the same shape.

Recess portions **238** and engaging projections **237** to be inserted therein are formed on the divided ends of the roller passage forming portions **221**, **221** and the divided ends of the connecting plate portion **226** and the divided ends of the resin pipes **223**.

[Third Modification]

FIGS. **25** to **26** show the third modification of the resin-formed body **220** for forming the roller circulation passage, which is described in the second embodiment.

In the third modification, there is not used the resin pipe **223** as a returning passage forming portion described in the second embodiment, and a resin-formed frame **220**E is obtained by integrally forming the both of the roller passage forming portions and the connecting plate portion **226** with the thin sheet portions **229**, **229** each having the pair of direction changing passage-inner guide forming portions **222**, **222**. The roller returning passage **209** is composed as a through-hole formed in the block body **213**.

In this case, an engaging projection **239***a*, which is engageable with a tapered portion **215** formed in the opening end of the roller returning passage **209** may be formed in the opening end of the roller hole **239** of the thin sheet portion **229**. Such a construction permits to make a proper connection of the end of the roller returning passage **209** and the direction changing passage-inner guide forming portion **222**.

In the illustrated example, an arcuate engaging projection **248** is additionally formed on the connection portion of the outer guide groove **210***b* for the direction changing passage with the roller returning passage **209**. The engaging projection **248** can be fitted into the roller hole **239** of the thin sheet portion **229** and engaged with the tapered portion **215** of the opening end of the roller returning passage **209**.

[Fourth Modification]

FIG. **26** shows the fourth modification of the resin-formed body **220** for forming the roller circulation passage, which is described in the second embodiment.

In the fourth modification, there is not used the resin pipe **223** described in the third modification, a resin-formed frame **220**F is obtained by integrally forming the roller passage forming portions **221** with the direction changing passage-inner guide forming portions **222** for the one side, the other resin-formed frame **220**F provided with the direction changing passage-inner guide forming portions **222** for the other side is separately formed from the above-mentioned resin-formed frame **220**F, and the resin-formed frames **220**F, **220**F are connected with each other by engagement of the engaging projection **235** with the recess **236**. The structure other than the above-mentioned construction is the same as that of the third modification.

[Modifications of the roller train]

In the second embodiment and the first to fourth modifications, there is described that two trains of the rollers are provided on the upper surface of the guide rail **2** and the single train of the rollers is provided on each of the side surfaces of the guide rail **2**, so as to provide the total number of trains of four. In the present invention, the other type of roller trains can however be applied as shown in the figures. With respect to the division of the resin-formed body **220** for forming the roller circulation passage, all the modifications are based on the divisional pattern of the first embodiment. All the divisional patterns of the first to fourth modifications may however be applied to the modifications of the roller train.

In the example as shown in FIG. **27**, two lower and upper trains of the rollers as rolling members are provided on each of the gaps between the right and left-hand side surfaces of the guide rail **202** and the inner surfaces of the right and left-hand wing portions **207**, **207** of the movable block **204**, so as to provide the total number of trains of four.

In this case, four inner guide portions **210***a* corresponding to the four trains of the rollers **203** are integrally formed with each other in the direction changing passage-inner guide forming portions **222**.

In the above description, the present invention is applied to the linear motion guiding apparatus, in which the movable block is arranged on the guide rail as a track shaft through the rolling members. The present invention may however be applied to a so-called ball-spline, in which an outer tube as a movable member is fitted on a spline shaft as a track shaft, as described below.

[THIRD EMBODIMENT]

A ball spline **301** as shown in FIGS. **28** to **30** is of a so-called "angular contact" ball spline, and has a spline shaft **302** as a guide member extending linearly and an outer tube **304** arranged so as to be movable along the spline shaft **302** through balls **303** as a large number of rolling members.

The spline shaft **304** is formed into a long bar shape having a circular cross-section. The spline shaft **304** has on its outer periphery three projections **306**. Two ball running grooves **305, 305** are formed on the both sides of each of the projections **306**, so as to provide the total number of groove of six.

The outer tube **304** has on its inner periphery three recesses **307** corresponding to the projections **306** of the spline shaft **302**, respectively. Ball running counter-grooves **308**, **308** are formed at the both corners of each of the recesses **307**, so as to correspond to the above-mentioned ball running grooves **305**, **305**.

In addition, the outer tube **304** has six ball returning passage **309**, **09**; **309**, **309**; **309**, **309**, which are in parallel with the six ball running counter-grooves **308**, **308**; **308**, **308**; **308**, **308**, and six direction changing massages **310**, **.310**; **310**, **310**; **310**, **310** formed into a U-shaped tube, which connect the ends of the above-mentioned ball running counter-grooves **308**, **308**; **308**, **308**; **308**, **308** with the ends of the above-mentioned ball returning passage **309**, **309**; **309**, **309**; **309**, **309**. The outer tube **304** has six circulation passages in this manner.

The ball arranged at each of the both side surfaces of the projection **306** of the spline shaft **302** comes in contact, at its opposite points, with the ball running groove **305** and the ball running counter-groove **308**, respectively. A line connecting the above-mentioned contact points is referred to as the "contact angle line". A contact angle α, i.e., an angle between the contact angle line and the radius line, which connects the center of the spline shaft **302** and the central portion of the projection **306** is relatively large. The ball returning passage **309** is located on the contact angle line.

In this third embodiment, the balls **303** inserted in each of the circulation passages are connected with each other by means of a ball retainer **312** so as to form the train of the balls **303**. The balls **303** are guided by means of the ball retainer **312** and circulated in each of the circulation passages. The ball retainer **312** has the same structure as shown in FIG. **14** and the description thereof is therefore omitted.

The outer tube **304** is composed of a tubular main body **313** having the ball running counter-grooves **308**, **308**; **308**, **308**; **308**, **308**, three resin-formed bodies **320**, **320**, **320** for forming the ball circulation passage, which are to be inserted in the main body **313**, and a pair of side cover plates **314**, **314** secured on the both ends of the main body **313** after the insertion of the resin-formed bodies **320**, **320**, **320** in the main body **313**.

In the third embodiment, the six circulation passages are formed by the three resin-formed bodies **320**, **320**, **320**.

Each of the circulation passages **311** of the resin-formed bodies **320** for forming the ball circulation passage has a pair of the ball passage forming portions **321**, **321** extending along the longitudinal side edges of the ball running counter-groove **308**, a pair of direction changing passage-inner guide forming portions **322**, **322** provided on the both ends of the main body **313**, and resin pipes **323** as a returning passage forming portion, which are inserted in through-holes formed in the main body **313**.

The ball passage forming portions **321**, **321** are provided with guide grooves for guiding the both side edges of the belt portion **312***b* of the ball retainer **312** in a loaded area. The guide grooves can prevent the ball retainer **312** not only from being swung during run of the ball, but also from being sagged by engaging the side edges of the belt portion **312***b* with the guide groove **321***a*, when the outer tube **304** is removed from the spline shaft **302**. The balls **303** are supported by the ball retainer **312**. More specifically, the ball retainer **312** is supported by a jaw portion of the guide groove **321***a*, with the result that the balls **303** are kept in its proper position so as not to come off the outer tube **304**.

Guide grooves **309***c*, **310***c* are also formed in the ball returning passage **309** and the direction changing passage **310** as non-loaded areas, in order to guide the side edges of the belt portion **312***b*. The guide grooves **309***c*, **310***c* are connected to the above-mentioned guide groove **321***a* in the loaded area so as to form an endless groove on the entire periphery.

In each of the resin-formed bodies **320** for forming the ball circulation passage, the ball passage forming portions **321**, **321** and the pair of the direction changing passage-inner guide forming portions **322**, **322** are integrally connected with each other. The resin-formed body **320** is divided at the other portions into separate parts so as to be able to be inserted in the main body **313**. In the third embodiment, a single resin frame **324** is obtained by integrally connecting the ends of the four sets of ball passage forming portions **321**, **321** with the end of the pair of direction changing passage-inner guide forming portions **322**, **322**, and the thus obtained resin frame **324** is divided at the connecting portion of the returning passage forming portion **323** with the direction changing passage-inner guide forming portions **322**, **322** into the separate parts so as to be able to be inserted in the main body **313**.

The adjacent two of the roller passage forming portions **321**, **321**, **321**, **321** are integrally connected with each other by means of a thin connecting sheet portion **326**. The direction changing passage-inner guide forming portion **322** is integrally formed with the thin sheet portion **329**, which is to be brought into contact with the end surface of the main body **313**.

The thin sheet portion **329** is provided with the first end plate portions **330**, **330** and the second end plate portion **231** for connecting the first end plate portions **330**, **330** with each other. Each of the pair of ball passage forming portions **321**, **321** is integrally connected with the inner edge of the first end plate portion **230**. The both ends of the connecting plate portion **326** are integrally connected with the inner edge of the second end plate portion **331**.

Each of the direction changing passage-inner guide forming portions **22** has a semi-cylindrical shape. On the outer periphery of the direction hanging passage-inner guide forming portion **322**, there is formed an inner guide groove **310***a* having a semi-circular cross section so as to form the inner guide portion for the direction changing passage **310**.

The one end of the inner guide groove **310***a* is connected to the end of the ball running counter-groove **308**. Accordingly, the one end of the inner guide groove **310***a* has the same cross-sectional shape as the ball running counter-groove **308** so as to make an alignment of the one end of the inner guide groove **310***a* with the end of the ball running counter-groove **308**. The other end of the inner guide groove **310***a* of the direction changing passage **310** is connected to the end of the ball returning passage **309**. Accordingly, the other end of the inner guide groove **310***a* has the same cross-sectional shape as the ball returning passage **309** so as to make an alignment of the other end of the inner guide groove **310***a* with the end of the ball returning passage **309**.

Cylindrical flange portions **333, 333** are formed on the both ends of the inner guide groove **310***a*. The distance between the respective outer surfaces of the cylindrical flange portions **333, 333** is larger than the width of the belt portion **312***b*. The cylindrical flange portions **333, 333** form a retainer-guide groove **310***c* for the ball retainer **312** in cooperation with the side cover plate **340** described later.

The both ends of the inner guide groove **310***a* for the direction changing passage **310** extend to the contacting surface of the first end plate portion **330** with the end surface of the main body **313** so as to be connected to the respective ends of the ball running counter-groove **308** and the ball returning passage **309**.

Pipe inserting holes **334, 334** having a semi-circular shape, in which he ends of for the outer peripheral side-half pipe member **323***a* for the resin pipes **323** for forming the roller returning passage **309** are to be inserted are formed on the first and third end plate portions **330, 332** of the thin sheet portion **329**. The resin pipe **323** is inserted into the circular through-hole **314** formed in the main body **313** so that the inner peripheral surface of the resin pipe **323** form the ball returning passage **309**.

The resin pipe **323** is composed of the inner peripheral side-half pipe member **323***a*, which is continuously connected to the inner guide groove **310***a* for the direction changing passage, and the outer peripheral side-half pipe member **323***b*, which is continuously connected to the outer guide groove **310***b* for the direction changing passage **310**, which is formed on the side cover plate **340**. The inner peripheral side-half pipe member **323***a* has an inner groove portion **309***a* having a rectangular cross section, and side edge portions **323***b* extending longitudinally along the inner groove portion **309***a*. The longitudinal edge portions **323***c* of the inner peripheral side-half pipe member **323***a* has the same width as the flange portion **333** of the direction changing passage-inner guide forming portion **322**.

The outer peripheral side-half pipe member **323***b* is formed into a linear member having the same rectangular cross section as the outer guide groove **310***b* for the direction changing passage, which is formed on the side cover plate **340**. The outer peripheral side-half pipe member **323***b* has a outer groove portion **309***b*, which is continuously connected to the outer guide groove **310***b*, and side edge portions **323***d* extending longitudinally along the outer groove portion **309***b*. The side edge portions **323***d* is provided on its outer edges with projections **323***e*, which are to be brought into contact with the side edge portions **323***c* of the inner peripheral side-half pipe member **323***a* to form the guide groove for the belt portion **312** of the ball retainer **312**.

The inner peripheral side-half pipe member **323***a* of the resin pipe **23** has the same length of the main body **313**. The inner peripheral side-half pipe member **323***a* is positioned so as to be brought into contact with the end surface of the direction changing passage-inner guide forming portion **322**, which is arranged on the side of the main body **313**.

The outer peripheral side-half pipe member **323***b* of the resin pipe **323** has on the other hand a longer length than the main body **313** by a length corresponding to the thickness of the first end plate portions **330, 330** of the thin sheet portion **329**, which are arranged on the both ends of the main body **313**. The outer peripheral side-half pipe members **323***b* are inserted in the inserting holes **334** of the first end plate portions **330, 332**. Longitudinal positional determination of the outer peripheral side-halfpipe member **323***b* is made by bringing the both ends of the outer peripheral side-half pipe member **323***b* inserted in the inserting holes **334** into contact with the peripheral edge of the end portion of the outer guide grooves **310***b* for the direction changing passage, which are formed on the side cover plate **340**. The projections **323***e* formed on the both longitudinal side edges **323** of the outer peripheral side-half pipe member **323***b* come into contact with the outer edges of the cylindrical flange portions of the direction changing passage-inner guide forming portion **322** to form a guide groove, and the outer peripheral side-half pipe member **323***b* and the inner peripheral side-half pipe member **323***a* are restricted to be turned in the inserting hole **314**.

The resin pipes **323** and the direction changing passage-inner guide forming portions **322** as the ball returning passage forming portions are accurately positioned through the inserting holes **334** formed on the first end plate portion **330, 330** of the thin sheet portion **329** and a proper assembling is carried out in this manner.

The side cover plate **340** is provided with four recess portions **341** having the outer guide grooves **310***b* for the direction changing passage, into which the direction changing passage-inner guide forming portions **322** are fitted, and screw-fixing portions for securing the side cover plate **340** to the main body **313**. In the screw-fixing portions, the side cover plate **340** is fixed to the main body **313** by inserting bolts **344** into holes **343** formed on the side cover plate **340** and engaging the bolts **344** with screwed holes **345** formed on the end surface of the main body **313**. The holes **343** are located between the first end plate portions **330, 330** of the thin sheet portion **329**.

The direction changing passage-inner guide forming portion **322** is fitted into the recess portion **341** of the side cover plate **340**. The thin sheet portion **329** is held between the side cover plate **340** and the end surface of the main body **313** through a clamping force so as to be firmly fixed therebetween.

The direction changing passage-inner guide forming portions **322** and the ball passage forming portion **321** are connected through the thin sheet portion **329**, thus making it possible to maintain an accurate positional relationship of the end of the inner guide grooves **310***a* for the direction changing passage relative to the ball passage forming portions **321**, as well as an accurate positional relationship of the inner guide groove **310***a* for the direction changing passage relative to the ball returning passage **309**.

The thin sheet portion **329** is uniformly urged against the flat end surface of the main body **313** through a clamping force applied to the side cover plate **340**. Even when the direction changing passage-inner guide forming portion **322** is not located in a correct position, the thin sheet portion **329** changes its shape, thus permitting the correct positioning of the direction changing passage-inner guide forming portion **322**. The thin sheet portion **329** is firmly clamped and fixed through a clamping force, which is applied to the side cover plate **340**, and frictional force caused by such a clamping step may prevent an unfavorable movement of the inner guide groove **310***a* for the direction changing passage.

According to the present invention, only the ball running counter-groove **308** for the circulation passage **311** is formed of the main body **313** having high rigidity, and the other portions are formed of the resin-formed bodies **320** for forming the ball circulation passage. Precision working of the ball running counter-groove **308** of the main body **313** suffices, thus permitting reduction in steps for working and decrease in the production cost.

The resin-formed body **320** for forming the ball circulation passage is separately formed from the main body **313**. Even when the outer tube **304** has a larger size, there is no restriction of flow of molten resin by the main body **313**, unlike the case where the main body **313** is integrally formed with the resin-formed body **320**. Increase in number of gates formed on a die may ensure proper run of the molten resin, thus improving the formability. Especially, the ball passage forming portions **321, 321** located at the opposite longitudinal sides of the ball running groove **308** are thin, with the result that molten resin may not reach every part of the space for forming the ball passage forming portions **321, 321**. It is therefore effective to form the resin-formed body **320** separately from the main body **313** in accordance with the embodiment of the present invention.

The ball passage forming portions **321, 321** are continuously and integrally connected with the direction changing passage-inner guide forming portions **322**, and the divided parts are jointed so as to make alignment of them to make a faucet joint. It is therefore possible to ensure a proper continuity of the connecting portion of the circulation passage and to make smooth run of the balls **303** from the ball running passage between the ball running groove **305** and the ball running counter-groove **308** to the direction changing passage **310**, as well as from the direction changing passage **310** to the ball returning passage **309**.

Description will be given of modifications of the resin-formed body **320** for forming the ball circulation passage, which is divided into parts. In the description of the modifications, modified features will only be explained in comparison with the third embodiment of the present invention. The same reference numerals will be given to the same components as those in the third embodiment of the present invention, and description thereof will be omitted.

[First Modification]
